The Structure of Linkage Disequilibrium in the Recently Admixed Populations. *H. Zhang, J. Jung, B. Grant.* National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, MD.

The linkage disequilibrium (LD) in human population is found to be stronger with increasing geographic distance from Africa, which reflects the Africa origin of human history. Recently admixed populations (such as African Americans and Hispanic Americans) are more likely to harbor a larger number of genetic variants, relative to their inferred ancestral populations. However, the pattern of linkage disequilibrium in these admixed populations are not well studied. Here, we conduct an analysis of linkage disequilibrium at 659,184 single nucleotide polymorphisms (SNPs) in 924 unrelated samples from 11 Hapmap3 populations and 24 samples from Karitiana population (Native American in Brazil from Human Genome Diversity Project). African Americans (ASW) derive their genomic ancestry from African and European with an average of 77.3% African and 20.0% European ancestry. Hispanic Americans (MXL) lie on a cline of an average of 45.5% European ancestry, 42.9% Native American ancestry, 4.9% East Asian ancestry and 4.4% African ancestry. The mean of SNP based haplotype heterozygosity across the whole genome in these two admixed populations is greater than that of their major inferred ancestral populations. We further use r^2 between all possible SNP pairs in various distance classes as a measure of LD and also focus on the proportion of SNP pairs with r^2 greater than 0.8. Both of these two admixed populations show intermediate LD (as measured in r^2 and the proportion of SNP pairs with r^2>0.8), compared with their two major inferred ancestral populations. The extent of LD (r^2) in African Americans (ASW) is more closer to that in African population (YRI) in the short distance classes, while the values of LD in African Americans (ASW) is more likely to be similar to the European Americans (CEU) with the increased distance classes. The amount of LD (r^2) in Hispanic Americans (MXL) shows the similar pattern, but it is much closer to European Americans (CEU) in all distance classes. The findings on the structure of LD in admixed populations are helpful to better understand the evolution of human population and the design of the genetic association studies in admixed populations.

Statistical genetic considerations for expansion of panel of DNA markers for forensic applications: Lessons learned from the panel of 29 autosomal STR loci. *M.R. Nolan, R. Chakraborty.* Department of Molecular and Medical Genetics, University of North Texas Health Science Center, Fort Worth, TX., USA.

With increasing success of using DNA markers for forensic applications, there are several recent attempts to expand the panel of autosomal short tandem repeat (STR) markers to solve more complex forensic problems and to achieve worldwide uniformity of DNA typing to aid in forensic investigations that cross international boundaries. This research deals with the relevant statistical genetic considerations that are needed to validate genotype databases of such expanded panel of markers. Recently, the US National Institute of Standards (NIST) has published genotype data for 29 autosomal STR loci typed in 1,036 unrelated individuals belonging to four populations (African-Americans - n = 342, US Caucasians - n = 361, US Hispanics - n = 236, and Asians - n = 97). Since these loci include all markers of the CODIS 13, Identifiler®15, Globalfiler®21, and PowerPlex®Fusion 22 panels, we conducted a comparative analyses of this expanded panel against the above 4 more restrictive panel of markers. Our analyses suggest that even with the increase of the number of loci, deviations from Hardy-Weinberg equilibrium and linkage equilibrium for this expanded panel did not exceed the number of deviations expected by chance alone (in each population). This is so even in the presence of 7 pairs of syntenic loci in this expanded panel (F13B and D1S1656 on 1q, TPOX and D2S441 on 2p, D5S818 and CFS1PO on 5q, SE33 and D6S1043 on 6q, vWA and D12S381 on 12p, FESFPS and Penta E on 15q, D21S11 and Penta D on 21q). This expanded panel improves the statistical power of human identification as well as kinship analyses in terms of all commonly used statistics of DNA forensics. The increased number of loci also more explicitly confirms some of the population genetic features of STR polymorphism, not clearly seen in the four more restrictive panels stated above (e.g., negative association of F_{ST} with heterozygosity at individual loci). However, while the average F_{ST} values (across the four subpopulations in the database) for the four restrictive panels are very similar (1.66 to 1.74%), addition of 7 more loci in this expanded panel increased the F_{ST} to 2.15%. This is largely due to the inclusion of the F13B locus, which has a large inter-population variation of allele frequencies and the lowest heterozygosity (42%) in the Asian population. Further expansion of panels of forensic markers should attempt to control further increase of F_{ST} for improving their power of forensic utility.

1927S

Multidrug-resistant pulmonary tuberculosis in Mexican population. Evidence of association of HLA class II and TNF-308 G/A polymorphism. *B. Silva[1], C. Saenz[1], L.A. Bracho-Vela[1], M.A. Bermúdez de León[1], S. Said-Fernández[2], J. Granados[3].* 1) CIBIN-IMSS, Monterrey, Nuevo León; 2) Fac de Medicina UANL, Nuevo León; 3) INCMN-SZ, México.

Tuberculosis (TB) remains a global emergency. It is estimated that one third of the world's population is infected with Mycobacterium tuberculosis (Mtb), and only 10% of those infected will develop clinical tuberculosis (TB), which indicates the existence of host factors regulating disease expression. We investigated the association of human leukocyte antigens (HLA) class II and tumor necrosis factor (TNF) gene with susceptibility to pulmonary TB in Mexicans with especial emphasis on their association with drug resistance. HLA-DRB1 and DQB1 gene polymorphism were analyzed in a 100 Mexican patients with Multidrug-resistant tuberculosis (MDR-TB denotes bacillary resistance to at least isoniazid and rifampicin) and 150 ethnically matched healthy controls using PCR-SSO (Luminex). Polymorphisms in the promoter region of the tumor necrosis factor (TNF) gene at positions -308 and -238 were studied using the TaqMan® allelic discrimination assays for both groups. The frequencies of HLA-DRB1*14:06 were significantly higher in patients with MDR-TB as compared to healthy controls (P=0.05). Higher frequency of TNF-308 rs1800629 G/A genotype was observed in MDR-TB cases. The results suggest that HLA-DRB1*14:06 in combination with TNF-308 rs1800629 G/A genotype influence to MDR-TB. Further studies are needed to confirm our findings using larger number of patients with MDR-TB.

1928M

A Renewal Theory Approach to IBD Sharing. *S. Carmi[1], P. Wilton[2], J. Wakeley[2], I. Pe'er[1].* 1) Department of Computer Science, Columbia University, New York, NY; 2) Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA.

Sharing of long, identical-by-descent (IBD) genomic segments is common in many human populations. Dense genotyping of large cohorts, together with sophisticated detection tools, have transformed IBD sharing into an important and popular tool in population genetics, with numerous applications ranging from demographic inference to selection detection, pedigree reconstruction, disease mapping, imputation, and phasing. Nevertheless, many key questions in the theory of IBD sharing are still open. Here, we introduce and analyze a novel theoretical framework for the IBD process, based on renewal theory. Using our renewal approach, we were able to derive, in some cases for the first time, several key quantities, including the distribution of the number and total length of shared segments. Specifically, we consider the IBD process for a pair of chromosomes under two Markovian approximations of the coalescent with recombination, SMC and SMC'. We then propose, and justify by simulations, the renewal process, in which lengths of successive shared segments are independent. We show that previously derived results for IBD sharing under SMC emerge naturally under our renewal framework at the limit of long chromosomes. Still under the same limit, we derive new results for the expected number and total length of shared segments under SMC', which is considerably more accurate for small populations, precisely where IBD sharing is abundant. We also derive expressions (for any chromosome length but in Laplace space) for the distribution of the number and total length of shared segments, verified by simulations, with explicit results for SMC. Finally, we generalize all results to populations with variable historical size. Our results provide a unified and natural analytical framework for the study of IBD sharing, with a number of potential applications from fine-scale demographic inference to pedigree reconstruction.

1929S

Using linkage disequilibrium to refine estimates of accelerating growth in human populations. *M. Reppell[1], J. Carlson[1], S. Zöllner[1,2], The BRIDGES Consortium.* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Psychiatry, University of Michigan, Ann Arbor, MI.

Correctly modeling the effective size of a population is critical to making accurate inferences about mutation and migration rates, and the strength of selective pressures. In humans, several large sequencing studies have given us novel insight into a genome characterized by an abundance of extremely rare genetic variation, consistent with a history of recent massive population growth. These large sequencing studies offer us unprecedented resolution for distinguishing between models of recent growth. To improve on conventional inference methods we propose a novel likelihood based approach that incorporates pairwise r^2, a measure of linkage disequilibrium, in addition to the site frequency spectrum. We observe that over short genetic distances, pairwise r^2 is a function of the variance in ancestral tree branch lengths, and therefore contains information about ancestral population sizes lacking from the site frequency spectrum, which is a function only of the mean total ancestral branch lengths. Using simulations we show that with large samples, the inclusion of pairwise r^2 improves the accuracy of demographic inference in populations that have undergone recent growth, relative to methods relying solely on the site frequency spectrum. We quantify how increasing sample size increases the accuracy of inferences about recent demography, and magnifies the improvement our method yields versus conventional approaches. Lastly, we apply our method to regions defined as neutral in whole genome sequence data from ~4,000 European ancestry individuals sequenced as part of the BRIDGES consortium. This dataset has ideal features for our purposes; providing both a large sample and non-coding genetic regions free from evidence of ongoing selection, a mixture unavailable from exome only or functional sequencing projects. We use a Monte Carlo method to estimate the likelihood of the observed data under a range of realistic growth models, including those incorporating continuous, accelerating, faster than exponential growth. With our data we are able to simultaneously make inferences about the mutation rate, μ, and the rate of accelerating growth experienced by the European population from which our sample is drawn.

1930M

Effect of negative selection on distribution of runs of homozygosity in outbred and consanguineous human cohorts. *K. Popadin[1,2], P. Makrythanasis[1,2], S.E. Antonarakis[1,2].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Institute of Genetics and Genomics of Geneva, Switzerland.

Offspring of consanguineous marriages are characterized by long Runs Of Homozygosity (ROHs) identical by descent. It has been shown that long ROHs are enriched in deleterious variants and thus they are subject to negative selection. In order to investigate the selection forces acting on the consanguineous human genome we analyzed the distribution of ROHs in the offspring of 60 consanguineous families and contrasted the observed pattern with the distribution of ROHs in outbred population. Using phased parental haplotypes in our in-house recombination pipeline we produced *in silico* parental gametes and fused them randomly, without any selection, generating 1000 expected offspring per each family. In order to reconstruct a null distribution of ROHs we analyzed ROHs in the genomes of expected offspring. Comparing the pattern of distribution of ROHs between expected (simulated) and observed (born) siblings in each family we observed a significant excess of long ROHs in expected siblings. This difference suggests purifying selection which eliminates unfitted fetuses (with many long ROHs) during embryogenesis. Additionally, we analyzed a distribution of ROHs across the human genome and observed that different genes are covered by ROHs in highly non-random pattern. We demonstrated that genes rarely covered by ROHs are characterized not only by the increased recombination rate but also by high haploinsufficiency score. This implies that negative selection more effectively eliminates ROHs from DNA regions with increased coefficients of dominance and thus dominant genes in homozygous state harbor higher genetic load than recessive genes in homozygous state. In order to explain the high genetic load of dominant genes in homozygous state we discuss selection coefficients of deleterious variants as well as synergistic interaction of the variants in dominant versus recessive genes. Finally, we conclude that the estimated genetic load of different ROHs may prioritize the search of genes causing recessive autosomal diseases.

1931S

Non-visual Opsin Evolution and Implications for Human Health. *A.B. Popejoy[1,2], J.H. Thomas[3], S.M. Fullerton[1,3,4].* 1) Institute for Public Health Genetics (IPHG), University of Washington, Seattle, WA; 2) Statistical Genetics Program, Department of Biostatistics, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Department of Bioethics & Humanities, University of Washington, Seattle, WA.

Visual photoreceptor proteins (opsins) are the key biological light receptors that allow animals to turn light into vision, and their complex evolutionary history has fascinated researchers for decades. Non-visual opsins, or biological light receptors not involved in the visual pathway, may be just as important as visual opsins and are expressed throughout the brain and central nervous system in humans. Nevertheless, the biological function and evolution of non-visual opsins in humans have been largely unexplored compared to visual opsins. In this study, we performed an in-depth phylogenetic analysis of human non-visual opsins using maximum likelihood in PhyML with 1000 bootstrap replicates on protein sequences obtained through ENSEMBL. The proteins were selected for phylogenetic analysis through a custom BLAST search using OPN5, a well-established non-visual opsin, as the query and verifying that each protein sequence identified (E-value < 1e-15) contains a lysine residue in the seventh transmembrane helix chromophore binding site, a key functional element of all photoreceptor proteins. Among the 9 distinct opsin proteins we identified in humans, 4 are well established as visual opsins: 3 cone cell opsins (OPN1SW, OPN1LW, OPN1MW) and 1 rod opsin (RHO). The 5 non-visual opsins we identified are RRH, RGR, OPN3, OPN4, and OPN5. The results of our analysis suggest that non-visual opsins are highly conserved and are under similar selection pressures as visual opsins, demonstrating the importance of further exploratory analyses to uncover their phenotypic associations.

Evolution and expression of duplicated genes in the human genome. *X. Lan[1], Y. Gilad[2], J.K. Pritchard[1,3,4].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Biology, Stanford University, Stanford, CA; 4) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

Gene duplication is regarded as an important driving force for the evolution of new biological functions. This study seeks to understand the mechanisms driving gene duplication events, when they occurred, and how they contributed to the evolution of tissue-specific functions. We constructed a database of duplicated genes pairs in the human genome based on the pairwise sequence similarity of protein coding genes. Using the synonymous substitution rate between a pair of duplicated genes and the conservation of these genes to their orthologs in other species, we estimated the time of the duplication event of the gene pairs. We found that pairs of genes that were duplicated earlier generally have lower expression similarity among different tissues, lower Dn/Ds and increased gene length compared to genes that were duplicated more recently. The majority of gene duplications appear to be due to segmental duplications, and a relatively small fraction appears to be due to retrotransposition. Duplicate genes tend to have more tissue-specific expression than singleton genes (ie., genes with no identified duplicates in the genome). We found that duplicated genes are significantly enriched for involvement in neurological functions compared to singleton genes; however interestingly the majority of these duplication events are relatively ancient, preceding the diversification of mammals. Similarly, the majority of gene duplicates that are primarily expressed in brain and cerebellum tissue arose before the divergence of mammals. Finally we describe patterns relating to classic models of the evolution of gene duplicates, including loss-of-function, neofunctionalization and subfunctionalization.

Can phylogenomic analysis of Hemopexin repeat-containing proteins provide insights into the evolution of adaptive immunity? *L. Likins, A. Smith, J. Wyckoff.* Division of Molecular Biology and Biochemistry, School of Biological Sciences, University of Missouri Kansas City (UMKC), Kansas City, MO.

Hemopexin (HPX), a glycoprotein in the blood plasma of many vertebrate organisms, has been shown to have the highest known binding affinity for heme. Many studies have shown that the primary function of the HPX protein product, Hemopexin is to sequester unbound heme released into the plasma from the breakdown of hemoglobin. The crystal structure of Hemopexin has been solved and the molecule consists of two structurally similar N-terminus and C-terminus beta-propeller domains joined by a flexible, unstructured linker peptide. This linker region is known to be part of the heme binding site. The gene that codes for Hemopexin (HPX) has been shown to have numerous sequences identified as recognizable hemopexin-like (HX) amino acid repeats in the primary structure of the protein. Structural mapping has revealed some interesting relationships between the functional motifs and the tertiary structure of the protein that may have implications for understanding the evolution of HPX proper, as well as its historical relationship to the several other classes of proteins that contain HX repeats, including: the myriad Matrix Metalloproteinases (MMP's), Proteoglycan-4 (PRG4) and Vitronectin (VTN). All these proteins are associated with the Extracellular matrix of multicellular animals, and research has implicated most of them in immune system dynamics. Earlier studies had deduced that the HPX protein was a complex of sequences that had evolved from ancestral molecular precursors, and as such, is the most derived of the proteins containing the hemopexin domain. However, more recent phylogenetic analyses of both primary amino acid sequences, gene nucleotide sequences, and tertiary structure of these proteins has determined that hemopexin is most likely the evolutionarily ancestral molecule. We conclude that the other proteins that have identifiable hpx domain structure have adapted the 4-blade beta-propeller which has then been modified for variable functionality. Importantly, our studies show for the first time that the beta-propeller has not arisen from amino acid identity over long periods of evolutionary time; instead, the propeller structure has remained unchanged even as the components of the propellers have been labile over long periods of evolutionary history. Our initial results show that these new insights reveal key details of the early evolution of the adaptive immune system in the Vertebrata and have clear implications for Human health.

1934M

POTE: an example of gene family evolution. *F. Anaclerio[1], G. Giannuzzi[1,2], M. Ventura[1].* 1) Department of biology, University of Bari, Bari, Italy; 2) Center for Integrative Genomics (CIG), University of Lausanne, Lausanne, Switzerland.

Eukaryotic genomes are characterized by the presence of gene families, set of genes derived from duplication events of a common ancestor. We described the genomic organization and evolutionary history of a primate specific gene family, POTE, whose members are expressed both in normal tissues and in many types of cancers (testis, prostate, ovary and breast). We studied the evolution of this gene family using both *in silico* and molecular cytogenetics approaches on six species: marmoset, macaque, orangutan, gorilla, chimpanzee and human. POTE gene family evolution has been characterized by both intra and inter-chromosomal duplication events leading to the increase of gene copies from one in marmoset to 14 (located on seven chromosomes) in human. In the analyzed species, we identified four different POTE gene isoforms: isoform 1, the unique encopassing exons 12-14, showed to be the ancestral form, isoform 2 appeared in the ancestor of Catarrhini and isoforms 3 and 4 appeared after the divergence of Old World Monkeys and Great apes. Isoform 3 and 4 are described as the most expressed in cancers and they are characterized by both the presence of a Long Inverted Repeat (LIR) within the last intron and by a processed actin retrogene in the last exon. The presence of a premature stop codon within the 15th exon in isoform 3 and the duplication of exons 8-11 in isoform 4 allowed us to distinguish these two isoforms. We proposed a model for the evolution of all the four isoforms from the first POTE gene on the ancestral chromosome 8 to the most recent human specific POTEF located on chromosome 2 and characterized by the presence of two additive exons harbored in the 5' UTR and responsable for a positive regulated expression. At 2q POTE genes map at the ancestral centromeric region that lost its function due to the fusion of the two ancestral acrocentic chromosomes that originated human chromosome 2. Analyzing the increase in the number of POTE genes and their localization on different chromosomes, we showed that a burst duplication of this gene family occurred since New World Monkeys split from the common ancestor of Catarrhini, moreover, exons loss and gain and the distribution of these events along the gene let us to suppose not only the acquisition of new function for this gene family in most recent species but also the potentiality to a further evolution.

1935S

Evolutionary Triangulation: Informing Genetic Studies with Evolutionary Evidence. *M. Huang[1], B. Graham[2], L. Muglia[3], S. Williams[1,2].* 1) Department of Genetics, Dartmouth College, Hanover, NH; 2) iQBS, Dartmouth College, Hanover, NH; 3) Perinatal Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Genetic studies of disease have been successful in identifying many variants associated with clinical outcomes. However, most have performed straightforward analyses without incorporating other factors that may affect risk. One such factor is evolution, as human populations have evolved under a variety of environments that have shaped disease risk. Using the unique evolutionary trajectories in diverse populations may improve our ability to extract important genetic factors in disease. Given that a large portion of common variants differ among populations in allele frequency, as do disease prevalences, we hypothesized that patterns of disease and population genetic structure may together inform association studies. Specifically, the distribution of allelic variants that associate with certain diseases will mirror the distribution of the diseases. Moreover, variants should be detectable most easily when three or more populations are assayed simultaneously, reducing the number of differences unrelated to diseases. We use three-way comparisons of evolutionary differentiation or Evolutionary Triangulation (ET). ET selects study populations based on differences in disease rates, with two having similar rates while a third is divergent. When the same genes affect disease risk in all populations, patterns of genetic variation should parallel disease distributions. In this study, we examine genetic differentiation (F_{ST}) of variants in three distinct continental populations (Europeans, CEU; South Asian, GIH; and West African, YRI) and use CEU as the outlier. SNPs that are highly differentiated between CEU and GIH/YRI, but not differentiated between GIH and YRI are identified as ET SNPs. ET SNPs are then mapped to ET genes with a ±100 Kb window. By surveying ET genes using the online HuGE Navigator, we identify genetic associations with all diseases. ET genes are enriched for those associated with diseases appropriately distributed among the three populations, with 12.12%, 7.39% and 5.46% under different cutoffs of F_{ST} used to generate the ET genes; fewer were detected using the same number of randomly selected genes. The enrichments are statistically significant with p values of 0.022, 0.002 and less than 10^{-4} accordingly depending on the exact F_{ST} thresholds used. The results indicate that ET can filter associated variants based on evolutionary comparisons among populations, and that it can be effectively filter association results.

1936M

MtDNA and health among Taiwanese. *J. Loo, T. Wang, J.A. Trejaut, M. Lin.* Mackay Memorial Hospital.

Previous analyzing the maternal heritage of Taiwanese through mitochondrial DNA (mtDNA) unanimously agree for an ancestral origin Taiwan Indigenous people coming from Mainland Southeast Asia (MSEA) Southeast China and Indo-China. Contemporary Non Taiwan Aborigines (often referred as Taiwan Han) have a more diversified range of origin with many finding their roots in Northern Asia and others in Southern Asia. In both groups, Taiwan Aborigines and Non-Aborigines some mtDNA lineages can trace their origin back to 15,000 YBP. Using association between mtDNA and systemic functional measurements (ATP, mitochondrial membrane potential, 8OHdG, lipid peroxidation, systolic BP, diastolic BP, blood glucose, total cholesterol, TG, LDL and HDL) we have shown that several measurements were significantly associated with mtDNA variation. Since many of these measurements are used in disease diagnosis, we asked whether mtDNA sequence variation could be used as a tool to foresee disease outcomes. We used DNA samples from Taitung area, where one third of the population is Taiwan Aborigines. We also included samples from the Taipei area where most people are Taiwan Han and have a very different mtDNA polymorphism. Efforts were directed toward determining significant associations between mtDNA SNP and disease determining functional measurements. Several mtDNA haplogroup/SNPs found potentially good indicators of disease development were further investigated in relation to ethnicity in view to pre-determine the likely health status of a group, with greater attention to disadvantaged groups in the Taiwanese population.

***RUNX3* GENE POLYMORPHISMS AND HAPLOTYPES IN MEXICAN PATIENTS WITH COLORECTAL CANCER.** *A.S. Suárez Villanueva[1], M.L. Ayala Madrigal[1], J. Peregrina Sandoval[2], M.W. Centeno Flores[3], V. Maciel Gutiérrez[4], M. Gutiérrez Angulo[5].* 1) Instituto de Genética Humana. CUCS. UdG; 2) Laboratorio de Inmunobiología. CUCBA. UdG; 3) Cirugía de Colon y Recto. Hospital Civil "Juan I Menchaca"; 4) Hospital Civil "Fray Antonio Alcalde"; 5) Departamento de Clínicas. CUAltos. UdG.

Background: The human RUNX3 gene is mapped to chromosome 1p36.1, contains six exons and its overall size is approximately 67 kb (1). The RUNX3 protein is required for neurogenesis of dorsal root ganglia and in intestinal epithelial participate with WNT and TGF-β pathways (2,3). The inactivation of RUNX3 gene has been associated with colorectal cancer. In this study, we analyzed the variants rs6672420 (exon 1, c.53 A>T), rs11249206 (intron 1, T>C), rs760805 (intron 3, T>A) and rs2236852 (intron 4, G>A) in colorectal cancer patients from Mexico. Material y Methods: Genomic DNA samples were obtained from peripheral blood of 176 Mexican patients with CRC at diagnosis and 195 individuals as control group. The polymorphisms were detected by PCR-RFLP. Association was estimated by calculating the odds ratio (OR). The haplotypes and linkage disequilibrium (LD) were established in Arlequin v3.5 software. Results: The RUNX3 rs2236852 AA genotype and A allele showed association with CRC (OR = 0.39 95% CI = 0.21 - 0.73 P <0.01; OR = 0.65 95% CI = 0.49 - 0.87 P <0.01, respectively), while rs6672420, rs11249206 and rs760805 polymorphisms displayed not significative results. The SNPs rs760805 and rs2236852 showed LD with r2 = 0.70 for controls and r2=0.44 for patients. The haplotype analysis revealed the most frequent was TG, constructed by combining the wild alleles. Moreover, the analysis showed CRC risk associated to TA haplotype OR = 2.52 95% CI = 1.47 - 4.30 P<0.01). Conclusion: The AA genotype and A allele of rs2236852 polymorphism have a decreased risk and TA haplotype have a risk to CRC development in Mexican patients. 1.Tsunematsu T, Kudo Y, Iizuka S, Ogawa I, Fujita T, Kurihara H, Abiko Y, Takata T: RUNX3 has an oncogenic role in head and neck cancer. Deep sequencing of the human MHC region reveals widespread and ancient structural variation. *A.Q. Fu[1], B. Howie[2], E.Y. Kim[3], M. Stephens[1,4], S. Wolinsky[3].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Adaptive Biotechnologies Corporation, Seattle, WA; 3) Division of Infectious Diseases, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Department of Statistics, University of Chicago, Chicago, IL.

The human major histocompatibility complex (MHC) region of 3.6 Mb harbors over 200 genes, most of which have important roles in innate and adaptive immunity. Several genetic variants in this region have been associated with risk for autoimmunity and disease progression in HIV infection and AIDS. The DNA sequence of the MHC is highly heterogeneous across individuals, and much of its population variation remains to be characterized. Here, we studied the genetic diversity of the extended MHC region in 64 HIV patients who carry no CCR5-delta32 allele but at least one copy of HLA-B*57:01 or B*57:03. We performed sequence capture and targeted enrichment of the MHC and its flanking regions for a total length of 4.7 Mb followed by ultra high-throughput DNA sequencing, generating long reads of ~400 bp at 55x coverage on average. Alignment of the sequencing reads to the human reference genome (hg19) led to the identification of ~60,000 SNPs, about 10 of which are in perfect linkage disequilibrium with HLA*B*57:01/03. De novo assembly of the reads revealed sequence segments that are more similar to the genomes of apes (chimp, gorilla, or orangutan) than to the human reference genome, indeed than to the 8 available human MHC reference haplotypes. These ape-like segments map to several loci in the MHC region of the ape genomes, and their presence correlates with the occurrence of several evolutionarily related HLA-A alleles. These ape-like segments of ~1000 bp were observed in about 20 of the 64 individuals in our study, and we hypothesize that they represent ancient structural polymorphisms. We further confirmed the presence of these long structural variants in several 1000G individuals by aligning sequencing reads in the 1000 Genomes project to the consensus ape-like sequence segments.

1939S

Estimating the generation time in human evolution. *P. Moorjani[1, 4], M. Wyman[1, 4], Z. Gao[2], M. Przeworski[1,3].* 1) Dept of Biological Sciences, Columbia University, New York, NY; 2) Committee on Genetics, Genomics and Systems Biology, University of Chicago; 3) Department of Systems Biology, Columbia University; 4) contributed equally.

Across mammals, decreased generation times (i.e., mean ages of reproduction) are known to correlate with increased neutral substitution rates. This observation is believed to reflect increased mutation rates due to higher numbers of cell divisions per unit time. Perhaps reflecting the same phenomenon, whole genome sequencing studies of human pedigrees, which reflect the mutation rate at present, yield a yearly estimate that is about two-fold lower than the one obtained from phylogenetic methods, which average over millions of years. One hypothesis is that increases in the generation time in the human lineage have led to a slow down of the mutation rate per unit time. Motivated by these considerations, we introduce an approach to estimate the generation time based on the insight that distinct types of mutations arise through different mechanisms and hence have different dependencies on the generation time. Notably, transitions at CpG sites are thought to occur primarily through spontaneous deamination, implying that their mutation rate should depend primarily on absolute time and should be relatively insensitive to the generation time. In contrast, replication-driven mutations at non-CpG sites occur in higher numbers following male puberty, and yearly mutation rates should depend on generation times. We characterize these different time dependencies from human pedigree data. By relating them to the observed average pairwise diversity values at CpG and non-CpG sites, we then obtain joint estimates of the mean coalescence time in years and the generation time over evolutionary history. To investigate if the age of reproduction has changed recently, we estimate the generation time from doubleton mutations, which reflect a more recent time depth than do average pairwise differences. Our results are consistent with the ethnographic literature and suggest a slight increase in the generation time towards the present. Beyond this application, our method provides a novel, population genetics based estimator of the generation time, applicable over different time depths of human evolution.

Role of Methylenetetrahydrofolate Reductase (MTHFR) in Risk of Opioid Abuse; Association between MTHFR and SOAPP®-R & ORT test. *T.G. Onojighofia, B. Meshkin, S.V Nguyen, D. Schwarz, B. Akindele, J. Hubbard, D. Holman.* Proove Biosciences, Inc.

Background: Folate is used by many biological processes to donate methyl groups to other compounds. Its active form is L-methylfolate which is produced through a reaction catalyzed by Methylenetetrahydrofolate Reductase (MTHFR). Mutations in MTHFR have been linked to everything from heart disease to cancer, but not, until recently, addiction. Objective: The objective of this study is to understand the association between MTHFR (MTHFR C677T, Rs1801133) and two popularly accepted tests in determining risk of opioid abuse/Misuse; Screener and Opioid Assessment for Patients with Pain (SOAPP®) and opioid risk tool (ORT). ORT (Low Risk 0 - 3, Moderate Risk 4 - 7, High Risk > 8) and SOAPP® (High risk SOAPP®-R score = 22 or greater, moderate risk SOAPP®-R score = 10 to 21, low risk SOAPP®-R score < 9*) Subjects: Subjects for this study were made up of two independent groups of patients. The SOAPP®-R test was taken by 2228 chronic pain patients in a clinic in Arizona. Another 3517 chronic pain patients across 55 clinical research sites in the US took the ORT test. Methods: The study evaluated data from both groups of subjects. The subjects were genotyped with TaqMan single nucleotide polymorphisms (SNP) assays using the proprietary Proove Narcotic Risk Genetics Profile Test (Proove Biosciences Inc, Irvine, California). The subjects were stratified into low, moderate, and high risk groups, based on the results from both questionnaires (i.e. ORT & SOAPP ®-R). Results: A cross tab analysis using IBM SPSS found an association between MTHFR (MTHFR C677T, Rs1801133) and risk of opioid abuse from both ORT and SOAPP® scores (p=0.028 and p= 0.042 respectively). A multinomial logistic regression showed that MTHFR homozygous mutation is more likely to be associated with the low risk group derived from SOAPP®-R compared to high risk group (P= 0.020, OR=4.273). In addition, it was found that Homozygous mutations in MTHFR is more associated with subjects with low ORT scores (P=0.028, OR 4.929) when compared to those with high risk stratified by ORT scores. Conclusion: This study suggests that an association exist between MTHFR and these two popular tests used to determine risk of opioid abuse/misuse. Findings in this study and further studies in this direction could improve understanding about the role of MTHFR in prescription opioid medication abuse or misuse.

Y Chromosome STR Mutation Rates: the Factor of 3 Connundrum. *D.E. Platt.* IBM T. J. Watson Research Center, Yorktown Hgts, NY., USA.

Y chromosome STR mutations serve as a prime clock for phylogeographical studies. However, there is a discrepancy between mutation rate estimates of roughly a factor of 3 between pedigree derived data vs. population based approaches. In 1995, Zhivotovsky et al constructed a Wright-Fisher based multi-step STR mutation model, extending Moran's ladder model of 1975. In 2004, Zhivotovsky, et al published an STR mutation rate using population data from a range of indigenous peoples that diverged from pedigree derived results, as noted by Di Giacomo et al in 2004. In 2005, Zhivotovsky, et al published a paper indicating that diversity fluctuations could produce a diversity bottleneck, yielding an apparently low mutation rate. Interestingly, their test population dynamics model was Poisson rather than Wright-Fisher. This left the question open of whether the Wright-Fisher model is inadequate for modeling diversity fluctuations in real populations. We present an argument showing that the Zhivotovsky Wright-Fisher dynamics model and the Poisson-based model may both be viewed as limiting cases of a model with binomially fluctuating population size in each generation. We show that the generation-by-generation Zhivotovsky formulation is preserved in both of these limits. Therefore, we conclude that Wright-Fisher dynamics is adequate for predicting the level of fluctuations expected for a Poisson model. Alternatively, Xu, Peng, and Fang proposed a model for STR mutations that allowed for a length dependent rate for decreasing single step mutations which could perhaps account for limited diversity, but assumed a Markov chain equilibrium state. We extend the Xu model first to consider the non-equilibrium Markov case, and second, incorporated this mutation model in a Wright-Fisher inheritance model. We show that the Markov model is robustly convergent, with equilibration sharing the same loss of information as predicted for the Jukes-Cantor model at equilibration, and dominating Wright-Fisher convergence. We identified regimes of back mutation length dependences that may satisfy bounds imposed by phylogeographical observations of human genetic diversity. We explored how BATWING (formulated on a single step model) parameter estimation responds to data generated from the extended Xu model. We see a reduction in predicted mutation rates accounting for at least some of the discrepancies, while still seeing correlations to adequate depth to capture modern human variation.

Extending the Ewens Sampling Formula to structured populations: Recursive computation of exact probabilities of allele frequency spectra. *M. Uyenoyama, S. Kumagai, B.D. Redelings.* Dept Biol, Duke Univ, Durham, NC.

To accommodate the enormous amount of information available in a sample of entire genomes, many evolutionary analyses have relied upon summary statistics or data reduction methods that marginalize over full genealogical trees. An approach that appears to have received relatively little attention involves the Ewens Sampling Formula (ESF), which provides a closed-form expression for the probability of the allele frequency spectrum (AFS) observed in a sample of arbitrary size under the infinite-alleles model of mutation. We extend the ESF to accommodate population structure, here accommodating migration between two demes. We develop a recursion which relates a sample to its immediate ancestor sample (vertical in time). We then characterize properties of the next-sampled gene, given the AFS already observed (horizontal in time). While the AFS probabilities are fully determined by the vertical recursion, their derivation is greatly simplified by the horizontal argument. A rescaling of time or mutation rate that would permit the use in structured populations of the ESF for unstructured population does not exist, even in the case in which the sample is derived entirely from a single deme in a multideme population. For that case, we propose an approximate scaling, which interpolates between no migration and the high migration limit. This approximation provides a qualitative description of the AFS probabilities: higher migration rates increase the effective mutation rate. Under other sampling conditions and for applications in which the exact likelihood is required, our method provides the AFS probabilities through a double recursion that accommodates successively greater numbers of observed alleles and successively greater sample sizes.

1943S

Whole genome sequencing of twenty Mauritian cynomolgus macaques (Macaca fascicularis). *M. Raveendran[1], R.A. Harris[1], D. Rio Deiros[1], A.J. Ericsen[2], G.L. Fawcett[1], F. Yu[1], C. Xue[1], R. Wiseman[2], D. Muzny[1], R.A. Gibbs[1], D. O'Connor[3], J. Rogers[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Wisconsin National Primate Center, Madison, WI; 3) University of Wisconsin, Madison, WI.

Cynomolgus macaques (Macaca fascicularis), also known as long-tailed or crab eating monkeys, are used in several aspects of biomedical research including studies of AIDS, diabetes and alcohol abuse. This species is widely used in pharmacology and drug development. The natural habitat of this species extends through Vietnam, Cambodia, the Philippines and Indonesia. An isolated population of cynomolgus macaques inhabits the island of Mauritius, and is descended from a small number of founder animals transported there by humans ~500 years ago. These Mauritian cynomolgus macaques (MCM) carry a very limited number of major histocompatibility complex (MHC) alleles and haplotypes. This makes these MCM more attractive for studies of infectious disease and other research questions where MHC variation can influence results. However, little is known about variation across the genome in the MCM population. We identified Single Nucleotide Variants (SNV) through whole genome sequencing of twenty MCM samples at a deep coverage using Illumina Hi-seq platform. The Illumina reads were mapped using BWA to the Indian rhesus macaque (IRM) reference genome (rhemac2) and variant calls made using Samtools. In total we identified 29,754,615 genome positions showing differences from the reference, and 22.59 million SNVs polymorphic among the 20 MCM. 7.16 million variants are fixed differences between these 20 MCM and the rhemac2, suggesting a 0.23% sequence divergence between MCM and IRM. The average number of polymorphic variants found in each animal is 9.96 million which is much higher than in human (4.2 million per person). We identified SNVs throughout the genome, including non-synonymous coding (51,132), synonymous coding (58,022), stop altered (1,619), splice altered (1,849), 3' UTR variant (82,307) and 5' UTR variant (21,429). Non-synomous variants are found in genes associated with human diseases, such as SBF2 (Charcot-Marie-Tooth), GAK (Parkinson's disease) CACNA1 (Neuroblastoma) and CAPN10 (diabetes). Analyses of the predicted impact of amino acid substitutions using Polyphen and DAVID are in progress. These results indicate that while MCM have reduced diversity in MHC haplotypes, they nonetheless exhibit significant levels of SNV with diversity higher than found in humans. Apparently the severe bottleneck in the founding of the Mauritius population had effects on the genetic composition of these animals, but did not reduce overall SNV levels dramatically.

1944M

Forensic Phenotyping in Brazilian population: SLC24A5 and ASIP as phenotypic predictors genes of skin, eye and hair color. *C. Fridman, F.A. Lima, F.T. Gonçalves.* Dept of Legal Medicine, Ethics and Occupational He, University of São Paulo, São Paulo, São Paulo, Brazil.

Pigmentation is a very variable and complex trait in humans and it is determined by the interaction of environmental factors, age, disease, drugs, hormones, exposure to ultraviolet radiation and genetic factors, including pigmentation genes. Many of these genes and their variants have been associated with phenotypic diversity of skin, eyes and hair color in homogeneous populations. SLC24A5, TYR, MC1R, SLC45A2, ASIP, OCA2 and HERC2 genes are noteworthy for their important contribution in pigmentation process. Prediction of phenotypes by using genetic information has benefited forensic area in many countries because it has made possible to infer physical characteristics from biological samples and, thus, lead criminal investigations. The aim of this study was evaluate polymorphisms in TYR, ASIP, SLC24A5 and SLC45A2 genes in a sample of 350 individuals of admixed population from Brazil, intending to use the data in forensic genetics casework in several situations. Volunteers answered a questionnaire where they self-reported their skin, eye and hair colors, sun sensitivity and lifestyle. No significant results were observed except for SLC24A5 and ASIP. The polymorphic homozygous allele of rs1426654 and rs6058017 in SLC24A5 (OR 32.88 $p<0.0001$) and ASIP (OR 8.68 $p< 0.007$) respectively, showed strongest association with fairer skin. Besides, the polymorphic homozygous allele in SLC24A5 exhibited relation to light eye color - green (OR 9.82 - $p<0.0001$), blond hair (OR 50.14 - $p<0.0001$) and also to increased sensitivity to sun exposure (OR 7.86 - $p<< 0.0002$). Our data suggests that polymorphic allele (A) in the SLC24A5 and ASIP genes is correlated with characteristics of light pigmentation, while the ancestral allele (G) is related to darker traits. Our findings corroborate previously published data on studies in European and African populations. These associations between pigmentation genes and skin, eyes and hair color shows that it is possible to use molecular information of an individual to access its phenotypic traits and use the obtained in attempt to help forensic investigations. Additional analyzes are ongoing as part of a project that evaluates 600 samples to check possible associations of phenotypic pigmentation in the Brazilian population with the mentioned genes. Financial Support: FAPESP (2012/02043-6), LIM 40/HCFMUSP and Department of Legal Medicine, Ethics and Occupational Health - FMUSP.

Interpretation of the high allele frequency of *GJB2* c.109 G>A variant in Chinese population: a pathogenic mutation or coincidental polymorphism? *Y. Lu[1,2], J. Cheng[2], H. Yuan[2].* 1) Otolaryngology Dept., No. 150 Central Hospital of PLA, Luoyang, Henan, China; 2) Otolaryngology Dept., Chinese PLA General Hospital, Beijing, China.

Hearing loss is a common sensory disorder in humans. Genetic factor plays more and more important role in the etiology of hearing loss than the environmental factors, which are controlled gradually and effectively with the development of the economy in the past two decades. Despite the high heterogeneity of genetic defects of hearing loss, *GJB2* mutations cause more than 17% nonsyndromic hearing loss in Chinese population. The pathogenic role of a common c.109 G>A variation in *GJB2* gene keeps uncertain in hearing loss cases. In this study, we recruited 37 subjects with homozygous c.109 G>A variation in *GJB2*, and 17 subjects with both heterozygous c.109 G>A and a heterozygous mutation in *GJB2*. All the subjects were excluded hotspot mutations in *SLC26A4* gene and mtDNA 12S rRNA, which were also common causative genes in Chinese deaf population. The hearing status of the subjects included normal(7 cases), mild to moderate (both prelingual and postlingual) (21 cases), severe to profound(26 cases). DNA samples from the parents were available. Fourteen tag-SNPs were selected based on the HapMap LD data set ($r^2>0.9$, MAF>0.1) in DFNB1 locus. Haplotypes of the subjects were derived from genotyping by SNaPshot technique. The results inferred that c.109 G>A in *GJB2* gene in Chinese population originated from a founder with a common LD block rather than a recurrent hotspot. Recent functional studies have produced somewhat contradictory results regarding the pathogenicity of the c.109 G>A variant. More than 6% allele frequency of c.109 G>A were detected both in hearing loss subjects and normal hearing controls in Chinese population. Although the penetrance of mild to moderate hearing loss in homozygotes is significant higher than heterozygotes and wild type subjects, the severity of hearing loss of *GJB2* c.109 G>A subject is still unpredictable in clinical practice. It is possible that other defects, such as CNV in the upstream sequence of *GJB2*, causes functional defect in connexin 26. The defects of other genes related to hearing loss need to be investigated with next generation sequencing. In conclusion, the pathogenic role of *GJB2* c.109 G>A needs further interpretation under next generation sequencing and functional study.

1946M

Target sequencing analysis of Parkinson's disease genes in a healthy Amerindian Population from Puno-Peru. *M. Cornejo-Olivas[1, 2], I.F. Mata[3,4], M.O. Dorschner[4], M. Inca-Martinez[1], A. Medina[1,7], A.C. Shetty[5], P. Kumari[5], K. Espinoza-huertas[1], D. Veliz-Otani[1], D. Incacutipa[7], V. Marca[1], O. Ortega[1], P. Mazzetti[1,8], C. Zabetian[3,4], T. O'Connor[5,6], Latin American Research Consortium on the Genetics of Parkinson's Disease (LARGE PD).* 1) Neurogenetics Research Center, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 2) Northern Pacific Global Health Research Training Consortium, Bethesda, MD; 3) Veteran Affairs Puget Sound Health Care System, USA; 4) University of Washington, USA; 5) Institute for Genome Sciences, University of Maryland School of Medicine; 6) Program in Personalized and Genomic Medicine, University of Maryland School of Medicine; 7) Universidad Nacional del Altiplano, Puno, Peru; 8) School of Medicine, Universidad Nacional Mayor de San Marcos. Lima, Peru.

Background: Both causal and susceptibility genes for Parkinson's disease (PD) known to date were discovered in either European or Asian populations. Studies on the genetics of PD in Latin-American populations are very much needed yet all such studies face a major obstacle in that there is no systematic information available on common genetic variability in healthy Amerindians to facilitate distinguishing pathogenic mutations from benign variants. **Objective:** To characterize genetic variability and estimate the frequency of genetic variants in 15 known causal PD genes in a Peruvian Quechua native population. **Methods:** Our study was performed using DNA samples and linked demographic data from 50 unrelated Amerindian subjects recruited in Puno, Peru through the Latin American Research Consortium on the Genetics of Parkinson's Disease. Sequencing analysis, including intron/exon boundaries was performed using a panel based on modified molecular inversion probes (MIPs) that included the 15 PD genes and 29 ancestry informative markers (AIMs). The resulting variants were categorized into different groups for comparison with other populations/datasets. We compared the frequencies of the single nucleotide variants (SNVs) to those in the 1000 Genomes Project (1KG) and Exome sequencing project databases (ESP). **Results:** Analysis of the 29 AIMs indicated that the average proportion of Amerindian ancestry in our sample of Peruvian Quechuas was 90%. Within the 15 PD genes, we detected 400SNVs. Of these variants 302 were not observed in 1KG, ESP or dbSNP 137. The majority of these unique variants were rare, but 18 had a minor allele frequency ≥ 5%. We found 124 novel non-synonymous variants and 9 novel nonsense mutations. **Conclusions:** Within a sample of healthy Amerindians from Peru, we found a surprisingly large number of previously unreported variants across the coding region of known PD genes . Annotating these variants in publicly available databases will aid future studies on the genetics of PD in Latin American populations. Furthermore, our results suggest that generating exomes or whole genomes in additional Amerindian controls (to supplement publicly available data) might be of benefit to genetic studies of other diseases conducted in populations with substantial Amerindian admixture.

1947S

Prevalence and sources of genetic variation in human mitochondria. *E. Glassberg[1], A. Harpak[1], D. Calderon[2], D. Cusanovich[3], M. Caliskan[3], Y. Gilad[3], C. Ober[3], J. Pritchard[1].* 1) Biology, Stanford University, Stanford, CA; 2) Biomedical Informatics, Stanford University, Stanford, CA; 3) Human Genetics, University of Chicago, Chicago, IL.

Heteroplasmy refers to the presence of multiple distinct organellar genomes within a single individual. In humans, heteroplasmic mutations in the mitochondrial genome are associated with a variety of bioenergetic defects and maternally inherited diseases. Here, we set out to quantify the prevalence of human mitochondrial heteroplasmy at the individual and population levels. We use the observed patterns of variation to infer the contributions of stochastic genetic drift and natural selection to mitochondrial evolutionary dynamics within and between human hosts. To identify heteroplasmic sites from next-generation sequencing data, we examine the log-likelihood ratio of simple statistical models of homoplasmy and heteroplasmy at each position of the mitochondrial genome. We apply this method to 2535 individuals from the 1000 Genomes Project and to RNASeq data from 432 individuals of varying degrees of relatedness from a founder population of Hutterites in South Dakota. In both cases, we observe widespread heteroplasmy. In the Hutterites, we find that heteroplasmic sites are significantly more likely to be shared between mother-child pairs than between unrelated individuals or father-child pairs. This pattern is more pronounced among sites at which the heteroplasmic allele is present at greater than five percent frequency in the mother. However, while some heteroplasmic sites are inherited maternally, the vast majority arise *de novo* within an individual. We then develop a novel inference algorithm to estimate the intensity of genetic drift experienced by the mitochondrial population during transmission from mother to child and during expansion from the germline to somatic cells. Separating the contributions of germline drift from those of somatic drift will allow us to clearly determine the population genetic setting in which inherited and *de novo* heteroplasmic variants are lost. Further, to understand the effects of selection on heteroplasmic sites, we compare observed patterns of heteroplasmy at sites that are likely to be neutral to those at sites that are likely to be influenced by selection, especially focusing on known disease-associated sites. These analyses form a basis for disentangling the contributions of various population genetic factors to observed patters of mitochondrial genetic variation.

1948M

Maternal Age Effect and Severe Germline Bottleneck in the Inheritance of Human Mitochondrial DNA. *M. Su[1], B. Rebolledo-Jaramillo[2], N. Stoler[2], J.A. McElhoe[3], B. Dickins[4], D. Blankenberg[2], T. Korneliussen[5], F. Chiaromonte[6], R. Nielsen[5], M.M. Holland[3], I.M. Paul[7], A. Nekrutenko[2], K.D. Makova[1].* 1) Department of Biology, Penn State University, USA; 2) Department of Biochemistry and Molecular Biology, Penn State University, USA; 3) Forensic Science Program, Penn State University, USA; 4) School of Science and Technology, Nottingham Trent University, UK; 5) The Department of Integrative Biology, the University of California at Berkeley, USA; 6) Department of Statistics, Penn State University, USA; 7) Department of Pediatrics, College of Medicine, Penn State University, USA.

The manifestation of mtDNA diseases depends on the frequency of heteroplasmy (the presence of several alleles in an individual), yet its transmission across generations cannot be readily predicted due to the lack of data on the size of mtDNA bottleneck during oogenesis. For deleterious heteroplasmies, a severe bottleneck may abruptly transform a benign (low) frequency in a mother into a disease-causing (high) frequency in her child. Here we present a high-resolution study of heteroplasmy transmission conducted on blood and buccal mtDNA of 39 healthy mother-child pairs of European ancestry (a total of 156 samples, each sequenced at ~20,000x/site). On average, each indivual carried one heteroplasmy, and one in eight individuals carried a disease-causing heteroplasmy, with minor allele frequency ≥1%. We observed frequent drastic heteroplasmy frequency shifts between generations and estimated the size of the bottleneck at only ~29-35 mtDNA molecules. Strikingly, we found a positive association between the number of heteroplasmies in a child and maternal age at fertilization, likely attributable to oocyte aging. Accounting for heteroplasmies, we estimate mtDNA germline mutation rate to be 1.3×10-8 mutations/site/year - lower than in previous pedigree studies but in agreement with phylogenetic studies, thus solving a long-standing controversy and informing the use of mtDNA in dating evolutionary events. This study takes advantage of droplet digital PCR (ddPCR) to validate heteroplasmies and confirm a de novo mutation. These results have profound implications for predicting the transmission of disease-causing mtDNA variants and illuminate mitochondrial genome evolutionary dynamics.

1949S

Cilioretinal artery: is it a variant angiogenesis under the effect of PAI-1 5G allele? *I. Akalin[1], A. Ardagil Akcakaya[2], S. Basaran Yilmaz[1], Y. Dag[3], M. Guzin Altinel[3], E. Kurum[4], E. Koyun[3], S. Ari Yaylali[2], H. Bayramlar[3].* 1) Medical Genetics, Istanbul Medeniyet University, Faculty of Medicine, Istanbul, Turkey; 2) Ophthalmology, Istanbul Medeniyet University, Goztepe Training and Research Hospital, Istanbul, Turkey; 3) Ophthalmology, Istanbul Medeniyet University, Faculty of Medicine, Istanbul, Turkey; 4) Biostatistics, Istanbul Medeniyet University, Faculty of Medicine, Istanbul, Turkey.

Purpose: Cilioretinal arteries (CRA) are small accessory arteries contribute to macular blood supply. The reason why some people have CRA while the others don't has not been elucidated yet, except its higher concordance in monozygotic twins. Here, we hypothesized whether genetic tendency to thrombosis due to well-known gene polymorphisms may induce CRA as a variant angiogenesis in embryonic life. Methods: We assessed plasminogen activator inhibitor-1 (PAI-1) 4G/5G, methylenetetrahydrofolate reductase (MTHFR), factor V leiden and prothrombin gene polymorphisms on 130 patients [82 females, 48 males; Median age: 57 (18-84) with CRA and 100 (64 females, 36 males; Median age: 55 (19-90)] without CRA. Genotyping was performed by melting curve analyses using a Rotor-Gene Q Real-Time PCR system (QIAGEN, Hilden, Germany) and PAI -1 4G/5G, MTHFR (C677T and A1298C), Factor V Leiden, Prothrombin G20210A mutation analyses kits (NLM , Settala, Italy). Multiple Logistic Regression model used to predict the dependent variable (occurrence of cilioretinal artery) using a set of independent variables (gene polymorphisms) in addition to test the association significance. Results: We found PAI-1 4G/5G; MTHFR (C677T and A1298C) have significant effects on the probability of occurrence of CRA at significance level 0.05. The odds ratio (OR) corresponding to PAI-1 4G/5G was 1,984 (95% CI: 1.320-3.000, p=0.001), which implies that keeping all other variables constant and having at least one 5G allele would increase the odds of having the cilioretinal artery by 98.4%. Additionally, we observed that while keeping all other variables constant, having at least one MTHFR C677T or A1298C allele would decrease the odds of having the cilioretinal artery by approximately 38% (OR=0.618, 95% CI: 0.394-0.961, p=0.035) or 44% (OR=0.558, 95% CI: 0.354-0.871, p=0.011), respectively. No significant differences were found between occurrence of CRA and Factor V Leiden or prothrombin. Conclusion: This is the first study to suggest the existence of strong association between the presence of CRA and genetic factors, up to the literature. Here we suggest that, not only the lack of genetic predisposition to thrombosis by MTHFR gene polymorphisms, but also the PAI-1 5G allele might promote variant angiogenesis by increasing pressure on endothelial cells as a result of decreasing the blood viscosity.

1950M

Tumor Necrosis Factor-alpha Gene Polymorphism in Turkish Patients with Psoriasis. *H. Akar[1], Y. Yildiray[2], E. Koç[2], E. Çalişkan[2], A. Akar[2], Y. Tunca[1].* 1) Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey; 2) Dermatology, Gulhane Military Medical Faculty, Ankara, Turkey.

Introduction and objectives: Psoriasis is a chronic dermatosis that includes genetic and environmental factors in the etiology. Although complex cytokine network of psoriasis has not been well enlightened yet, tumor necrosis factor-α (TNF-α) is considered as main mediator in the pathogenesis of psoriasis. In addition to this, an association between single nucleotide polymorphisms (SNPs) at positions -238, -308, -857 in the promoter region of TNF-α and psoriasis were reported previous studies in different populations. In this study, we aimed to investigate potential association of TNF-α promoter gene polymorphisms with psoriasis compared with healthy controls in Turkish population. Materials and methods: We investigated 40 patients with psoriasis vulgaris and 40 healthy controls. SNPs at positions -208, -308, -857 in the promoter region of TNF-α were analysed by competitive allele specific-polymerase chain reaction method in both groups. SNPs frequencies were compared between the two groups and significance was evaluated by chi-squired test and two-tailed Fisher's exact test. Results: At the end of the study, we found that the TNF-α -308 AA and -857 CC homozygosities were significantly increased in patients with psoriasis in comparison with healthy controls (62.5% vs. 10%, p<0.01, OR=15.000; 47.5% vs. 7.5%, p<0.01, OR=11.159). TNF-α -308 AG and -857 TC heterozygosities were significantly decreased in patients with psoriasis in comparison with healty controls (32.5% vs. 75%, p<0.01, OR=0.160; 15% vs. 47.5%, p<0.01, OR=0.195). No significant difference was observed in SNP at -238 position. Conclusion: In conclusion, our findings suggested that TNF-α -308 AA and -857 CC homozygosities were associated with psoriasis vulgaris in Turkish population and these polymorphisms might be used as biological markers for psoriasis risk prediction. In contrast to previous studies, no significant differences were observed at -238 position. Further studies with larger populations are needed to confirm associations between -308 AA and -857 CC homozygosities and risk of psoriasis development in Turkish population.

1951S

Whole genome sequencing of a gibbon parent-offspring quartet to examine mutation rate variation in apes. *D.M. Bobo[1], O. Gokcumen[2], L. Carbone[3], M.F. Hammer[4], J.D. Wall[5], K.R. Veeramah[1].* 1) Ecology & Evolution, Stony Brook University, Stony Brook, NY; 2) Department of Biological Sciences, University at Buffalo, Buffalo, NY; 3) Department of Behavioral Neuroscience, Oregon Health and Science University, Portland, OR; 4) Arizona Research Laboratories Division of Biotechnology, University of Arizona, Tucson, AZ; 5) Institute for Human Genetics, University of California San Francisco, San Francisco, CA.

Understanding the evolution of the human germ line mutation rate (μ) is vital for numerous aspects of medical, population and evolutionary genetics. Traditionally, μ is estimated using a phylogenetic approach in which genetic divergence between two species is calculated. This divergence is then calibrated using some external estimate of when the species split and an assumed generation time to give the phylogenetic mutation rate per generation. More recently, direct observation of *de novo* mutations from whole genome sequencing of parent-child trios in humans have resulted in pedigree estimates of μ per generation that are approximately half of the phylogenetic rate. This discrepancy may be explained by the 'hominoid slowdown' where μ is thought to have decreased per unit time during the transition from small ancestral primates to larger apes with a longer generation times and lower mass-specific metabolic rates. As gibbons lie intermediate of old world monkeys and great apes with regard to phylogeny, body size and generation time, they are a potentially important extant primate family for testing the robustness of the hominoid slowdown hypothesis. Therefore we generated high coverage short read second-generation sequencing data for a family quartet from Nomascus gabriellae (the yellow-cheeked gibbon) in order to estimate the *de novo* pedigree mutation rate for this species. The male sibling was sequenced using Illumina's 1TB technology and yielded ~67x mean mapped read depth. The Illumina HiSeq 2500 was used for sequencing the parents and female sibling, with genome coverage ranging from 25-33x mean read depth. A custom bioinformatics pipeline was implemented incorporating published likelihood-based methods to weight candidate germline *de novo* variants and determine the probable parent of origin. Extensive validation of *de novo* candidates across a range of confidence scores was performed using multiple methods. We then used this data to develop a machine learning algorithm to estimate μ for the two individuals in this quartet for comparison to the recent pedigree estimates in humans. We were also able to identify *de novo* copy number variation using comparisons of normalized whole genome read depth. Finally, we used a HMM method to infer inheritance states across the genome and obtain fine-scale resolution of paternal and maternal recombination events, demonstrating that gibbons show a female recombination bias similar to that observed in humans and mice.

1952M

Significant association of Pro129Thr polymorphism in the fatty acid amide hydrolase (*FAAH*) gene with body mass index in Oceanic populations. *I. Naka[1], N. Nishida[2], T. Furusawa[3], R. Kimura[4], T. Yamauchi[5], K. Natsuhara[6], M. Nakazawa[7], Y. Ataka[8], T. Ishida[9], T. Inaoka[10], Y. Matsumura[11], R. Ohtsuka[12], J. Ohashi[1].* 1) University of Tsukuba, Tsukuba, Ibaraki, Japan; 2) Research Center for Hepatitis and Immunology, International Medical Center of Japan Konodai Hospital, Ichikawa, Japan; 3) Graduate School of Asian and African Area Studies, Kyoto University, Kyoto, Japan; 4) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Nakagami, Okinawa, Japan; 5) Department of Health Sciences, Hokkaido University School of Medicine, Sapporo, Hokkaido, Japan; 6) The Japanese Red Cross Akita College of Nursing, Akita, Akita, Japan; 7) Department of International Health, Kobe University Graduate School of Health Sciences, Kobe, Hyogo, Japan; 8) School of Policy Studies, Kwansei Gakuin University, Sanda, Hyogo, Japan; 9) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Bunkyo, Tokyo, Japan; 10) Department of Human Ecology, Faculty of Agriculture, Saga University, Saga, Saga, Japan; 11) Faculty of Health and Nutrition, Bunkyo University, Chigasaki, Kanagawa, Japan; 12) Japan Wildlife Research Center, Taito, Tokyo, Japan.

Oleoylethanolamide (OEA), an appetite-suppressing mediator, is degraded by an integral membrane enzyme encoded by the fatty acid amide hydrolase (*FAAHItalic Text*) gene. A previous study demonstrated that the activity of FAAH enzyme was influenced by a non-synonymous SNP (rs324420; Pro129Thr) in the *FAAH* gene. The FAAH activity has been suggested to be higher in subjects homozygous for rs324420-C (129Pro) than in those for rs324420-A (129Thr) due to a post-translational mechanism. The possible association of rs324420 with overweight/obesity has been assessed in various populations to date. However, the association studies have yielded contradictory results. In the present study, the associations of rs324420 with anthropometric measurements (i.e., height, weight, and body mass index [BMI]) were examined in 694 adult subjects living in Solomon Islands and Tonga. A multiple regression analysis adjusted for age, sex, and population revealed that a copy of rs324420-C allele significantly increased weight by 2.3 kg (P-value = 0.0201), whereas rs324420-C was not associated with height. The rs324420-C allele was also significantly associated with increase in BMI (P-value = 0.00627 and slope = 0.91 kg/m2). Our results suggest that the efficient degradation of OEA due to 129Pro-FAAH protein may lead to excessive food intake and significant weight gain in Oceanic populations.

Brazilian population data on 26 non-CODIS STR loci used for paternity and kinship analysis. *V.S. Sotomaior[1], T.F.C. Pereira[1,2], N. Gaburo Júnior[2], J.C.M. Magalhaes[3], M. Malaghini[2].* 1) Graduate Program in Health Sciences, PUCPR, Curitiba, Brazil; 2) Diagnósticos da América S.A., Brazil; 3) Department of Genetics, Universidade Federal do Paraná, Curitiba, Brazil.

Microsatellites or short tandem repeats (STRs) are molecular markers that are widely used in population genetics and forensic analyses because of their high degree of polymorphism and heterozygosity. However, only a few population studies have been carried out in Brazil, particularly using markers that are not included in the US criminal justice DNA database systems - Combined DNA Index System (CODIS). In this study, we investigated 26 autosomal non-CODIS STRs (D1GATA113, D1S1627, D1S1677, D2S441, D2S1776, D3S3053, D3S4529, D4S2364, D4S2482, D5S2500, D6S474, D6S1017, D8S1115, D9S1122, D9S2157, D10S1248, D10S1435, D11S4463, D12ATA63, D14S1434, D17S974, D17S1301, D18S853, D20S482, D20S1082, and D22S1045) in a sample of the Brazilian population. This sample was composed of 1,068 unrelated individuals who had undergone genetic kinship analyses between 2007 and 2013. The individuals (n = 1068) were from 5 Brazilian regions (south: 717, southeast: 163, central west: 36, northeast: 129, and north: 23). For some analyses and whenever data was available, the individual's self-declared ethnicity was taken into consideration, according to IBGE's criteria (white: 641, black: 43, brown: 174, and yellow: 19). All the loci analyzed showed great diversity, the number of alleles varied from 5 (D4S2364) to 14 (D10S1435) and the mean of alleles number in all loci was 8.6. The majority of alleles exhibited a frequency that was higher than 1%, being allele 9 at locus D4S2364 the most frequent allele (q = 0.572). No significant deviations from the Hardy-Weinberg equilibrium were observed in any locus or sample; similar findings were obtained for F_{IS} values. The heterozygosity observed for each locus varied from 0.559 (D4S2364) to 0.851 (D9S2157). All 26 markers exhibited information capacity of use in kinship tests, with PIC > 0.5. The PDM was 81%, the PEE was 99.999999%, and the ITP was 99.99999%. In order to investigate population structure, the F_{ST} values for each pair of samples were calculated according to region and ethnicity. Although differences were observed for some loci, none of the obtained values reached significance, indicating low genetic differentiation among subsamples. Therefore, it has been demonstrated that the panel of markers investigated in this study are an important tool in the analysis of complex cases during kinship investigation, allowing the use of Brazilian population allele frequencies to infer the evidential value of kinship tests in Brazil.

1954M

An estimate of the average number of recessive lethal mutations carried by humans. *Z. Gao[1], D. Waggoner[2,3], M. Stephens[2,4], C. Ober[1,2,5], M. Przeworski[6,7].* 1) Committee on Genetics, Genomics and Systems Biology; 2) Dept of Human Genetics; 3) Dept of Pediatrics; 4) Dept of Statistics; 5) Dept of Obstetrics and Gynecology, University of Chicago, Chicago, IL; 6) Dept of Biological Sciences; 7) Dept of Systems Biology, Columbia University, New York, NY.

The effects of inbreeding on human health depend critically on the number and severity of the recessive deleterious mutations carried by an individual. In humans, estimates of the burden of recessive mutations per individual are based either on comparisons between consanguineous and non-consanguineous couples, an approach that confounds socioeconomic and genetic effects, or on carrier screening for disease-causing mutations, which suffers from other biases, notably the highly incomplete catalogue of disease-causing mutations. To circumvent these limitations, we sought to estimate a lower bound of the burden by focusing on recessive lethal disorders in a founder population with almost complete Mendelian disease ascertainment and a known pedigree. By considering all autosomal recessive lethal diseases recognized in the population and simulating allele transmissions along the pedigree, we estimated that each haploid human genome carries on average approximately one autosomal recessive allele that leads to severe disorders at or after birth in homozygous condition. When compared with previous estimates, our result suggests that recessive mutations that are lethal constitute a substantial fraction of the total burden of recessive deleterious mutations in humans.

1955S

Testing the infinite sites assumption using the 1000 genomes dataset. *S. Huang, D. Yuan.* State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China.

The infinite sites model of the neutral theory is a fundamental assumption underlying nearly all population genetic and phylogenetic studies today but has yet to be properly tested. We here examined it from two novel perspectives using the 1000 genomes dataset. First, we studied the genetic diversity patterns of different human populations using a variety of different types of SNPs, such as noncoding, stop codon, nonsyn, syn, etc. Patterns shown by noncoding SNPs are expected to be similar to those shown by known functional stop codon SNPs, if most SNPs are not neutral. In contrast, neutral SNPs should show a most different pattern from stop codon SNPs. Second, it has long been well known that most genetic variations are shared among different human groups, which has been interpreted to mean few genetic differences among the ethnic groups (Lewontin, 1972). But the possibility of saturation or independent mutations to account for this phenomenon has yet to be examined and excluded. Saturation would mean limited rather than infinite sites and fast evolving DNAs are expected to reach saturation faster. We compared the number of shared SNPs in DNAs of different evolutionary rates among different human populations to see if shared SNPs are more common in fast evolving DNAs relative to slow ones. Results from these tests and their implications for phylogenetic studies will be presented.

1956M

Inference of mutation rates using hidden relatedness. *P.F. Palamara[1,2,3], P. Wilton[4], M. Fromer[5,6], G. Kirov[7], S. McCarroll[3,6,8], P. Sklar[5,9], M. Owen[7], S. Purcell[5,6,10], M. O'Donovan[7], J. Wakeley[4], I. Pe'er[11, 12].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA, USA; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Boston, MA, USA; 4) Department of Organismic and Evolutionary Biology, Harvard University, Boston, MA, USA; 5) Division of Psychiatric Genomics in the Department of Psychiatry, and Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 6) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Boston, MA, USA; 7) Medical Research Council Centre for Neuropsychiatric Genetics and Genomics, Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University, Cardiff, UK; 8) Department of Genetics, Harvard Medical School, Boston, Massachusetts, USA; 9) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 10) Analytic and Translational Genetics Unit, Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 11) Center for Computational Biology & Bioinformatics, Columbia University Medical Center, New York, NY, USA; 12) Department of Computer Science, Columbia University, New York, NY.

Reliably estimating the mutation rate in modern humans has several implications for our understanding of demographic history (Scally and Durbin, Nature Reviews Genetics 2012). Recent estimates of the mutation rate obtained using de novo mutations in next-generation sequencing of families, however, were found to disagree with phylogenetic mutation rates derived from fossil evidence, motivating the development of new analytical methods. We describe an approach for the inference of mutation rates based on sharing of identical-by-descent (IBD) segments in sequencing data across purportedly unrelated individuals from a population. Using coalescent theory, we derive theoretical results for the distribution of mutation events found on IBD segments longer than a specified centimorgan threshold, for arbitrary demographic settings, under the SMC and SMC' models. Leveraging the relationship between the length and the age of shared IBD haplotypes, we devise a method to estimate both genotype error rates and mutation rates. The proposed approach based on hidden relatedness offers a substantial increase in statistical power compared to family-based analysis of de-novo mutations. This gain in power occurs despite the fact that the fraction of genome shared through long (e.g. >1cM) IBD segments across purportedly unrelated individuals is usually small, since IBD regions harbor events which have occurred in the recent past, over tens to hundreds of generations. Furthermore, analysis of de-novo mutations in trio-based studies is limited to genomic regions transmitted through known pedigree relationships, while when accurately phased data is available, mutation events can be analyzed on IBD segments across the quadratically larger set of all pairs of unrelated individuals. We validate the proposed methodology using synthetic datasets for a variety of demographic scenarios, and analyze mutation rates in 1246 trio-phased unrelated individuals from a recent exome sequencing study (Fromer et al., Nature 2014) of schizophrenia patients.

1957S

Hundreds of shared 'deletions' in ancient hominins are polymorphic in modern human populations. *D. Radke[1,2], C. Lee[3], S. Sunyaev[1,2].* 1) Harvard Medical School, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) The Jackson Laboratory for Genomic Medicine, Farmington, CT.

Deciphering the genetic uniqueness of modern humans in relation to distant hominins and other primates is one of the central goals of human evolutionary genomics. Recently, with the availability of high-coverage sequence data for both Neanderthal and Denisova, it is now possible to more precisely determine the particular loci responsible for modern human uniqueness. While much of the distinguishing variation may be due to single nucleotide variants, genomic structural variants may also play a crucial role. Structural variants can be a potent phenotype-shaping force, particularly for unbalanced events, such as deletions, as they can alter reading frames and remove regulatory component space. Analyzing sequence read depth across archaic genomes, we find hundreds of 'deleted' regions in Neanderthal and Denisova (including many shared deletions), which are polymorphic in modern human populations. Some shared deletions overlap genes, and shared deletions as a set have a significantly higher allele frequency in modern human populations. Because these deletions are polymorphic in modern humans, they may represent regions of modern human-specific insertion, regions lost in archaic human lineages, or deletions polymorphic in both modern and archaic populations.

1958M

The evolution of genes underlying autism and schizophrenia and its impact on disease susceptibility. *M-.J. Favé[1], J. Hussin[2], P. Awadalla[1,3].* 1) CHU Sainte-Justine, Department of Pediatrics, Faculty of Medicine, Université de Montréal, Montreal, Quebec, Canada; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) CARTaGENE, 3333 Queen Mary Road, Office 493, Montreal, Quebec.

It has been hypothesized that a genotypic and phenotypic continuum exists between autism and schizophrenia, with both disorders showing diametric patterns in the impairment of language, communication and social behaviour. Recent work proposes that the human susceptibility to develop these disorders may originate as a collateral consequence of the selection for cognitive traits. Over the last decade, hundreds of both rare and common variants associated with the development of these disorders have been identified: several common variants have been found by genome-wide association studies, and rare *de novo* mutations have been captured by whole-exome sequencing studies of sporadic cases, for which no family history exists. We can therefore test whether genes harbouring common and *de novo* variants have evolved under different selective regimes, and whether local genomic features influence their variation and evolution. Using a recombination map from a French Canadian population recruited by the CARTaGENE project, we found that *de novo* variants associated with these disorders are enriched in regions of low recombination rate, whereas no such biases are found for common variants. Low recombining genes harbouring *de novo* variants are predominantly involved in fundamental cellular processes, whereas the few genes (49, or 2.7%) found in high recombination regions are enriched in membrane-proteins, axonal guidance and neuronal differentiation. In order to detect if genes harbouring common and *de novo* variants associated with autism and schizophrenia evolved under different selective pressures, we measured signals of selection using dN/dS ratios on the whole gene, and using sliding windows within genes. We performed these tests along the mammal and the primate lineage to estimate the timing of any selective event. Although most genes show patterns of evolution consistent with purifying selection, some genes in which many recurrent *de novo* mutations hits have been detected, such as *ABCA13*, *LRP1* and *MYH9*, show strong signals of positive selection in at least one domain of the gene, and along the primate lineage specifically. While genes involved in neurodevelopmental disorders mainly evolved under purifying selection in low recombining regions of the genome, these results show that diversity in specific domains of key genes may have been subjected to positive selection during primate evolution.

1959S

Systematic detection of positive selection in the human-pathogen interactome. *E. Corona[1], A.J. Butte[2], C.J. Patel[1].* 1) Biomedical Informatics, Harvard University, Boston, MA; 2) Biomedical Informatics, Stanford University, Stanford, CA.

Infectious disease has affected the human genome around the world. Identifying positive selection associated with infectious disease provides information regarding pathogen exposure in distinct human populations. Human-pathogen interactions are a constantly evolving interface between host and disease. We created a human pathogen interaction database and used the integrated haplotype score (iHS) to detect recent positive selection in genes that interact with proteins from 24 different infectious organisms. The Human Genome Diversity Panel was used to identify specific populations harboring pathogen-interacting genes that have undergone positive selection. We found that genes that interact with 12 pathogen species have undergone recent positive selection. The 12 pathogens are human immunodeficiency virus 1, Yersinia pestis, human respiratory syncytial virus, human herpesvirus 8, Bacillus anthracis, measles virus, dengue virus, murid herpesvirus 1, Francisella tularensis, Zaire ebolavirus, hepatitis C virus, and influenza A virus. Human genes in the Italian, Miao, and Biaka Pygmy populations that interact with Yersinia pestis show significant signs of selection. Our results show strong positive selection in genes that interact with human immunodeficiency virus 1, providing further support for the hypothesis that ancient humans were repeatedly exposed to lentivirus pandemics. These results indicate that infectious disease created distinct genetic footprints within affected populations.

1960M

Convergent mechanisms underlying hypoxia adaptation in Drosophila and Humans. *A.R. Jha[1,2,3], D. Zhou[4,5], C.D. Brown[1,2], G.G. Haddad[4,5], M. Kreitman[1,2,3], K.P. White[1,2,3].* 1) Institute for Genomics and Systems Biology, The University of Chicago, Chicago; 2) Department of Human Genetics, The University of Chicago, Chicago, USA; 3) Department of Ecology and Evolution, The University of Chicago, Chicago, USA; 4) Department of Pediatrics, Division of Respiratory Medicine, University of California at San Diego, San Diego, CA, USA; 5) Rady Children's Hospital, San Diego, CA, USA.

The ability to withstand low oxygen (hypoxia) is a highly polygenic yet mechanistically conserved trait that has important implications for both human health and evolution. However, little is known about the diversity of genetic mechanisms involved in hypoxia-adaptation in evolving populations. We used experimental evolution and whole-genome sequencing in Drosophila melanogaster to investigate the role of natural variation in adaptation to hypoxia. Using a Generalized Linear Mixed Model we identified significant allele frequency differences between three independently evolved hypoxia-tolerant populations and normoxic controls for ~4000 single nucleotide polymorphisms. Many of these variants are clustered in 66 distinct genomic regions representing long-distance linkage in our populations. These regions are enriched for genes associated with metabolic processes and contain genes that are differentially expressed between hypoxia-tolerant and normoxic populations. Additional genes associated with open tracheal system development and notch signaling pathways also showed evidence of directional selection. Knocking down the gene expression of a handful of candidate genes showed striking enhancement in survival in severe hypoxia, demonstrating their functional relevance in hypoxia adaptation. Using whole genome genotyping data from three high-altitude human populations, namely— Sherpas, Tibetans, and Ethiopians , we show that the human orthologs of the genes under selection in flies are also under positive selection in all three high-altitude human populations. Therefore, comparative genomics approaches, such as the one we have taken here, can be powerful in revealing genes and pathways underlying evolutionarily ancient traits that have conserved functions for millions of years.

1961S

Evaluating the impact of recent human demography on the frequency spectra using numerical solution of time-inhomogeneous diffusion equation. *E. Koch[1], J. Novembre[2].* 1) Department of Ecology and Evolution Unversity of Chicago, Chicago, IL; 2) Department of Human Genetics Unversity of Chicago, Chicago, IL.

Differences in recent demographic history appear to be an important driver of observed levels of genetic diversity among human populations. Recent attention has particularly centered on how populations that went through the out-of-Africa bottleneck have lower heterozygosity and polymorphic sites that are proportionally more likely to be nonsynonymous or predicted to be damaging. These results have suggested differences in the frequency spectrum of deleterious variation are also caused by varying population demographic histories. To investigate these phenomena in more detail, we perform numerical solutions to time-inhomogeneous diffusion equations for the allele frequency spectrum under the Poisson Random Field Model. This allows us to efficiently examine how the frequency spectra has evolved through time under a large number of possible human demographies and distributions of selective effects. We also are able to easily stratify variation observed today by the age at which the variation was generated. Using these tools, we demonstrate the ability of natural selection and demography to produce observed patterns and evaluate the relative impacts of population bottlenecks, recent growth rates, and changing efficacy of selection on the abundance of different variant types. The results emphasize how human frequency spectra are far from equilibrium and make more clear how frequencies are affected by major human demographic events at different timescales. For instance, in out-of-Africa populations the impacts of the bottleneck on the frequency spectra are still being realized, even as more recent growth events lead to an overlaid influx of rare variants. We quantify these effects and discuss their importance for interpretation of human genetic variation patterns. .

1962M

The Genetic Architecture of Skin Pigmentation in the Southern African ≠Khomani San. *A.R. Martin[1], J.M. Granka[2], C.R. Gignoux[1], M. Lin[3], C. Uren[4], M. Möller[4], C.J. Werely[4], J.M. Kidd[5], M.W. Feldman[2], E.G. Hoal[4], C.D. Bustamante[1], B.M. Henn[1,3].* 1) Genetics Department, Stanford University, Stanford, CA; 2) Department of Biological Sciences, Stanford University, Stanford, CA, 94305; 3) Department of Ecology and Evolution, SUNY Stony Brook, NY 11794; 4) Division of Molecular Biology and Human Genetics, Stellenbosch University, Tygerberg, South Africa; 5) Department of Human Genetics, University of Michigan, Ann Arbor MI.

Skin pigmentation is one of the most recognizably diverse phenotypes in humans across the globe, but its highly genetic basis has been primarily studied in northern European, Asian, and African American populations. The Eurasian pigmentation alleles are among the most differentiated variants in the genome, suggesting strong selection for light skin pigmentation. Light skin pigmentation is also observed in the far southern latitudes of Africa among KhoeSan hunter-gatherers of the Kalahari Desert. The KhoeSan hunter-gatherers are among the oldest human populations, believed to have diverged from other populations 100,000 years ago, and maintain extraordinary levels of genetic diversity. It is unknown whether light skin pigmentation represents convergent evolution or the ancestral human phenotype. We have collected ethnographic information, pigmentation phenotypes, and genotype data from 136 individuals in the ≠Khomani San from the Kalahari. To understand the genetic basis for light skin pigmentation, we have also exome sequenced 83 ≠Khomani San individuals to high coverage, generating one of the largest indigenous African exome datasets sequenced outside of the 1000 Genomes Project. In this study, ≠Khomani individuals have 11.5% admixture with Europeans and 10.9% admixture with Bantu speakers on average. European ancestry significantly lightens skin and explains 13.3% of the variance in pigmentation, and Bantu ancestry significantly darkens skin and explains 16.1% of the variance in pigmentation on average. We estimate that pigmentation is highly heritable ($h2 = 0.887 \pm 0.188$ standard error) and find that most of the heritability can be explained by 50 known pigmentation genes (0.527 ± 0.310 or 64.1% on average). After controlling for admixture with European and Bantu-speaking populations, a linear mixed model GWAS approach does not identify variants significantly associated with pigmentation. However, pigmentation genes are among the most globally differentiated between the ≠Khomani San and European or Bantu individuals, and aggregating differentiation with association data improves power to detect variants influencing selected traits. We identify highly differentiated variants between the ≠Khomani and both European and Bantu populations in multiple canonical pigmentation genes, including OCA2 and MITF. Our results highlight the strength of diverse population studies to explain phenotypic variation impacted by human evolutionary history.

1963S

Association study confirms that two OCA2 polymorphisms are involved in normal skin pigmentation variation in East Asian populations. *E. Parra, K. Eaton, P. Kavanagh, M. Edwards, S. Krithika.* Dept Anthropology, Univ Toronto, Toronto, ON, Canada.

The last decade has witnessed dramatic advances in our understanding of the genetic architecture of normal skin pigmentation variation in European populations. However, evidence is much more limited for East Asian populations. Recently, we carried out a study aimed at identifying putative signatures of positive selection in pigmentation candidate genes in populations of East Asian ancestry. Based on the list of genes that show putative signatures of selection in East Asia, we prioritized a number of polymorphisms based on 1/ allele frequency information (e.g. differences in frequency between East Asian and non-East Asian populations) 2/ potential functional effects (e.g. Polyphen, SIFT and CADD scores) and 3/ conservation (e.g. GERP++ scores). The panel of SNPs selected includes 3 markers in the LYST gene (rs3754234, rs7522053 and rs4659610), one marker in the MLPH gene (rs2292881), 2 markers in the OPRM1 gene (rs1799971 and rs6917661), one marker in the EGFR gene (rs2227983), 4 markers in the BNC2 gene (rs9406647, rs3739714, rs10756778 and rs10962591), one marker in the TH gene (rs4930046), 3 markers in the OCA2 gene (rs1800414, rs74653330 and rs7497270), one marker in the TRPM1 gene (rs3809578) and 2 markers in the MC1R gene (rs33932559 and rs885479). We evaluated the association of these polymorphisms with skin pigmentation measured quantitatively using a DSM II colorimeter in a sample comprising 452 individuals of East Asian ancestry. Two previously described nonsynonymous polymorphisms within the OCA2 gene, rs1800414 (His615Arg) and rs74653330 (Ala481Thr) were strongly associated with melanin levels in this sample. Under an additive model, the common rs1800414 G allele, coding for Arginine, is associated with a decrease of 0.9 units in melanin levels. The rs74653330 A allele, coding for Threonine, is present at low frequency in East Asia (around 3% in our sample) and has a stronger effect on melanin levels than rs1800414 (decrease of 1.3 melanin units). No significant associations with skin pigmentation were observed for any of the other variants.

1964M

Positive Selection on Loci Associated with Drug and Alcohol Dependence. *B. Sadler[1], G. Haller[1,3], A. Goate[1,2,3].* 1) Department of Psychiatry, Washington University, St. Louis, MO, USA; 2) Department of Genetics, Washington University, St. Louis, MO, USA; 3) Department of Neurology, Washington University, St. Louis, MO, USA.

Much of the evolution of human behavior remains a mystery, including how certain disadvantageous behaviors are so prevalent. Nicotine addiction is one such phenotype. Several loci have been implicated in nicotine related phenotypes including the nicotinic receptor gene clusters (*CHRNs*) on chromosomes 8 and 15, and the nicotine metabolizing gene CYP2A6 on chromosome 19. Here we use 1000 Genomes sequence data from 3 populations (Africans, Asians and Europeans) to examine whether natural selection has occurred at these loci. We used Tajima's D and the integrated haplotype score (iHS) to test for evidence of natural selection. Our results provide evidence for strong selection in the nicotinic receptor gene cluster on chromosome 8, previously found to be significantly associated with both nicotine and cocaine dependence as well as evidence of weaker, but still detectable, selection acting on the region containing the *CHRNA5* nicotinic receptor gene on chromosome 15, that is genome wide significant for risk for nicotine dependence. To examine the possibility that this selection is related to memory and learning, we utilized genetic data from the Collaborative Studies on the Genetics of Alcoholism (COGA) to test variants within these regions with three tests of memory and learning, the Wechsler Adult Intelligence Scale (WAIS) Block Design, WAIS Digit Symbol and WAIS Information tests. Of the 17 SNPs genotyped in COGA in this region, we find one significantly associated with WAIS digit symbol test results. This test captures aspects of reaction time and memory, suggesting that a phenotype relating to memory and learning may have been the driving force behind selection at these loci.

1965S

Neanderthal Origin of the Haplotypes Carrying the Functional Variant Val92Met in the *MC1R* in Modern Humans. *Q. Ding[1], Y. Hu[1], S. Xu[2], C. Wang[1], H. Li[1], R. Zhang[1], S. Yan[1], J. Wang[1], L. Jin[1,2].* 1) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai Institute for Biological Sciences (SIBS), Chinese Academy of Sciences (CAS), Shanghai, China.

Skin color is one of the most visible and important phenotypes of modern humans. Melanocyte-stimulating hormone and its receptor played an important role in regulating skin color. Here we present evidence of Neanderthal introgression encompassing the melanocyte-stimulating hormone receptor gene *MC1R*. The haplotypes from Neanderthal introgression diverged with the Altai Neanderthal 103.3 KYA, which postdates the anatomically modern human - Neanderthal divergence. We further discovered that all of the putative Neanderthal introgressive haplotypes carry the Val92Met variant, a loss-of-function variant in *MC1R* that is associated with multiple dermatological traits including skin color and photoaging. Frequency of this Neanderthal introgression is low in Europeans (~5%), moderate in continental East Asians (~30%), and high in Taiwanese aborigines (60-70%). Since the putative Neanderthal introgressive haplotypes carry a loss-of-function variant that could alter the function of *MC1R* and is associated with multiple traits related to skin color, we speculate that this Neanderthal introgression, together with the previously reported Neanderthal introgression at *HYAL2*, may have played an important role in the local adaptation of modern Eurasians to sunlight intensity.

1966M

Altitude adaptation in Tibet caused by introgression of Denisovan-like DNA. *E. Huerta-Sanchez[1,2,3], X. Jin[2,4], A. Asan[2,5,6], Z. Bianba[7], B. Peter[1], N. Vinckenbosch[1], Y. Liang[2,5,6], M. As modern humans migrated out of Africa, they encountered many different environmental conditions including temperature extremes, new pathogens, and high altitude. These diverse environments have likely acted as agents of natural selection and led to local adaptations. One of the most illustrious examples in humans is the adaptation of Tibetans to the hypoxic environment of the high-altitude Tibetan plateau. A hypoxia pathway gene, EPAS1, was previously identified as having the most extreme signature of positive selection in Tibetans, and was shown to be associated with differences in hemoglobin concentration at high altitude. Re-sequencing the region around EPAS1 in 40 Tibetan and 40 Han individuals, we find that this gene has a highly unusual haplotype structure that can only be convincingly explained by introgression of DNA from Denisovans or Denisovan-related individuals into humans. Scanning a larger set of worldwide populations, we find that the selected haplotype is only found in Denisovans and in Tibetans, and at very low frequency among Han Chinese. Furthermore, the length of the haplotype, and the fact that it is not found in any other populations, makes it unlikely that the Tibetan/Denisovan haplotype sharing was caused by incomplete ancestral lineage sorting rather than introgression. Our findings illustrate that admixture with other hominin species has provided genetic variation that helped humans adapt to new environments.

1967S

Whole genome sequencing to uncover adaptation to high altitude in the Andes. *M. Muzzio[1,2], K. Slivinski[3], M.C Yee[4], T. Cooke[5], C.D Bustamante[5], G. Bailliet[1], C.M. Bravi[1,2], E.E. There is interest in human adaptation to a diversity of environments, including finding the genetic basis to phenotypes favorable to pressures such as hypoxia. We have preliminary Illumina Exome Array data on a set of 43 individuals from high altitude villages in the Andes from the Humahuaca area, Argentina (~2500 meters above sea level) and 11 individuals from a neighboring lowland population, Tartagal, Argentina (less than 500 meters above sea level), all with over 90% Native American ancestry estimated using the Admixture software. Currently, we are sequencing full genomes of 10 individuals from each of these populations, in search for new population-specific variants. We will use the population branch statistics (PBS) to identify highly differentiated genomic regions between the highlanders (Andean) and lowlanders (Chaqueños). We will discuss the results of our scan in light of related work on the adaptation of Tibetans, Ethiopians, and other Andean populations to hypoxia.

1968M

***IFNL3*/*IFNL4* region shows evidence for recent positive selection specific to Asian populations.** *G.L. Wojcik, C.D. Bustamante.* Department of Genetics, Stanford School of Medicine, Stanford, CA.

Hepatitis C virus (HCV) is a global health burden, chronically infecting 130-150 million people and causing 350,000-500,000 deaths per year from HCV-related liver disease. Twenty-five years after the discovery of HCV, there is no vaccine and treatment remains ineffective in a large proportion of individuals. Heterogeneity in clinical outcomes such as spontaneous clearance of the virus, as well as sustained virologic response (SVR) after treatment, has been observed between individuals of different genetic ancestry. Previous genetic studies have pinpointed a single nucleotide polymorphism (SNP) in the interferon-γ 3 and 4 (*IFNL3*/*IFNL4*) region (rs12979860) as being strongly associated with clinical outcome. While the derived and favorable allele of rs12979860 (C) is present globally, its frequency is greatly differentiated by continent with the lowest in African populations (34-49%), and the highest in Asian populations (89-96%). To determine if these differences are due to selective pressures, data from the phase 3 release of the 1000 Genomes Project (TGP) was analyzed for population-specific signatures of selection. Derived allele frequency (DAF), F_{st}, nucleotide diversity (π), and haplotype structure were examined and compared in populations from Europe, Africa, Asia, and the Americas. A 5 kilobase (kb) region around *IFNL3*/*IFNL4* showed decreased nucleotide diversity, high DAF, and increased haplotype homozygosity in Asian populations. This pattern is not found in Native American populations, suggesting recent positive selection specific to Asia. Historical selective pressures from HCV, or likely a related ancestral virus, may have driven the favorable rs12979860 allele to near fixation. However, Asia currently has disproportionately high HCV-related morbidity and mortality despite this adaptation, suggesting further evolution of the virus. Differences in clinical outcomes within Asian populations may therefore be also due to non-*IFNL3*/*IFNL4* genetic variation. Further studies are needed to identify additional genetic associations that will better our knowledge of how HCV interacts with the human immune system.

1969S

A genome-wide natural selection scan using 1000 high-coverage, Alzheimer's-specific whole-genome sequences. *M. Ebbert[1], H. Smith[1], T. Dawson[1], S. Grossman[2], M. Norton[3], J. Tschanz[3], R. Munger[4], C. Corcoran[5], P. Ridge[1], J. Kauwe[1], ADNI.* 1) Department of Biology, Brigham Young University, Provo, UT; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Department of Family Consumer and Human Development, Utah State University, Logan, Utah; 4) Department of Nutrition, Dietetics, and Food Sciences, Utah State University, Logan, Utah; 5) Department of Mathematics and Statistics, Utah State University, Logan, Utah.

Natural selection studies have impacted genetic research and our understanding of human adaptations, including malaria resistance, skin pigmentation, and others. More recently, Grossman et al. discovered adaptations to bacterial response and specific human phenotypes by performing a genome-wide selection scan using the 1000 Genomes data—identifying specific adaptive mutations without foreknown, adaptive phenotypic traits. This scanning approach successfully reversed the study type from a hypothesis-driven to a hypothesis-generating study. While the genome-wide scan was successful, there are potential limitations: (1) the 1000 Genomes data has only 179 whole-genome sequences; (2) the sequences were low coverage (2-6x average coverage); and (3) genotypes for the 1000 Genomes data may be inaccurate due to low coverage and because they were not genotyped using modern 'joint-calling' algorithms. We are performing an updated analysis including 1000+ Alzheimer's-specific, whole-genome sequences with 37x average coverage. Our data set includes 152 Alzheimer's disease (AD) cases and 211 'super controls'. The 'super controls' are APOE ε4 positive individuals aged 75+ that do not exhibit AD symptoms. Using our large, high-coverage data set, we will explore whether larger sample size and deeper coverage reveals previously undiscovered loci under selection. We will also explore whether using an AD-specific data set will enhance selection signals related to AD under the premise that AD-related loci are known to be under selection. As such, AD may be the result of a conflicting pleiotropic effect of an otherwise beneficial genotype. After joint calling all samples using GATK's HaplotypeCaller, we will perform a genome-wide natural selection scan using the Composite of Multiple Signals (CMS) algorithm on our data set to identify specific loci under selection. These results will be compared to Grossman et al.'s previous results to determine whether any new loci show evidence of selection and whether any previously identified regions were eliminated (potential false positives). Previous and newly identified loci will be examined for potential AD implications based on known disease associations and functional annotations. Top candidates will be tested using an association test. Natural selection studies reveal important genetic artifacts for observed phenotypes. Many AD-related genes are under selection and there are likely other undiscovered AD-related genes.

1970M

Identification of functional signals of recent selection in the Sea Island Gullah African Americans. *C.D. Langefeld[1], S. Sajuthi[1], J. Divers[1], Y. Huang[2], U. Nayak[2], W.M. Chen[2], K.J. Hunt[3], D.L. Kamen[3], G.S. Gilkeson[3], J.K. Fernandes[3], IJ. Spruill[3], W.T. Garvey[4], M.M. Sale[2], P.S. Ramos[3].* 1) Biostatistical Sciences and Center for Public Health Genomics, Wake Forest Medicine, Winston-Salem, NC; 2) Department of Medicine and Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Department of Medicine, Medical University of South Carolina, Charleston, SC; 4) Department of Nutrition Sciences and Birmingham VA Medical Center, University of Alabama, Birmingham, AL.

Many common diseases are more prevalent in specific ethnic groups. Given the growing number of disease-associated loci in regions that show evidence of selection, identification of alleles under selection may provide insight into disease susceptibility. Relative to other African-Americans (AA), the Gullah population has lower European admixture and higher ancestral homogeneity from the Sierra Leone area in Far-West Africa. We sought to capitalize upon the relative closeness between the Gullah and Sierra Leoneans to identify regions that differentiate both populations and may be under recent population-specific selective pressures. We integrated these signals with functional annotation to identify biologically relevant variation. Using 277 Gullah and 400 Sierra Leonean samples, we computed a linear regression model of the HapMap YRI principal component (PC2) as a quantitative outcome. We adjusted for European admixture via the CEU component (PC1) as a covariate. We computed the cross population extended haplotype homozygosity test (XP-EHH), as a formal test of selection. In total, 679,513 SNPs with MAF>5% were used in this analysis. SNPs with strong evidence of association with PC2 and strong evidence for selection from the XP-EHH test were prioritized, as measured by the smallest Euclidean distance (L2-norm) between both tests. The top 1,000 variants with combined evidence for differences in PC2 and extended haplotype homozygosity were annotated and prioritized based on the potential impact of amino acid changes and regulatory functions using RegulomeDB and HaploReg. Some of the regions that best differentiate the Gullah from the Sierra Leonean and show evidence for selection harbor missense SNPs (HLA, RAI14, SEC31B and PRR14L genes). Other regions harbor multiple SNPs with high regulatory scores based on the simultaneous presence of eQTLs, transcription factor binding and DNase sites, including those of the MTRR, SEPP1, HLA, RAPGEF5, AUTS2, TNKS, HBG1, and L2HGDH genes. Enhancer enrichment analysis of the top 1,000 SNPs revealed a 10.8 fold significant enrichment of strongest enhancers in H1 human embryonic stem cells. In summary, we identified several functional variants that differentiate the Gullah from the Sierra Leoneans, suggesting that recent selection may be operating at these loci. Identification of functional regions that might be under selection in the Gullah has the potential to elucidate disease risks in AA.

1971S

Dissecting Genetic Architectures of Human Zinc Transporter Genes and Searching Footprints of Natural Selection in Global Populations. *J. Li, C. Zhang, S. Xu.* CAS-MPG Partner Institute for Computational Biology, Shanghai, China.

Zinc transporters play very important roles in all eukaryotes by maintaining the rational zinc concentration in the cells. The genetic diversities of those transmembrane proteins are expected to affect the biologic functions of both zinc transporters themselves and the other zinc-related enzymes. Although there are many works about the huge diversity of Zn content in soils or crops around globe-scales, the diversity of Zinc transporter genes (ZTGs) in worldwide human populations have not been well studied. Here, we investigated the global genetic diversity of 24 human ZTGs, including 10 SLC30A and 14 SLC39A family genes basing on full sequencing data of 1000 genomes project. Intriguingly, we found some of ZGTs are very evolutionarily conserved in all human populations, such as SLC30A6 with significant low GA-FST (0.015), while some other ZGTs exhibited the extremely high differentiations among populations, such as SLC30A9(GA-FST, 0.284), SLC30A3 (GA-FST, 0.154), etc. Moreover, ZTGs harbored higher differentiated SNPs than random genes, suggesting that large genetic differentiations among population exhibited in ZTGs. More surprisingly, SLC30A9 was conformed to be selected both in East Asians and Africans but the selective pressures were different in the continental groups. In SLC30A9, the frequencies of two different alleles of a non-synonymous SNP, rs1047626, are almost fixed in Africans and East Asians, respectively, i.e. 96.4% A in CHB, 92% G in YRI. Therefore, there are two different functional haplotypes exhibited dominated abundance in Africans and East Asians, respectively. Furthermore, according to previous studies of global distributions Zn contents in soils or crops, strong correlation was observed with the haplotype frequencies of SLC30A9 among different human populations. We speculate that population was forced to utilize advantageous functional haplotype to adapt to the local zinc state or diets and the genetic differentiation of ZTGs could contribute to population heterogeneity in zinc transporting capability in different living environment so that the balance of zinc concentration in serum or cell can be kept properly. Our investigations should facilitate to further functional studies of ZTGs and medical studies on worldwide and regional nutrient problem and zinc-related diseases.

Genomic Patterns of Natural Selection on Toll-Like Receptors and N-Glycosylation Genes in Humans and Toll Genes in Drosophila: A Comparative Study on the Evolution of Innate Immunity Genes from Invertebrates to Vertebrates. *S. Mukherjee[1], D. Ganguli[2], P.P. Majumder[2].* 1) BioMedical Genomics Centre, Kolkata, West Bengal, India; 2) National Institute of Biomedical Genomics, Kalyani, West Bengal, India.

Background: The innate immunity genes are the first line of host defence, being developed before the separation of invertebrates and vertebrates. There is considerable interest to decipher the effect of natural selection on these genes across diverse human populations, and also across invertebrates and vertebrates, to account for the change in pathogen load and diversity. Among them the most important are the cell surface Toll-Like Receptors (TLRs) that engage in direct host-pathogen interactions in humans and other mammals. They are the homologs of Toll genes identified in Drosophila. Furthermore, genes involved in the N-Glycosylation pathway that shapes the cell-surface glycome moiety regulates the innate immune response through host-pathogen interactions and are hence potential candidates for natural selection. Objectives: To study the differential natural selection patterns on the Toll-Like Receptors and the N-Glycosylation genes across human populations and characterizing the TLR homologous Toll genes in multiple Drosophila genomes. Methods: We have generated DNA sequence data on the important cell surface TLR genes in pre and post agricultural populations of India (n=266) and analysed them in conjunction to the data available in the 1000 Genomes Project (n=1092). The TLR homologs in Drosophila Toll genes are identified and genome-level data are downloaded from the Drosophila Reference Gene Panel for further analysis. For studying the N-Glycosylation genes across Indian populations, we have analysed genome-wide data from diverse ethnicities and performed data analyses for SNPs in these genes. Results: For the TLR genes in humans, we observed an excess of rare variants and a large number of low frequency haplotypes, non-synonymous changes are few (dN/dS<1) and tests of neutrality (Tajima's D, FuLi's D*,F*,Fu's Fs) are found to be negative. No evidence of extended haplotype homozygosity is observed. In the Drosophila Toll genes, SNVs with MAF<0.05 are predominant. The results are quite similar to that observed in humans. The N-Glycosylation genes in humans show significantly lower heterozygosity values compared to neutrality. Population differentiation indices (FST) are lower for all the genes across multiple populations. Inference: The results obtained suggest possible role of purifying selection operating on key innate immunity genes across both invertebrates and vertebrates, thus focusing on their immense importance in the survival of the host.

1973S

Evolutionary history of pigmentation candidate gene diversity in a Melanesian population. *H. Norton, E. Werren.* Department of Anthropology, University of Cincinnati, Cincinnati, OH.

Pigmentation of the skin, hair, and eyes are complex phenotypic traits determined by multiple loci. Human skin pigmentation is a trait that is believed to have evolved under strong natural selection in response to varying levels of ultra-violet radiation (UVR) intensity. Lighter skin color has evolved multiple times in human evolutionary history, but it is unclear if the darker skin color observed in many high UVR populations is also the result of evolutionary convergence (suggesting that population-specific mutations may have been favored by positive selection) or if instead ancestral variants associated with darker skin color have been maintained in high-UVR populations via purifying selection. To begin to address this question we compare DNA sequence variation from multiple pigmentation candidate genes in a Melanesian population to variation observed in European, East Asian, and African populations sequenced in the 1000 Genomes Project. Summaries of the site frequency spectrum, including Tajima's D (TD), for three genes, *ASIP*, *OCA2*, and *TYRP1*, do not indicate that any of these genes were targeted by positive selection in the Melanesian population (*ASIP* TD = 0.037, *OCA2* TD = -0.85, *TYRP1* TD = -0.55). With the exception of a single novel haplotype in the *OCA2* locus observed at a frequency of ~10% there is little evidence that Melanesians exhibit any high frequency population-specific haplotypes at these loci, suggesting that if an independent adaptation to high UVR conditions occurred in Melanesians then other pigmentation loci are responsible. However, there is also little evidence that Melanesians are similar to Africans at these loci, which one might expect if Melanesians share ancestral haplotypes with other high UVR populations: pairwise F_{ST} estimates between Melanesians and Africans for the pigmentation loci examined here range from 0.043-0.443, and the majority of Melanesian haplotypes are common haplotypes shared between Africans, Europeans, and East Asians. We explore these patterns of sequence variation and inter-population divergence at pigmentation loci in the context of evolutionary models for pigmentation change in the human species and with consideration to Melanesian population history.

1974M

Inference of the strength of purifying selection based on haplotype patterns. *D. Ortega Del Vecchyo[1], K.E. Lohmueller[1,2], J. Novembre[3].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, CA; 2) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA; 3) Department of Human Genetics, University of Chicago, IL.

The strength of purifying selection is a central factor underlying levels of genetic diversity in a population and is important to characterize to understand the expected genetic architecture of disease traits. Recent sequencing studies with large sample sizes have revealed a much higher proportion of non-synonymous variants among rare versus common variants in human populations. This finding suggests that natural selection is acting against such variants to keep them at low frequencies in the population. To estimate the strength of purifying selection, we have developed a method that uses the lengths of pairwise haplotype identity among rare-variant-carrying haplotypes. Unlike previous approaches, our method conditions on the present-day frequency of the allele and is based on the intuition that alleles under purifying selection are on average younger than neutral alleles and, therefore should have higher average levels of haplotype identity among variant carriers. To obtain the probability distribution on the lengths of pairwise haplotype identity, one needs to perform two integrations: one over all possible allele frequency trajectories and another one over all pairwise coalescent times given a certain allele frequency trajectory. The integration over the space of possible allele frequency trajectories is done using a fast importance-sampling algorithm while the integration over the coalescent times is done using an analytical solution. Using the probability of the lengths of the haplotypes under different selective coefficients, we can calculate the likelihood for a selective coefficient for a single variant or set of variants. We use simulations to test how accurately the method estimates the selective coefficient under different demographic scenarios, such as a constant population size and a realistic model of European population growth. Variants with the same selective coefficient are harder to differentiate from neutral variants in scenarios of recent population growth. These methods will be applied to a set of 202 drug target genes sequenced in 14,002 individuals (Nelson et al, 2012, Science) to identify which genes are most likely to harbor damaging variants that may predispose to disease.

1975S

Highlighting strongly differentiated regions using three high coverage genomes each from a set of worldwide human populations. *L. Pagani[1,2,3], T. Kivisild[1].* 1) Division of Biological Anthropology, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; 2) The Wellcome Trust Sanger Institute, CB10 1SA, Hinxton, UK; 3) Molecular Anthropology Lab, Department of Biological Geological and Environmental Sciences, University of Bologna, Italy.

Following the steady reduction in sequencing costs, several international projects will shortly make available sets of 2-4 high coverage genomes each from hundreds of worldwide human populations. While these resources allow for refining the demographic histories of the studied populations, little can be done to detect signatures of differentiation, possibly driven by natural selection, on these populations. The selection scan methods available to date indeed focus on various genomic components (SNPs, Haplotypes, LD blocks), yet relying on genome frequencies rather than on the full sequence information. Here we show how the top 1% of genic regions analysed using only three genomes each from two populations (CEU and YRI) contains as many as 25% of the top 5% FST candidates obtained using 160 low coverage individuals from the 1000 Genomes Project. The three genomes from each chosen population are combined in three pairs, and FST based on average pairwise differences is calculated between populations. The average FST is computed on a sliding window of 10000 or 50000 bp across all the pop1-pop2 sets of genomic pairs. The top 1% windows showing the highest differentiation were selected and inspected for their gene content. Of the 1785 genes identified by the FST scan based on the 160 low coverage individuals (taken as the gold standard), 98 were found among the 439 genes included in the top 1% 50000bp windows of the YRI-CEU pairs. This 2.4-fold enrichment was found significant with a chi-squared test (p=10-19). The empirical ranking nature of the gold standard did not allow a formal assessment of the false positive rate of our newly developed method. However, the overlap between the top genes retrieved using the 10000 and 50000 bp windows showed a significant enrichment in high ranking FST signals. In summary the proposed approach based on three genomes per population is capable of retrieving at least 25% of the genes under putative natural selection found from traditional methods. Ongoing power assessment will also inform on the optimal number of high coverage genomes per population required to further reduce the false positive rate. These promising results, given the limitations imposed by the small sample sizes, make our method suitable to be applied on newly sequenced populations (expected to be released on Mid June 2014, during the SMBE conference).

1976M

Identification of functional variants under positive selection in the Gullah African American population of South Carolina. *P.S. Ramos[1], S. Sajuthi[2], J. Divers[2], Y. Huang[3], U. Nayak[3], W.-M. Chen[3], K.J. Hunt[1], D.L. Kamen[1], G.S. Gilkeson[1], J.K. Fernandes[1], I.J. Spruill[1], W.T. Garvey[4], M.M. Sale[3], C.D. Langefeld[2].* 1) Department of Medicine, Medical University of South Carolina, Charleston, SC; 2) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest Medicine, Winston-Salem, NC; 3) Department of Medicine and Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 4) Department of Nutrition Sciences and Birmingham VA Medical Center, University of Alabama, Birmingham, AL.

Relative to other African-Americans (AA), the Gullah population has lower European admixture and higher ancestral homogeneity from the Sierra Leone (SL) area in Far-West Africa. The shorter genetic distance between the Gullahs and SL suggests that population genetic signals, such as regions under recent selection, may be more easily detected in the Gullahs than in other AA populations. Since both protein-coding and regulatory variation have important roles in recent human adaptation, the goal of this study was to integrate evidence for natural selection with functional annotation for the identification of biologically relevant signals. We computed the cross population extended haplotype homozygosity test (XP-EHH) to identify alleles with higher than expected frequency relative to their haplotype length in the Gullah (n=277) relative to SL (n=400), to HapMap Phase II YRI (n=203), and CEU (n=165). In total 679,513 SNPs with MAF>5% met standard GWAS QC criteria. Variants that met suggestive significance (|XP-EHH|>4, P<E-04) were annotated and prioritized based on the potential impact of amino acid changes and regulatory functions using RegulomeDB and HaploReg. Nearly the same number of loci showed suggestive evidence for selection between the Gullah and YRI (0.15% of all SNPs), and Gullah and SL (0.14%), although only 106 SNPs in 12 regions showed evidence for selection in both comparisons. Fewer loci showed evidence for selection between Gullah and CEU (0.06%). Enhancer enrichment analysis revealed a significant enrichment of strongest enhancers in H1 human embryonic stem cells. Several regions harbor missense SNPs, including those showing evidence of selection between the Gullah and the YRI (CENPO, FSHR, CHUK, PKD2L1, USP31), Gullah and SL (PRR14L), and Gullah and CEU (ADPRHL2, LCT). Other regions harbor multiple SNPs with high regulatory scores based on the simultaneous presence of eQTLs, transcription factor binding and DNase sites, including those showing evidence of selection between Gullah and YRI (e.g. CCR2, ADCY2, HLA, CD36), Gullah and SL (e.g. CCR2, ADCY2, TNKS), and Gullah and CEU (e.g. NARS2). These results reveal several novel regions with evidence for selection and concomitant high functional potential in the Gullah AA population. Given that many common diseases are more prevalent in specific ethnic groups, identification of functional regions under selection in the Gullah has the potential to elucidate disease risks in AA.

1977S

A model for gene expression level evolution to identify expression conservation, divergence, and diversity. *R. Rohlfs, R. Nielsen.* Integrative Biology, University of California, Berkeley, Berkeley, CA.

As RNA-Seq becomes more available, we see more extensive comparative expression datasets, particularly datasets with multiple individuals sampled per species. These new data facilitate transcriptome-scale analyses of expression variance between and within species. We have developed a phylogenetic model of expression level evolution which can be used to specifically investigate the ratio of within to between species expression variance. We have applied this method to a phylogeny of 15 mammals, mostly primates. We have identified genes with high expression divergence between species as putative targets for expression level adaptation. Conversely, we have identified genes with high expression diversity within species and conservation between species, which likely have plastic responses to environmental inputs. Additionally, we identified genes on the human and catarrhine lineages which show a shift in expression level, putatively due to lineage-specific expression level adaptation. This analysis shows the flexibility and utility of our model in facilitating comparative expression analyses to illuminate the biological meaning of expression levels in humans and other organisms.

1978M

The Clade Fitness Proxy haplotype score: delineating the progression of soft selective sweeps at the haplotype level. *R. Ronen[1], G. Tesler[2], S. Zakov[3], N.A. Rosenberg[4], V. Bafna[3].* 1) Bioinformatics and Systems Biology Program, University of California, San Diego, La Jolla, CA; 2) Department of Mathematics, University of California, San Diego, La Jolla, CA; 3) Department of Computer Science and Engineering, University of California, San Diego, La Jolla, CA; 4) Department of Biology, Stanford University, Stanford, CA.

The dynamics of selective sweeps have long been of interest in population and evolutionary genetics. Of particular interest is the problem of selection on standing variation, when the beneficial allele already segregates in the population at a non-negligible frequency at the time that selection begins. In this case, multiple haplotypes all carrying the beneficial allele will drift relative to one another, while outcompeting other haplotypes. Moreover, the beneficial allele may fix without any of the carrying haplotypes reaching fixation. Consequently, we observe a soft selective sweep, or a weakening of the classical signature of a selective sweep. To identify regions undergoing soft sweeps, we develop a new coalescent-based statistic dubbed the Clade Fitness Proxy (CFP) score, which scores individual haplotypes based on the frequencies of alleles they carry. We develop the statistical properties of the CFP score in the framework of a neutral coalescent model. We use theoretical calculations and simulated data to demonstrate its utility both as a general test of selection and as a proxy for the relative fitness of individual haplotypes. Under a soft sweep, we observe a bimodal distribution of CFP scores, where 'fit' haplotypes have high CFP score and 'unfit' haplotypes have low CFP score. This bimodality can be used in a general test of selection. Perhaps more interestingly, it suggests that CFP scores can serve as a proxy for the relative fitness of individual haplotypes. Thus, the CFP score may be useful for elucidating the state of a selective sweep within a population sample (i.e., at the level of individual haplotypes). Once a sweep has completed and the beneficial mutation has reached fixation (all haplotypes are 'fit'), the in-sample distribution of CFP scores is no longer bimodal. While at this stage the relative fitness of haplotypes is not of interest, as it is by definition equal, the distribution of CFP scores is still highly informative about the occurrence of a sweep in the population's history for many generations thereafter. We expect that the CFP score will be a powerful tool to study regions undergoing soft selective sweeps, and that it will contribute to uncovering the structure of relative fitness within population samples.

1979S

Searching for soft selective sweeps in worldwide human populations. *Z.A. Szpiech[1], R.H. Hernandez[1,2,3].* 1) University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Institute for Quantitative Biosciences (QB3), University of California, San Francisco, San Francisco, CA.

There is ample debate about the strength and mode of natural selection that has occurred in recent human evolution. This is particularly so for classical hard sweeps, during which an adaptive allele quickly drags a single haplotype to high frequency. An alternative model of adaptation involves soft sweeps, whereby multiple haplotypes are brought to high frequency (i.e. when a previously segregating neutral or slightly deleterious allele becomes adaptive in a new environment). Existing haplotype-based tests—such as the integrated haplotype score (iHS) that scans for positive selection by tracking the decay of haplotype homozygosity—work under the assumption that a positively selected region will be dominated by a single haplotype. However, iHS is expected to lose power under a soft sweep. Here we develop a statistic, inspired by iHS and recent work in Drosophila population genetics, designed to detect recent soft sweeps by tracking the decay of homozygosity of multiple haplotypes away from a core locus. We evaluate our statistic with rigorous simulations under multiple realistic models of human demography. We find that it has high power to detect both hard and soft sweeps and has improved power compared to iHS. In particular, for a fixed selection coefficient, our simulations suggest that we have greatest power to detect soft sweeps in African populations, which have been understudied to date. We apply this statistic and iHS to a large human genotype dataset of 1,728 unrelated individuals spanning 20 worldwide populations from the 1000 Genomes Project. A large number of regions identified by our statistic are not identified by iHS, in particular in African populations. This suggests a possibly important role of soft sweeps in recent human evolution.

Natural selection at the melanocortin-3 receptor gene loci. *I. Yoshiuchi.* Dept Diabetes Mellitus and Medicine, Yoshiuchi Medical Diabetes Institute, Kamakura, Kanagawa, Japan.

Obesity is significantly associated with type 2 diabetes mellitus, metabolic syndrome, hypertension, stroke, and cardiovascular diseases. The worldwide prevalence of obesity is increasing steadily. Obesity is highly heritable disease that causes serious health problems. During the traditional cycles of feast and famine, natural selection of obesity-related genes would be significant because these genes control body weight and fat levels. Human adaptation to environmental changes in food supply, lifestyle, and geography may have influenced the selection of genes associated with the metabolism of glucose, lipids, carbohydrates, and energy. The melanocortin-3 receptor (MC3R) gene is one of obesity-associated genes, and MC3R mutations have been shown to be associated with obesity. MC3R-deficient mice showed increased fat mass. Here, We aimed to uncover evidence of selection at the MC3R gene loci. We performed a three-step method to detect selection at the MC3R gene loci using the HapMap population data. We used Wright's F statistics as a measure of population differentiation, the long-range haplotype test to test extended haplotypes, and the integrated haplotype score test to detect selection at the MC3R gene loci. We observed natural selection at the MC3R gene loci by the integrated haplotype score test in the African population. This finding provides evidence of natural selection at the MC3R gene loci. Further discoveries are warranted on the adaptive evolution of obesity-associated genes.

1981S

Identification of putative high altitude adaptation determinants in Tibetan whole genome sequences. *J. Downie[1], H. Hu[2], T. Simonson[3], D. Witherspoon[1], G. Glusman[4], J. Roach[4], G. Cavalleri[5], M. Brunkow[4], A. Cole[5], M. McCormack[5], N. Petousi[6], P. Lorenzo[7], R. Gelinas[4], J. Prchal[7], P. Robbins[6], C. Huff[2], L. Jorde[1].* 1) Department of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT 84112 USA; 2) Department of Epidemiology, The University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030 USA; 3) Division of Physiology, Department of Medicine, University of California San Diego, La Jolla, California, USA; 4) Institute for Systems Biology, Family Genomics Group, Seattle, WA 98109 USA; 5) Royal College of Surgeons in Ireland, Molecular and Cellular Therapeutics, St Stephen's Green, Dublin 2, Ireland; 6) University of Oxford, Department of Physiology, Anatomy and Genetics, Oxford, OX1 3PT, United Kingdom; 7) Division of Hematology, University of Utah School of Medicine, Salt Lake City, UT 84112 USA.

Despite its extreme high-altitude environment, the Tibetan Plateau has been inhabited by humans for thousands of years. Tibetans possess heritable adaptations that allow them to better survive in hypoxic conditions. A number of genes that could account for Tibetans' ability to live at high altitude have been found, including *EGLN1* and *EPAS1*, using SNP arrays and low-coverage exome-sequencing. However, there has been little success thus far in finding specific variants responsible for the adaptive traits seen in Tibetans. To address this, we performed Complete Genomics whole-genome sequencing of 17 Tibetans from the United Kingdom (12) and Utah (5). The Tibetan ancestry of these genomes was confirmed by comparing them with genotypes of other Tibetan and Eurasian samples using *EIGENSOFT*. We phased the 17 Tibetan genomes using *SHAPEIT*. Next, the integrated haplotype score (iHS) and cross-population extended haplotype homozygosity (XP-EHH) tests, using 1000 Genomes CHB+CHS as a comparison, were employed to detect selective sweeps. We calculated the number of iHS values ≥ |2.0| and the max XP-EHH value for 200kb non-overlapping windows. We compiled a candidate gene list based on their function in the Gene Ontology and PANTHER to search for adaptive genes. Intersecting the candidate list with genes in the top 1% of iHS regions returned 8 putatively advantageous genes (*MTOR*, *PIK3R3*, *EGLN1*, *EPAS1*, *VHL*, *RAF1*, *UBE2D2, TPTE*) while the top 1% of XP-EHH windows also contained 8 genes (*EGLN1*, *KLRK1*, *CALM1*, *EPAS1*, *EP300*, *TLR2*, *NRF1*, *LOXL2*). We searched for novel, nonsynonymous variants in these genes that might be responsible for high-altitude adaptation but found no such variants at appreciable frequency. Further, described nonsynonymous variants in these genes were found at similar frequency as the Han-Chinese population. In conclusion, we identified both novel and previously described positively selected regions of the genome in Tibetans but found no novel nonsynonymous variants in these regions.

1982M

Positive selection in smallpox associated genes among Mesoamericans. *O.A. Garcia[1], K. Arslanian[2], D. Whorf[1], M. Shriver[3], L.G. Moore[4], T. Brutsaert[5], A.W. Bigham[1].* 1) Department of Anthropology, University of Michigan, Ann Arbor, MI; 2) Department of Anthropology, Yale University, New Haven, CT; 3) Department of Anthropology, Penn State University, University Park, PA; 4) Department of Obstetrics and Gynecology, University of Colorado, Aurora, CO; 5) Department of Exercise Science, Syracuse University, Syracuse, NY.

During the colonization of Mesoamerica, one of the major causes of death was the introduction of novel infectious diseases. Among the most lethal infectious diseases was smallpox. Therefore, studying signatures of natural selection in genes related to smallpox infection and immune response not only provides a window to our evolutionary past but is also a particularly attractive strategy to identify host factors for modern infectious disease. To characterize host risk factors within Mesoamerican populations, we interrogated 906,600 SNPs assayed using the Affymetrix 6.0 genotyping array for signatures of natural selection in 231 immune response genes. Our populations included: Mesoamerican: 25 Maya and 14 Nahua, Mixtec, and Tlapanec speakers from Mexico, Andean: 25 Aymara from Bolivia, and 24 Quechua from Peru. Additionally, we used available data from 60 Europeans of northern European ancestry and 90 East Asians from China and Japan. We applied three statistical tests to identify signatures of natural selection: locus specific branch length (LSBL), the natural log of the ratio of heterozygosities (lnRH), and Tajima's D. Furthermore, we analyzed partial and hard sweeps with two haplotype texts: integrated haplotype score (iHS) and cross population extended haplotype homozygosity (XP-EHH). We determined statistical significance based on an empirical distribution. Among our strongest results for positive selection were *CD74*, *ZAP-70*, and *IKZF1* that were significant in all the statistical tests at the 5% and 1% level for Mesoamericans between East Asians and European Americans comparisons. Furthermore, they were statistically significant in comparison to the Andean populations. *CD74* is major histocompatibility complex class II (MHC II) invariant chain. Studies have shown *CD74*'s protein to function as a receptor for cytokine MIF, a critical immune response factor. *ZAP-70* is an integral part of the T-cell signaling pathway thereby regulating adaptive immune response. Several studies have shown *CD74* and *ZAP-70* expression to be correlated. *IKZF1* has mostly been studied as in autoimmune disorders as part of the pathway regulating haematopoiesis. The results of this study will aid future studies by pinpointing candidate genes for infectious disease susceptibility and resistance in Mesoamerican populations.

1983S

Selection and reduced population size cannot explain higher amounts of Neanderthal ancestry in East Asian than European human populations. *B. Kim[1], K. Lohmueller[1,2].* 1) Ecology and Evolutionary Biology, University of California Los Angeles, Los Angeles, CA; 2) Interdepartmental Program in Bioinformatics, University of California Los Angeles, Los Angeles, CA.

Understanding the Neanderthal ancestry of modern humans may provide crucial insights into the evolution of different human populations. It is believed that Neanderthals admixed with European and Asian populations to a much greater degree than with African populations. Additionally, recent studies show a higher frequency of Neanderthal alleles in East Asians relative to Europeans. Several hypotheses to explain this difference have been proposed. One hypothesis posits that there was a single admixture event in the population ancestral to modern Europeans and East Asians and that many of the Neanderthal alleles were weakly deleterious in modern humans. Because East Asians have historically had smaller population sizes than Europeans, purifying selection may have been less effective at removing the Neanderthal alleles from East Asian populations, leading to the observed higher proportion of Neanderthal ancestry in East Asians. Here we test this hypothesis using forward-in-time population genetic simulations. These simulations include plausible models of European and East Asian population history which have been estimated from data as well as models of the fitness effects of Neanderthal alleles in humans that include different dominance scenarios and a distribution of selection coefficients. Starting with the same amount of Neanderthal ancestry in both populations, we find that the differences in population size between European and East Asians combined with purifying selection cannot lead to the observed increase in the amount of Neanderthal ancestry in East Asian populations. Furthermore, when starting with the same initial amount of Neanderthal ancestry in both populations, realistic population size changes alone are insufficient to decrease or increase the Neanderthal ancestry in one population relative to the other. The observed data must be explained by some other process, such as additional waves of Neanderthal admixture into East Asian populations.

1984M

Identifying incomplete selective sweep using Sequential Markov Coalescent. *K. Liao[1], W. Hsieh[2], C. Tang[1].* 1) Department of Computer Science, National Tsing-Hua University, Hsinchu City, Hsinchu, Taiwan; 2) Institute of Statistics, National Tsing-Hua University, Hsinchu City, Hsinchu, Taiwan.

Positive selection leaves signatures in genomes of the population and identifying such signatures provides insight into the genetic basis of how human is different from other species. Among these signatures, long-haplotypes are useful for identifying incomplete selective sweep, but it is usually difficult to compute the likelihood of statistics based on long-haplotype under the neutrality assumption. Hence, the statistical significance must be evaluated by empirical distribution derived from a large number of simulations. Sequentially Markov Coalescent (SMC) is a promising framework of haplotype-based analysis and it has the potential to be extended to various population genetics model. We implemented a long-haplotype based test for incomplete selection under SMC framework. The likelihood of a sample is computed with Product of Approximate Conditionals (PAC) and the statistical significance can be evaluated by the likelihood-ratio test. In addition, the strength of selection is estimated through maximizing PAC-likelihood function. The procedures will be evaluated with simulated data and compared with other methods based long-haplotype signatures.

1985S

Asian diversity project: a survey of population structure and local adaptations in Asian populations. *X. Liu[1,2], D. Lu[3], W.Y. Saw[1], T.H. Ong[1], C. Simmons[4], P. Suriyaphol[5], S. Tongisma[6], B.P. Hoh[7], N. Kato[8], Y.Y. Teo[1,9].* 1) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 2) NUS Graduate School, National University of Singapore, Singapore; 3) Max Planck Independent Research Group on Population Genomics, Chinese Academy of Sciences and Max Planck Society Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences,, Shanghai, China; 4) Oxford University Clinical Research Unit, Hospital for Tropical Diseases, Ho Chi Minh City, Viet Nam; 5) Division of Bioinformatics and Data Management for Research, Mahidol University, Bangkok, Thailand; 6) Genome Institute, National Center for Genetic Engineering and Biotechnology, Pathumtani, Thailand; 7) Insitute of Medical Molecular Biotechnology (IMMB), Faculty of Medicine, Universiti Teknologi MARA (UiTM) Malaysia, Sg Buloh, Selangor, Malaysia; 8) Department of Gene Diagnostics and Therapeutics, Research Institute, National Center for Global Health and Medicine, Tokyo, Japan; 9) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

As the largest continent on Earth, Asia hosts more than 60% of the human populations in the world. Great genetic diversity exists in the Asian populations. The HUGO Pan-Asian SNP consortium provided a valuable genetic resource of Asian populations and performed a thorough survey of genetic diversity and population history of Asian populations. However, the sparse coverage of SNPs made the analysis of natural adaption difficult to perform. In this study, we collected dense genotyping data from 46 populations across Asia. More than 4093 individuals from East Asia, Central Asia, Southeast Asia and South Asia were genotyped on various genotyping platforms. Principal components analysis (PCA) and admixture analysis were performed to elucidate the population structure in ADP populations. It was revealed that geographic played an important role in shaping the population structure of Asian populations; and the ADP populations were further grouped into East Asian, Central Asian, Southeast Asian and South Asian subgroups. We performed a genome wide scan of positive selection signals in the ADP populations using iHS, XP-EHH and haploPS. A total of 669 candidate selection regions were detected across the 46 ADP populations. A PCA analysis on the selection signals were performed to investigate the degree of sharing of the selection signals in the 46 populations. It was found that clustering of populations by selection signals resembles the clustering inferred from population structure analysis. East and Southeast Asian groups share the largest number of selection signals; and the South Asian group possesses distinct selection signals from the rest of the Asian populations. For selection signals shared by multiple populations, we studied the origin of the selection, *ie.* either the selection originated from a single mutation in the common ancestor followed by subsequent gene flow, or it was the result of convergent evolution, where the selection emerged separately from multiple mutation events. The origins of positive selection signals were investigated by calculating the haplotype similarity index. The haplotype similarity index identified 36 selection regions under convergent evolution, and most of them involve aboriginal populations from Southeast Asia.

1986M

The pleiotropic effects of *EDARV370A* in an admixed Uyghur population. *Q. Peng[1], J. Li[1], J. Tan[2,3], Y. Yang[2,3], Y. Guan[4], L. Zhang[4], Y. Jiao[4], P. Sabeti[5,6], L. Jin[1,2,3], S. Wang[1].* 1) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 2) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) CMC Institute of Health Sciences, Taizhou, Jiangsu Province, China; 4) Department of Biochemistry, Preclinical Medicine College, Xinjiang Medical University, Urumqi, Xinjiang, China; 5) The Broad Institute of Harvard and MIT, Cambridge, USA; 6) Center for Systems Biology, Department of Organismic and Evolutionary Biology.

An adaptive variant of the human Ectodysplasin receptor, *EDARV370A*, showed one of the strongest signals of recent positive selection from genome-wide scans. In transgenic mice and in humans, it is found that *EDARV370A* affects ectodermal related phenotypes, including hair thickness and shape, active sweat gland density, and teeth formation. However, previous human studies were all based on East Asian populations, in which the frequencies of ancestral allele 370V are low. It is inconclusive whether the genetic model of *EDARV370A* is additive or dominant. The lack of power was due to the low presence of 370V homozygotes, which made it impractical to explore a large spectrum of potentially affected ectodermal related phenotypes. In this study, we took advantage of an admixed population between East Asian and European - the Uyghur, to investigate the pleiotropic nature and the genetic model of *EDARV370A*. By examining a series of ectodermal related phenotypes and the *EDARV370A* genotype in 294 Uyghur samples, we replicated the previous association findings in incisors shoveling (P= 5.76×10^{-12}) and hair straightness (P=3.37×10^{-03}), and further confirmed the association is following an additive genetic model. We also found *EDARV370A* associated with novel phenotypes including higher total sweat gland density (P=0.03) and triangular earlobes (P=2.05×10^{-04}). By revealing more pleiotropic effects of *EDARV370A* and confirming its genetic model, our study provides a more complete picture for the adaptive evolution of *EDARV370A* in human history.

1987S

A hidden Markov framework to estimate the timing of selection for hard sweeps. *J. Smith[1], M. Stephens[2], M. Przeworski[3], G. Coop[4], J. Novembre[2].* 1) Department of Ecology and Evolution, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Department of Biological Sciences, Columbia University, New York, NY; 4) Department of Evolution and Ecology, University of California--Davis, Davis, CA.

Dispersal across the globe has resulted in humans occupying a wide range of ecological habitats. Natural selection seems to have played a role in this process, as current methods have identified a number of well supported loci that have undergone a recent selective sweep. In some cases, comparing estimates for the timing of selection with events in the historical/archeological record can provide a more clear picture of the ecological context driving adaptation in a population. For example, an overlap between cultural shifts towards dairy food production with the timing of selection on the lactase persistence allele has helped evaluate a possible cause for the observed selective sweep. As a result, there is substantial interest in methods to infer the age of a positively selected allele. A key principle for allele age estimation is that due to recombination and mutation, the signature of a selective sweep decays at a constant rate per generation. Current methods to estimate the age of selective sweeps either rely on a heuristic estimate of the length of the selected haplotype or employ a simulation-based framework to identify the distribution of ages that produce the observed summary statistics of the complete data. In practice the confidence intervals for these estimates are large. Here, we provide methods for inferring the ancestral haplotype of the selected allele and the recombination breakpoints off of this haplotype in order to provide more refined estimates of allele age. We do so using a hidden Markov model framework which allows us to integrate over uncertainty in recombination breakpoints. This framework uniquely uses both the present day length distribution of the ancestral haplotype and the number of derived mutations to estimate the number of generations since the sweep occurred. The joint use of haplotype lengths and derived mutations increases the total number of observed events and provides more narrow confidence intervals for the age estimate. Using this joint estimator on simulated data, 95% quantiles for estimates of sweep ages from 400 to 500 generations are within 35 generations of the true value. Whereas estimates based on derived mutations or haplotype lengths alone provide 95% quantiles ~70 generations from the true value. Future applications will revisit the timing of selection for lactase persistence in Northern Europeans, skin pigmentation alleles in Europe and Asia, and malaria resistance at the G6PD locus in Africa. .

1988M

Genome wide survey of positive selection signals in African Americans since admixture. *H. Wang[1], Y. Choi[2], X. Wang[3], B. Tayo[4], u. Broeckel[5], C. Hanis[6], S. Kardia[7], S. Redline[8], R. Cooper[4], H. Tang[2], X. Zhu[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Departments of Preventive Medicine, Biomedical Informatics, and Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 4) Department of Public Health Science, Loyola University Medical Center, Maywood, IL; 5) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 6) 6 Department of Epidemiology, Human Genetics and Environmental Sciences, University of Texas Health Science Center at Houston, Houston, TX; 7) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 8) Department of Medicine, Harvard Medical School, Boston, MA, USA.

In an admixed population such as African Americans, over or deficient ancestry in a local genomic region may suggest natural selection. We scanned three large African American cohorts of 20,153 individuals but failed to identify any genome-wide significant over or deficient signals. We showed that the failure to identify any significant selection signals can be attributed to the estimated variance of the test, which consists of two components: variance due to sampling error and variance due to genetic random drift. The proportion of variance due to genetic random drift increases when sample size increases. Thus, a test based on examining local ancestry excess is not efficient and its power will not increase when increasing sample size. We also showed that the high correlations of local ancestries between different cohorts are due to the historical recombination and genetic random drift. Assuming African-Americans have been admixed for 8 to 12 generations, we estimated the effective population size as between 32,000 to 48,000.

1989S

Differential purifying and positive selection across genes stratified by X chromosome inactivation status. *A. Slavney[1], F. Gao[2], A. Clark[1,2], A. Keinan[2].* 1) Genetics, Genomics & Development, Cornell University, Ithaca, NY; 2) Biological Statistics & Computational Biology, Cornell University, Ithaca, NY.

In eutherian mammals, dosage compensation between XX females and XY males occurs through ChrX inactivation (XCI). XCI randomly silences transcription from one of the two X chromosomes in each female cell, but at least 25% of human ChrX loci escape XCI to varying degrees, creating three broad gene groups: genes that i) are consistently inactivated, ii) escape XCI in some indivuduals, and iii) consistently escape XCI. Evolutionary mechanisms underlying XCI status are poorly understood, but the predominant model posits that XCI evolved in response to ChrY degeneration. In this model, XCI escapers encode products that are dosage-sensitive and/or female-biased, and thus highly conserved. We therefore tested the hypothesis that mutations in group ii) and iii) genes are more likely to be deleterious than those in group i) genes

To evaluate the effects of mutations in each XCI group, we first used European American single nucleotide variant (SNV) data from the NHLBI Exome Sequencing Project to compare synonymous (S) and non-synonymous (NS) SNV frequency distributions and estimated the individual burden of private mutations (IBPM) for all groups. These analyses showed a greater NS:S excess at low SNV frequencies and greater IBPM estimates in groups ii) and iii) than in i), suggesting stronger conservation in XCI escapers. We then incorporated divergences from chimpanzee to estimate statistics derived from the McDonald-Kreitman test, including the fractions of strongly (d) and weakly deleterious (b) sites, for each group. We found significantly higher d and lower b values in groups ii) and iii) than in group i), which support stronger conservation in escapers. However, we were surprised to find that group ii) showed evidence of experiencing stronger purifying selection than group iii) as per the IBPM, d and b values.

In conclusion, we report that polymorphism and divergence data support a model of XCI escape driven by ancient and ongoing evolutionary conservation, but that heterogeneous escapers show stronger purifying selection than consistent escapers. These results suggest a potentially important role for XCI escapers in phenotypes that affect fitness, but also demonstrate a need for further investigation into the true extent of XCI profile heterogeneity among tissues and individuals.

1990M

Inference of Neandertal gene expression from modern samples. *E.E. Quillen, M.A.A. Almeida, J.M. Peralta, J.E. Curran, M.P. Johnson, H.H.H. Goring, R. Duggirala, S. Williams-Blangero, J. Blangero.* Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

The sequencing of multiple Neandertal specimens has opened up the possibility of estimating Neandertal phenotypes based on the effect of "Neandertal alleles" present at low frequency in modern human populations. To capture a portion of the functional effects of Neandertal variants, we consider whole genome sequence and mRNA expression profiles obtained using an Illumina Sentrix Human Whole Genome BeadChip microarray from lymphocytes drawn from 921 participants in the San Antonio Family Study (SAFS). 56,294 single nucleotide variants (SNVs) were identified as monomorphic in the three Vindja Neandertal genomes, but polymorphic in the SAFS. Of these SNVs, 2,950 are located upstream of genes represented by high-quality, heritable probes on the microarray in a putatively cis-regulatory position. 81 SNV-probe pairs were found to be significantly associated ($p < 1E-5$) in a variance components-based association analysis performed in SOLAR. Additionally, the effect of genome-wide Neandertal ancestry on transcript expression levels was considered. The full set of SNVs were used to generate a covariance matrix derived from LDAK which calculates kinship coefficients while correcting for linkage disequilibrium. A variance component model was fit for each of the 2,869 probes and the variance explained by the Neandertal ancestry covariance matrix was determined. Neadertal ancestry had significant ($p < 0.05$) explanatory power for 61 probes. To contextualize these results, all significant probes were considered in a gene-set enrichment analysis of biological domains defined from the Kyoto Encyclopedia of Genes and Genomes (KEGG) database. Enrichment was determined by an empirical p-value derived from comparing the test set of significantly associated mRNA transcripts to 1000 randomly selected sets of equal numbers of transcripts represented on the array. These results indicate an enrichment of related to the growth, development, and innervation of the epithelium and immune-related pathways among probes associated with Neandertal ancestry. With these results and additional data which will become available as more Neandertal sequencing occurs, we can infer a portion of a hypothetical transcriptome of our hominid relatives and better understand how Neandertals and modern human populations differ.

1991S

Khoisan hunter-gatherers have been the largest population throughout most of modern human demographic history. *HL. Kim[1,2], A. Ratan[2], GH. Perry[3], A. Montenegro[4,5], W. Miller[2], SC. Schuster[1,2].* 1) Singapore Centre on Environmental Life Sciences Engineering, Nanyang Technological University, Singapore; 2) Center for Comparative Genomics and Bioinformatics, Pennsylvania State University, PA, USA; 3) Department of Anthropology, Pennsylvania State University, PA, USA; 4) Department of Geography, Ohio State University, OH, USA; 5) Campus do Litoral Paulista, Unesp - Univ Estadual Paulista, Brazil.

We sequenced the complete genome sequences of five Khoisan hunter-gatherers from the Kalahari Desert and one Bantu-speaking agriculturalist individual also from southern Africa, with a high accuracy. Compared the 420K SNP genotyping dataset from 490 worldwide individuals, admixture analyses showed that three of our Khoisan genomes from the Ju/'hoansi group (northern Khoisan) have no or minimal admixture from non-Khoisan populations, allowing us to assess the early demographic history of the human species. Population genomic analyses for our complete genome sequences along with those from eight non-Khoisan humans were performed to infer their effective population sizes and demonstrated that the Ju/'hoansi population have maintained their large effective population size and been the people most isolated from all the other human populations, since the earliest population split between the Khoisan and other populations ~100-150 thousand years ago (kya). In contrast, all other human populations, including the ancestral Bantu-speaking agriculturists (currently the largest population within Africa in terms of census size), have experienced severe bottlenecks and lost more than half of their genetic diversity from ~120 to 30 kya. According to paleoclimate records and models, west-central Africa became drier, while southern Africa experienced increases in precipitation, ~80-100 kya. We hypothesize that these climate differences might be related to the divergent ancestral population history within African human populations.

1992M

Insights from low-coverage whole Y chromosome sequencing of 1,244 individuals. *Y. Xue for The 1000 Genomes Project 1000Y Group.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The 1000 Genomes Project Phase 3 has sequenced 1,244 males belonging to 26 populations from Africa, South and East Asia, Europe and the Americas. In addition to these low coverage (~4-6x) sequences, the project also includes over two hundred males sequenced to high coverage by Complete Genomics and several sets of SNP genotype data used for validation. The group generated a union set of 80,895 Y-SNP, 2,830 Y-MNP and 6,076 short indel calls by combining results from seven different callers. Approximately 6,000 Y-STRs and ~1,000 large structural variants were also called, using two callers for each class. Validation suggests that the Y-SNP, Y-STR and large deletion and duplication calls have very high quality, but that the Y-MNPs and indels do not. Using 59,666 stable high confidence Y-SNPs, we have constructed a phylogenetic tree, to which the more complex classes of variant can be added. The tree recapitulates and extends the established phylogeny. It confirms a very rapid Paleolithic expansion (in number) of Y lineages post-dating the movement out of Africa, and Neolithic or later expansions of independent Y lineages in Africa, Europe, East Asia and South Asia. We observe different patterns in different continental regions, suggesting that this male expansion was extremely rapid in Europe, rapid in Africa, and less rapid in South and East Asia. These data thus provide powerful new insights into male evolutionary history and promise further insights into Y-chromosomal mutation and selection processes.

1993S

Exploring the Y-Chromosome Variation of Modern Panamanians. *A. Achilli[1], V. Battaglia[2], V. Grugni[2], U.A. Perego[1,3], H. Lancioni[1], M. Tribaldos[4], A. Olivieri[2], I. Cardinali[1], E. Rizzi[5], A. Raveane[2], M.R. Capodiferro[1], S.R. Woodward[3,6], J.M. Pascale[4], R. Cooke[7], N. Myres[3,6], A. Torroni[2], J. Motta[4], O. Semino[2].* 1) Dept. of Chemistry, Biology and Biotechnology, University of Perugia, Perugia, Italy; 2) Dept. of Biology and Biotechnology, University of Pavia, Pavia, Italy; 3) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 4) Gorgas Memorial Institute for Health Studies, Panama City, Panama; 5) Institute of Biomedical Technologie, National Research Council (ITB-CNR), Segrate, Milano, Italy; 6) Ancestry, Provo, Utah, USA; 7) Smithsonian Tropical Research Institute, Panama City, Panama.

The Isthmus of Panama - the narrow neck of land connecting the northern and southern American landmasses - was a forced corridor for the Paleo-Indian expansion that originated from Beringia ~15-17,000 years ago. Archaeological findings suggest that some descendants of the earliest migrants remained on the isthmus, while accounts from early European explorers witnessed the presence of two main indigenous groups (the Cueva and the Coclé) in pre-Columbian times - populations that have since disappeared due to disease, warfare, and enslavement following the Spanish conquest. Today's indigenous groups total about 5.3% of the Panamanian population, and are mainly represented by the Ngöbé, Buglé, Kuna, Emberá, and Wounan tribes, which traditionally appear to have settled in Panama from surrounding regions after the autochthonous natives were decimated. However, there is no evidence that the ancestral indigenous gene pool was completely replaced. If this was the case, the populations of modern Panama should have retained at least a fraction of the native pre-Columbian gene pool, possibly at a variable extent, given the differential degree of geographical and genetic isolation of the different Panamanian communities during the past five centuries. A recent study of the mtDNA history of the modern Panamanian population (Perego et al., 2012), based on a sample of 1565 individuals with Native American maternal ancestry, concludes that (1) the first settlement of Panama occurred quite rapidly after the initial colonization of the American continent, (2) based on complete sequence analyses, the founder ages of the most common lineages point to an ancient expansion supporting the antiquity of the Pacific coastal route, 3) the mitochondrial gene pool exemplifies the link between pre- Columbian and modern Panamanian populations (in fact, 83% of modern Panamanians clusters into native pan-American lineages). It appears that the Spanish conquistadores and additional more recent European demographic influences did not contribute significantly to today's genetic composition of Panama, at least with regard to the maternal side. In this study, we have now tested the same scenario from the paternal side by employing the analysis of the Y-chromosome variation in modern Panamanians.

1994M

Population specific patterns of novel haplotype groups at the *PAH* locus. *G. Povysil[1], S. Wieser[2], S. Hochreiter[1], J. Zschocke[2].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria.

The phenylalanine hydroxylase (*PAH*) gene is of particular interest for population genetic studies because the distribution patterns of well-defined phenylketonuria (PKU [MIM 261600]) mutations can be linked with distinct SNP haplotypes for the assessment of ancient migration. Through family segregation analysis and molecular haplotyping with long-range PCR in PKU patients (232 *PAH* mutant alleles) and controls (157 *PAH* normal alleles) from various European countries we identified five major haplotypes in the distal 15 kb region of the *PAH* gene. Haplotypes differ by 3-16 specific SNPs each and have been quite stable over the last millennia. The 29 common European PKU mutations can be linked to specific haplotypes with little evidence of recombination in the *PAH* gene. The results were compared to available sequencing data of Africans, East Asians, Europeans, and Admixed Americans from the 1000 Genomes Project. Additional data from chimpanzee, orangutan, and macaque, as well as high coverage sequences of Neandertal and Denisova, were used in conjunction with these data to establish a possible evolutionary tree of haplotype emergence. There are five major distal *PAH* haplotypes that can be found in all continental populations, but at different relative frequencies. For Europeans and Asians they make up more than 98% of all *PAH* alleles. While Europeans have comparably high frequencies for all of them, the most common haplotype in Asians amounts to almost 78% of *PAH* alleles. In contrast, Africans have many very rare haplotypes that can only be found in Africans, or Africans and Admixed Americans. The ancestral haplotype that matches the sequences of chimpanzee, orangutan, and macaque, has only been found in Africans and one Admixed American individual. The haplotype that matches the Neandertal and Denisova sequence can be found in Africans, Admixed Americans and one Asian individual. Interestingly, additional variations on the Asian haplotype are more similar to the Neandertal than to other present day individuals with this haplotype. The combination of disease mutations and common gene variants with molecular haplotyping and available genetic data from different countries allows a unique insight in the genetic history of human populations.

1995S

High-coverage sequencing of diverse Y chromosomes via in-solution capture. *A.F. Adams[1], G.D. Poznik[1], R.E.W. Berl[2], N.A. Hammond[1], F.L. Mendez[1], O.E. Cornejo[2], M. Napel[1], M. Schertler[1], P.A. Underhill[1], M.W. Feldman[1], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) School of Biological Sciences, Washington State University, Pullman, WA.

As the longest stretch of non-recombining DNA in the human genome, the Y chromosome provides unique insight into the demographic and evolutionary history of modern humans. However, most large-scale studies of human Y chromosome diversity have been confined to a small number of STRs and SNVs. We conduct high-throughput sequencing of Y chromosomes to study male-line demography and evolution.

Having previously determined which regions of the Y chromosome are amenable to short-read sequencing, we designed a set of NimbleGen biotinylated DNA probes to target these 10.4 Mb. We then performed in-solution, hybridization-based capture, using 105 individuals from the 1000 Genomes Project to optimize and validate our capture protocol. Because our approach yields higher coverage than that obtained by the 1000 Genomes Project, we are able to increase resolution at the tips of the phylogeny—the portion most informative of recent demography, such as admixture within the Americas. Following protocol optimization, we performed Y-chromosome capture on 34 saliva-extracted samples from three southern Ethiopian minority ethnic groups. These data provide an unprecedented look at the population structure of southern Ethiopia.

Our capture protocol can increase coverage of the Y-chromosome target regions by two orders of magnitude, as compared to whole-genome shotgun sequencing. We achieve >30× coverage of the targeted region for each of 24 samples multiplexed in a single HiSeq lane. We report some of the first high-coverage sequencing of the hgA and hgA0 lineages and uncover deep novel substructure within the poorly characterized E2 haplogroup. We are now working to apply this capture method to a large panel of individuals from a wide range of populations in order to gain a greater understanding of human Y chromosomal diversity.

1996M

The Kalash isolate from Pakistan. *Q. Ayub[1], L. Pagani[1,2], M. Mezzavilla[1,3], C. Tyler-Smith[1].* 1) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 2) Division of Biological Anthropology, University of Cambridge, Cambridge, United Kingdom; 3) Institute for Maternal and Child Health — IRCCS "BurloGarofolo" — Trieste, University of Trieste, Trieste, Italy.

The Kalash represent an enigmatic isolated population that has been living for centuries in the Hindu Kush mountain ranges of present-day Pakistan. Previous uni-parental (Y and mitochondrial) DNA markers provided no support for their claimed Greek descent following invasion of this region by Alexander III of Macedon, and analysis of autosomal loci provide evidence of a strong genetic bottle-neck. To understand their origins and demography further, we genotyped 23 unrelated Kalash samples on the IlluminaHumanOmni2.5 BeadChip and sequenced a male individual at high coverage on an Illumina Hi-Seq 2000. Comparisons with neighboring populations confirmed results based on genotyping 650,000 common single-nucleotide polymorphisms in the Kalash samples from the Centre Etude Polymorphism Humain (CEPH) Human Genome Diversity Project (HGDP) Cell Line Panel. However, we observed no evidence for admixture as suggested recently by Hellenthal et al. The mean time of divergence between Kalash and other populations currently residing in this region, that also speak Indo-European languages, was estimated to be 11.8 (10.6 -12.6) KYA. Since the split the Kalash have experienced little, or no, gene flow from their geographic neighbors and have maintained a low long-term effective population size (2,247-2,780). They could represent some of the earliest migrants into the Indian sub-continent.

1997S

Identifiability and efficient inference of population size histories and locus-specific mutation rates from large-sample genomic variation data. *A. Bhaskar[1,2], Y.X.R. Wang[3], Y.S. Song[1,2,3,4].* 1) Simons Institute for the Theory of Computing, University of California, Berkeley, Berkeley, CA; 2) Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, Berkeley, CA; 3) Department of Statistics, University of California, Berkeley, Berkeley, CA; 4) Department of Integrative Biology, University of California, Berkeley, Berkeley, CA.

Several recent large-sample human genetics studies have found a massive excess of rare variants compared to predictions of previously inferred demographic models of human history. A widely cited explanation is that such polymorphism patterns are indicative of explosive and accelerating population growth in recent human history. Using the site frequency spectrum (SFS), a summary of genetic variation in a set of sequences that counts the segregating sites as a function of the mutant allele frequency, we develop an efficient method for inferring recent population demography that can scale to samples involving tens or hundreds of thousands of individuals. Using analytic results for the expected SFS under the coalescent and by leveraging the technique of automatic differentiation, we develop a very efficient algorithm to infer piecewise-exponential models of the historical effective population size from the distribution of sample allele frequencies. Our method is orders of magnitude faster than previous demographic inference methods based on the frequency spectrum and can also accurately estimate locus-specific mutation rates. We show that our method can accurately infer multiple recent epochs of rapid exponential growth, a signal which is difficult to pick up with small sample sizes. We apply our method to a recent large-sample exome-sequencing dataset of 11,000 European individuals and find evidence of rapid recent exponential population growth of 1.5% per generation during the last 370 generations. We also study the statistical identifiability aspect of this inference problem. It has been recently shown that very different population demographies can generate the same SFS for arbitrarily large sample sizes. Although in principle this non-identifiability issue poses a thorny challenge to statistical inference, the population size functions involved in these counterexamples are arguably not biologically realistic. We revisit this problem and show that the SFS of even moderate-sized samples uniquely determines the population demography when the population size is *piecewise-defined* with each piece belonging to some family of biologically-motivated functions. In the cases of piecewise-constant, piecewise-exponential, and piecewise-generalized-exponential models, which are often assumed in population genomic inferences, we provide explicit values for the sample sizes that are sufficient for identifying the demographic model from the SFS.

1998M

Does genetic hypermutability contribute to the current prevalence of connexin 26 deafness? *D.C. Braun[1], E.A. Craft[1], B.K. Herold[1], K.S. Arnos[1], M. Tekin[2,3], A. Pandya[4].* 1) Department of Science, Technology, and Mathematics, Gallaudet University, Washington, DC; 2) John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Pediatrics, Ankara University School of Medicine, Ankara, Turkey; 4) Department of Human Genetics, Virginia Commonwealth University, Richmond, VA.

Approximately 35% of congenital deafness in North America results from recessive mutations in the *GJB2* (connexin 26) gene, making it the most prevalent cause for hereditary deafness [MIM 220290] in this population. There are more than 100 known *GJB2* mutations, placing it in the top 1% of mutational diversities reported by the Human Gene Mutation Database. Another remarkable characteristic of *GJB2* is that some mutations have ethnic associations: 35delG in Caucasians, 235delC in Asians, and 167delT in Ashkenazi Jews. These associations would normally suggest single origins in founders. Some researchers have proposed that *GJB2* is hypermutable. For example, the 35delG mutation occurs within a homopolymeric run of six guanines and could have arisen repeatedly due to strand slippage. *GJB2* also possesses sequence motifs associated with hypermutability in humans or other organisms. The hypermutability hypothesis is important because it could explain the prevalence of *GJB2* deafness. To test the hypothesis of generalized hypermutability in *GJB2*, we analyzed the historical mutation rate of *GJB2* by directly sequencing an 8 kilobyte region of genomic DNA, containing *GJB2*, from participant samples from two different repositories: Virginia Commonwealth University, which holds the largest repository of genetic deafness in North America, and Ankara University in Turkey. First, we directly measured this substitution rate using orangutan and chimpanzee outgroups and their known evolutionary distances. Second, we reconstructed the molecular genealogy using BEAST software, which provided inference of the substitution rates. These analyses generated values that fell within average human genome-wide mutational rates reported elsewhere. Next, we examined whether 35delG occurred on different haplotypic backgrounds. Consistent with hypermutability, we discovered two backgrounds, which we named haplogroups A and B. All North American participants with 35delG carried haplogroup A, whereas Turkish samples carried haplogroup A or B. We conclude that the 8 kb locus containing *GJB2* is not generally hypermutable. However, our discovery of two 8 kb haplogroups for 35delG confirms that it has multiple origins and therefore, strand-slippage hypermutability within the hexaguanine run may drive the prevalence of 35delG mutations. Our research is significant because it directly addresses the causes for the prevalence of *GJB2* deafness, which is not yet understood.

1999S

Identity by descent segments within and across worldwide populations from sequence data. *S.R. Browning[1], B.L. Browning[1,2].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

Segments of identity by descent (IBD) shared by individuals within and across populations provide information on key aspects of demographic history, such as effective population sizes and migration rates.

Sequence data present opportunities and challenges for IBD analysis. Sequence data are more informative than SNP array data, improving power to accurately detect smaller IBD segments and hence obtain higher levels of information about demographic history. On the other hand, low-coverage sequence data have high rates of error, whereas SNP array data are usually extremely accurate.

We recently developed two IBD segment detection methods: Refined IBD and IBDseq. Refined IBD is a haplotype-frequency-based method designed for SNP array data, while IBDseq is an allele-frequency-based method designed for low-coverage sequence data. Both methods were developed in the context of samples from a homogeneous population. When using frequency-based methods in a heterogeneous setting we expect increased rates of false-positive IBD within sub-populations.

We use 1000 Genomes Project data and simulated data to investigate the performance of the IBDseq and Refined IBD methods when analyzing sequence data from world-wide populations. We find that the allele-frequency-based IBDseq method suffers from increased rates of false positive detected IBD segments due to population heterogeneity, whereas the haplotype-frequency-based Refined IBD approach is much less affected. We develop a strategy using multiple runs of Refined IBD and a process of filling small gaps between adjacent detected segments in order to recover near-complete large IBD segments while having high power to detect short segments. Our approach enables powerful IBD detection in the 1000 Genomes project data.

The Population Genomic Landscape of Human Genetic Structure, Admixture History and Local Adaptation in Peninsular Malaysia. *L. Deng[1], B. Hoh[2], D. Lu[1], R. Fu[1], M. Phipps[3], S. Li[4], A. Nur-Shafawati[5], W. Hatin[6], E. Ismail[7], S. Mokhtar[2], L. Jin[4], B. Zilfalil[5], C. Marshall[8], S. Scherer[8,9], F. Al-Mulla[10], S. Xu[1].* 1) Max Planck Independent Research Group on Population Genomics, Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology (PICB), Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shangh; 2) Institute of Medical Molecular Biotechnology, Faculty of Medicine, Universiti Teknologi MARA, Sungai Buloh Campus, Jalan Hospital, 47000, Sungai Buloh, Selangor, Malaysia; 3) Jeffrey Cheah School of Medicine and Health Sciences, Monash University (Sunway Campus), Selangor 46150, Malaysia; 4) Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 5) Department of Pediatrics, School of Medical Sciences, Universiti Sains Malaysia, Kelantan 16150, Malaysia; 6) Human Genome Center, School of Medical Sciences, Universiti Sains Malaysia, Kelantan 16150, Malaysia; 7) School of Biosciences & Biotechnology, Faculty of Science & Technology, Universiti Kebangsaan Malaysia, Bangi 43600, Malaysia; 8) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 9) McLaughlin Centre and Department of Molecular Genetics, University of Toronto, Toronto, Canada; 10) Department of Pathology, Faculty of Medicine, Kuwait University, Safat 13110, Kuwait.

Peninsular Malaysia is a strategic region which might have played an important role in the initial peopling and subsequent human migrations in Asia. However, the genetic diversity and history of human populations—especially indigenous populations—inhabiting this area remain poorly understood. Here, we conducted a genome-wide study using over 900,000 single nucleotide polymorphisms (SNPs) in four major Malaysian ethnic groups (MEGs; Malay, Proto-Malay, Senoi and Negrito), and made comparisons of 17 world-wide populations. Our data revealed that Peninsular Malaysia has greater genetic diversity corresponding to its role as a contact zone of both early and recent human migrations in Asia. However, each single Orang Asli (indigenous) group was less diverse with a smaller effective population size (N_e) than a European or an East Asian population, indicating a substantial isolation of some duration for these groups. All four MEGs were genetically more similar to Asian populations than to other continental groups, and the divergence time between MEGs and East Asian populations (12,000—6,000 years ago) was also much shorter than that between East Asians and Europeans. Thus, Malaysian Orang Asli groups, despite their significantly different features, may share a common origin with the other Asian groups. Nevertheless, we identified traces of recent gene flow from non-Asians to MEGs. Finally, natural selection signatures were detected in a batch of genes associated with immune response, human height, skin pigmentation, hair and facial morphology and blood pressure in MEGs. Notable examples include *SYN3* which is associated with human height in all Orang Asli groups, a height-related gene (*PNPT1*) and two blood pressure-related genes (*CDH13* and *PAX5*) in Negritos. We conclude that a long isolation period, subsequent gene flow and local adaptations have jointly shaped the genetic architectures of MEGs, and this study provides insight into the peopling and human migration history in Southeast Asia.

Redon[1,2,3,4].* 1) institut du Thorax, Nantes, France; 2) CNRS, UMR 6291, Nantes, France;; 3) Université de Nantes, Nantes, France;; 4) CHU Nantes, l'institut du thorax, Service de Cardiologie, Nantes, France;; 5) CHU Nantes, Service de Génétique Médicale, 44093 Nantes CEDEX 1, France; 6) Institute of Clinical Physiology, National Research Council, Pisa, Italy;.

The 'Common Variant - Common Disease' hypothesis was only partly verified through effective discovery of statistical associations. This empirical observation led the research community to reconsider the involvement of rare genetic variation in predisposition to common disease. Rare alleles of recent origin are likely to cluster geographically in communities with limited migration rates, such as the French rural populations before the 20th Century. Should these rare alleles strongly increase disease risk, one would expect outbreaks of disease prevalence and enhanced power to establish the variant-phenotype relationship. Recently, we demonstrated genetic structure at the level of Brittany and Anjou (Karakachoff, 2014). In two new datasets, we propose to confirm this observation at a much finer scale. The first dataset (VACARME) includes 190 individuals which have their four grand-parents born within a distance of less than 15 kilometers. The second dataset includes 170 individuals born in the same area. Geographical location of individuals used to perform spatial analysis was defined according to the declared place of birth (or that of their grand-parents). The birthplaces are restricted in a small area spanning 200x200 kilometers in Western France. Individuals were genotyped on Affymetrix Axiom genome-wide CEU-1 array plates (1st dataset) and CytoChip 370k (2nd dataset). In the preliminary Principal Components Analysis, the first two principal components revealed an important correlation with latitude ($p<1e-16$) and longitude ($p<1.e-06$) with a better correlation for grand-parent's place of birth. Moreover, part of the distinction is possibly attributable the Loire river acting as a barrier. These preliminary results show for the first time, to our knowledge, that population stratification can be observed even at a very fine geographical level in populations usually considered as open and panmictic. This strongly suggests that recent rare alleles are likely to cluster geographically even in these populations. Therefore, identification of rare variants inducing disease susceptibility can benefit from a strategy focusing on small geographic units. Moreover, we will apply spatially explicit methods like spatial-PCA in order to better discriminate between clinal structure and presence of genetics clusters. We are now investigating through simulations which allele frequency spectrum can be expected to cluster geographically given this differentiation pattern.

2002M

Shared Identity by Descent segments within current Italian population reveals new details about recent population history. *G. Fiorito[1,2], C. Di Gaetano[1,2], F. Rosa[1], S. Guarrera[1,2], B. Pardini[1], A. Piazza[1,2], G. Matullo[1,2].* 1) Human Genetics Foundation, Turin, TORINO, Italy; 2) Department of Medical Sciences, University of Turin, Turin, Italy.

The inference of Identity by Descent (IBD) shared segments were recently enabled by high-resolution genomic data from large cohorts and novel algorithms for IBD detection. This approach permits to examine more in detail the genetic structure of a population as well as to get information about recent demographic events such as bottlenecks and migrations. This study aims to characterize the genetic variability within the Italian population. We present analytical results on the relationship between IBD sharing across 301 unrelated Italian individuals genotyped for about 2.5 million Single Nucleotide Polymorphisms (SNPs). Each sample has well-defined geographical origins (four grandparents coming from the same geographical region). Due to the well-known common ancestral origin of the Italian population we focused our attention on long-range and relatively recent shared IBD segments. By using Principal Component Analysis (PCA) and ancestry estimation, we ascertain Sardinia as the genetic outlier within Italy. Moreover a certain degree of differentiation is still detectable within Aosta Valley population. For each of the 11 subpopulation, we find a significant highest number of shared IBD segments within vs. between population, suggesting isolation by distance. Samples sharing the highest number of internal IBD blocks are Sardinian as expected, followed by those living in Aosta Valley, Tuscany and Sicily. We also evaluate the relationship between shared IBD segments and geographical distance. Contrary to what is expected, the decay of IBD with distance is not steeper for longer (recent) blocks. Such result suggests a constant exchange due to several migratory waves within Italy and/or to the considerable high number of population that have lived in Italy. We finally demonstrate that regions of increased IBD sharing are enriched for structural variation and loci implicated in natural selection and we highlighted the relationship between shared IBD haplotypes and demographic events occurred both in Sardinia and in the Italian peninsula. In conclusion, our results suggest that the study of shared IBD segments between populations is a useful method to detect novel details about relatively recent population history.

2003S

Reconstruction of ancestral human haplotypes using genetic and genealogical data. *J.M. Granka[1], R.E. Curtis[2], K. Noto[1], Y. Wang[1], J.K. Byrnes[1], M.J. Barber[1], N.M. Myres[2], C.A. Ball[1], K.G. Chahine[2].* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Provo, UT.

The genomes of individuals who lived long ago may persist in modern populations in the form of genomic segments broken down by recombination and inherited by their descendants. We develop a novel computational method to reconstruct the chromosomal haplotypes of human ancestors given genetic data from a sufficient number of their present-day descendants. After genealogical information is used to identify descendants of an ancestor (and therefore also of their partner), we use phased genome-wide single nucleotide polymorphism (SNP) data to find regions of the genome that are identical-by-descent (IBD) among them. We develop a novel stitching algorithm to reconstruct up to four chromosomal haplotypes of an ancestor and their partner given the descendant IBD segments and haplotypes. The method aims to remove spurious IBD segments caused by false inference, inaccurate genealogical information, or multiple common ancestors. Short regions of the genome with missing data can also be imputed given flanking reconstructed haplotypes. Lastly, given descendants of other individuals related to the ancestral couple, we show that it is sometimes possible to tease apart the personal identity of each of the reconstructed chromosomal haplotypes (i.e., which are the ancestor's, and which are their partner's). Through simulations, we calculate the amount of the genome that can theoretically be reconstructed given the number of generations back to the ancestor and the number of actual and sampled descendants. Given sufficient data, we can reliably reconstruct the haplotypes of in silico ancestors with high precision and recall; performance is sensitive to genealogical tree quality and accuracy of inferred IBD. We apply our method to phased genome-wide SNP data, obtained from the AncestryDNA customer database, from several hundred individuals descended from an 18th century couple. In genomic regions with many inferred IBD segments, we can reconstruct the haplotypes of the couple, in some cases assigning each haplotype to a specific member of the pair. In regions of the genome with fewer segments, we are less able to discover all haplotypes with certainty. Finally, we demonstrate that given these reconstructed haplotypes, we can infer a given ancestor's ancestry and select physical features. Our study highlights the feasibility of reconstructing the genomes of human ancestors and has immediate applications in population genetics, medical genetics, and genealogy research.

2004M

Identity by descent between humans, Denisovans, and Neandertals. *S. Hochreiter, G. Povysil.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria.

We analyze the sharing of very short identity by descent (IBD) segments between humans, Neandertals, and Denisovans to gain new insights into their demographic history. Short IBD segments convey information about events far back in time because the shorter IBD segments are, the older they are assumed to be. The identification of short IBD segments becomes possible through next generation sequencing (NGS), which offers high variant density and reports variants of all frequencies. Only recently HapFABIA has been proposed as the first method for detecting very short IBD segments in NGS data. HapFABIA utilizes rare variants to identify IBD segments with a low false discovery rate. We applied HapFABIA to the 1000 Genomes Project whole genome sequencing data to identify IBD segments which are shared within and between populations. Some IBD segments are shared with the reconstructed ancestral genome of humans and other primates. These segments are tagged by rare variants, consequently some rare variants have to be very old. Other IBD segments are also old since they are shared with Neandertals or Denisovans, which explains their shorter lengths. The Denisova genome most prominently matched IBD segments that are shared by Asians. Many of these segments were found exclusively in Asians and they are longer than segments shared between other continental populations and the Denisova genome. Therefore, we could confirm an introgression from Deniosvans into ancestors of Asians after their migration out of Africa. While Neandertal-matching IBD segments are most often shared by Asians, Europeans share more than other populations, too. Again, many of the Neandertal-matching IBD segments are found exclusively in Asians, whereas Neandertal-matching IBD segments that are shared by Europeans are often found in other populations, too. Neandertal-matching IBD segments that are shared by Asians or Europeans are longer than those observed in Africans. This hints at a gene flow from Neandertals into ancestors of Asians and Europeans after they left Africa. Interestingly, many Neandertal- or Denisova-matching IBD segments are predominantly observed in Africans - some of them even exclusively. IBD segments shared between Africans and Neandertals or Denisovans are strikingly short, therefore we assume that they are very old. This may indicate that these segments stem from ancestors of humans, Neandertals, and Denisovans and have survived in Africans.

2005S

Inferring demographic history from whole genome using Approximate Bayesian Computation. *F. Jay, F. Austerlitz.* Laboratoire Eco-Anthropologie et Ethnobiologie, Muséum National d'Histoire Naturelle, Paris, Paris, France.

Reconstructing past demography from neutral genetic data is essential as it both improves our knowledge about human history and provides an accurate neutral model against which selective hypotheses can be tested. Approximate Bayesian Computation (ABC) has proven to be useful for inferring demography from microsatellite or SNP data. This approach consists in simulating genetic data under a large range of complex demographic scenarios and realistic biological processes. Simulations are then compared to observed data using a set of informative summary statistics. Whole-genome data are expected to be extremely rich in information about past demography but, because simulations were, until recently, computationally too costly, ABC methods have not been thoroughly tested on such very long sequences. Dense polymorphism data contain extra information that is not available from unlinked site polymorphisms, and will, therefore, hopefully improve the reconstruction of demographic history. They allow computing specific statistics, such as the decay of linkage disequilibrium with distance, the distribution of length of haplotypes shared between two or more individuals, or the "allele frequency identity-by-state" as described by Theunert et al. (2012). The power given by some of these statistics to infer demographic parameters has been investigated. However, studies were done independently on single classes of statistics, and not always under the approximate Bayesian framework.

Here, we examine how combining these "dense data statistics", with "classical statistics" (e.g. pairwise differences, heterozygosity) in an ABC framework improves the inference of demographic history. Furthermore, we describe how sequencing errors that are usually more frequent in full sequences than SNP data impact the summary statistics and the ABC inference. To diminish these effects we propose to either (i) filter data drastically and prune summary statistics that are highly sensitive to errors, or (ii) model errors within our ABC and incorporate them into simulations. We benchmark these different approaches for simple demographic scenarios, and focus more specifically on population expansion events that happened in recent human history.

Theunert C et al (2012) Inferring the history of population size change from genome-wide SNP data. MBE, 29, 3653-3667.

2006M

Genetic Structure of North-Indian Punjabi Population Based on Autosomal Microsatellite Loci. *M. Kaur, B. Badaruddoza.* Deptt. of Human Genetics, Guru Nanak Dev University, Amritsar, India.

The population of Punjab, India, possesses an exclusive genetic profile, primarily due to the many migratory events in this region which caused an extensive range of genetic diversity. Hence, the present study is an attempt to find out the genetic similarity and phylogenetic position of north-west Punjabi population with respect to past history of admixture of foreign populations, especially, Caucasoid Populations. In this study, six microsatellite markers: THO1, TPOX, CSF1PO, vWA, D7S820 and FGA have been analyzed among 516 samples from five endogamous population groups, Jat Sikhs, Mazhbi Sikhs, Brahmins, Ramdasias and Muslims of north-west border districts of Punjab. The number of alleles ranged from 8 to 12 at six STR loci. The exact test probabilities for HWE suggested some significant departures in certain loci and population groups. In general, the average observed heterozygosity was lower than expected heterozygosity in six STR markers among the five population groups. The average sub-ethnic genomic differentiation (Fst) among five population groups of northwest Punjab was 0.0335. The CSF1PO showed highest sub-ethnic differentiation (0.0649), whereas, the lowest Fst has been observed for FGA locus (0.013). The percentage of genomic diversity attributable to different populations relative to the total genomic diversity (Gst) varied between 6.1% for CSF1PO locus and 0.9% for D7S820. When all the loci were jointly considered, 3.0% of the total genomic diversity was attributable to the five population groups. The maximum gene flow was observed in FGA (Nm=18.77%), which was followed by THO1 (15.92%). The lowest amount of gene flow was observed in CSF1PO (3.6%). However, in general with all loci the gene flow was observed to be 7.2% among these studied population groups. To understand the extent of sub-structuring among five northwest Punjabi population. Structure analysis was also performed with different values of K. The log probability values and the membership proportion of each group showed clear sub-structure among the population groups. Overall, five Punjabi speaking population groups of northwest Punjab are regionally well differentiated and exhibit strong genetic affinity based on their origin, settlement and their shared ethno-historic background.

Demographic inference of human population by diffusion model with nonparametric regression. *Y. Kawai, Y. Sato, Y. Yamaguchi-Kabata, N. Nariai, S. Sugimoto, T. Mimori, K. Kojima, M. Nagasaki.* Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan.

The demographic inference of human population is important not only for archeological and evolutionary studies but also for guiding sampling design for medical genetic study. Recent increase in the amount of human genetic data combined with the population genetic method contributed to the understandings of the demographic history of modern human. Both theoretical and experimental studies have shown that some populations have experienced the rapid population growth resulting in more low-frequency alleles than expected under the neutral and constant population size model. Thus, large samples, which include substantial amount of low-frequency alleles, are necessary for the demographic inference of rapidly growing population. The coalescence-based inference methods are commonly used for demographic inference with such large samples. With the aid of progress in computational power, a forward-time simulation under Wright-Fisher diffusion model is also applicable for observed allele frequency spectrum. We developed a method for demographic inference based on a diffusion approach, in which variable population size is estimated by nonparametric regression. By applying this method to the complete sequences of mitochondrial DNA from Japanese and Basque populations, we observed the recent population growth in both populations but with different growth rates and different time periods of growth.

Decoding ancient Bulgarian DNA with semiconductor-based sequencing. *Y. Ku[1], M.L. Carpenter[2], M. Sikora[2], H. Schroeder[3], C.C. Lee[1], C. Davies[1], M.T.P. Gilbert[3], C.D. Bustamante[2], G.D. Meredith[1].* 1) Thermo Fisher Scientific, South San Francisco, CA. USA; 2) Stanford University, Stanford, CA, USA; 3) Centre for GeoGenetics, Copenhagen, Denmark.

With the development of Next Generation Sequencing Technology (NGS), the field of hominin paleogenetics has transformed significantly from studying specific DNA markers to revealing whole genome information. However, ancient DNA of interest is usually highly fragmented so an NGS library protocol optimized to capture short DNA fragments (40bp to 200bp) was developed. The improved workflow includes the use of column-based DNA purification and concentration and automated gel-based size-selection. This workflow permitted production of "shotgun" genomic libraries from very limited input DNA (6ng to 39ng). Methods that permit the use of such low input, degraded DNA enable the partitioning of exceedingly rare samples into multiple analytical workflows. For example, to establish highest confidence SNP calls from ancient genomes it is best to sequence the sample on multiple orthogonal platforms. To pilot this approach, DNA extracted from 4 human tooth specimens from Bulgaria (ancient Thracians) that date to the Bronze and Iron Ages (1500-400 yr BCE) were sequenced on a semiconductor-based platform. Per individual sample, 259 million to 312 million sequence reads were produced. Deep sequencing (467 Mb) on one of the samples (P192-1) yielded detection of ~400,000 SNPs. Using principal component analysis that included more than 1,300 modern Europeans, this large number of SNPs indicated clustering of P192-1 (from an ancient farming community) closely with modern Sardinians; this result resolves ambiguity in the ancestral lineage of this individual that was recently reported based on ~10-fold fewer SNP calls and supports the hypothesis that the ancient Thracians and Sardinians share a heritage that dates to the initial spread of farming into Europe about 7,000 years ago. Data from two orthogonal sequencing platforms for these ancient Bulgarian samples demonstrated very similar base-substitution profiles with C>T and G>A variants accounting for ~75-80% of all SNPs called in both datasets. With such orthogonal validation, we expect to be able to reduce the false positive rate and generate a "truth" list of SNPs that will enhance our understanding of ancient population genomics and migrations. In summary, we have demonstrated a library preparation and semiconductor-based NGS workflow that is applicable for processing contaminated and degraded samples and can be used for ancient DNA research. For Research Use Only. Not for use in diagnostic procedures.

2009S

Exploring Detailed Demographic Histories of Human Populations Using SNP Frequency Spectrums. *X. Liu, Y.-X. Fu.* Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX.

Inferring human demographic history using genetic information can shed light on important prehistoric evolutionary events such as population bottleneck, expansion, migration, and admixture, among others. It is also the foundation of many population genetics analyses, as demographic history is one of the most important forces shaping the polymorphic pattern of DNA sequences. We developed a novel model-free method called stairway plot, which infers detailed population size changes over time using SNP frequency spectrums. This method can be applied to low-coverage sequence data, pooled sequence data and even reference-free sequence data for species whose reference genome are not yet available. Another advantage of this method is the ability to handle whole-genome sequences of hundreds of individuals. Using extensive simulation we compared our method to Li and Durbin's method based on the pairwise sequentially Markovian coalescent (PSMC) framework and the results show that our method outperformed the PSMC method for inferring recent population size changes. We applied our method to the genomes of nine non-admixed populations (CEU, GBR, TSI, FIN, CHB, CHS, JPT, YRI and LWK) from the 1000 Genomes Project, and showed a detailed pattern of human population fluctuations from 10 to 500 thousand years ago (kya). The results supported many mainstream viewpoints on the demographic histories of human populations, and at the meantime also produced several interesting observations worth further and more careful investigations.

Exome sequencing of 3,000 individuals reveals differences in recent demographic history between East Asian and European populations. *K.E. Lohmueller[1], M. He[2,3], Y. Li[3], B. Kim[1], L. Sun[4], X. Zhang[4], X. Jin[3], K. Kristiansen[3,5], T. Hansen[6,7], J. Wang[3], O. Pedersen[7,8,9], E. Huerta-Sanchez[10], R. Nielsen[5,10].* 1) Ecology and Evolutionary Biology, University of California, Los Angeles, Los Angeles, CA; 2) Bioinformatics and Computational Biology Program, Iowa State University, Ames, IA; 3) BGI-Shenzhen, Shenzhen, China; 4) Department of Dermatology, First Affiliated Hospital, Anhui Medical University, Hefei, China; 5) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 6) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; 7) The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 8) Faculty of Health Sciences, Aarhus University, Aarhus, Denmark; 9) Institute of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark Denmark; 10) Integrative Biology, University of California, Berkeley, Berkeley, CA.

Studies of genetic variation in thousands of individuals have found evidence for extreme population growth within the last 10,000 years in European and African American populations. The magnitude of recent growth in other continental populations, such as East Asians, has received comparatively little attention. In order to learn more about recent population history in East Asia, here we analyze high-coverage exome sequencing data from 1,449 Han Chinese individuals sampled from the Anhui province of China and 1,449 Danish individuals. We estimated recent demographic history using the site frequency spectrum. We find that the current effective size of the Han is approximately 4-fold larger than that estimated in the Danish population. Thus, while previous studies of common variants suggest historically smaller effective sizes in East Asian populations relative to European populations, our estimates of recent effective population sizes show the opposite pattern and trend in the same direction as the census population sizes. Next, we characterize the relationship between our estimates of the current effective population sizes and the census sizes. The ratio of the census size (over the last 200 years) to the recent effective size is significantly higher in the Han population than in the Danish population ($P<2\times10^{-4}$). This difference can be explained by greater variance in reproductive success in the Han population as compared to the Danish population. Alternatively, this result could be due to greater migration into the Danish population than the Han population. While it is appreciated that effective sizes of human populations are smaller than the census sizes, here we demonstrate that the magnitude of this difference varies across populations, even after accounting for population size changes. Finally, we examine patterns of deleterious variants in the Han and Danish populations. We find that the proportion of private variants that are nonsynonymous is higher in the Han sample (67.6%) than in the Danish sample (64.6%; $P<10^{-10}$), consistent with recent population growth increasing the input of weakly deleterious mutations into the population that selection has not had sufficient time to remove. Our study provides the first analysis of recent population history and exploration of neutral and deleterious rare variants in an East Asian population.

2011S

Analysis of Genetic Diversity Representation of the 1000 Genomes in Worldwide Human Populations. *D. Lu, S. Xu.* Partner institute for Computational Biology, Shanghai, Shanghai, China.

The 1000 Genomes Project (1KG) aims to provide a deep characterization of human genome sequence variation, by design was expected to aims to provide a comprehensive resource on human genetic variation. With an effort of sequencing 2,500 individuals, 1KG is expected to cover the majority of the human genetic diversities worldwide. However, it would be interesting to evaluate to what extent the 1KG data represent the genetic diversity of human populations in each region, which will give insight into the power of 1KG and also give guidance to regional efforts for further sequencing project and study design. In this study, using analysis of population structure based on genome-wide single nucleotide polymorphisms (SNPs) data, we examined and evaluated the coverage of genetic diversity of 1KG samples with the available genome-wide data from 3,831 individuals representing 140 worldwide population samples. We demonstrated that the 1KG does not have sufficient coverage of human genetic diversity in Asia, especially in Southeast Asia. We thus suggest a better coverage of Southeast Asian populations be considered in 1KG or a regional effort be initialized to provide a more comprehensive characterization of the human genetic diversity in Asia, which is important for both evolutionary and medical studies in the future.

2012M

Visualizing the Geographic Distribution of Genetic Variants. *J.H. Marcus, J. Novembre.* Department of Human Genetics, University of Chicago, Chicago, IL.

One of the core features of any genetic variant, beyond its potential phenotypic effects or its frequency, is its geographic distribution. The geographic distribution of a genetic variant can shed light on where the variant first arose, in what populations it survived and spread within, and in turn help us learn about historical patterns of migration and natural selection. Collectively the geographic distribution of genetic variants can help to explain how populations have been related through time (e.g. levels of gene flow and divergence). For variants with large effects, it can also help us understand the geographic distribution of spatially-varying phenotypes. For these reasons, visual inspection of geographic maps for genetic variants is common practice in genetic studies. Here we develop a series of reusable interactive visualizations for illuminating the geographic distribution of genetic variants. We specifically address several non-trivial challenges of this type of visualization; in particular, how to represent non-uniform levels of uncertainty in allele frequencies due to variable sample sizes; how to represent results from data with >10,000 individuals in which allele frequencies can vary over 4 orders of magnitude; how to display data for regions of the globe with dense sampling of populations; and how to quickly access frequency data from large samples. To meet these challenges, we implement a flexible REST API for allowing for easy access to allele frequency and sample size data from large scale public genomic datasets. Built upon this API we develop a web-based browser, entitled the Geography of Genetic Variants (GGV) browser for visualizing the geographic distribution of genetic variants. The GGV browser rapidly provides maps of derived allele frequencies in populations distributed across the globe. The GGV browser builds upon past tools such as the HGDP Selection browser by allowing for more interactive features, new representations of rare variation, as well as incorporating uncertainty in allele frequency estimation. As ancillaries, we also develop a research visualization toolkit that includes a method for displaying high Fst outlier SNPs from the joint site frequency spectrum and an interactive version of commonly used PCA figures. We hope the GGV browser will be a valuable research and education tool for exploring population genetics data.

2013S

A Novel Likelihood Ratio Test Framework for Sex-Biased Demography and its Application to Human and Dog Genomic Data. *S. Musharoff[1], S. Shringarpure[1], T. Cooke[1], A. Adams[1], O. Cornejo[2], C.D. Bustamante[1], S. Ramachandran[3].* 1) Genetics, Stanford Univ Sch Medicine, Stanford, CA; 2) School of Biological Science, Washington State University, Pullman WA; 3) Ecology and Evolutionary Biology, Brown University, Providence, RI.

Sex-bias is defined as an unequal number of breeding males and females in a population. This can be caused by variance in reproductive success, demographic events involving unequal numbers of males and females, and/or differential selection at sex-linked genomic loci. A commonly used estimator of the proportion of females is based on the test statistic Q where Q is the ratio of current neutral genetic diversity estimated from the X chromosome to that estimated from the autosomes. This is problematic if the population changed in size: because X chromosomal diversity recovers from size changes at a different rate than autosomal diversity due to unequal effective population sizes, this estimator of the proportion of females based on current diversity will be biased. To this end we present a novel likelihood ratio test framework for sex-bias in a single population based on the Poisson random field model. We use the program dadi to estimate demographic parameters jointly from autosomal and X chromosomal data and test first for a persistent sex¬ bias and then for a sex-biased demographic event. When applied to simulated data, our test has more power to detect sex-bias from unlinked or partially linked sites than the commonly used test statistic Q for a range of demographic scenarios. Encouragingly, our test is well powered for events relevant to human history including recent rapid expansion whereas the test statistic Q is not. We recover the true proportion of females with our framework whereas the estimator based on Q underestimates the magnitude of sex-bias. To test for sex-bias in humans we applied our methodology to genome-wide data from three Thousand Genomes populations and find evidence for female sex-bias in Europeans, Asians, and Africans after modeling recent demographic events including a bottleneck and recent growth. Our method takes autosomal and X chromosomal site frequency spectra as input and can be applied to organisms with sex chromosomes. To investigate sex-bias in dogs, we analyzed a novel genome-by-sequencing (GBS) dataset comprised of genome-wide putatively neutral regions. After applying our methodology to breed dogs and to village dogs, we find that both groups show evidence of female bias with the breed dogs showing a more extreme bias than village dogs. These findings argue for the importance of modeling demography when assessing sex-bias in populations and highlight the role of sex-bias in the history of humans and of dogs.

2014M

Inferring the effective founder size of a spatially expanding population. *B.M. Peter, M. Slatkin.* University of California, Berkeley, Berkeley, CA.

The gradual loss of diversity associated with range expansions is a well known pattern that can be explained with a serial founder model. Using a branching process model, we show that this loss in diversity can be mainly attributed to the difference in offspring variance between individuals at and away from the expansion front. We use this model to define an effective founder size as a measure of the decrease of genetic diversity with distance. We show that many classical properties of the effective population size, such as the two-sex formula and the harmonic mean for time-varying models extend naturally to expanding populations. We demonstrate that the predictions from the branching process model fit very well with Wright-Fisher forward simulations and backwards simulations under a modified Kingman coalescent, and further show that estimates of the effective founder size are robust to possibly confounding factors such as migration between subpopulations.

2015S

Finding the oasis of humanity in Neanderthal deserts. *B. Vernot, JM. Akey.* Department of Genome Sciences, University of Washington, Seattle, WA.

As anatomically modern humans dispersed out of Africa, they encountered Neanderthals in Eurasia and low levels of hybridization occurred such that approximately 2% of each non-African's genome is inherited from Neanderthal ancestors. Recently, we developed an approach to identify surviving Neanderthal lineages in contemporary individuals, and recovered over 600 Mb of the Neanderthal genome present in modern non-African populations [1]. The map of surviving Neanderthal sequences shows marked heterogeneity across the genome, and we identified many "deserts of Neanderthal sequence" that are almost entirely devoid of Neanderthal sequence. These genomic regions are of particular interest because they delimit sequences that may confer uniquely human characteristics. For example, the largest Neanderthal desert is a 15Mb region on Chromosome 7, centered around the FOXP2 gene, which has previously been implicated in speech and language. Here, we present a detailed characterization of Neanderthal deserts by analyzing surviving archaic sequences in an expanded sample of geographically diverse individuals. We have developed a formal statistical test to identify genomic regions significantly depleted of Neanderthal lineages, and performed extensive simulations to infer the strength of purifying selection acting on these Neanderthal deserts. Additionally, we have utilized extensive bioinformatics analyses superimposing heterogenous functional genomics data to identify candidate causal variants. These analyses provide significant new insights into regions of the human genome that harbor sequences that have played a critical role in the evolution of anatomically modern humans, and suggest that regulatory sequences responsible for muscle, bone, and brain development were key differences between humans and Neanderthals. [1] Vernot and Akey, Science, 2014.

2016M

Coalescent times of 63 males estimated using the complete Y-chromosomes. *E. WONG[1], S. Limborska[2], A. Valouev[1].* 1) Department of Preventive Medicine, Keck School of Medicine of University of Southern California, Los Angeles, CA; 2) Department of Human Molecular Genetics, Russian Academy of Sciences, Moscow, Russia.

The Y-chromosome contains the longest non-recombining region in the genome and is useful for inferring human population history. Previous studies on the Y-chromosome mostly rely on rapidly mutating microsatellites or selected single nucleotide polymorphisms ascertained from small panels of individuals. These approaches likely underestimate the genetic diversity of the Y-chromosomes. Complete sequencing of the Y-chromosome to high coverage would enable us to more accurately estimate the coalescent times of populations across the world and reconstruct past events in human evolution. We sequenced the complete Y-chromosomes of 12 males sampled from Asia and Europe. We analyzed these chromosomes together with publicly available high-coverage complete Y-chromosomes of 51 males from across the world with known ethnicities. In our analysis, we excluded regions of the Y-chromosome that are subject to recombination and regions that are ill-suited for short-read sequencing due to low complexity and homology to the X-chromosome. By focusing our analysis on 10.45 million sites, we identified over 15,000 single nucleotide variants (SNVs) in 63 males from 38 populations across the world and constructed a maximum likelihood tree. We performed haplogroup analysis for these Y-chromosomes, based on the SNVs present in the International Society of Genetic Genealogy (ISOGG) database. We estimated the Y-chromosome coalescent time to be around 129 thousand years, which is in line with previous estimates. By estimating the coalescent time of these Y-chromosomes, we are able to understand more about the history of these populations and the migrations of their ancestors.

2017S

Detecting and dissecting the fine-scale genetic population structure of Spain. *C. Bycroft[1], A. Carracedo[2], C. Fernandez-Rozadilla[1,2], C. Ruiz-Ponte[2], I. Quintela-García[2], S. Myers[1], P. Donnelly[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Galician Public Fundation of Genomic Medicine (FPGMX)-Grupo de Medicina Xenómica-Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERer)-IDIS, Santiago de Compostela, Spain.

The Iberian Peninsula has been the subject of diverse population movements, both from Europe and North Africa, over millennia. The patterns of genetic variation within Spain reflect these movements, together with local isolation of populations due to cultural, linguistic, and geographical factors. Here we describe the largest genome-wide study of population structure across Spain, involving over 500,000 markers in ~600 individuals, analysed with powerful, recently developed statistical tools which exploit patterns of linkage disequilibrium. These analyses reveal striking patterns of genetic population structure at very fine geographic scales and shed light on the demographic history of populations within Spain. The genetic differences we identify distinguish individuals from many parts of Spain, including Galicia, the Basque Country, Catalonia, and the Balearic Islands. These differences correlate with both physical barriers to migration, and different languages spoken within Spain. Interestingly, we detect some genetic clusters that span from the north to the south of Spain, while groups differ more strongly east-west, suggesting predominantly north-south movements of people within Spain. Differing amounts of ancestry shared with individuals from Basque-speaking regions in populations from different parts of Spain also suggests a historic population movement out of the Basque region, largely in a southerly direction. Finally, we use a mixture model-based approach and a recently developed method, GLOBETROTTER, to quantify and date the genetic impact of migrations into Spain from groups including the Moors from North Africa and other European populations.

2018M

Using constraints on F_{ST} to interpret genetic differentiation in genomic data. *M.D. Edge[1], M. Jakobsson[2], N.A. Rosenberg[1].* 1) Department of Biology, Stanford University, Stanford, CA; 2) Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

The availability of genomic polymorphism data from large, worldwide samples has made it possible to study population structure at loci with rare alleles and low genetic diversity. Computation of F_{ST} is often a first step in population-genomic analyses of data from multiple populations. F_{ST} is a theoretically rich measurement of genetic differentiation, interpretable as an index of excess homozygosity due to population structure, as an excess coalescence time for alleles drawn from different subpopulations, and as the proportion of variance in allelic indicator variables attributable to population structure. At the same time, F_{ST} has sometimes behaved in surprising ways in genomic studies of human populations. For example, subpopulations within Africa often have low estimated F_{ST}, despite having considerable population structure as detected via individual-based clustering. Rare variants can generate low F_{ST} despite being more geographically localized than common variants. We suggest that one way to understand these surprising phenomena is to consider mathematical bounds on F_{ST} as a function of other population-genetic statistics. We have previously determined strict upper bounds on F_{ST} as a function of homozygosity and as a function of the frequency of the most frequent allele for loci with arbitrarily many alleles. Here, we extend these bounds to accommodate loci with specified numbers of alleles, showing that F_{ST} is highly constrained both for low and high levels of diversity and can only reach values near the theoretical maximum of 1 for loci with intermediate diversity levels. These bounds provide an explanation for the surprising behaviors of F_{ST}: for example, the low values for African subpopulations can be explained in terms of the particularly high genetic diversity in Africa. As genomic studies continue to examine rarer and more localized alleles - which generate loci with low genetic diversity -- our bounds can facilitate the sensible interpretation of F_{ST} results.

2019S

Population structure of Amerindian 19 populations in South America. *S. Nishikawa[1], R. Saito[1], N. Konno[1], G. Tamiya[1], N. Fuse[1], Y. Nakamura[2], J. Yasuda[1], I. Danjoh[1].* 1) Department of Integrative Genomics , Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Cell Engineering Division, BioResource Center, RIKEN Tsukuba Institute, Tsukuba, Ibaraki, Japan.

<Introduction> Ancestors of Amerindians migrated from Eurasia to North American continent via Bering Strait, and then reached South American continent over 10 thousand years ago. The study of HTLV-1 in South American populations indicates that they can be divided into two major ethnic groups. However, detailed population structure and genetic diversity in Amerindians are still unclear. To address these questions, we obtained genome-wide SNP data from the Sonoda-Tajima Cell Collection, that is a vast collection of B lymphoblastoid cell lines established from 550 native Americans belong to 29 tribes in South America (Danjoh et al., 2011), and analyzed population structure within and among tribes, and then analyzed the genetic structure of Amerindian populations.

<Methods> The standard SNP and samples quality control (QC) procedures including the estimation of "cryptic relatedness" were applied to the genome-wide SNP data on Genome Studio software and PLINK software, and removed closely related samples. After this step, 10 tribes retained insufficient number of samples, therefore we did not process them for further analysis. Remaining 19 tribes were used for the following analysis. The between-population Fst estimation, neighbor-joining (NJ) tree construction, and PCA were carried out with Arlequin, MEGA, and EIGENSTRAT software, respectively. The number of clusters (K) in Amerindian populations was estimated with ADMIXTURE.

<Results and Conclusion> NJ-tree showed that Samuna and Chipaya are distant from other populations. Moreover, PCA and cluster analysis showed that Sanuma formed a distatnt cluster along PC1 and PC2, on the other hand, Chipaya was clustered with the other populations. The result of cluster analysis showed that our 19 populations of Amerindian was constituted of 7 clusters. This is the first report for the detailed population structure of these Amerindians including Samuna.

2020M

Distribution of *CYP2C9*2* and *CYP2C9*3* variants in two Native populations of Mexico. *L.C. León-Moreno, J. Sánchez-Corona, A.M. Saldaña-Cruz, A.G. García-Zapién, M.C. Morán-Moguel, S.E. Flores-Martínez.* Molecular Medicine, Centro de Investigación Biomédica de Occidente, IMSS., Guadalajara, Jalisco, Mexico.

Presence of polymorphisms in the CYP450 enzymes genes is one of the principal determinants for individual variability in drug response. Particularly, CYP2C9 enzyme metabolizes almost 20% of the existing drugs. *CYP2C9* gene exhibits more than 57 variants, of which *CYP2C9*2* (rs1799853) and *CYP2C9*3* (rs1057910) have been associated with a reduced catalytic activity compared with wild type (*CYP2C9*1*). Variation in frequencies has been described for these two variants in Mexico, mainly between mestizos and native groups. This variation might be the cause, at least in part, of the disparities in drug disposition between ethnic groups. The present study is aimed to analyzing the *CYP2C9*2* and *CYP2C9*3* variants in two Native populations of Mexico to increase the information about the polymorphisms of pharmacogenomic relevance in the Mexican population. **Methods.** DNA samples from two Native Mexican populations (Lacandonians n=223 and Yaquis n=103) were genotyped for two variants in the *CYP2C9* gene (*CYP2C9*2* and *CYP2C9*3*). The variants were identified using PCR-RFLPs. Genotypic and allele frequencies and the Hardy-Weinberg equilibrium were performed using a package of statistical analysis for genetic marker data, ARLEQUIN v3.5.1.2. **Results.** In Lacandonian population, both heterozygous genotypes to *CYP2C9*2* and *CYP2C9*3* variants were found in a frequency of 0.4%. In Yaquis population, the heterozygous genotype to *CYP2C9*2* variant was found with a frequency of 3.9%, while heterozygous genotype to *CYP2C9*3* variant with a frequency of 14.6%. The compound heterozygous genotype *CYP2C9*2/*3* was observed only in Yaquis population. The *CYP2C9*2* or *CYP2C9*3* variants in homozygote state were no detected in none population. No significant deviations from HWE expectations were observed in any of the two studied populations. **Conclusions.** Variation in allele and genotype frequencies is evident between northern and southern Mexican native population, reflecting the differences among Mexican populations. The presence of these variants could represent a risk factor of drug resistance or adverse reactions to those drugs metabolized by CYP2C9 enzyme in individuals of both populations.

2021S

Full ancient mitochondrial genomes using the Ion Proton platform: Analyzing the genetic diversity of the Neo-Eskimo. *J. Tackney[1], A.M. Jensen[2], S. Watkins[3], J. Brenner-Coltrain[1], D.H. O'Rourke[1].* 1) Department of Anthropology, University of Utah, Salt Lake City, UT; 2) UIC Science LLC, Barrow, AK; 3) Department of Human Genetics, University of Utah, Salt Lake City, UT.

A cultural shift occurred in the North American Arctic archaeological record beginning around 1000 AD. This culture, known as the Neo-Eskimo Thule, quickly occupied the region from Alaska to Greenland, and their descendants are modern Iñupiat/Inuit. Nuvuk is a long-term Thule village at Pt. Barrow, AK. Its cemetery has yielded archaeological material with radiocarbon dates between 980-1300 AD, suggesting that human remains from the site should span from the classic Thule period to modern Iñupiat Eskimo.

Mitochondrial haplogroup D is the second most common haplogroup in northern Asia and it is present at high frequency in central and eastern Asia, as well as in the Americas. One subclade of D4 seems to have originated in southern Siberia and spread northward into northern Asia and the Americas post-Last Glacial Maximum. This subclade is present in the Inuit/Iñupiat populations of North America at low frequency (~5%), is shared with some Siberian Chukotkans, and is absent in more southern Amerindian populations. To help further characterize the sequence variation present in this haplotype, we assessed the mitochondrial genomes of two samples previously typed for HVS1 SNPs, and assigned to D3/D4b1a2a1a. The bone samples were directly dated with median intercept calibrated dates of 1269 and 1313 AD.

We optimized the Ion Torrent sequencing library creation and the Torrent Suite bioinformatics pipeline for ancient DNA analysis by limiting reaction clean-up steps, determining PCR cycle numbers using qPCR, and expanding the mapping algorithms performed on the unaligned reads. Using mtDNA hybridization probe capture, we generated complete mtDNA for each sample on the Proton sequencing platform. The full genomes allowed us to place these samples with high phylogenetic confidence in the mtDNA tree. Sequences suggest population continuity with modern Iñupiat/Inuit and the D3/D4b1a2a1a haplotypes confirm that the Thule belong in the Beringian, and not Asian or Pan-American, gene pools.

This research was supported by NSF grants OPP-0732846 AND OPP-0637246 to DHO'R, OPP-0820790 to JBC, and ARC-0726253 to AMJ.

Large scale whole-genome sequencing of the Icelandic population isolate. *D.F. Gudbjartsson[1,2], H. Helgason[1,2], S.A. Gudjonsson[1], F. Zink[1], A. Oddsson[1], A. Gylfason[1], G. Magnusson[1], B. Halldorsson[1,3], S. Besenbacher[4], A. Kong[1], G. Masson[1], U. Thortsteinsdottir[1,5], A. Helgason[1,6], P. Sulem[1], K. Stefansson[1,5].* 1) Dept Statistics, deCODE Genetics/Amgen, Inc, 101 Reykjavik, Iceland; 2) School of Engineering and Natural Sciences, University of Iceland, 101 Reykjavik, Iceland,; 3) Institute of Biomedical and Neural Engineering, Reykjavík University, 101 Reykjavík, Iceland,; 4) Bioinformatics Research Centre, Aarhus University, C.F. Mollers Alle, 8000 Aarhus C, Denmark; 5) Faculty of Medicine, University of Iceland, 101 Reykjavik, Iceland,; 6) Department of Anthropology, University of Iceland, 101 Reykjavik, Iceland.

Here we describe the insights gained from sequencing the whole genomes of 2,636 Icelanders to a median depth of 20X. Twenty million single nucleotide polymorphisms (SNPs) and 1.5 million insertions/deletions (indels) passed stringent quality control. We report the number of sequence variants by minor allele frequency (MAF) and functional annotation. Almost all SNPs with derived allele frequency (DAF) over 2% in Iceland have been recorded in international databases of sequence variants, while for SNPs with a DAF of 0.1%, half of those in protein coding regions and 20% of those in non-protein coding regions have been recorded outside Iceland. The corresponding fractions of Icelandic indels that have been recorded elsewhere are substantially lower. Sequence variants in genes involved in the function of the nucleus have the lowest density and the highest fraction of rare variants (DAF < 0.5%, FRV), while variants in genes involved in sensory perception have the highest density and the lowest FRV. In particular, variants in olfactory receptors have a higher density and are more common than the genome average. Loss of function (LoF) and missense variants have a higher density and are more common in the first and last exons of genes than they are in the middle exons. Missense and LoF variants in genes that have been associated with disease in the Online Mendelian Inheritance in Man, catalog through a dominant mode of inheritance, are less dense and rarer than variants in genes that have not been associated with disease. Variants with a chromatin state annotation have a density and FRV that fall between intergenic and untranslated regions. Sequence conservation between mammals, measured by the GERP score, predicts variant density and frequency. However, after accounting for the GERP score, sequence annotation has a substantial effect on variant frequency but not on variant density. Consistent with a founder effect and the small size of the Icelandic population, there are 56% more stop gained SNPs in the frequency range between 0.1% and 1% in Iceland than in the European American part of the Exome Sequence Project data. Icelanders are more likely to be homozygotes than Hardy-Weinberg equilibrium would predict by a factor of 3 for variants with a MAF of 0.1%. We have described the sequence diversity and structure of the Icelandic population isolate and evaluated several types of sequence annotations based on the strength of selection signature.

Identifying Clusters of Rare Skeletal Genetic Disoders in Brazil - preliminary data. *D. Cavalcanti, C. Moreno.* Skeletal Dysplasia Group. Medical Genetics Department, FCM, University of Campinas (UNICAMP), Campinas, São Paulo, Brazil.

The identification of clusters of rare genetic diseases has significant medical and scientific implications. The establishment of an investigation group of skeletal genetic disorders [osteochondrodysplasias (OCD) and skeletal malformations or dysostosis] at our institution has contributed to the creation of a register of these conditions in which familiar and demographic data in addition to the clinical ones have been sistematically collected. This presentation aims to show the preliminary results related to the identification of clusters of OCD and dysostoses in Brazil. The data base was revised with special attention to the clinical and demographic data. The more common registered cases as FGFR3 group, osteogenesis imperfecta as well as campomelic dysplasia, type 2 collagenopathies, and inconclusive diagnosis were all excluded of the present analysis. Thus, among 359 cases 52 different diagnoses were established. The autosomal recessive (AR) inheritance pattern was observed in 62% (32/52) of the cases and parental consanguinity was present in 28% (30/107). The molecular investigation found a pathogenic mutation confirming the diagnosis in 25 cases of 21 families. Among 11 cases for whom parental consanguinity was referred as negative a homozygous mutation was found in seven patients and for five ones both paternal and maternal ancestors came from small and identical/close cities, suggesting a common origin with an unknown and distant consanguinity. The following were considered evidence of a cluster: the presence of a rare mutation in different families associated or not with families from the same region, and cluster evidence already known from the literature. So far, five new clusters were found, and they are distributed in different states: Blomstrand dysplasia (Alagoas), Pycnodysostosis (Ceará), Short-rib polydactyly dysplasia type 3 (Maranhão and Pernambuco), Opsismodysplasia (Pernambuco), Spondyloenchondrodysplasia (Minas Gerais). All these conditions are associated with parental consanguinity. We also found a case of Grebe dysplasia (Bahia), and a case of Richeiri-Costa-Pereira syndrome (São Paulo), reinforcing clusters already known from the literature. In conclusion, we found five new clusters of AR skeletal conditions in Brazil, for whom the associated inbreeding suggests founder effect. [Supported by grants from CNPq # 402008/2010-3, 590148/2011-7].

The CARTaGENE Genomics Project: How successive bottlenecks have shaped the present French Canadian founder population. *H. Gauvin[1,2], JP. Goulet[1], JC. Grenier[1], M. Capredon[1], T. de Malliard[1], V. Bruat[1], E. Gbeha[1], E. Hip-Ki[1], A. Hodgkinson[1], P. Awadalla[1,3].* 1) Sainte-Justine Hospital Research Center, Université de Montréal, Montreal, QC, Canada; 2) Department of Social and Preventive Medicine, Université de Montréal, Montreal, QC, Canada; 3) Department of Pediatrics, Université de Montréal, Montreal, QC, Canada.

French Canadians (FC) are a population of *Nouvelle-France*'s settlers who established themselves before the British conquest. The population has undergone recent rapid growth, with limited genetic exchange with other populations, and has colonized the whole province in successive waves leading to regional founder effects contributing to population structure. It is known that levels of kinship and disease prevalence vary from region to region within Quebec, making the population a particularly interesting case-study for understanding the origins of rare genetic diseases; in this study we attempt to disentangle and describe the processes driving these patterns. Using participants from the CARTaGENE project, the provincial biobank, we generated whole genome genotyping data for ~1000 individuals sampled in three regions (Montreal, Quebec City and Saguenay) with the OMNI2.5 chip, and then examined the fine structure of the Quebec population and searched for signals of genetic drift and selection using a haplotype-based approach. Focussing on individuals with FC descent, which was inferred from principal component analysis and information provided by participants, we performed a high-resolution analysis of the genetic structure of the population using the Chromopainter and FineSTRUCTURE clustering algorithm. FineSTRUCTURE analysis showed differences between two geographically close regional populations, Montreal and Quebec City, and provided greater resolution of the migration patterns within the province. Furthermore, using HaploPS, we identified genomic signatures of positive selection and genomic regions that have potentially drifted to particularly high frequency among FC. Among these regions we located one, at a 50% frequency among FC from Saguenay, encompassing the RYR1 gene found to be implicated in malignant hyperthermia. This is a pharmacogenetic disorder for which cases were previously identified in families coming from Abitibi-Temiscamingue, another region of Quebec. It was reported that common ancestors of those cases were found before the colonization of this recently inhabited region meaning that mutations causing the disease could have spread in others regions of Quebec. Collectively, these results provide a refinement of previous analyses of the structure of the Quebec population and suggest that the unique demographic history of FC may have affected specific regions of the genome that are relevant to the population's health.

Dominant mutation in GJB2 causes hearing loss in northeast mexican family. *F. Loeza-Becerra[1,2,3], R. Rivera-Vega[2,3], E. Gutierrez-Contreras[4], P. Berruecos-Villalobos[2,3], SA. Cuevas-Covarrubias[2,3].* 1) UMSNH Morelia, Michoacán, Mexico; 2) Secretaria de Salud; 3) UNAM, Mexico DF; 4) Centro de Rehabilitacion Gpe. H. de De las Fuentes DIF-Torreon Coah.

To know mutations in GJB2 and GJB6 that causes hearing loss in mexican population, we make genotyping and audiometric study in n=95 families (trios and more) from the Mexican Republic to the north, north-east, north-west and west with at least one case non-syndromic sensorineural hearing loss (NSSNHL). It was 70% wild type (mutations in no-GJB2 nor GB6 or mADN), eighteen different mutations and this: c.36GA (p.G12R). Most of the cases are sporadic or reccesives, and only one north-eastern family has the mutation c.36GA (p.G12R) in nine members, three generations, both sexes affected and transmission male-to-male. All affected has neurosensorial hearing loss. Now corroborated no anatomical anomalies. We remarks that its importance is clinical and epidemiological because the hearing loss by GJB2 is classically reccesive and it is northern that mutation.

2026M

Clinical Implications and Frequency of Variants in Nonsyndromic Hearing Impairment Genes in a Population-Based Sample of African-Americans and European-Americans. *H. Dai, G.T. Wang, R.L.P. Santos-Cortez, S.M. Leal.* Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX, 77030.

A large number of studies on nonsyndromic hearing impairment (NSHI) have been performed using samples collected from the Indian subcontinent, Middle East and Europe. There has been limited study of NSHI in African-Americans (AA) and sub-Saharan Africans. We evaluated the frequency of previously reported "pathogenic" variants in NSHI genes using data from the NHLBI-Exome Sequencing Project (ESP) which is a population-based study of AA (N=2203) and European-Americans [EA (N=4300)]. Of 201 observed variant sites which are pathogenic according to ClinVar and/or the Deafness Variation Database, we reclassified 121 (60.2%) variant sites as non-pathogenic based on literature, high allele frequencies in ESP and bioinformatics tools. In ESP, 80 pathogenic variant sites were observed in 5 autosomal dominant (AD) and 14 autosomal recessive (AR) NSHI genes, of which 24 variant sites in 7 genes cause syndromic hearing impairment (HI), e.g. *MYO7A* (MIM 276903) variants cause both NSHI and Usher syndrome. Of these variant sites, 49 (91 alleles) were found only in EA, 18 (23 alleles) only in AA, and 13 (194 alleles) in both EA and AA. *GJB2* (MIM 121011) c.35delG (p.G12Vfs) was the ARNSHI variant site with the highest allele frequency in EA [N=89; 1.09% (95%CI:0.88%,1.34%)] but with a much lower allele frequency in AA [N=4; 0.094% (95%CI:0.03%,0.2%)]. Additionally *OTOF* (MIM 603681) c.2348delG (p.G783Afs) was identified in 4 AA alleles [0.095% (95%CI:0.03%,0.2%)] but is very rare in EA [N=1; 0.01% (95%CI:0.0003%,0.07%)]. For EA, pathogenic variant sites were identified in 11 AR and 5 AD NSHI genes including variant sites in 7 genes which cause syndromic HI, while for AA pathogenic variant sites were identified in 13 AR and 2 AD NSHI genes, of which 6 genes have variant sites which cause syndromic HI. *MYO7A* c.3764delA (p.K1255Rfs) which was reported to cause Usher syndrome, is homozygous in 1 AA and 3 EA individuals. The use of EVS in order to exclude nonpathogenic variants must be done cautiously due to NSHI-causal variants within EVS. Knowledge of the frequency of NSHI variants in large population samples from different ethnic backgrounds is not only important to evaluate clinical significance but also aids in evaluating pathogenicity. Although population-based samples of AA aids in evaluating population-specific frequency of pathogenic variants, AA and sub-Saharan Africans with HI need to be studied to better understand the genes and variants underlying disease etiology.

2027S

Human population growth and purifying selection have increased the burden of autosomal and X-linked private mutations. *F. Gao, A. Keinan.* Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Several recent projects have sequenced the exome or whole-genome of a large number of individuals. A common feature discovered in these data sets is the significant elevation of rare variants, which are the segregating sites that have their minor allele in only one or a few chromosomes across the entire sequenced sample. This phenomenon can be explained by the effect of recent human population growth and purifying selection. Here, we considered the amount of rare variants in the prism of the burden of private mutations. We defined the burden of private mutations as the proportion out of all heterozygous sites in an individual that are unique compared to the rest of the sample. This quantity also answers the following question: Considering a large number of sequenced individuals, how many new variants will be ascertained with each additional individual sequenced? We studied the burden of private mutations by calculating the prediction from different demographic models and comparing with empirical estimates based on the Neutral Regions (NR) dataset that we recently published and that from the NHLBI Exome Sequencing Project (ESP). By analyzing autosomal SNVs, we observed a significant excess in the proportion of private mutations in the empirical data compared with models of demographic history without a recent epoch of population growth. Incorporating recent growth into the model provides a much improved fit to empirical observations. This phenomenon becomes more marked for larger sample sizes. For example, after sequencing 10,000 individuals from the same population, still about 1 in 400 heterozygous sites (~6,000 variants) at the 10,001st individual are predicted to be novel, 18-times more than predicted in the absence of recent population growth. The burden of private mutations is additionally increased by purifying selection, generally with intergenic SNVs exhibiting the lowest burden and splice sites the highest. Finally, we contrasted the burden of private mutations between the autosomes and the X chromosome, across different functional annotations and across matched allele sample sizes ranging from $n = 1$ to $n = 3027$. The results of this comparison point to a combination of sex-biased demographic history and purifying selection differentially affecting X and the autosomes. The very large numbers of private mutations in human genomes suggest that careful consideration is needed in the design and analysis of sequencing-based association studies.

Whole Genome Sequence of Japanese from Tohoku Medical Megabank Prospective Cohort Study. *M. Nagasaki[1,3], F. Katsuoka[1], N. Nariai[1], K. Kojima[1], I. Danjo[1], Y. Kawai[1], S. Saito[1], X. Pan[1], J. Yokozawa[1], R. Saito[1], Y. Sato[1], T. Mimori[1], Y. Yamaguchi-Kabata[1], K. Tsuda[1], Y. Kuroki[1], K. Kinoshita[1,3], J. Yasuda[1], M. Yamamoto[1,2], Tohoku Medical Megabank Organization Tohoku University Project.* 1) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Sendai, 980-8575, Japan; 2) Department of Medical Biochemistry, Tohoku University Graduate School of Medicine, Sendai, 980-8575, Japan; 3) Department of Applied Information Sciences, Graduate School of Information Sciences, Tohoku University, 6-6-05 Aramaki Aza Aoba, Aoba-ku, Sendai, Miyagi 980-8579, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) located at the north-eastern Japan is now developing a biobank (the final goal is 150,000 volunteers with millions samples) that combines medical and genome information during the process of rebuilding the community medical system and supporting health to foster the reconstruction from the Great East Japan Earthquake on Mar/11/2011. One of the missions of ToMMo is to reveal a fine genetic architecture of Japanese population to tackle the further GWAS analysis by combining the knowledge, which is daily accumulated in the ToMMo prospective genome cohort project, e.g. questionnaire data, physiological data, medical treatment records and other omics data from serum, plasma and immortalized lymphocytes. The first goal is to sequence 1K samples to cover MAF > 0.5% variants including short indels and large structural variants in Japanese for constructing a Japanese 1K reference panel. In our experimental design, to minimize the biases caused by the different equipment, protocol and bioinformatics analysis, we performed whole genome sequencing of 1K samples with 30X high coverage using the HiSeq 2500 rapid run mode and analyzed by the same bioinformatics pipeline. We have catalogued reliable SNPs with MAF > 0.5. In addition, variants categorized into rare frequency (MAF ≤ 0.5%) were detected with the same precision thanks to the variant call from high coverage sequencing without imputation. We also present other preliminary findings while constructing Japanese 1K reference panel.

2029S

Analyzing the impact of consanguinity and admixture on the Middle East Variome. *E.M. Scott[1], E. Spencer[1], B. Copeland[1], M. Abdellateff[1], S. Gabrielle[2], J. Gleeson[1].* 1) Neurogenetics Laboratory, Howard Hughes Medical Institute, Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093, USA; 2) The Broad Institute of MIT and Harvard, Cambridge, MA 02141, USA.

The Middle East has been an important hub of human migration, population admixture, and contribution of genetic diversity. Although details are disputed, several large-scale human migrations into an out of Africa, along with many more recent invading populations could have contribute to a complex heterogeneous Middle Eastern genome. Additionally, cultural practices predisposing consanguineous marriage have resulted in some of the highest known inbreeding coefficients, which theoretically should depress burdens of deleterious variants. Despite the size and uniqueness of these populations, so far they have been severely underrepresented and understudied. Here we investigate the genetic landscape of the Middle Eastern genome by repurposing a cohort of 2000 exomes samples resulting from three separate recruitment efforts focusing collection in the Gulf region, North Africa and Central Asia, collectively termed Middle East. Analysis of this cohort provides evidence for unique admixture components, and confirmatory evidence for inter-mixing of Sub-Saharan African and European populations. High levels of consanguinity resulted in a markedly higher rate of inbreeding coefficients compared with 1000G controls along with longer runs of homozygosity. Finally, we investigated potential impact these trends on the load of deleterious variant, demonstrating surprisingly a higher than expected burden of deleterious variants compared with European ancestry controls.

2030M

Rare variant stratification in a German/Austrian sample set. *E. Tilch[1,2], B. Schormair[1,2], B. Pütz[3], D. Czamara[3], M. Müller-Nurasyid[4,5,6], P. Lichtner[2], C. Trenkwalder[7,8], W. Genome wide association studies of complex traits with common genetic variants could only explain a part of a trait's heritability. The missing heritability is expected to be partially explained by rare genetic variation. But this variation was shown to already stratify populations across relatively short geographical distances within Europe. A German/Austrian sample set of 3,654 patients with the same common complex disease from geographically distinct recruitment areas as well as 2,911 convenience controls (KORA) were genotyped for mainly rare variants using Illumina®'s Infinium HumanExome BeadChip. After quality control, all polymorphic markers were grouped into bins by MAF and conservation, which was defined by exceeding all median conservation scores (PhyloP, GERP++ and SiPhy annotations provided by CHARGE), and were pruned by LD ($r^2 > 0.2$). The bins were used for identity-by-state (IBS) calculations between individuals and the subsequent stepwise assignment to partially dependent sample clusters (as implemented in PLINK). Differentiation of samples within these clusters is negatively correlated with MAF and positively with degree of conservation. Furthermore, IBS calculations were used for multidimensional scaling (MDS) to visualize genetic distances between individuals. The first two MDS components were not correlated between common and rare variant marker bins. The results suggest that (especially conserved) rare variants might offer better discrimination between sub-populations in Germany/Austria than more common variants. Thus inflation of p-values may be a major concern in association analysis of rare variants.

2031S

Population structure in the UK: Rare variant analysis using whole genome sequencing in 3,621 samples in the UK10K cohorts project. *K. Walter[1], S. Metrustry[2], E. Zeggini[1], Y. Memari[1], J. Min[3], J. Huang[1], M. Cocca[4], S. Schiffels[1], I. Mathieson[5], D. Lawson[6], N. Soranzo[1], UK10K Consortium Cohorts Group.* 1) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Twin Research & Genetic Epidemiology, Kings College London, United Kingdom; 3) MRC CAiTE Centre, University of Bristol, United Kingdom; 4) Institute for Maternal and Child Health-IRCCS "Burlo Garofolo"-Trieste, University of Trieste, Italy; 5) Harvard Medical School, Boston MA 02115, United States; 6) Heilbronn Institute, School of Mathematics, University of Bristol, United Kingdom.

Population structure is a well-characterized potential confounder of association studies based on common variants, but the structural pattern for rare variants and their influence on association studies is less understood. The cohorts arm of the UK10K project undertook whole-genome sequencing at low-read depth (median ~7x) in nearly 4,000 individuals from two large population samples in the UK (TwinsUK, N=1,754 and the Avon Longitudinal Study of Parents and Children (ALSPAC), N=1,867) in a comprehensive exploration of associations between rare and common genetic variants and a set of 61 bio-medically important quantitative phenotypes. The two study cohorts have marked differences in demographic profile with ALSPAC participants originating from a geographically restricted area (Bristol) in the South West of the UK, while the TwinsUK participants were born in different parts of the UK. After stringent QC steps, the data set comprises 42 million SNPs, 3.5 million INDELs and about 18,000 large deletions across 3,621 study participants. Here we describe the extent to which geographic stratification exists at rare variants by focusing on 31 shared 'core' phenotypes in 1,139 twins with available place of birth data throughout the United Kingdom. We modeled genetic structuring using a Euclidian distance metric, a regional grid and generalized additive models (GAM) applied to latitudinal and longitudinal data, and for single nucleotide variants of different minor allele frequencies separately. We further modeled correlation of genotypic and phenotypic data at these geographical locations, and compared them to simulated datasets. Finally, we applied Mantel tests to analyze the significance of genotypic and phenotypic relationships given the distance metrics. Overall, these analyses suggested that there is a moderate genetic structuring of very rare alleles (MAF=0.1-0.3%), however this structure is not associated with phenotypic variation and is unlikely to pose a serious concern for association studies of complex quantitative phenotypes and rare variation in the UK.

2032M

Rare variation and the genomic context of allele-specific expression. *J.R. Davis[1], D.A. Knowles[2], S.B. Montgomery[1,3,5], A. Battle[4,5].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Computer Science Dept., Stanford University, Stanford, CA; 3) Department of Pathology, Stanford University, Stanford, CA; 4) Computer Science Dept., Johns Hopkins University, Baltimore, MD; 5) Co-senior authors.

The functional impact of rare regulatory variation remains largely unexplored, in part due to the limited power of existing genetic association studies and the difficulty of interpreting regulatory variation in general. Allele-specific expression (ASE) offers a powerful, within-individual view of regulatory effects that is robust to the frequency of potential causal variants. However, until now the regulatory context of ASE has primarily been explored in conjunction with common genetic variants underlying expression quantitative trait loci (eQTLs). In this study, we assess the use of ASE to evaluate the impact of non-coding genetic variation, with a focus on rare variants. We use publicly available RNA sequencing data in 373 lymphoblastoid cell lines from the GEUVADIS consortium to perform over 3.3M tests of ASE at roughly 10K genes. This data provides sufficient power to evaluate the association of diverse genomic sequence annotations at candidate regulatory loci with allelic imbalance of nearby genes. Specifically, individuals heterozygous at non-coding loci are pooled to estimate the odds of allelic imbalance in the context of each annotation of interest. Our results demonstrate a positive association between ASE and the level of heterozygosity near a gene in each individual, which is strongly modulated by the position of heterozygous variants with respect to the TSS. Additionally, we find that the likelihood of ASE is associated with the severity of nearby heterozygous mutations; in particular heterozygous SNPs have a weaker effect than indels, which are weaker than structural variants. We determine the value of roughly 65 additional genomic annotations in predicting ASE, including DNase hypersensitivity, transcription factor binding, allele frequency and evolutionary conservation. Finally, we extend this work to develop a statistical model that combines these genomic annotations to predict ASE from individual sequence information. Using this framework, we characterize the effects of rare variation and contrast the genomic context of rare versus common regulatory variants.

2033S

Targeted transcriptomics to compare the susceptibility of human naive and pre-immune volunteers to an infection challenge with viable *Plasmodium vivax* sporozoites. *ML. Rojas-Pena[1], A. Vallejo[4], S. Herrera[3,4], M. Arévalo-Herrera[2,3], G. Gibson[1].* 1) Biology, Georgia Institute of Technology, Atlanta, GA; 2) Faculty of Health, Universidad del Valle, Cali, Colombia; 3) Malaria Vaccine and Drug Development Center, Cali, Colombia; 4) Caucaseco Scientific Research Center, Cali, Colombia.

Malaria is one of the most serious infectious diseases around the world, with an estimated 300 to 500 million cases annually, most of which occur in tropical areas. Infection rates vary across regions of Colombia due to different geographical conditions. Individuals living in high-prevalence malaria regions acquire a natural immunity that gradually eases the symptoms of the disease, and is likely to impact the efficacy of vaccines for malaria. Additionally, little is known about the immunological response to early infection and how the immune system may be boosted during vaccination. This study hypothesizes that the delayed onset and decrease of clinical and parasitological manifestations of malaria observed in pre-immune volunteers from Buenaventura (high prevalence of malaria) compared to naive individuals from Cali (low prevalence of malaria) is associated with altered peripheral blood gene expression. Here we describe the use of nanofluidic Fluidigm quantitative RT-PCR arrays targeting a set of 96 transcripts that are broadly informative of the major axes of variation, to explore the difference in gene expression between Cali and Buenaventura individuals experimentally exposed to viable Plasmodium vivax sporozoites and monitored at six timepoints (Pre-challenge, day 5, day 7, day 9, week 3 and month 4). The largest sources of variation are individuals and time. Site has a relatively minor effect, although it does separate the two clusters in the overall profiles of expression among the samples. Our analyses show that week 3, at the peak of parasitemia, is the most perturbed of the different time points, while among the axes, axis 3 related to B-Cell activation is most perturbed. RNA of the samples will be used to assess transcript abundance genome-wide and to perform gene expression profiling by RNA-seq of the samples to identify differentially expressed genes. Gene expression profiling of lymphocytes can thus be used to identify the type and duration of the immune signals that are biomarkers for vaccine immunogenicity, and establish how pre-immune exposure modifies their activation.

2034M

Conflations of short IBD blocks can bias inferred length of IBD. *C.W.K. Chiang[1], P. Ralph[2], J. Novembre[3].* 1) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 2) Computational Biology and Bioinformatics, USC, Los Angeles, CA; 3) Human Genetics, University of Chicago, Chicago, IL.

Identity-by-descent (IBD) is a fundamental concept in genetics with many genetic applications. A common working definition of IBD blocks is that they are contiguous segments of the genome inherited from a recent shared common ancestor without intervening recombination. Long IBD blocks (> 1cM) can be efficiently detected by a number of programs using high-density SNP array data of a population sample. However, all programs detect IBD based on contiguous segments of identity-by-state (IBS). As such, detected IBD blocks could often be due to the conflation of smaller IBD blocks inherited from different common ancestors. Here, we show through theory and simulation that the conflation of small IBD blocks can occur with appreciable frequencies and can lead to errors in estimating the length distribution of IBD blocks, thereby affecting downstream inferences. Specifically, we used coalescent simulations where we know the precise genealogy of the sample and found that, under a realistic demographic model of human history, >35% of the detected IBD segments of 1cM or longer are composed of at least two subsegments, oftentimes each of appreciable length. This effect is universally observed across different IBD detection programs and demographic histories, and was more pronounced for shorter segments (1 to 2cM long) compared to longer segments (>2cM long). Furthermore, we characterized the rate of subsegment conflations as a function of minimum subsegment lengths and gap sizes, and obtained a conflation rate of 0.67 per 1000 pairs of individuals due to segments as small as 0.2cM. Based on this rate, ~28% of all IBD segments between 1 to 2 cM would be due to conflation. Finally, we propose a novel estimator of the de novo mutation rate using IBD blocks detected in population samples. We have found via simulations that such an approach will only work if it explicitly models the conflation of short IBD segments (e.g. 15-fold higher estimates are obtained if conflation is ignored). Thus, the conflation effect should be carefully considered as methods to detect shorter IBD blocks using sequencing data are being developed.

2035S

A systematic analysis of genetic forms of dilated cardiomyopathy reveals numerous ubiquitously expressed and muscle-specific genes. *F.W. Asselbergs[1], G. Kummeling[1], A. Sammani[1], M.P.M. Linschoten[1], A.F. Baas[2], J.J. van der Smagt[2], P.A. Doevedans[1], D. Dooijes[2], M. Mokry[3], M. Harakalova[1].* 1) Department of Cardiology, University Medical Center Utrecht, Utrecht, Netherlands; 2) Department of Medical Genetics, University Medical Center Utrecht, Netherlands; 3) Division of Pediatrics, Wilhelmina Children's Hospital, University Medical Center Utrecht, Netherlands.

Background: Dilated CardioMyopathy (DCM) is a genetic disorder with several tens of genes known to underline its etiology. Despite considerable progress being made in developing next generation sequencing-based diagnostic panels using a subset of the most prevalent 40 DCM genes, the genetic cause remains unsolved in the majority of patients. This suggests that to increase the yield of diagnostic testing all relevant DCM-implicated genes need to be catalogued and carefully considered. Methods and Results: We have conducted a systematic literature search on PubMed, Embase, and OMIM, to find genes that have been implicated in syndromic and non-syndromic DCM and PeriPartum CardioMyopathy (PPCM). Besides strong evidence for mitochondrial inheritance, our search yielded a total of 113 nuclear protein-coding genes. In addition to 42 genes sufficiently reviewed elsewhere we provide a comprehensive annotation of the level of genetic evidence for the set of remaining 71 genes. Next, we investigated the tissue specificity of collected genes using public RNA sequencing data. We show that genes primarily expressed in heart more likely result in DCM with possible myopathies while genes expressed ubiquitously cause DCM with extramuscular manifestations. Conclusions: This comprehensive analysis of genetic evidence of DCM revealed a much higher number of genes than routinely screened at the moment. However, these finding have to be carefully considered and validated in larger cohorts. Our results suggest that targeted sequencing of all known protein-coding genes and the whole Mt-DNA together with consideration of the tissue specificity of mutated genes, will likely increase the yield of genetic testing and facilitate further genotype-phenotype studies in DCM.

2036M

The -844 GA PAI-1 polymorphism is associated with Acute Coronary Syndrome in Mexican population. *I.J. García-González[1,2], Y. Valle[1], E. Sandoval-Pinto[1,3], E. Valdes-Alvarado[1,3], FJ. Introduction: Acute coronary syndrome (ACS) has an important impact in public health with high morbidity and mortality. Pro-thrombotic and pro-inflammatory states are involved in the pathogenesis of the disease. Plasminogen activator inhibitor-1 (PAI-1) is the major inhibitor of the fibrinolysis and also is part of immune response. The -844 GA gene polymorphism is related to increased PAI-1 protein levels. Aim: We evaluate the association of -844 GA PAI-1 polymorphism with ACS. Methods: A total of 646 individuals were recruited from Western Mexico: 350 unrelated healthy subjects and 296 patients with diagnosis of ACS. PCR-RFLP and PAGE with silver stain were used to identified the polymorphism. Results: The most important risk factor in our population was hypertension, followed by smoking. The genetic distribution showed an association of the A allele (OR=1.27, p=0.04) and AA genotype (OR=1.86, p=0.02) with ACS. The recessive model displayed similar results (OR= 1.76, p=0.02). As additional finding, we observed significant differences in the genetic distribution of ACS dyslipidemic patients (p= 0.04). Conclusion: The A allele and AA genotype of -844 polymorphism of PAI-1 gene are risk factors for ACS. The AA genotype might be associated with the development of dyslipidemia in ACS patients.

MAT2A Mutations Cause Familial Thoracic Aortic Aneurysms and Aortic Dissections. *D. Guo[1], L. Gong[1], E.S. Regalado[1], R.L. Santos-Cortez[2], B. Cai[1], R. Zhao[1], S. Veeraraghavan[3], M. Willing[4], G. Jondeau[5], C. Boileau[6], M.J. Bamshad[7], J. Shendure[7], D.A. Nickerson[7], S.M. Leal[2], H. Pannu[1], R. Moran[8], C.S. Raman[3], E.C. Swindell[9], D.M. Milewicz[1].* 1) Dept Internal Med, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Mol & Hum Genet, Baylor College of Medicine, Houston, TX; 3) Sch of Pharmacy, Univ Maryland, Baltimore, MD; 4) Washington Univ/Sch Medicine, St. Louis, MO; 5) 5Centre National de Référence pour le syndrome de Marfan et apparentés, Hôpital Bichat, Paris, France; 6) 6INSERM U383, Hôpital Necker-Enfants Malades, Université Paris, Paris, France; 7) Dept Genome Science, Univ Washington, Seattle, WA; 8) Genomic Med Inst, Cleveland Clinic, Cleveland, OH; 9) Dept Pediatrics, Univ Texas/Houston Med Sch, Houston, TX.

We performed genome-wide linkage and exome sequencing using DNA from members of a large family (TAA059) with autosomal dominant inheritance of thoracic aortic aneurysms and dissections (FTAAD) associated with bicuspid aortic valve (BAV). Analysis of DNA from an affected family member identified no mutation in known FTAAD genes and no novel copy number variants (CNV) on an Illumina SNP array analysis. Exome sequencing of DNA from multiple affected family members identified only a single rare variant in MAT2A, c.1031A>C (p.Glu344Ala), that fell under the major linkage peak and segregated with TAAD in the family (two-point LOD score of 2.10). This variant was predicted to lead to loss of function of the protein, was located near the active site, and altered a conserved amino acid. Sequencing of an additional 409 unrelated probands with FTAAD identified another MAT2A variant, p.Arg356His, which was also in the active site, conserved, and predicted to be damaging; no additional samples were available to test the segregation of this variant with disease in the family. MAT2A is highly expressed in aortic smooth muscle cells and encodes S-adenosylmethionine synthase isoform type-2, which catalyzes the synthesis of S-adenosylmethionine (SAM). Reduction of cellular SAM levels would be predicted to decrease methylation capacity and increase oxidative stress in cells. To confirm the mutation disrupts protein function, an antisense mat2aa-specific morpholino was used to knockdown expression in zebrafish. The mat2aa-specific morpholino produced a range of cardiovascular phenotypes at 72 h postfertilization, ranging from mild (pericardial edema) to severe cardiovascular phenotypes (prominent cardiac and pericardial edema). Co-injection of the morpholino with wild-type MAT2A mRNA partially rescued these phenotypes, whereas mRNA with the MAT2A p.Glu344Ala alteration did not, indicating the mutation disrupts protein function. In conclusion, both genetic and functional data suggest that loss-of-function MAT2A mutations may be a rare cause of familial thoracic aortic aneurysms and dissections associated with bicuspid aortic valve.

Associations of Endothelial System Genes with Blood Pressure Changes and Hypertension Incidence: the GenSalt Study. *F. Liu[1,2], J. He[2], D. Gu[1], D. Rao[3], J. Huang[1], J. Hixson[4], C. Jaquish[5], J. Chen[1], C. Li[2], X. Yang[1], J. Li[1], T. Rice[3], L. Shimmin[4], T. Kelly[2].* 1) Department of Evidence Based Medicine, Fuwai Hospital, National Center of Cardiovascular Diseases, PUMC & CAMS, Beijing, China; 2) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine; 1440 Canal Street, Suite 2000, New Orleans, LA 70112, USA; 3) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; Campus Box 8067, 660 South Euclid Ave. St. Louis, MO 63110-1093, USA; 4) Department of Epidemiology, Human Genetics and Environmental Sciences, University of Texas School of Public Health, Houston, TX, USA; 1200 Pressler Street, Houston, TX 77030, USA; 5) Division of Prevention and Population Sciences, National Heart, Lung, Blood Institute, Bethesda, Maryland, USA.

High blood pressure (BP) is a complex trait, influenced by multiple environmental and genetic determinants. Although established as a heritable trait, the genomic mechanisms underlying BP regulation remain largely unknown. The objective of the current study was to examine the associations of 206 common variants in 15 endothelial system genes with BP changes and hypertension incidence among 1,775 Han Chinese participants of the family-based Genetic Epidemiology Network of Salt Sensitivity (GenSalt) follow-up study. Nine BP measurements were obtained at baseline and during each of two follow-up observations using a random-zero sphygmomanometer. The associations of 206 SNPs in 15 endothelial system genes with BP changes and hypertension incidence were assessed using mixed models to account for the correlations of repeated measures among individuals and within families. A genotype by time interaction term was used to model differences in longitudinal BP change according to genotype over time. Gene-based analyses were conducted using the truncated product method. The Bonferroni method was used to adjust for multiple testing in all analyses. Among those free from hypertension at baseline, 513 (32.1%) GenSalt participants developed hypertension during the average 7.2 years of follow-up. In single-marker analyses, each copy of the minor alleles of SELE markers rs4656704, rs6427212 and rs5368 was associated with increased risk of hypertension with relative risks (95% confidence intervals) of 1.42 (1.18, 1.71), 1.46 (1.21, 1.75) and 1.46 (1.21, 1.77), respectively (P= 1.66×10-4, 7.44×10-5 and 8.51×10-5, respectively). SELE marker rs3917436 predicted longitudinal DBP change (P=8.27×10-5). Results of gene-based analyses showed the SELE gene was significantly associated with SBP change, DBP change and hypertension incidence (all P<1.00×10-6). Furthermore, the DDAH1, SELP, and COL18A1 genes were associated with SBP change (P=2.00×10-6, 9.00×10-5, and 1.00×10-6, respectively), while EDNRA was associated with hypertension incidence (P=2.00×10-4). In conclusion, the current study provides strong evidence of a role of endothelial system genes in BP progression and hypertension incidence. Future studies will be required to identify the causal variants underlying the observed associations.

2039S

Novel NKX2.5 mutation associated with congenital heart disease in South Indian patients. *S. Mattapally[1], S. Nizamuddin[3], KS. Murthy[2], K. Thangaraj[3], SK. Banerjee[1].* 1) Division of Medicinal Chemistry and Pharmacology, CSIR-Indian Institute of Chemical Technology, Uppal Road, Hyderabad 500 007, India; 2) Innova Children's Heart Hospital, Tarnaka, Hyderabad 500017, India; 3) CSIR-Centre for Cellular and Molecular Biology, Uppal Road, Hyderabad 500 007, India.

Background: NKX 2.5 is one of the transcription factors, it is a cardiac specific homeobox gene and act as early marker genes for heart field development. Heterozygous NKX 2.5 germline mutations were reported to cause congenital heart disease (CHD), hence the aim of this study is to find the association of NKX 2.5 mutations with CHD among the south Indian CHD patients. Method: NKX 2.5 gene was sequenced in 100 CHD patients (ASD, VSD, TOF and SV) and 200 controls. Functional significance of the observed NKX2.5 mutations were analyzed using in silico software such as; Polyphen, SIFT, PMut, plink, etc. Results: Our analysis with NKX2.5 gene revealed a total of 7 mutations, out of which, 3 were in intronic region, 3 mutations were in coding region and 1 mutation was in 3' UTR. Of the above mutations, one was found to be associated with Tetralogy of Fallot (TOF) and two (rs2277923 and a novel mutation) were strongly associated with VSD. Interestingly, one novel missence mutation (p-value = 0.009744; Asp16Asn) was most significant findings of this study. Our 'in silico' analysis also provides evidence that some of the mutations reported above are pathogenic. Conclusion: The present study found that NKX2.5 genetic variations are associated with TOF and VSD in South Indian patients.

2040M

A replication study for fifteen coronary artery disease susceptible loci in a Japanese population. *K. Ozaki[1], Y. Sakata[2], S. Suna[2], Y. Onouchi[1,3], T. Tsunoda[4], M. Kubo[5], I. Komuro[2,6], T. Tanaka[1,7].* 1) Lab for Cardiovascular Diseases, RIKEN, Ctr Integrative Medical Sci, Yokohama, Japan; 2) Dept of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Japan; 3) Dept of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 4) Lab for Medical Sci Mathematics, RIKEN, Ctr for Integrative Medical Sci, Yokohama, Japan; 5) Lab for Genotyping Development, RIKEN Ctr for Integrative Medical Sci, Yokohama, Japan; 6) Dept of Cardiovascular Med, Graduate School of Med, The University of Tokyo, Tokyo, Japan; 7) Dept of Human Genetics and Disease Diversity, Tokyo Medical and Dental University, Tokyo, Japan.

Recent large-scale association analysis for coronary artery disease (CAD) identified fifteen new loci with genome wide statistical significance. Replication for the genetic association in other ethnic population is one of important issue to investigate a clinical benefit in the future. We conducted here the reproducibility for the association of the 15 single nucleotide polymorphism (SNP) loci (*IL6R*; rs4845625, *APOB*; rs515135, *ZEB2-AC074093.1*; rs2252641, *VAMP5-VAMP8-GGCX*; rs1561198, *ABCG5-ABCG8*; rs6544713, *GUCY1A3*; rs7692387, *EDNRA*; rs6842241, *SLC22A4*; rs17689550, *KCNK5*; rs10947789, *PLG*; rs4252120, HDAC9; rs2023938, *LPL*; rs264, *TRIB1*; rs2954029, *FLT1*; rs9319428, *FURIN* rs17514846) and CAD with 7,990 cases and 6,582 controls in a Japanese population. We found a convincing association with statistical significance for rs9319428 in intron 6 of *FLT1*, encoding fms-related tyrosine kinase 1, for CAD susceptibility ($P = 5.98 \times 10^{-8}$). We also found the replication for the association of two SNPs, rs6842241 in 5'-fanking region of *EDNRA*, encoding endothelin receptor type A, and rs17514846 in intron1 of *FURIN*, encoding a calcium-dependent serine endoprotease, with CAD (P = 0.000207 and P = 0.00208, respectively). Our validation results revealed that the three loci were genetic risk factor for CAD in the Japanese population.

2041S

Relations between PAI-1 plasma levels and adipose tissue expression of PAI-1 and hsa-miR-421 microRNA. *DA. Tregouet[1], M. Civelek[2], L. Markku[3], MC. Alessi[4], AJ. Lusis[2], PE. Morange[4].* 1) UMR_S 1166, INSERM, Paris, France; 2) Departments of Microbiology, Medicine, and Human Genetics, UCLA School of Medicine, Los Angeles, USA; 3) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 4) Inserm U1062, Aix-Marseille University, Marseille, France.

Several works have demonstrated that increased plasminogen activator inhibitor (PAI)-1 levels, the main inhibitor of the fibrinolytic system, could predict the risk of metabolic syndrome (MetS) and associate with its separate components, such as visceral obesity, increased blood glucose levels and dyslipidaemia. Biological mechanisms responsible for these associations are still debated and several arguments are in favor of a key role of adipose tissue in these phenomena. As part of the METSIM study, we measured plasma PAI-1 activity in a sample of 850 healthy males for which the subcutaneous adipose tissue expression of the SERPINE1 gene coding for PAI-1 was also available. We demonstrated that adipose tissue SERPINE1 expression was correlated to plasma PAI-1 activity ($\rho = 0.23$, $p = 2.68\ 10^{-11}$) and all MetS components (ρ as low as 0.31, $p < 10^{-16}$). The influence of SERPINE1 expression on MetS components was mainly independent on plasma PAI-1 activity levels as their correlations were hardly modified by the adjustment on plasma PAI-1 activity. Conversely, all correlations were strongly reduced (ρ no higher than 0.14, $p = 2.30\ 10^{-5}$) after adjusting for BMI. In a subsample of 194 METSIM individuals, we were also able to show that both plasma PAI-1 activity and adipose tissue SERPINE1 mRNA expression positively correlated with adipose tissue expression of the hsa-miR-421 microRNA ($\rho = 0.22$, $p = 0.0018$, and $\rho = 0.23$, $p = 0.0014$, respectively), a microRNA whose plasma levels have been recently shown to correlate with plasma PAI-1 levels. Interestingly, the association between adipose tissue levels of hsa-miR-421 and plasma PAI-1 activity was still significant after adjusting for BMI ($p = 0.015$) and SERPINE1 mRNA levels ($p = 0.013$). This study confirms in a large epidemiological cohort the strong association between PAI-1 plasma levels and adipose tissue serpin 1 expression, and provides novel elements suggesting, for the first time, that this expression may be influenced by adipose tissue expression of the hsa-miR-421 microRNA.

2042M

Functional fine mapping of the genes involved in plasma lipid metabolism in the LD-block of *NCAN/CILP2/PBX4* region. *S. Boonvisut, S. Makishima, K. Watanabe, K. Nakayama, S. Iwamoto.* Division of Human Genetics, Center for Molecular Medicine, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Dyslipidemia is a major risk factor of cardiovascular diseases. The estimated heritability ranges 0.20-0.60. *NCAN/CILP2/PBX4* region is the initially identified locus by GWAS that substantially influences plasma lipid concentrations. In addition, the genetic analysis of non-alcoholic fatty liver disease (NAFLD) reported that risk allele increasing LDL and TG levels in this region reduced the risk of NAFLD. These studies suggested that liver is one of the main organs where the responsible gene acts to regulate plasma lipid metabolism. However, *NCAN/CILP2/PBX4* region is in a tight linkage-disequilibrium block spanning over 300kb, in which 11 genes are encoded and the responsible gene has not yet been identified. This study aims to identify the molecule involved in lipid metabolism from this region. Four genes expressed in liver, *Tm6sf2*, *Sugp1*, *Gatad2a*, and *Yjefn3*, were chosen from the 11 genes referring to ENCODE database. The short-hairpin RNA (shRNA) templates against them were synthesized and inserted in adenovirus vectors. The recombinant adenoviruses were administrated into mice and the plasma lipid levels were followed up. Knocking-down of *Sugp1* showed increased serum cholesterol level in both feeding and fasting states ($p = 0.044$ and 0.043 respectively), and *shGatad2a* decreased it in fasting state ($p = 0.0411$). While, transcriptome Analysis of these mice revealed that knocking down of *Gatad2a* and *Sugp1* affected on several lipid metabolism pathways, such as fatty acid metabolism, steroid synthesis and bile acid biosynthesis, it was noteworthy that *shSugp1* enhanced the expression of *ApoB* expression (3.99 fold, p-value < 0.01). In order to study the effect of SUGP1 on the expression of *APOB* in another main organ, intestinal epithelium, Caco-2 cells with enforced expression and knockdown of *SUGP1* were established using lentiviral gene transduction. The established cells were induced to be differentiated by culturing on filter insert. The mRNA of *APOB*, secreted APOB-48 and -100 protein levels and the ratios of them were increased by the knock-down of *SUGP1*. The *APOB* mRNA-editing for the conversion from APOB-100 to -48 in differentiated Caco-2 cells was increased by the knocking-down and decreased by the enforced expression of *SUGP1*. SUGP1 (SURP and G patch domain containing 1) is estimated to be involved in mRNA processing. These data indicated that *SUGP1* is the most powerful candidate gene regulating serum lipid levels in *NCAN/CILP2/PBX4* region.

2043S

Mutations in genes NKX2.5, GATA4 and TBX5, associated to congenital heart disease with septal defect in pediatric patients from the Guadalajara Civil Hospital Fray Antonio Alcalde. *R. Diaz Martinez[1,2], G. Perez-Garcia[1], M.L. Ornelas-Arana[1], M.S. Hernandez-Flores[3], S.J. Jasso-Bernal[3], X.M. Boldo-Leon[2], J.M. Magaña-Cerino[2], C. Rodriguez-Perez[2], M.C. Martinez-Lopez[2].* 1) Clinical Genetic, Hospital Civil de Guadalajara, Guadalajara, Mexico; 2) Laboratorio de Diagnóstico Molecular, DACS-UJAT, Tabasco, Mexico; 3) Pediatric Cardiology, Hospital Civil de Guadalajara, Guadalajara, Mexico.

Introduction. Congenital heart disease is the leading cause of birth defects, affecting approximately 1%; of all live births. It presence has been associated with single mutations in transcription factors that regulate heart development. The genes frequently reported are GATA4, NKX2.5 and TBX5. These interact during cardiogenesis. Objectives. Investigate the mutations frequently reported in literature of the genes, GATA4 , NKX2.5 and TBX5 in children with congenital heart disease involving septal defects in HCFAA. Material and Methods. We selected 30 children with congenital heart disease (CHD) with septal defect, a genetic history was elaborated and by echocardiography CHD type in each patient was determined. DNA was extracted from peripheral blood for genotyping by PCR -HRM mutations in GATA4 (c.886G > A), TBX5 (c.238G > A) and NKX2.5 (c.73C>T and c.533 C>T) genes, to patients and their parents. The results were analyzed by descriptive statistics. Results. In total 84 samples of all participants were taken, 30 of these samples were from patients diagnosed with CHD with septal defect and 54 of their parents. We found seven patients with mutations in genes previously selected for this study, the mutations seen in patients were also seen in all occasions in one or both parents. We found 3 female parents with mutations, and 5 male. In 23.33%; of patients with CHD with septal defect found association between two or more of the studied mutations. In parents of patients with mutations we found that one or both parents had the same mutations. The frequency of mutations in index cases (N = 30) was 13.3%; (4) for mutation in TBX5 , 16.6%; (5) for mutation in GATA4 and 10%; (3) for mutation in NKX2.5 (c.73C > T) . Finding that approximately 60%; of patients with this mutations appeared in double or triple, mainly related to the GATA4 gene. Conclusions. We found a frequency of these mutations in the index cases of 13.3%; for the mutation in TBX5, 16.6%; for the mutation in GATA4 and 10%; mutations in NKX2.5 (c.73C> T). No patient had mutation c.533C> T in gene NKX2.5. From 30 families we found that 23%; of them had single or combined mutations of the genes studied. The type of inheritance resembles autosomal dominant. In carrier parents no abnormalities were reported, however they inherited the mutation.

2044M

Standard Schnauzer dogs with dilated cardiomyopathy have a 22 bp deletion and frame shift in RBM20. *D. Gilliam[1], M.W. Harmon[2], G.S. Johnson[1], T. Mhlanga-Mutangadura[1], L. Hansen[1], J.F. Taylor[3], R.D. Schnabel[3], S.B. Leach[2].* 1) Veterinary Pathobiology, University of Missouri, Columbia, MO; 2) Department of Veterinary Medicine, University of Missouri, Columbia, MO; 3) Animal Sciences, University of Missouri, Columbia, MO.

To identify the molecular genetic cause for dilated cardiomyopathy (DCM) in Standard Schnauzers, we generated a 30-fold average coverage whole genome sequence (WGS) with DNA from a male Standard Schnauzer that died at 13.5 months of age with DCM and congestive heart failure. This WGS contained 69 homozygous sequence variants that were predicted to alter the primary structure of the gene product and absent from the WGSs of 101 canids not exhibiting DCM. A homozygous 22 bp deletion and frame shift in exon 11 of *RBM20* was the sequence variant considered most likely to be causal because mutations in the human and rodent orthologs cause DCM. All 9 of the confirmed DCM cases for which DNA was available tested homozygous for the deletion allele (del/del). A prospective screen for the mutation identified 653 Standard Schnauzers that were homozygous for the wild type allele, 225 Standard Schnauzers that were heterozygous, and 13 additional Standard Schnauzers that were homozygous for the deletion allele. Eight of these 13 del/del Standard Schnauzers have subsequently been diagnosed with occult DCM via echocardiography. The other 5 were not available for evaluation and 3 of them were <1 year old, before clinical signs typically appear. Echocardiographic evaluation of 17 Standard Schnauzers that were heterozygous for the deletion allele, including a 15 year old Standard Schnauzer, has revealed no echocardiographic evidence of myocardial dysfunction. Thus, *RBM20*-associated DCM appears to be recessive in Standard Schnauzers; whereas, human *RBM20*-associated DCM is reported to be a dominant trait. In addition, there appears to be a gender difference in survival time among Standard Schnauzers. Male Standard Schnauzers with the homozygous *RBM20* deletion have survived to a mean age of 16.8 months (range 10.5 months to 30 months). Female Standard Schnauzers with the homozygous RBM20 deletion have survived to a mean age of 43.4 months (range 19 months to 55 months). To our knowledge, a similar gender difference has not been reported for human *RBM20*-associated DCM patients.

Disruption of the SEMA3D gene in a patient with congenital heart defects. *C. Le Caignec[1,2,3], M. Sanchez-Castro[2], O. Pichon[1], D. Poulain[1], A. Briand[1], V. Gournay[4], A. David[1].* 1) Medical genetics department, CHU Nantes, Nantes, France; 2) INSERM, UMR1087, l'institut du thorax, Nantes, France; 3) Université de Nantes, Nantes, France; 4) Pediatric cardiology department, CHU Nantes, Nantes, France.

Congenital heart disease (CHD) is the leading malformation among all newborns. Although genetic variation contributes to CHD, the genetic basis for the disease remains unknown in the majority of the patients. We report a child with transposition of the great arteries, ventricular septal defect and coarctation of the aortic isthmus. By array comparative genomic hybridization (aCGH), we identified a duplication of the 5' half of the semaphorin 3D (SEMA3D) gene. Breakpoint sequencing and fiber fluorescent in situ hybridization showed a tandem duplication. SEMA3D expression studies, performed on the patient's immortalized lymphoblasts, showed a higher level of expression of SEMA3D mRNA compared to the controls. Moreover, we demonstrated the presence of a truncated SEMA3D poly-A tailed mRNA, resulting from an abnormal transcription of the partial duplication of SEMA3D. Sema3D is an axon guidance protein essential for the correct migration of cardiac neural crest cells into the outflow tract during cardiogenesis. Sema3D null mice present with anomalous pulmonary venous connections and atrial septal defects but the role of SEMA3D in humans remains unclear. The results suggest that a truncated SEMA3D may have hampered the migration of cardiac neural crest cells during heart development, and consequently contributed to CHD in our patient.

Long QT Syndrome - Family Studies in Ion Channel Encoding Gene. *P. Nallari.* Dept. of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India.

Congenital Long-QT syndrome (cLQTS) is an inherited arrhythmogenic disease characterized on ECG by a prolonged QTc interval. The ECG manifestation reflects an abnormally prolonged ventricular action potential, which can be the substrate for life-threatening arrhythmias that lead to syncope and sudden cardiac death. Heterogeneity of clinical manifestations corroborated with genetic etiology is well established. Screening of ion channel encoding genes was carried out by PCR-SSCP analysis followed by commercial sequencing in 46 LQTS probands and 69 available family members. We report novel variations in four LQTS probands and their family members in KCNQ1 gene. In-silico analysis predicts that these variations may lead to abnormal IKs channel and altered ion fluxes. The variation is also observed in the family members of the probands which helps in predictive testing and prognosis. The study is aimed at highlighting the importance of family screening in clinical management of LQTS with emphasis on personalized medicine.

Assessment of the *TNF*-α rs1799964 (-1031T>C) polymorphism and soluble protein concentration in Acute Coronary Syndrome: association with circulating levels. *E. Sandoval-Pinto[1,2], JR. Padilla-Gutiérrez[2], E. Valdes-Alvarado[1,2], IL. García-González[2,3], A. Valdez-Haro[2,3], JF. Muñoz-Valle[2], HE. Flores-Salinas[4], F. Rivas[5], Y. Valle[2].* 1) Doctorado en Ciencias Biomédicas, CUCS, UdeG, Guadalajara, Jal., Méx; 2) Instituto de Investigación en Ciencias Biomédicas, CUCS UdeG, Guadalajara, Jal., Méx; 3) Doctorado en Genética Humana, CUCS, UdeG, Guadalajara, Jal., Méx; 4) CMNO, IMSS; Centro Médico Nacional de Occidente, Guadalajara, Jal., Méx; 5) Hospital General de Occidente, Secretaria de Salud Jalisco, Guadalajara, Jal., Méx.

Introduction: The acute coronary syndrome (ACS) is a complex disease where genetic and environmental factors are involved. *TNF*-α is a candidate gene for ACS progression due to its contribution in the inflammatory process and endothelial function. The rs1799964 polymorphism in the *TNF*-α gene consists of a T>C change at the -1031 promoter region. The C allele has been associated with changes in gene expression and plasmatic levels thus associated with a decrease in the risk of cardiovascular disease. Objective: To associate the *TNF*-α rs1799964 polymorphism with ACS and to measure the serum levels of TNF-α. Methods: Were recruited 251 patients with ACS classified according to American College of Cardiology and 164 healthy subjects (HS) age-matched from Western Mexico. The study was made in accordance with de Declaration of Helsinki. All individuals accepted to participate and an informed written consent was obtained. The rs1799964 polymorphism was identified by PCR-RFLP. Fragments were separated in polyacrylamide gel electrophoresis. The TNF-α was measured using an enzyme-linked immunosorbent assay. The genotype and allele differences were estimated by Fisher's exact test. The association measure was evaluated by OR and 95% of confidence intervals. The Mann-Whitney U test was applied in order to compare the TNF-α serum lelevels. The significance level was $p<0.05$. Results: The genotype and allele frequencies of the rs1799964 polymorphism showed statistically differences between groups (OR= 0.317, p= 0.01; OR= 0.688, p= 0.03, respectively). These results suggest that the C allele carriers have 1.44 less susceptibility to ACS. Also, the goodness of fit was performed to identify the most likely heritage model. In this context, significant differences were found in the recessive genetic model (OR: 0.333, p = 0.02). The TNF-α levels were significantly higher in ACS patients compared to HS (38.05 vs 23.92 ng/mL, p=0.0001). The C/C genotype carriers showed lower levels of TNF-α when compared to heterozygous ACS patients; this finding could not be replicated in HS (36.95 vs 33.52 ng/ml, p=0.03). Conclusion: The *TNF*-α gene polymorphism rs1799964 (-1031T>C) is a susceptibility genetic marker for Acute Coronary Syndrome in Western Mexico population. In addition, serum levels of TNF-α may be a biological marker of ACS.

2048M

Whole exome sequencing identifies a *NEXN* mutation in a family with left ventricular noncompaction. *J.M. Taylor[1], K. Thomson[1], J. Williams[1], L. Witty[2], J. Craft[2], J. Taylor[2,3], A. Seller[1], E. Blair[4], H. Watkins[2,5].* 1) Oxford Medical Genetics Laboratories, Oxford University Hospitals NHS Trust, Oxford., UK. OX3 7LE; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK OX3 7BN; 3) NIHR Biomedical Research Centre, Oxford, UK; 4) Department of Clinical Genetics, Oxford University Hospitals NHS Trust, Oxford, UK OX3 7LE; 5) Department of Cardiovascular Medicine, University of Oxford, Oxford, UK. OX3 9DU.

Background: Hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM) are genetically and phenotypically heterogeneous. *NEXN*, which encodes a component of the cardiac Z disc, has been previously reported to contain mutations in patients with HCM and DCM. The age of onset and disease severity associated with *NEXN* mutation has shown some inter-individual variability.

Methods: Whole exome DNA sequence analysis was performed on a small nuclear family with maternal left ventricular noncompaction (LVNC) cardiomyopathy and in-utero "dilated" cardiomyopathy with severe hydrops fetalis in two affected children. All 3 affected individuals also had a large ASD. Post mortem analysis on one of the children revealed LVNC cardiomyopathy. Interestingly the other affected child's cardiac studies normalised ex-utero. Standard clinical molecular analyses including array CGH, candidate nuclear gene analysis and selected mitochondrial genome mutation analysis had failed to identify a pathogenic variant. Exome capture was undertaken using the NimbleGen SeqCap EZ v2.0 library and sequenced using an Illumina HiSeq2000. The data were masked and analysed for 54 genes previously implicated in causing HCM or DCM or LVNC.

Results: An inframe single amino acid deletion (p.Gly650del) in the last exon of the *NEXN* gene was identified in all three affected individuals. The p.Gly650del variant has been previously reported in adult patients with dilated cardiomyopathy; animal studies supported pathogenicity of this variant, however segregation studies were not reported. The extreme phenotypic diversity seen in our family and the normalisation of the cardiac studies in the proband remain unexplained. Further clinical evaluation of the maternal family is being planned.

Conclusion: Using an exome sequencing strategy we have successfully identified a likely pathogenic variant within the *NEXN* gene and provided evidence that LVNC is associated with variants in this gene. Further analysis is underway to examine the extreme phenotypic variability seen with the p.Gly650del variant and to determine whether this result can be used for prenatal diagnosis in this family.

2049S

Association of rs4340 ACE polymorphism with acute coronary syndrome in Mexican population. *A. Valdez Haro[1,2], Y. Valle[1], I.J. García-González[1,2], E. Sandoval-Pinto[1,3], E. Valdes-Alvarado[1,3], JF. Muñoz-Valle[1], JR. Padilla-Gutiérrez[1].* 1) Instituto de Investigación en Ciencias Biomédicas, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, 44350, Guadalajara, Jalisco, México; 2) Doctorado en Genética Humana, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, 44350, Guadalajara, Jalisco, México; 3) Doctorado en Ciencias Biomédicas, Centro Universitario de Ciencias de la Salud, UdeG. Sierra Mojada 950, 44350, Guadalajara, JAL, Mexico.

Introduction: Acute Coronary Syndrome (ACS) is an important public health problem and a main cause of death, in which the classic risk factors can barely explain half of the cases. A proposed explanation is that the sum of unfavorable gene polymorphisms and a proper environment may lead to the disease. Angiotensin converting enzyme (ACE) increase angiotensin II (AII) plasmatic levels, which is a powerful vasoconstrictor that leads to endothelial and myocardial oxidative stress and aterosclerosis. The polymorphism rs4340 consists in an Insertion/deletion (I/D), in which the D allele has been related to increase ACE levels, therefore to risk for ACS. Aim: To determine the association of rs4340 polymorphism of ACE gene in ACS. Methods: 266 ACS patients and 147 healthy subjects (HS) matched by age, were recruited from western Mexico. The ACS selection based on the American College of Cardiology criteria. An informed written consent was obtained from all patients. The rs4340 polymorphism was identified by PCR and PAGE with silver stain. Results: The genetic frequencies in healthy subjects were on Hardy-Weinberg equilibrium expectations (p=0.13). Allelic and genotype distributions were compared. Significant differences between groups were found. The allele D was 1.47 more frequent in ACS patients than HS subjects (OR = 1.47, p= 0.008). The genotype D/D was also more commonly found in the SCA group (OR = 1.96, p = 0.014). The recessive model supported this results (p=0.03). Conclusion: The D allele and DD genotype is a genetic marker for susceptibility to ACS in Western Mexican population.

2050M

HLA-DRB1*01 allele associates with Acute Coronary Syndrome (ACS) in Finnish population. *E. Vlachopoulou[1], M. Marchesani[1], J. Nokelainen[1], M.S. Nieminen[2], J. Sinisalo[2], M-L. Lokki[1].* 1) Transplantation Laboratory, Haartman Institute, Haartmaninkatu 3, University of Helsinki, Helsinki, Finland; 2) HUCH Heart and Lung Center, Division of Cardiology, Helsinki University Central Hospital, Finland.

Background: Acute Coronary Syndrome (ACS) is one of the leading causes of death in the world, still being a diagnostic and management challenge. Inflammation has a central role in the pathophysiology of ACS. However, the ultimate reasons for the inflammation remain unrevealed. The system that regulates inflammation and immunity lies in big part in the Human Leukocyte Antigen (HLA) system on chromosome 6p21.31. Our previous smaller candidate gene study suggested that HLA-DRB1*01 allele of MHC class II is associated with ACS. The aim of this study is to confirm this association in a larger material. Methods: We studied 2090 ACS patients and 1580 geographically-matched controls (Corogene study) having information of various risk factors and survival data. All subjects were genotyped for the HLA-DRB1*01 allele to determine allele copy numbers with the genomic real-time quantitative polymerase chain reaction. The HLA-DRB1*01 was tested for association with ACS. Results were replicated in two different replication materials from Finland. Results: HLA-DRB1*01 was associated with ACS (freq. cases 38.9% vs. freq. controls 32.4%; odds ratio 1.33; P = 7.7 ×10-5). Interaction analysis showed that total cholesterol, low-density lipoprotein cholesterol, and triglyceride levels interacted with HLA-DRB1*01 (odds ratio 1.23 [95% CI 1.01-1.49]; P = 0.04, odds ratio 1.20 [95% CI 1.06-1.36]; P = 0.004, odds ratio 1.18 [95% CI 1.02-1.37]; P = 0.03, respectively). The survival curves stratified for HLA-DRB1*01 copies did not show any statistical difference. Conclusion: We showed that HLA-DRB1*01 is associated with ACS in Finnish materials. This gene may play a role in promoting ACS by affecting antigen presentation. Peptide fragments of oxidized low-density lipoprotein cholesterol may connect the cholesterol pathway to inflammation and immunology in atherosclerosis progression.

2051S

Exploring the role of common and rare platelet traits-associated variants in cardiovascular disease risk. *N. Chami[1,2], S. de Denus[1,2], M.P. Dubé[1,2], J. Rioux[1,2], J.C. Tardif[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, PQ, Canada; 2) Faculté de Médecine, Université de Montréal, Montréal, Québec, Canada.

Introduction: Platelets are pivotal components of the hemostatic and thrombotic responses. Their count and volume are also useful biomarkers for several human diseases, and platelet features and activation have been associated with cardiovascular diseases (CVD). Platelet phenotypes are highly heritable: h2~0.5-0.6. Genome-wide association studies (GWAS) have identified >65 loci that carry common DNA sequence variants associated with platelet count or Mean Platelet Volume (MPV). In this study, we sought to evaluate the relationship between the known platelet traits-associated variants and prevalent CVD. Methods: We genotyped 9,660 individuals from the biobank of the Montreal Heart Institute (MHI) on the IlluminaExomeChip array. We generated a genetic risk score (GRS) using genotypes from 35 SNPs and four rare variants associated with platelet traits, and tested the association between this GRS and CVD. We also considered the effect of deleterious rare variants in 12 thrombocytopenia and 7 myeloproliferative neoplasm (MPN) genes on platelet traits and CVD risk in the MHI biobank. Results: The GRS was significantly associated with platelet count and MPV (both P<1×10-16) and with increased risk of CVD (OR=1.46, P=0.025). Interestingly, inclusion of recently published rare variants associated with platelet traits in the GRS improved the association with CVD (OR=1.65, P=0.004). With rare variants in the model, the GRS was also associated with stroke (OR=2.11, P=0.035) and myocardial infarction (OR=1.49, P=0.023). Using the sequence kernel association test (SKAT), we tested the association between rare (minor allele frequency <0.1%) nonsense, missense and splice site variants in 19 thrombocytopenia or MPN genes with platelet count and MPV. JAK2 and MYH9 were significantly associated with platelet count (P=7.15×10-8 and P=5.50×10-3, respectively) and TUBB1 with MPV (P=0.0001). The gene-based results for JAK2 and TUBB1 had previously been described. Further, rare coding variants in ITGB3, a gene implicated in thrombocytopenia, were associated in aggregate with stroke (P=0.0019), although the association with platelet count or volume was not significant. Conclusion: Our results suggest that common and rare variants within genes associated with platelet traits and disorders influence CVD risk.

2052M

GWAS-identified loci for coronary heart disease are associated with intima-media thickness and plaque presence at the carotid artery bulb. *M. den Hoed[1], R. Strawbridge[2], P. Almgren[3], S. Gustafsson[1], T. Axelsson[4], G. Engström[3], U. de Faire[5], B. Hedblad[3], S.E. Humphries[6], C.M. Lindgren[7], A.P. Morris[7,8], G. Östling[3], A-C. Syvänen[4,9], E. Tremoli[10], A. Hamsten[2], E. Ingelsson[1], O. Melander[3], L. Lind[11].* 1) Medical Sciences, Mol. Large-scale genome-wide association studies (GWAS) have so far identified 45 loci that are robustly associated with coronary heart disease (CHD) in data from adult men and women of European descent. We examined whether these loci are also associated with measures of atherosclerosis in data from up to 9,582 individuals of European ancestry. Forty-five SNPs representing the CHD-associated loci were genotyped in middle-aged to elderly individuals of European descent from four independent population-based studies (IMPROVE, MDC-CC, ULSAM and PIVUS). Intima-media thickness (IMT) was measured by external B-mode ultrasonography at the far wall of the bulb and common carotid artery. Plaque presence was defined as a maximal IMT of the bulb >1.5 mm. We meta-analysed single-SNP associations across the four studies, and combined them in a genetic predisposition score. We subsequently examined the association of the genetic predisposition score with prevalent CHD and the three indices of atherosclerosis, adjusting for sex, age and Framingham risk factors. As anticipated, the genetic predisposition score was associated with prevalent CHD, with each additional risk allele increasing the odds of disease by 5.5% ($p=4.1\times10^{-6}$). Moreover, each additional CHD-risk allele across the 45 loci was associated with a 0.24% increase in IMT at the far wall of the bulb ($p=4.0\times10^{-3}$), and with a 2.8% increased odds of plaque presence ($p=7.4\times10^{-6}$), independently of traditional risk factors. The genetic predisposition score was not associated with IMT of the common carotid artery (p=0.47). Our results suggest that the association between the 45 previously identified loci and CHD at least partly acts through atherosclerosis.

2053S

Transethnic replication of the gene-gene interaction of the prostaglandin E_2 system in determining blood pressure reactivity. *X. Kong[1,2], Q. Zhao[1], TN. Kelly[1], C. Li[1], D. Gu[3], J. He[1].* 1) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, US; 2) Department of Endocrinology, China-Japan Friendship Hospital, Beijing, China; 3) State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center of Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

Increased blood pressure (BP) reactivity to cold stress has been suggested as a risk factor for hypertension and cardiovascular disease. Prostaglandin E_2 (PGE_2), the most abundant prostanoid in humans, plays a critical role in BP regulation. This study aimed to systematically investigate individual and interaction effects of genetic variants of the PGE_2 system on BP reactivity to cold stress in both Chinese and Whites. The cold pressor test (CPT) was performed among 1,881 Han Chinese individuals from the Genetic Epidemiology Network of Salt Sensitivity (GenSalt) study. BP reactivity variables were calculated as the changes between the highest BP levels during the CPT and those prior to the CPT. A total of 397 single nucleotide polymorphisms (SNPs) covering 10 genes from the PGE_2 system, including synthases (*PLA2G4A*, *PTGS1*, *PTGS2*, *PTGES*, *PTGES2*, *PTGES3*) and receptors (*PTGER1*, *PTGER2*, *PTGER3*, *PTGER4*) of the PGE_2, were genotyped for the analysis. In addition to single marker analyses, gene-based and gene-gene interaction analyses were conducted using the truncated *P* value method. Results were further replicated in 1,448 participants of European ancestry from the Coronary Artery Risk Development in Young Adults (CARDIA) study, in which a similar CPT was conducted. SNPs from the *PTGER3* and *PTGER4* genes were significantly associated with BP reactivity variables of diastolic BP (DBP) or mean arterial pressure (MAP) in both Han Chinese and Whites. In gene-based analyses, *PTGER4* was associated with DBP and MAP responses in both Han Chinese (both $P < 1.0\times10^{-6}$) and Whites ($P = 0.029$ and 0.038). In addition, gene-gene interactions were identified between several pairs of genes from the PGE_2 system. For example, *PLA2G4A* and *PTGES2* genes showed the strongest interaction for systolic BP and MAP responses in both Han Chinese (both $P < 1.0\times10^{-5}$) and Whites (both $P < 1.0\times10^{-5}$). Transethnic replication of genetic associations identified in this study may suggest an important role of genetic variation of the PGE_2 system in affecting BP reactivity to stress.

2054M

Role of common sarcomeric gene polymorphisms in genetic susceptibility to left ventricular dysfunction. *B. Mittal[1], S. Kumar[1], A. Mishra[1], A. Srivastava[1], N. Garg[2], S. Agarwal[3], S. Pande[3].* 1) Genetics, SGPGIMS, Lucknow, U.P., India; 2) Cardiology, SGPGIMS, Lucknow, UP, India; 3) CVTS, SGPGIMS, Lucknow, U.P, India.

Background: Mutations in sarcomeric genes are common genetic cause of cardiomyopathies. An intronic 25-bp deletion in MYBPC3 at 3' region is associated with dilated (DCM) and hypertrophic (HCM) cardiomyopathies in Southeast Asia. However, the frequency of sarcomeric gene polymorphisms and associated clinical presentation has not been established with left ventricular dysfunction (LVD). Therefore, the aim of the present study was to explore the association of MYBPC3 25 bp deletion, TTN 18 bp I/D, TNNT2 5bp I/D, and Myospryn K2906N polymorphisms with LVD. Methods: The study included 988 consecutive patients with angiographically confirmed CAD and 300 healthy controls. Among 988 CAD patients, 253 with reduced left ventricle ejection fraction (LVEF≤45%) were categorized as LVD. MYBPC3 25 bp deletion, TTN 18 bp I/D and TNNT2 5bp I/D polymorphisms were determined by direct polymerase chain reaction (PCR) method while Myospryn K2906N polymorphism by TaqMan assay. Results: Our results showed that MYBPC3 25 bp deletion polymorphism was significantly associated with elevated risk of LVD (healthy controls v/s LVD: OR=3.85, p-value<0.001; and Non-LVD v/s LVD: OR=1.65, p-value=0.035) while TTN 18 bp I/D, TNNT2 5bp I/D, and Myospryn K2906N polymorphisms did not show any significant association with LVD. The results also showed that MYBPC3 25 bp deletion polymorphism was significantly associated with other parameters of LV remodeling i.e. LV dimensions (LV end diastole dimension: LVEDD; p-value=0.037, and LV end systolic dimension: LVESD; p-value=0.032). Conclusion: Our data suggests that MYBPC3 25 bp deletion may play significant role in conferring LVD risk in Southeast Asian populations. Financial support from DBT, Government of India.

2055S

Identification of TMEM241 as the underlying gene in the chromosome 18q11.2 triglyceride region in Mexicans. *A. Rodriguez[1], L. Gonzalez[1], Y. Bhagat[1], E. Nikkola[1], T. Tusie-Luna[3,4], C.A Aguilar-Salinas[3], P. Pajukanta[1,2].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Molecular Biology Institute at UCLA, Los Angeles, USA; 3) Instituto Nacional de Ciencias Médicas y Nutrición, Salvador Zubiran, Mexico City, Mexico; 4) Instituto de Investigaciones Biomédicas de la UNAM, Mexico City, Mexico.

High serum triglyceride (TG) levels are a critical risk factor for cardiovascular disease (CVD). We recently identified a locus on chromosome 18q11.2 to be associated with high serum TGs in Mexicans in a genome-wide association study (GWAS). However, the biological mechanism(s) underlying this signal has not been elucidated yet. Characterization of GWAS hits is an important area of research in the field of functional genomics. The 18q11.2 locus in particular could have implications in the treatment and diagnosis of CVD in the rapidly growing Hispanic populations. To characterize the biological mechanism, we performed a cis-eQTL analysis utilizing 856 publicly available human adipose, skin, and lymphocyte RNA microarrays of the MuTHER resource, and discovered that the lead SNP rs9949617 is a genome-wide significant cis-eQTL, regulating the expression of one of the 5 regional genes on 18q11.2, the transmembrane protein 241 (TMEM241) gene. However, lead GWAS SNPs are often not the underlying causal variant. Therefore, to identify the causal variant, we performed a regional linkage disequilibrium (LD) analysis using PLINK and found a total of 9 single nucleotide polymorphisms (SNPs) in high LD (R2>0.8) with rs9949617, suggesting that anyone of these SNPs can be the underlying susceptibility variant. To prioritize the variants for functional analysis, we filtered the variants through systematic data mining including ENCODE ChIP-seq data and found that rs17259126 resides in a predicted nuclear receptor subfamily 2 (NR2F2), transcription factor binding site and an enhancer region identified by a co-occurrence of H3K27ac and H3K4me1. NR2F2 has previously been associated with lipid metabolism in humans. Therefore, we hypothesize that rs17259126 resides in an enhancer and that G/A alleles result in a differential TMEM241 expression, ultimately leading to the TG phenotype. To prove our hypothesis, we cloned a 500-bp sequence surrounding the SNP upstream of a minimal promoter in the pGL4.23 vector (Promega) and transferred the firefly/Renilla reporters via Lipofection into human hepatocellular carcinoma cells (HepG2). Luciferase assays at 48 hrs post transfection confirmed that the A allele in rs17259126 has an increased reporter expression ($p<0.05$) compared to the reference G allele in 3 biological replicates. These results suggest that TMEM241 is the potential candidate gene underlying the TG GWAS signal on chromosome 18q11.2 in Amerindian origin populations.

2056M

Contribution of genetic variation of ATP-binding cassette transporter A1 (*ABCA1*) to the regulation of plasma lipid/lipoprotein levels in US Non-Hispanic Whites. *F.Y. Demirci[1], V. Niemsiri[1], X. Wang[1], M.M. Barmada[1], J.E. Hokanson[2], R.F. Hamman[2], M.I. Kamboh[1].* 1) Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO.

Abnormalities in plasma lipid/lipoprotein levels have been linked to the risk of coronary heart disease (CHD). *ABCA1* (ATP-binding cassette, subfamily A (ABC1), member 1) encodes a member of the ATP-binding cassette transporters superfamily that functions as a cholesterol efflux pump and *ABCA1* mutations are known to cause hereditary high-density lipoprotein (HDL) deficiency. In this study, we sequenced *ABCA1* (exons, most introns, and ~1 kb of each of 5' and 3' flanking regions) in 95 US Non-Hispanic Whites (NHWs) with extreme HDL cholesterol (HDL-C) levels using the Sanger method and identified 404 variants (402 bi-allelic and 2 tri-allelic). A total of 237 bi-allelic variants, including those identified by sequencing (common tagSNPs with MAF≥5% and selected uncommon/rare variants) plus additional tagSNPs from the HapMap project, were genotyped in our entire NHW sample comprising 623 individuals. The resulting quality control (QC)-passed genotyping data (including 183 variants; 117 common and 66 uncommon/rare) were then evaluated for associations with 5 major lipid/lipoprotein traits (HDL-C, low-density lipoprotein cholesterol (LDL-C), triglyceride (TG), apolipoprotein (apo) A1, and apoB levels). In single-site analysis, 35 common variants showed significant association ($P<0.05$) with at least one lipid/lipoprotein trait. Although significant associations were observed with all interrogated lipid/lipoprotein traits (for at least 2 variants per trait), the strongest and highest number of associations (21 of 35 significant SNPs) were detected with TG levels. The rare variant and haplotype analyses are currently underway. Our preliminary findings suggest a role for common *ABCA1* variants in modulating the lipid/lipoprotein levels (and especially the TG levels), which is in line with the recent studies implicating *ABCA1* in the metabolism of various major plasma lipoproteins as a contributor to the metabolic link between them.

2057S

A high yield of variants with a putative role as modifiers in patients with hypertrophic cardiomyopathy. *S. Bardi[1], F. Girolami[1], M. Benelli[1], B. Tomberli[2,3], E. Contini[1], G. Marseglia[1], C. Pescucci[1], G. Castelli[2], A. Fornaro[2], F. Cecchi[3], I. Olivotto[2], F. Torricelli[1].* 1) Diagnostic Genetic Unit, Careggi University Hospital, Florence, Italy; 2) Referral Centre for Myocardial Diseases, Careggi University Hospital, Florence, Italy; 3) University of Florence, Department of Clinical and Experimental Medicine, Florence, Italy.

Next Generation Sequencing enables simultaneous screening of multiple genes for multiple patients in a single run. We designed a panel of 111 genes known to be associated to CMs to study 94 unrelated patients (80 with Hypertrophic Cardiomyopathy, HCM; 18 with Dilatative Cardiomyopathy, DCM and 6 with Arrhythmogenic Cardiomyopathy, AC). Targeted resequencing was performed on Illumina platform (98,13% of the regions with a depth of coverage of 20X or more, mean coverage on target of 530X). A mean of 1016 variants were found for each patient. Rare (frequency <0.05), non-synonymous, loss- of- function and splice-site variants were defined as candidates. Pathogenic or likely-pathogenic variants were all confirmed by Sanger and cosegregation was tested when possible. Excluding titin missense variants, we identified 48 variants (27 novel) in sarcomeric or associated genes in 48/70 HCM patients (68%), with 14% of complex genotype. MYH7, MYBPC3 and TNNI3 resulted the high-yield genes; 19 additional candidate variants (13 novel) in desmosomal and ion-channel genes in 14 patients (20%) were identified in this group. We identified 10 candidate variants (7 novel) in 7/18 DCM patients (39%) and 5 candidate variants in 3/6 AC patients (50%). A targeted protocol allowed the identification of likely pathogenic variants in a large proportion of patients with CMs, irrespective of phenotype. The unexpected finding of rare non synonymous variants in desmosomal and ion-channel genes among HCM patients raises important issues regarding their role as previously unappreciated modifiers of the disease, potentially relevant to risk prediction and counseling.

2058M

Genetic dissection of a novel X-linked congenital heart syndrome. *C. Preuss[1], S. Yang[2], M. Samuels[3], P. Awadalla[3], P. Chetaille[4], H. Björck[5], S. Mohamed[6], P. Eriksson[5], G. Andelfinger[1].* 1) Department of Pediatrics, Centre Hospitalier Universitaire Sainte Justine, Montreal , Quebec, Canada; 2) Department of Cardiology, Nanjing Children's Hospital, Nanjing Medical University, Nanjing, China; 3) Department of Pediatrics, Faculty of Medicine, Sainte-Justine Research Center, University of Montreal, Montreal, QC, Canada; 4) Cardiology Service, Centre Mère-Enfants, Centre Hospitalier Universitaire de Québec, Université de Laval, Québec City, Québec, Canada; 5) Atherosclerosis Research Unit, Center for Molecular Medicine, Department of Medicine, Karolinska Institutet, Stockholm, Sweden; 6) Department of Cardio and Thoracic Vascular Surgery, University Clinic of Schleswig-Holstein, Luebeck, Germany.

The major burden of congenital heart disease (CHD) is caused by left ventricular outflow tract obstructions (LVOTO). This heterogeneous group of cardiac malformations constitutes to an increased risk of valve replacements and aortic aneurysms. Although a strong male predominance has been described for the highly heritable trait, the genetic basis for these cardiac malformations remains poorly understood. Here, we describe a comprehensive genetic study in two French Canadian pedigrees with 15 affected male individuals with septal defects, aortic valve lesions and bicuspid aortic valve. Linkage analysis and genetic fine mapping using the Illumina Omni 5.0 platform revealed a significant interval on chromosome Xq28 (LOD score = 3.29) harboring a 260kb haplotype co-segregating with disease in both families. The disease associated haplotype is rare (MAF < 5%) among 960 genotyped French Canadian controls. Whole-exome sequencing of six patients and re-sequencing of the disease haplotype did not reveal rare (MAF < 2%) coding or splice-site mutations. Validation of all identified rare and novel mutations in the disease haplotype using a Sequenom panel confirmed only one mutation co-segregating with disease in an X-linked manner. This highly conserved intronic mutation (GERP score > 4) in *FLNA* is absent among public (dbSNP138, 1000 Genomes) and in-house sequencing data sets. In silico analysis predicts the hemizygous mutation to create a high affinity MyoD binding site. Expression data from patients with bicuspid aortic valve revealed that *FLNA* shows the highest expression patterns in the aortic media of dilated aortas compared to all expressed transcripts in the disease associated haplotype. Reconstruction of ascending genealogies supports the notion of a founder effect for this novel X-linked syndrome, dating back to a common founder couple in 1788.

2059S

Large-scale metabolomic profiling identifies novel biomarkers for incident coronary heart disease. *A. Ganna[1], S. Salihovic[2], J. Sundström[2], C.D. Broeckling[3], A.K. Hedman[4], P.K.E. Magnusson[1], N.L. Pedersen[1], A. Larsson[5], A. Siegbahn[6], M. Zilmer[7], J. Prenni[3,8], J. Ärnlöv[4,9], L. Lind[2], T. Fall[4], E. Ingelsson[4,10].* 1) Medical epidemiology and biostatistics, Karolinska institutet, Stockholm, Sweden; 2) Department of Medical Sciences, Cardiovascular Epidemiology, Uppsala University, Uppsala, Sweden; 3) Proteomics and Metabolomics Facility, Colorado State University, Fort Collins, Colorado, USA; 4) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 5) Department of Medical Sciences, Biochemial structure and function, Uppsala University, Uppsala, Sweden; 6) Department of Medical Sciences, Coagulation and inflammation science, Uppsala University, Uppsala, Sweden; 7) Department of Biochemistry, The Centre of Excellence for Translational Medicine, University of Tartu, Tartu, Estonia; 8) Department of Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, USA; 9) School of Health and Social Studies, Dalarna University, Falun, Sweden; 10) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, United Kingdom.

Background: Analyses of circulating metabolites in large prospective epidemiological studies could lead to improved prediction and better biological understanding of coronary heart disease (CHD).

Methods and Results: We performed a mass spectrometry-based non-targeted metabolomics study for association with incident CHD events in 1,028 individuals (131 events; 10 y. median follow-up) with validation in 1,670 individuals (231 events; 4 y. median follow-up). Four metabolites were robustly replicated and independent of established risk factors [lysophosphatidylcholine 18:1 (hazard ratio [HR] per standard deviation [SD] increment= 0.77, P-value<0.001), lysophosphatidylcholine 18:2 (HR=0.82, P-value= 0.002), monoglyceride 18:2 (MG 18:2; HR=1.16, P-value=0.032) and sphingomyelin 28:1 (HR=0.86, P-value=0.010)]. Together they contributed to moderate improvements in discrimination and re-classification in addition to traditional risk factors (C-statistic: 0.76 vs. 0.75; NRI: 9.2%). MG 18:2 was associated with CHD independently of triglycerides. Lysophosphatidylcholines were negatively associated with BMI, glucose, C-reactive protein and with less evidence of subclinical cardiovascular disease in 970 PIVUS participants; a reverse pattern was observed for MG 18:2. MG 18:2 showed an enrichment (P-value=0.002) of significant associations with CHD-associated SNPs (P-value=1.2×10^{-7} for association with rs964184 in the ZNF259/APOA5 region) and a weak, but positive causal effect (odds ratio=1.05 per SD increment in MG 18:2, P-value=0.05) on CHD, as suggested by Mendelian randomization analysis.

Conclusions: We identified four lipid-related metabolites with evidence for clinical utility, as well as a causal role in CHD development.

2060M

Genetic and Metabolic Causes of Neonatal Cardiomyopathy. *C. Prada[1,2], I. Villamizar-Schiller[1], J. Castro[3], L. Pabon[1], A. Duran[3].* 1) Centro de Medicina Genómica y Metabolismo, Cardiovascular Foundation of Colombia, Floridablanca, Colombia; 2) Dept Pediatrics Genetics, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH; 3) Division de Cardiologia Pediatrica, Cardiovascular Foundation of Colombia, Floridablanca, Colombia.

Background: Neonatal cardiomyopathy is an important cause of pediatric cardiac deaths. This is a heterogeneous disease with a strong genetic component. The objective of this study was to determine the prevalence of genetic and metabolic etiologies in patients with neonatal cardiomyopathy. Study Design: A retrospective analysis of data from clinical records of 40 neonates with cardiomyopathy seen at the Cardiovascular Foundation of Colombia between 2011 and 2014 was performed. Results: In a total of 29 neonates (72.5%) a genetic or metabolic etiology was identified. The most common group of causes was metabolic (13/29, 45%) followed by syndromic (10/29, 34%), and maternal diabetes (6/29, 21%). The single most common diagnosis were RASopathies (7/25, 28%) followed by maternal diabetes, mitochondrial and fatty acid oxidation defects. Mortality was higher in the group of metabolic disorders (7/13, 54%). Hypertrophic cardiomyopathy was identified in 25 of the 40 patients (62.5%). Sixty percent of patients with cardiomyopathy (24/40) survived beyond their first year of life. Extra-cardiac manifestations were more prevalent in the syndromic group. Family history of a sibling with unexplained death was seen in the metabolic group. Conclusion: Neonatal cardiomyopathy has a strong genetic component in the majority of patients. An underlying metabolic or syndromic cause was identified in 72.5% of neonates. Identification of etiology is important for management and family counseling and recurrence.

2061S

Targeted Oligonucleotide-Selective Sequencing for Genetic Diagnostics of Pulmonary Arterial Hypertension. *E.H. Seppälä[1], S. Vattulainen[2], J. Aho[3], J. Tallila[1], M. Gentile[1], M. Sankelo[4], T. Laitinen[5], J.W. Koskenvuo[1,3], T.-P. Alastalo[1,2], S. Myllykangas[1,6].* 1) Blueprint Genetics, Helsinki, Finland; 2) Childrens Hospital Helsinki, University of Helsinki, Helsinki, Finland; 3) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Finland; 4) Department of Internal Medicine, Tampere University Hospital, Tampere, Finland; 5) Division of Medicine, Department of Pulmonary Diseases and Allergology, Turku University Hospital and University of Turku, Turku, Finland; 6) Institute of Biomedicine, University of Helsinki, Helsinki, Finland.

Pulmonary arterial hypertension (PAH) is a severe and progressive disease. The genetic basis of idiopathic PAH is well recognized but rarely utilized in a diagnostic setting. Hundreds of mutations in seven genes have been reported to associate with idiopathic and familial forms of PAH. Next-generation sequencing for comprehensive genetic testing improves diagnostics, prognostics and treatment optimization of the index patient and allows an effective screening of asymptomatic family members. We utilized novel next-generation sequencing and bioinformatics approaches for genetic diagnostics of PAH. We applied Oligonucleotide-Selective Sequencing (OS-Seq) and custom data analysis and interpretation pipelines to identify pathogenic base substitutions, insertions and deletions in seven genes associated with PAH (BMPR2, BMPR1B, ACVRL1, ENG, SMAD9, CAV1 and exon 2 of KCNK3). Targeted sequencing covered all coding exons, exon-intron boundaries and known intronic mutations (12,638 bases). In OS-Seq, oligonucleotide-functionalized Illumina flow cells are used for both capture and sequencing of DNA. We automated target DNA capture and sequencing using the MiSeq Sequencing system. We analyzed 21 Finnish PAH patients. Sequencing depth was evaluated in each target base to demonstrate the efficiency of targeted sequencing. Average sequencing depth was 791 and 99.88% of target regions were covered >15x. We identified six idiopathic PAH patients with likely pathogenic variants in the BMPR2 gene. The identified mutations caused stop, frameshift and missense changes and had minor allele frequency of <0.001 reported in the 1000 genomes database. Mutations or potential variants were not identified from 6 other analyzed genes. Our results show that a comprehensive next-generation sequencing panel is an effective tool for genetic diagnostics of PAH and 29% of the Finnish PAH patients carried mutations in BMPR2.

2062M

Use of a Gene Expression Score in a Primary Care Setting to Evaluate African American Patients Presenting with Symptoms Suggestive of Obstructive Coronary Artery Disease. *L. Wilson[1], M. Brown[2], D. Smith[3], B. Rhees[1].* 1) CardioDx, Inc., Redwood City, CA; 2) Providence - Dayton Primary Care, Dayton, OH; 3) Novant Heart and Vascular Institute, Huntersville, NC.

Purpose: Approximately 3 million pts without diabetes present annually to primary care clinicians with symptoms suggestive of obstructive coronary artery disease (CAD). After a detailed examination, physicians still rely heavily on advanced imaging diagnostic tests, to determine the etiology of symptoms. Given the heterogeneity in clinical manifestations of CAD amongst different ethnic populations in the US, the use of a gene expression score (GES) may allow clinicians to more consistently evaluate across the spectrum of primary care pts, thereby appropriately avoiding unnecessary referrals and advanced diagnostic tests. We hypothesized that use of the GES would show clinical utility for a clinician evaluating African Americans pts presenting with symptoms suggestive of CAD. Methods: A previously validated gene expression diagnostic test (Corus® CAD, CardioDx, Inc.) has a 96% NPV in ruling out obstructive CAD among symptomatic pts with no previous history of diabetes or myocardial infarction. GES results are predefined as low (GES ≤15) or elevated (GES >15), with low score pts having a low likelihood of obstructive CAD. Previous evaluation showed no significant difference in test performance between non-white and white populations. This was a single primary care practice study with a large African American pt population. De-identified pt data from 2011-2013 was collected. Results: This cohort included 582 African American pts who received a GES, with 325 (56%) female pts and 201 (35%) being >65yrs. Approximately 90% (518/582) of pts presented with typical or atypical symptoms suggestive of obstructive CAD. Mean GES was 19 (range, 1-40), and 245 pts (42%) had low scores. In this analysis, 11/245 (5%) of low GES pts were referred to cardiology and/or further diagnostic testing, whereas 248/337 (74%) of elevated GES pts were referred to cardiology and/or further diagnostic testing (p-value<0.0001). Conclusions: The personalized GES showed clinical utility in the evaluation of symptomatic African American pts. The findings show fewer cardiology referrals and/or further diagnostic testing for those African American pts with low GES, thereby improving pt care by avoiding unnecessary, and potentially harmful, advanced diagnostic testing. This low rate of referral among low GES pts is similar to that observed in largely non-minority pt cohorts from previous GES studies: COMPASS, IMPACT-PCP, IMPACT-Cardiology, Registry I, and the PRESET Registry.

2063S

Extended genetic diagnosis of Familial Hypercholesterolemia using next-generation sequencing. *M.M. Motazacker[1], B. Sjouke[2], O.R.F. Mook[1], M.A. Haagmans[1], G.K. Hovingh[2], J.C. Defesche[3], A.R. Mensenkamp[4], M.M.A.M. Mannens[1].* 1) Department of Clinical Genetics, Academic Medical Center, Amsterdam, The Netherlands; 2) Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands; 3) Department of Experimental Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands; 4) Department of Human Genetics, Radboud University Medical Center, Nijmegen, The Netherlands.

Familial Hypercholesterolemia (FH) is a major risk factor for coronary artery disease. FH is caused by mutations in the genes coding for the low-density lipoprotein receptor (*LDLR*), apolipoprotein B (*APOB*) and proprotein convertase subtilisin/kexin 9 (*PCSK9*). Routine genetic diagnosis of FH is often limited to sequencing *LDLR* followed by partial sequencing of *APOB* and *PCSK9* in cases with no *LDLR* mutations. This is mainly due to the large size of *APOB* and rarity of *PCSK9* mutations which makes Sanger sequencing inefficient. Using DNA from 20 patients with 31 known mutations (including single-nucleotide coding and promoter variants, insertions, deletions, indels and large copy-number variants), we employed an Ion AmpliSeq™ enrichment of coding sequence (and 25 bp flanking intronic regions) of all three FH genes followed by sequencing using Ion-PGM™ sequencing platform (Life technologies™). The sequence data were then analyzed using SeqNext software (JSI medical systems). We could successfully identify all previously detected mutations. Interestingly, we also identified additional 8 rare variants including *PCSK9* p.Cys679X and 7 *APOB* variants (e.g. p.Arg532Trp, p.Asp1113His, p.Lys3076Met, etc.), some of which already reported in the literature to be functional while others predicted to be functional using *in silico* prediction models. Identification of these extra variants may help in explaining unexpected phenotypes (which are usually justified by incomplete penetrance of the phenotype) seen frequently in the families with dyslipidemia. Our study suggests a fast, cost-effective and accurate approach for extended genetic diagnosis of FH which can increase the yield of FH diagnosis and improve phenotype-genotype correlation studies in pedigrees with phenocopy or non-penetrant FH mutations.

2064M

Evidence for the novel variant, c.1937 C>T (p.Ser646Phe) in the membrane binding domain of the *ANK2* gene contributing to Long QT syndrome in a First Nations community of Northern British Columbia. *L.T Arbour[1,2,3], A.K.J Boyce[2], J. Christensen[2], S. MacIntosh[1], S. Lauson[3], S. Tung[4], C. Kerr[4], L.A Swayne[2].* 1) Department of Medical Genetics, University of British Columbia, Victoria, BC; 2) Division of Medical Sciences, University of Victoria, Victoria, BC; 3) Island Health and the BC Inherited Arrhythmia Program, Victoria BC; 4) Department of Medicine, University of British Columbia, Vancouver, BC Canada.

Long QT syndrome (LQTS) is a rare inherited cardiac condition named for a prolonged QT interval on ECG (corrected for rate) conferring susceptibility for life-threatening ventricular arrhythmias. An estimated 75 percent of hereditary LQTS is caused by mutations in 12 genes that encode ion channels or functionally related proteins. In Northern British Columbia, through participatory methods, a First Nations community was previously identified to have a disproportionately high rate of LQTS, accounted for largely by a novel missense founder mutation (p.V205M) in the *KCNQ1* gene causing LQTS1. Mechanistic and clinical evaluation supported pathogenesis and studies on the variable phenotype and natural history are on-going. Although the majority of cases in the community have been confirmed with the founder mutation, there are some families with LQTS who are mutation negative. We report on two distinct families within this First Nations community where clinical 12 gene sequencing on 2 apparently unrelated probands revealed the same likely pathogenic variant (c.1937 C>T) in exon 18 of the *ANK2* gene (NM_001148.4) resulting in a serine to phenalanine substitution at position 646 in the membrane binding domain. This variant was undetected in ~6500 controls in the NHLBI exome sequencing project and noted to be conserved across species. Nine variant carriers from the two families have been identified, with a range in peak QTc (QT interval corrected for rate on ECG) from 426-509 ms. Five of the 9 with the variant have a peak QTc > 470 ms. A sudden death at age 50 in an obligate carrier and a recent sudden death in a 36 year old male relative at high risk for the variant exemplify the family implications. The protein encoded by the *ANK2* gene, Ankyrin2, acts as a scaffold for ion channels and transporters critical in cardiomyocyte excitability. Although mutations in the Ankyrin2 C-terminal domain have been reported to cause LQTS (type 4), this is the first mutation identified in its membrane binding domain. To determine the effects of the Ser646Phe mutation on Ankyrin2 localization and cellular metrics (such as cell size, shape proliferation, and viability), cardiomyoblasts were transfected with GFP-tagged wildtype and Ser646Phe variant Ankyrin2 for confocal microscopy and live cell kinetic imaging experiments. Our findings support pathogenesis for this uniquely situated mutation in the *ANK2* gene.

2065S

Novel variants in *VINCULIN* and *TROPOMYOSIN1* combinatorially predispose patients to dilated cardiomyopathy. *D.C. Deacon[1,2,3,5], A.M. Manso[1,4], B.C. Nelson[1,5], R.S. Ross[1,2,4], E.D. Adler[1], N.C. Chi[1,2,3].* 1) School of Medicine, University of California San Diego, La Jolla, CA; 2) Biomedical Sciences Graduate Program, UCSD; 3) Medical Scientist Training Program, UCSD; 4) Veterans Affairs San Diego Healthcare System; 5) California Institute of Regenerative Medicine Fellow.

Dilated cardiomyopathy (DCM) may affect as many as 1 in 250 individuals and is the leading cause of heart failure necessitating heart transplant. We have identified a large family presenting with multiple cases of DCM across four generations. The proband for this study, a 14-year old male patient, presented with severe heart failure and required heart transplantation. His father was also diagnosed with DCM while his sister, who had a normal heart by echocardiography, died suddenly and, on autopsy, showed mild cardiac hypertrophy. We have identified sequence variants in the genes encoding the costameric protein VINCULIN (VCL) and the sarcomeric regulatory protein TROPOMYOSIN 1 (TPM1) in this family. Targeted sequencing at these loci in 31 family members showed that the combination of *VCL* and *TPM1* variants cosegregated with all family members diagnosed with cardiomyopathy. Given the genetic cosegregation of these novel heterozygous variants in *VCL* and *TPM1*, we hypothesize that the functional interaction between costameric and sarcomeric structures is critical to the proper regulation of cardiomyocyte force generation and transmission. In order to study the effects of these variants on cardiac structure and function, we have utilized CRISPR-mediated genomic editing to introduce these patient-specific variants into a mouse model. Both of these genes are over 99% conserved between human and mouse at the protein level and mutations in both have been previously associated with cardiomyopathies, though the molecular mechanisms governing these pathophysiologies have not been fully described. We will determine the consequences of these variants on cardiac contractility and sarcomeric and cytoskeletal organization in single and double variant heterozygous mice to elucidate the mechanisms underlying the observed combinatorial disease inheritance pattern. A further understanding of the genetic and molecular interactions between costameric and sarcomeric proteins in proper cardiac function could pave the way for new therapies to treat heart failure.

2066M

A novel mutation in the *RYR2* gene (c.527 G>T, p.R176L) identified in a 4 generation family presents with a catecholaminergic polymorphic ventricular tachycardia (CPVT) phenotype with variable penetrance. *S. Lauson[1,2], B. Sinclair[2,3], A.A. Collier[4,5], F. Curtis[4,5], F. Van Petegem[6], B.A. Fernandez[4,5], A.E. Williams[7], S. Connors[7], C.G. Templeton[7], K. Hodgkinson[5,9], R. Leather[2,8], S. Sanatani[2,10], L. Arbour[1, 2, 11].* 1) Medical Genetics, Island Health, Victoria, BC, Canada; 2) BC Inherited Arrhythmia Program, Victoria/Vancouver, BC; 3) Pediatric Cardiology, Island Health, Victoria, BC; 4) Provincial Medical Genetics Program, Eastern Health, St. John's, NL; 5) Discipline of Genetics and Medicine, Memorial University of Newfoundland, St. John's, NL; 6) Department of Biochemistry, University of British Columbia, Vancouver, BC; 7) Division of Cardiology, Discipline of Medicine, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL; 8) Division of Cardiology, Island Health, Western Cardiology, Victoria, BC; 9) Clinical Epidemiology, Discipline of Medicine, Memorial University, St. John's, NL; 10) Department of Pediatrics, Children & Women's Hospital, University of British Columbia, Vancouver, BC; 11) Department of Medical Genetics, University of British Columbia, Vancouver BC.

Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) is a rare condition with population incidence estimated to be 1:10,000 and confers substantive risk for sudden cardiac death in the young. Four known genes cause the condition (*RYR2, CASQ2, TRDN*, and *CALM1*) but the identification of large extended families are rare. Stress and exercise-induced releases of catecholamines can lead to aberrant calcium ion flux, and the hallmark feature of bidirectional ventricular tachycardia (VT). Other inherited arrhythmia conditions can mimic the presentation, including Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) and Long QT syndrome (LQTS) with overlapping implicated genes. We present a large Newfoundland family presenting with a significant history of cardiac arrests. The proband had two previous cardiac arrests (age 28 and 32) one while undergoing surgery. She was initially investigated and tested for ARVC due to the common regional founder gene mutation, *TMEM43* (p.S358L). Subsequent comprehensive testing for ARVC included the *RYR2* gene, revealing a novel *RYR2* gene variant (c.527 G>T, p.R176L). Confirmation of bidirectional VT in her son suggested the CPVT phenotype. He had no evidence of ARVC. Of interest, this family also harbours a known pathogenic LQTS gene mutation (R518Q in *KCNQ1*), and two siblings are heterozygous for both. The R176L variant was not seen in 600 alleles from controls, and results in a non-conservative amino acid substitution of a polar Arginine with a non-polar Leucine at a highly-conserved region. Crystallographic studies show that R176 is involved in interactions with a neighboring RyR2 subunit. These interactions stabilize the RyR2 closed state, and any weakening through R176L would result in facilitated channel opening, leading to premature or prolonged release of calcium ions. Currently 16 individuals in 4 generations have been identified with the mutation. Cardiac arrest during surgery (age 29), was documented in a variant carrier (cousin to the proband), and bidirectional VT has been confirmed in another during exercise testing supporting clinically that the phenotype segregates with the mutation alone. However, the carrier father of the proband (age 76) remains apparently unaffected. ECGs, echocardiograms, Holter monitors and stress tests are being carried out on family members. This family provides a unique opportunity to explore the variable penetrance and expression of an *RYR2* mutation causing CPVT.

2067S

Harnessing genomic data to identify drug targets for reduction of LDL cholesterol and CAD risk that do not impact upon glycaemic status. *V. Tragante do O[1], F.W. Asselbergs[1], M.V. Holmes[2].* 1) Divisie Hart & Longen, University Medical Center Utrecht, Heidelberglaan 100, 3584CX Utrecht, Netherlands; 2) Division of Transplant Surgery, Perelman School of Medicine, University of Pennsylvania, 3400 Spruce St, Philadelphia, PA 19104, USA.

Introduction LDL cholesterol (LDL-C) reduction is recognized as an efficacious therapeutic means to reduce risk of coronary artery disease (CAD). However, the most widely prescribed LDL-reducing drugs (statins) are associated with an increased risk of type 2 diabetes (T2D). We used data from genome-wide association studies for CAD and glycaemic traits to identify potential drug targets for LDL-C reduction that have no impact on glycaemic status. Methods and Results We obtained summary-level results from a GWAS on LDL cholesterol from Global Lipids Genetics Consortium (GLGC), CAD/MI from CARDIoGRAMplusC4D, T2D from DIAGRAM consortium and glucose, insulin and related traits from MAGIC consortium, and standardized all effects to 1 unit of increase in LDL-C. A p-value filter of P<5E-08 for GLGC results was employed, and the SNPs surpassing this threshold were further filtered with P<0.05 for CARDIoGRAMplusC4D and DIAGRAM. Directions of effect were the same for GLGC and CARDIoGRAM for 81 out of 84 SNPs passing the significance threshold (binomial P=4.93E-21), whereas all 17 SNPs passing significance thresholds for DIAGRAM and MAGIC had the same direction of effect (binomial P=7.63E-06). We then performed a multiple-trait meta-analysis of all MAGIC subcomponents (referred to as "metabolic burden") and searched for SNPs that are significant for LDL and CAD/MI, but did not associate with metabolic burden (P>0.05). Eighteen loci met these criteria, and were further investigated for their potential druggability. Six of those present interaction with one or more commercially available drugs, including LDLR, HNF1A, OASL, PLG, PTPN11 and SLC22A3. Conclusions These findings provide novel information for prioritizing therapeutic targets for reduction of LDL-C and CAD risk that should be free from adverse consequences on glycaemic status. Keywords Coronary artery disease, type 2 diabetes, LDL cholesterol, drug target.

From Identification of Differing TIE2 Mutations with Distinct Cellular Characteristics in Four Types of Venous Anomalies towards a Murine Model and a Therapeutic Pilot Study. *M. VIKKULA[1], N. LIMAYE[1], J. SOBLET[1], M. UEBELHOER[1], M. NETYNKI[2], E. BOSCOLO[3], L. EKLUND[2], J. BISCHOFF[3], L.M. BOON[1,4].* 1) Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Oulu Center for Cell-Matrix Research, Biocenter Oulu and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Finland; 3) Vascular Biology Program and Department of Surgery, Boston Children's Hospital, Harvard Medical School, MA, USA; 4) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires Saint Luc, Brussels, Belgium.

Venous anomalies are composed of ectatic veins with irregular smooth muscle coverage. They are commonly cutaneous. They usually occur as a single lesion without family history (sporadic Venous Malformation, VM). Some sporadic patients have multifocal lesions (Multifocal Sporadic Venous Malformation, MSVM). In the sporadic Blue Rubber Bleb Nevus syndrome (BRBN), patients also have multifocal lesions; pathognomonic are rubbery palmoplantar lesions and those located in the GI-track. In rare cases, venous malformations are multifocal because of autosomal dominant inheritance (Mucocutaneous Venous Malformation, VMCM). VMs progressively expand causing deformity, pain and local intravascular coagulopathy. Despite sclerotherapy or excision, lesions often progress or recur. We have identified activating mutations in the endothelial tyrosine kinase receptor TIE2 in all four forms. VMs are mostly due to a single somatic amino acid change L914F. MSVMs and BRBNs are due to double mutations in cis. The BRBN mutations are somatic, whereas MSVM mutations seem mosaic. Moreover, a distinct cis-mutation is seen in MSVM. The inherited VMCM is due to a germline mutation combined with a somatic second-hit. These clinicogenetic entities are reflected by phenotypic differences in cells overexpressing mutant receptors. Activation of AKT is yet a common phenomenon. The capacity to form lesions clearly resides in mutant endothelial cells, which when injected to immunodeficient mice generate lesions mimicking human VM. Interestingly, an mTOR inhibitor is able to deter lesion development. Finally, in our therapeutic pilot study comprising five patients with VMs refractory to standard-of-care, an mTOR inhibitor diminished pain, intravascular coagulopathy and improved quality of life.

2069S

A novel pathway involved in the susceptibility of non-alcoholic fatty liver diseases. *S. Makishima, S. Boonvisut, K. Watanabe, K. Nakayama, S. Iwamoto.* Division of Human Genetics, Center for Molecular M, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Background. *Mammalian tribbles homolog 1* (*TRIB1*) is a locus that has convincing impact on cardiovascular diseases and levels of plasma triglyceride (TG) and LDL-cholesterol across several ethnic groups. The genetic associations have been shown in both genome-wide SNP association studies (GWAS) and the replication studies. In addition, we recently showed a deep association of *TRIB1* SNP with non-alcoholic fatty liver diseases (NAFLD) in Japanese (P = 9.39E-7). The risk allele of NAFLD decreased transactivation activity in reporter gene assay. Furthermore, knockdown of *Trib1* expression in mouse liver increased plasma and hepatic lipid levels, whereas the over expression decreased them. Although the enhanced lipogenesis in mouse liver was estimated to result from the reduced decay of carbohydrate response element binding protein (ChREBP), molecular pathways for the hepatic lipid accumulation were still uncovered. **Methods.** The novel molecular targets of TRIB1 were explored using Yeast two-hybrid system. The positive clones were further screened functionally using shRNA template via adenoviral gene transduction system into mice liver. Plasma and hepatic lipid levels of the mice were measured to identify the genes involved in the hepatic lipid accumulation. **Results and discussion.** Nine cDNA clones were repeatedly identified through the Yeast two-hybrid screening, four of them simultaneously showed molecular interaction with TRIB1 protein in mammalian cells. Knocking-down one of the four genes, *SAP18*, reduced plasma TG levels and increased hepatic lipid accumulation, suggesting impaired lipid secretion. Transcriptome analysis of the mice liver using gene chip revealed significant reduction of the expression of *microsomal triglyceride transfer protein* (*MTTP*), one of the causal gene of abetalipoproteinemia. SAP18 is a subunit of Sin3A-HDAC complex. ChIP studies using halo-chip system and anti-Sin3A showed enrichment of *MTTP* regulatory sequences. These results showed a possible molecular mechanism of NAFLD associated with *TRIB1* expression levels.

Association of the eNOS -786T > C gene polymorphism and coronary artery disease in Iranian population. *S. Mehrtashfar[1], M. Safarpour[2], A. Esmaeli Khatir[3], A. Ebrahimi[2].* 1) Biology Dept, Guilan University, Rasht, Guilan, Iran; 2) Research Institute for Endocrine Sciences, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 3) Sasan Hospital, Tehran, Iran.

Introduction: Coronary artery disease (CAD) is the most common type of cardiovascular disease and one of the major causes of mortality worldwide. CAD is a complex, multi system disease that is caused by plaque formation along the coronary arteries , which restricts the heart blood supply. This process is called atherosclerosis. CAD is a multifactorial disease which is influenced by both genetic and environmental factors. One of the most important genes involved in cardiac disease is nitric oxide synthase 3 (NOS3) gene which its product synthesize nitric oxide from L-Arginine. The endothelium plays an important role in maintaining vascular tone and blood pressure and that is largely mediated by nitric oxide (NO). Since reduced NO synthesize has been involved in the development of coronary atherosclerosis, polymorphisms of the NOS3 gene can be associated with increased susceptibility to CAD. So, The aims of the present study was to evaluate the possible association between the endothelial nitric oxide synthase (eNOS) gene polymorphism and occurrence of Coronary artery disease. Methods: In this case-control study, one variation with more clinical significance in cardiac disease (T786C) was studied in 50 patients with CAD and 100 healthy individuals as control group. This variation was studied using ARMS-PCR method on extracted DNA from peripheral blood cells. Results: According to the findings, the C allele in T786C variation in patients was significantly higher than control group in Iranian population. (OR=1.67, 95%, P-value= 0.041). Conclusion: This study indicates a possible association between the presence of C allele in T786C and the risk of coronary artery disease in Iranian population and suggests this variation as a potential marker for estimating the risk of CAD.

2071S

Novel association between genetic variation in the platelet endothelial aggregation receptor 1 (*PEAR1*) gene and platelet count is not modified by anti-platelet treatment with clopidogrel and aspirin. *A.S. Fisch, L.M. Bozzi, K.A. Ryan, R.B. Horenstein, J.R. O'Connell, B.D. Mitchell, A.R. Shuldiner, L.M. Yerges-Armstrong, J.P. Lewis.* University of Maryland School of Medicine, Department of Medicine, Division of Endocrinology, Diabetes, and Nutrition, Program in Personalized and Genomic Medicine, Baltimore, MD.

While an increasing body of evidence suggests that *PEAR1*, a recently identified transmembrane receptor on the surface of platelets, influences platelet activation and aggregation upon exposure to anti-platelet agents, this protein has also been implicated in megakaryopoiesis and thrombopoiesis via modulation of the PI3K/PTEN pathways. To validate and extend these findings, we evaluated whether genetic variation in *PEAR1* significantly affects several platelet-related traits including platelet count (PC), mean platelet volume (MPV), and platelet distribution width (PDW) in 687 healthy old order Amish (OOA) participants of the Pharmacogenomics of Anti-Platelet Intervention (PAPI) Study. Platelet phenotypes were measured at baseline and after exposure to 7 days of clopidogrel (75 mg/day) treatment as well as 1 day of dual anti-platelet therapy (DAPT) including both clopidogrel and aspirin (325 mg/day). Genotyping was performed using the Taqman system, and association analyses were conducted under a dominant model using a multivariable linear regression model that simultaneously adjusted for the effects of age, sex, and the relationship structure of the OOA. We observed a significant association between a well-characterized single nucleotide polymorphism in intron 1 (rs12041331) and PC at baseline (β = 12.6 x 10^3, P = 0.013) as well as after clopidogrel (β = 13.2 x 10^3, P = 0.009) and DAPT (β = 13.4 x 10^3, P = 0.008) exposure. In contrast, no evidence of association was observed between rs12041331 and MPV or PDW regardless of time point. Consistent with prior reports, these results indicate that *PEAR1* likely influences the production of platelets, yet does not influence platelet volume or distribution width. Future studies will be required to more precisely understand the mechanisms by which *PEAR1* and its genetic variants influence these platelet measurements, which could ultimately lead to the development of more individualized and effective anti-platelet therapy.

High blood pressure (BP) is the most common cardiovascular risk factor worldwide and a major contributor to heart disease and stroke. We previously discovered a BP-associated missense SNP -rs2272996-in the gene encoding vanin-1, a glycosylphosphatidylinositol (GPI)-anchored membrane pantetheinase. In the present study, we first replicated the association of rs2272996 and BP traits with a total sample size of nearly 30,000 individuals from the Continental Origins and Genetic Epidemiology Network (COGENT) of African Americans (P=0.01). This association was further validated using patient plasma samples; we observed that the N131S mutation led to significantly lower plasma vanin-1 protein levels, and thus the N131S mutation retains apparent protective effects in individuals of lowering systolic BP. We hypothesized that variant vanin-1 is subjected to rapid endoplasmic reticulum-associated degradation (ERAD) as the underlying mechanism for reduction in the gene product. Using HEK293 cells stably expressing vanin-1 variants, we show that N131S vanin-1 was degraded significantly faster than wild type (WT) vanin-1. Consequently, there were only minimal quantities of variant vanin-1 present on the plasma membrane and greatly reduced pantetheinase activity. Application of MG-132, a proteasome inhibitor, resulted in accumulation of ubiquitinated variant protein. Application of hypertension drugs reduced the endogenous vanin-1 protein levels. Our study provides strong biological evidence for the association of the identified SNP with BP and suggests that vanin-1 misfolding and degradation are the underlying molecular mechanism.

The majority of disease-associated loci identified by genome-wide association studies (GWAS) do not affect protein-coding genes and current loci often only explain a modest proportion of heritability for any trait, suggesting that genetic variants in non-coding regions may contribute to disease phenotypes. Here, we integrate genetic information from GWAS and epigenomic maps to show that enhancers significantly overlap known loci associated with QT interval and QRS duration traits. We find that enhancers that overlap QT/QRS loci share similar features including increased H3K27ac density, tissue-selective activity, and regulatory motif enrichment that persist below the genome-wide significance threshold. Using these criteria, we developed a machine-learning framework to identify potential novel loci associated with myocardial repolarization that do not meet genome-wide significance. Remarkably, knockdown of the predicted enhancer gene targets led to repolarization phenotypes in zebrafish, demonstrating that epigenomic signals can reveal new disease genes. Our work suggests that enhancer regions harbor sub-threshold variants, and provides a general strategy for the discovery of novel disease genes for complex human traits.

Metabolic syndrome (MetS), a cluster of risk factors for coronary heart disease (CAD) and type 2 diabetes, is one of the fastest growing epidemics worldwide. Although, a heritable disease, identification of disease genes that underlie the association of its multiple risk factors has been elusive. As with many common disorders, genetic approaches have been complicated by unknown mode of inheritance and number of alleles involved. To overcome this complexity we characterized a subpopulation, which included multiple kindreds with cluster of early onset CAD, central obesity, diabetes and hypertension (HTN). Using combined Whole Genome Linkage analysis and Exome Sequencing we identified a single missense mutation (c.304C>T) (p.[R102C]) in DYRK1B (Gene ID: 9149), which segregated with most features of MetS in affected family members. Overexpression of the mutant allele in vitro demonstrated gain of function effects, characterized by increased expression of the key gluconeogenic enzyme glucose-6-phosphatase (G6PC) and adipogenic proteins PPARGC1A and PPARG. Administration of i.p. Lentivirus vectors carrying wildtype and mutant DYRK1B to C57Bl/6 mice resulted in dramatic rise of blood glucose level and increased body weight compared to empty vector. This was associated with increased hepatic FOXO1 and G6PC expression. Accordingly, oral Glucose Tolerance Test (OGTT) in mutation carriers revealed increased insulin resistance compared to unaffected family members. Mutation carriers had higher ratio of skeletal muscle fast-twitch fibers, indicative of preferential glycolytic catabolism compared to unaffected relatives. Correspondingly, the mutation carriers had lower levels of skeletal muscle peroxisome proliferator-activated receptor gamma protein, coactivator 1 alpha (PPARGC1A), indicative of downregulated oxidative metabolism and mitochondria biogenesis. In conclusion, altered DYRK1B function is associated with MetS, likely due to combination of increased hepatic gluconeogenesis and skeletal muscle insulin resistance. Thus, Dyrk1B is a potential target for development of novel therapeutics against diabetes and obesity.

Revealing the genetic and gene expression variation in a case-control study for Acute Myocardial Infarction in a Pakistani population. *N.I. Panousis[1,2,3], S. Tuna[4], L. Lataniotis[4], A. Rasheed[5], N. Shah[5], J. Danesh[6], E.T Dermitzakis[1,2,3], D. Saleheen[5,7], P. Deloukas[4,8].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva (iGE3), University of Geneva Medical School, Geneva, Switzerland; 3) Swiss Institute of Bioinformatics, Geneva, Switzerland; 4) William Harvey Research Institute, Queen Mary University of London, London, UK; 5) Center for Non-Communicable Diseases, Karachi Pakistan; 6) Department of Public Health and Primary Care, University of Cambridge, UK; 7) Department of Biostatistics and Epidemiology, University of Pennsylvania, USA; 8) Wellcome Trust Sanger Institute, Hinxton, Cambridge UK.

The risk of coronary heart disease (CHD), the leading cause of death worldwide, is higher in South Asians compared to individuals of European descent. Although lifestyle and congenital factors, which stimulate metabolic dysfunctions, have been proposed to increase the risk for myocardial infarction (MI) there is limited knowledge of the genetic basis of the elevated incidence of CHD in these populations. Here we report an RNA-seq analysis of monocytes from 71 cases of confirmed acute MI and 77 healthy individuals from the Pakistan Risk Of Myocardial infarction study (PROMIS). RNA was extracted and sequenced on the Illumina HiSEQ2000 (median 42,8 million reads, 75 bp paired-end). All individuals have genome-wide SNP data. We identified 972 differentially expressed genes (FDR 5%, fold chance ≥ 2) and performed pathway and functional annotation analyses. Multidimensional scaling analysis based on gene expression reveals distinct clusters within and between cases and controls suggesting different expression patterns. Allele-specific expression (ASE) was estimated for every individual for all the heterozygous sites. We identified on average 182 sites in ASE (FDR 5%) per individual. In order to find genetic variants that affect the gene expression levels of monocytes we performed expression quantitative trait locus (eQTL) analysis. We discovered 5267 eQTLs (FDR 5%, significance level based on permutations) using a 1 Mb window upstream or downstream of the TSS of the genes. Following these results we are examining if there are ASE sites induced or repressed in cases and controls and will undertake a functional annotation analysis of all ASE sites. We are also conducting an enrichment analysis in MI GWAS SNPs for MI-specific eQTLs in order to identify putative causative variants. Overall, these findings together with the ongoing analyses will allow us to investigate further the genetic architecture of CHD in the Pakistani population and better understand the relationship of genetic regulatory variation and gene expression.

Association of Cytochrome P450 2C9 (CYP2C9) and VKORC1 polymorphisms and warfarin dosage in Iranian patients refer to Shahid Rajaie Heart Center. *r. kameli[1], m. Babanejad[1], m. Imeni[1], m. Soveizi[1], m. Afshari[2], s.h. jamaldini[1].* 1) Cardiogenetics Research Center , Shahid Rajaie Cardiovascular Medical & Resear, Tehran, IranÆ; 2) Zabol University of Medical Sciences, Zabol, IranÁ.

Introduction: Warfarin is a commonly prescribed oral anticoagulant for the treatment and prevention of thrombotic diseases. Warfarin dose has a large interindividual variation. Patients with CYP2C9*2 and/or CYP2C9*3 and VKORC1 (-1639G>A) polymorphisms need lower dose than patients with wild-type variant. These patient metabolized warfarin more slowly than wild patients and traditional dose results in overdose and bleeding in this patients. Objective: This study was conducted to identify the associations between demographic characteristics (sex, height, weight, age, ethnicity), and genetic polymorphisms of CYP2C9 and VKORC1 (-1639G>A) with warfarin dose among Iranian patients. Method: Our study concluded 200 patients that reached to a stable dose of warfarin. By PCR-RFLP method CYP2C9*2 and CYP2C9*3 polymorphisms of CYP2C9 gene and VKORC1 (-1639G>A) was genotyped. Results and Conclusion: Our study showed that CYP2C9 polymorphisms had significant influence on Iranian daily warfarin dose(P= 0.007). Our results suggested that patients with AA genotype in VKORC1 (-1639G>A) require lower doses of warfarin than those with AG or GG genotype(P=0). Height and weight did not have a significant correlation with the warfarin maintenance dose. In addition there was no significant relationship between sex and ethnicity with the maintenance dose of warfarin ($p < 0.05$).

Regulatory Polymorphisms in DBH Affect Peripheral Gene Expression and Sympathetic Phenotypes. *E.S. Barrie[1], D. Weinshenker[2], A. Verma[3], S.A. Pendergrass[3], L.A. Lange[4], M.D. Ritchie[3], J.G. Wilson[5], H. Kuivaniemi[6], G. Tromp[6], D.J. Carey[6], G.S. Gerhard[7], M.H. Brilliant[8], S.J. Hebbring[8], J.F. Cubells[2], W. Sadee[1].* 1) Pharmacology, Center for Pharmacogenomics, The Ohio State University Wexner Medical Center, Columbus, OH; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322, USA; 3) Center for Systems Genomics, Pennsylvania State University, University Park, PA 16802, USA; 4) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC 27599, USA; 5) University of Mississippi Medical Center, Jackson, MS 39216, USA; 6) The Sigfried and Janet Weis Center for Research, Geisinger Health System, Danville, PA 17822, USA; 7) Institute for Personalized Medicine, The Pennsylvania State University College of Medicine, Hershey, PA 17033, USA; 8) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI 54449, USA.

Rationale: Dopamine β-hydroxylase (DBH) catalyzes the conversion of dopamine to norepinephrine in the CNS and peripherally. DBH variants have been associated with large changes in circulating DBH and norepinephrine and are implicated in multiple disorders, yet causal relationships and tissue-specific effects remain unresolved. **Objective**: To characterize regulatory variants in *DBH* mRNA, effect on expression in human tissues, and role in modulating sympathetic tone and disease risk. **Methods and Results**: Analysis of *DBH* mRNA in human tissues confirmed high expression in the brain (locus coeruleus, LC) and adrenal gland, but also unexpectedly in sympathetically innervated organs (liver>lung>heart). Allele-specific expression assays of mRNA in LC and adrenals yielded small allelic differences (<twofold), whereas pronounced allelic differences in the liver (2-11 fold) revealed regulatory effects. The minor alleles of two variants, promoter region rs1611115 and exon 2 rs1108580, were associated with significantly reduced DBH mRNA expression in liver and lung, but not brain and adrenals. In mice, *Dbh* mRNA levels in the liver correlated with cardiovascular risk phenotypes. Using a PheWAS (phenome-wide association study) analysis, the minor alleles of rs1611115 and rs1108580 were associated with sympathetic phenotypes including angina pectoris. Testing combined effects of rs1611115 and rs1108580 indicated robust protection against myocardial infarction in two separate clinical cohorts, which was replicated in a third cohort demonstrating increasing protective effect with an increasing number of minor alleles. **Conclusions**: These results demonstrate profound effects of common *DBH* variants on expression in sympathetically innervated organs, modulating clinical phenotypes responsive to peripheral sympathetic tone. This work was supported in part by NIH grant U01092655.

2078M

Obstructive heart defects associated with candidate genes, maternal obesity, and folic acid supplementation. *X. Tang[1], M.A. Cleves[2], T.G. Nick[1], M. Li[1], S.L. MacLeod[2], S.W. Erickson[2], J. Li[1], G.M. Shaw[3], C.A. Hobbs[2].* 1) Biostatistics Program, Department of Pediatrics, College of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Division of Birth Defects Research, Department of Pediatrics, College of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 3) 3Division of Neonatal and Developmental Medicine, Department of Pediatrics, Stanford University Medical School, Palo Alto, CA.

Right-sided and left-sided obstructive heart defects (OHDs) are subtypes of congenital heart defects, in which the heart valves, arteries, or veins are abnormally narrow or blocked. Previous studies have suggested that the development of OHDs involved a complex interplay between genetic variants and maternal factors. Using the data from 569 OHD case families and 1644 control families recruited from the National Birth Defects Prevention Study (NBDPS) between October, 1997 and December, 2008, we conducted an analysis to investigate the genetic effects of 877 single nucleotide polymorphisms (SNPs) in 60 candidate genes for association with the risk of OHDs, and their interactions with maternal use of folic acid supplements, and prepregnancy obesity. Applying log-linear models based on the hybrid design, we identified a SNP in methylenetetrahydrofolate reductase (MTHFR) gene (C677T polymorphism) with a main genetic effect on the occurrence of OHDs. In addition, multiple SNPs in betaine-homocysteine methyltransferase (BHMT and BHMT2) were also identified to be associated with the occurrence of OHDs through significant main infant genetic effects and interaction effects with maternal use of folic acid supplements. We also identified multiple SNPs in glutamate-cysteine ligase, catalytic subunit (GCLC) and DNA (cytosine-5-)-methyltransferase 3 beta (DNMT3B) that were associated with elevated risk of OHDs among obese women. Our findings suggested that the risk of OHDs was closely related to a combined effect of variations in genes in the folate, homocysteine, or glutathione/transsulfuration pathways, maternal use of folic acid supplements and prepregnancy obesity.

2079S

Notch1 haploinsufficiency increases risk of congenital heart defects in the setting of maternal diabetes by an epigenetic mechanism. *M. Basu[1], K. Bosse[1], V. Garg[1, 2].* 1) Center for Cardiovascular and Pulmonary Research, The Research Institute at Nationwide Children's Hospital , 700 Children's Drive, Columbus, OH 43205, USA; 2) Departments of Molecular Genetics & Pediatrics, The Ohio State University, Columbus, OH., USA.

Rationale: Congenital heart disease (CHD) is the leading noninfectious cause of infant morbidity and mortality. Epidemiologic studies have demonstrated the importance of genetic and environmental factors in the multifactorial etiology of CHD. Pre-gestational maternal diabetes is one of the non-genetic risk factors that predispose individuals to CHD. Diabetes is associated with endothelial cell dysfunction and we recently demonstrated a genetic interaction between endothelial nitric oxide synthase and Notch1, which encodes a transmembrane receptor, is important for heart development. We hypothesized that maternal diabetes in combination with Notch1 heterozygosity of the developing embryo will predispose to the development of CHD. **Methods:** We tested the hypothesis using streptozotocin-induced mouse model of diabetes in mice heterozygous for a null allele for Notch1. To elucidate the molecular mechanism underlying this gene-environment interaction, studies were performed using cardiomyoblast (H9C2) and endocardial-derived cell lines, chick embryos and mouse models. Gene expression was measured using qRT-PCR and Western blotting. **Results:** Histologic analysis of E13.5 *Notch1*$^{+/-}$ embryos exposed to maternal hyperglycemia demonstrated an 85% (12/14) incidence of ventricular septal defects compared to 22% (2/9) in wildtype littermates. Gene expression studies in non-diabetic wildtype, diabetic wildtype and diabetic *Notch1*$^{+/-}$ embryos showed that hyperglycemia was associated with a gradual decrease in Notch1 mRNA and a concomitant upregulation in Jarid2, a histone H3K9 demethylase known to regulate Notch1. In H9C2 and endocardial-derived cells along with chick embryos, we showed that hyperglycemia decreases expression of Notch1 and its downstream targets Hey1, Hey2, and Nrg1 in a dose-dependent manner. Similarly, Jarid2 expression increased with hyperglycemia. Further link between hyperglycemia and Notch signaling was demonstrated by reduced CBF-luciferase activity in H9C2 cells transfected with a constitutively active Notch1 intracellular domain that were exposed to high glucose. Studies demonstrating the relative enrichment of Jarid2 on Notch1 locus with hyperglycemia by ChIP-qPCR are in process. **Conclusions:** Our data demonstrate that maternal hyperglycemia disrupts cardiac development by deregulating Notch1 signaling pathway. Our preliminary findings suggest that this gene-environment interaction is mediated by an epigenetic mechanism involving Jarid2.

2080M

eNOS GENE POLYMORPHISM IN NEWBORN PATIENTS WITH PERSISTENT PULMONARY HYPERTENSION. *ML. Lemus-Varela[1], LM. García[1], R. Ramírez[2], MP. Gallegos[2].* 1) Departamento de Neonatología, Hospital de Pediatría, UMAE, CMNO, IMSS, Guadalajara, Jal,. Mex, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Genética Molecular, División de Medicina Molecular, CIBO. IMSS.

Introduction: Persistent pulmonary hypertension of the newborn (PPHN) is a serious condition with high morbidity and mortality , is characterized by increased pulmonary vascular resistance and activity of endothelial nitric oxide synthase (eNOS), that is critical for pulmonary vasodilation. Objective: Identify the T786C and I/D (VNTR) polymorphisms of eNOS gene in patients with PPHN. Material and Methods: Genomic DNA extraction was performed 42 newborns (NB), 21 with PPHN, confirmed by echocardiography (study group) and 21 healthy RN without PPHN (control group). PCR method was performant with specific primers of T786C and I / D (VNTR 27 bp) polymorphisms of eNOS gene. Statistical analysis was analyzed by Student t, and X2 test of Hardy- Weinberg equilibrium. Statistical significance was considered when P value was < 0.05 with confidence intervals of 95%. Results: The study group with PPHN was lower gestational age (35.6 ± 2.81 vs 38.1 +1.9 weeks , p = 0.008) , therefore the average body weight was lower in this group: 2622 ± 626 g, in contrast to the control group : 2,992 ± 565 g . The T786C polymorphism of the eNOS gene, showed statistically significant differences in both genotype distribution and binding of genotypes T / CC / C , observed in 59% (13 /21) of patients with PPHN in contrast to 25 % (5 /21) in the control group and behaved as a risk factor [OR 4.33 (95 % CI 1.15-16.2) , p = 0.029] . In contrast, the T / T genotype, observed in 43% (9/21) of patients with PPHN and 76 % (16/ 21) of the control group (without PPHN), behaved as a protective factor [OR 0.23 (95 % CI 0.06-0.88), p < 0.029] . The I / D genotype , observed in 50% (11/21) of patients with PPHN compared with 10% (2/21) in the control group ; behaved as a risk factor [OR 10.4 (95 % CI 1.9-76.38) , p = 0.002] . The identified mutations alter the function of eNOS , a key pathway in nitric oxide / cGMP pathway , thus favoring pulmonary vasoconstriction and perhaps poor or no response to inhaled nitric oxide . Conclusions: Polymorphisms identified in the eNOS gene partly explain the vasoreactivity characteristic of this serious disease, and vascular remodeling. To our knowledge there are no previous studies exploring characteristic polymorphisms in patients with PPHN.

2081S

A transcriptomic study reveals KLF15 as a circadian metabolic switch in the heart. *L. Zhang, M. Jain.* Dept Med/Human Gen, Case Western Univ SOM, Cleveland, OH.

Physiological parameters of the cardiovascular (CV) system and pathological states such as heart attacks show a circadian rhythm. We have previously identified that in multiple CV diseases, including atherosclerosis and heart failure, KLF15, a zinc-finger transcription factor, expression is reduced. Interestingly, its expression also oscillates in a circadian fashion under the direct regulation of core clock. To study the role of KLF15 in the circadian regulation of CV health and disease, we performed a transcriptomic study of the heart in wild type and cardiomyocyte specific *Klf15* null mice (cKO). We have identified 1335 genes oscillating in the wild type mice heart. These genes fall into two distinctive groups, one peaks at rest to active phase, another peaks at active to rest phase. Interestingly, in addition to the core clock genes, genes peaking at the beginning phase of activity are strongly associated with metabolic processes including amino acid and fatty acid catabolism, ABC transporters, as well as "de-tox" pathways, such as drug and xenobiotic metabolism. This is consistent with the increased energy demand and food intake. The genes expressed highly at the resting phase are associated with cell migration, cell shape and cell cycle regulation. This suggests the resting phase is vulnerable to both hypertrophy and hyperplasia, and is a critical phase for cardiac repair and remodeling. This novel discovery has important implication for chronotherapy in management of patient with CV disease. There are 1003 oscillating genes showed autonomous KLF15 dependency, specifically, cKO mice showed a loss of all metabolic gene induction upon active phase, including lysine, tryptophan, branch chain amino acids and fatty acid metabolism. The oscillation of core clock genes, "de-tox" genes and ABC transporters are preserved. This observation suggests KLF15 is the switch for metabolic control in the heart for the active phase and loss of function of KLF15 in the diseased state likely results in an energy deficiency state in the heart. We have also identified 473 genes, which gained oscillation in the cKO mice without an increase of other cell types including inflammatory cells. De novo motif prediction has identified enrichment of EGR2, NR5A2, MYC and several others. This is the first report of gaining circadian oscillation in a genetic mutant mice. We are in the process of confirming and studying the molecular mechanism of this phenotype.

2082M

A Large Scale Genome Wide Association Study of Varicose Veins in the 23andMe Cohort. *R.K. Bell, E.Y. Durand, C.Y. McLean, N. Eriksson, J.Y. Tung, D.A. Hinds.* 23andMe Inc., Mountain View, CA.

Varicose veins are a common chronic condition in which veins become enlarged and twisted due to deficient functioning of one-way valves that normally return blood to the heart. They usually appear in the legs, and are more common in women than men. While they are most commonly considered a cosmetic problem, in some cases they can lead to, or signal, more serious circulatory problems. We carried out a GWAS of self-reported varicose veins in the legs in the 23andMe participant cohort, including approximately 20,000 cases and 65,000 controls of European ancestry, imputed against 1000 Genomes reference haplotypes. We identified several novel associations for varicose veins near or in genes involved in various circulatory and blood related functions, including blood group determination, regulation of blood pressure and/or circulation, vascular growth factors. Our strongest association was with SNP rs507666 (p=5.2e-20), found in ABO, which encodes a protein defining the ABO blood group. Variation in SNP rs507666 determines A1 blood subgroup status. This finding is consistent with a previous study that reported the association between the A blood group and varicose veins. It also identified an additional SNP, rs966562 (p= 1.8e-16), near XKR5 involved in Kell blood group determination. Our study also identified SNPs in genes which have previously been characterized as players in the regulation of blood pressure or circulation, including SNP rs11121615 (8.1e-12) in CASZ1, associated with blood pressure variation and SNP rs7111987 (2.2e-10) near ADM which encodes a peptide which may function as a hormone in circulation control. Finally, the GWAS of varicose veins points to a role of genes involved in circulatory development: SNP rs1433196 (5.2e-11) is found in ANGPT1 that encodes a type of angiopoietin, a group of proteins with important roles in blood development; SNP rs966562 (mentioned above) near ANGPT2, that encodes an antagonist for ANGPT1; and SNP rs6905288 (1.5e-8) near VEGFA which encodes a protein whose effects include angiogenesis, vasculogenesis and endothelial cell growth.

An extreme phenotype approach to identify genes in Caribbean Hispanics for carotid plaque, a preclinical marker of atherosclerosis. *S.H. Blanton, A.H. Beecham, H. Gardener, L. Wang, C. Dong, D. Cabral, R. Sacco, T. Rundek.* Human Genetics, Univ Miami, Miami, FL.

Carotid plaque is a measure of subclinical cardiovascular disease and is a risk factor for stroke and heart attack. The genetic underpinnings of plaque are not known. The study goal was to identify risk/protective loci for plaque using an extreme phenotype approach in the analysis of our genome-wide association study. In individuals from the population-based Northern Manhattan Study, plaque was detected by high-resolution B-mode ultrasound and plaque area was measured by automated edge detection software and expressed as total plaque area, a sum of all plaque areas within an individual. Genotyping was done with the Affymetrix 6.0 SNP array. Among the 908 Hispanics, we first calculated the residual score for each participant by regressing plaque area on significant known risk factors (age, sex, packyears of smoking, SBP, diabetes, LDL:HDL ratio, homocysteine levels, high school completion, LDL, lipid lowering medication, and WBC count). To enrich the genetic effects and increase our power to detect associations, we next identified the individuals in the extreme 10% and 20% of the residual distribution, for a total of 90 and 200 individuals on each side respectively, thus ensuring that the phenotypic extremes were largely unexplained by these known risk factors. For each of the extreme thresholds, we performed logistic regression analysis on 877K SNPs, while controlling for the top 3 PCs. A gene based analysis was then performed based on the SNP results using VEGAS. The top gene from the 10% threshold (p=3.80E-05) was member RAS oncogene family (RAB2B). Members of the RAS family are thought to play a critical role in endothelial function. The top gene from the 20% threshold (p=7.60E-05) was retinal pigment epithelium-specific protein 65kDa (RPE65). In addition to the gene based analysis, we also conducted a pathway based analysis using genes with a p<0.05 as input into WebGestalt. After adjusting for multiple testing, several pathways of interest were identified. In particular for the 10% threshold, the taste transduction pathway was significant (p=5.0E-04). An analysis of our diet data found differences (p<0.05) in the intake of vegetables (but not fruit) between the lower 10% and upper 10%, as well as the lower and upper 20%, with individuals with smaller than expected plaque area consuming more vegetable, suggesting that genetic variants affecting taste could contribute to plaque development via influencing vegetable consumption.

2084M

Genetic variants in *LEKR1* and *GALNT10* modulate sex-difference in carotid intima-media thickness: A genome-wide interaction study. *C. Dong[1], A. Beecham[2], L. Wang[2], D. Cabral[1], S.H. Blanton[2], R.L. Sacco[1,2,3], T. Rundek[1,3].* 1) Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL; 2) John T. McDonald Department of Human Genetics, John P Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 3) Department of Public Health Sciences, Miller School of Medicine, University of Miami, Miami, FL.

There is an established sex difference in carotid artery intima-media thickness (IMT), a recognized marker of atherosclerosis. However, the genetic underpinnings that modulate sex-differences in gene-IMT associations are largely unknown. With a multistage design using 722,379 single nucleotide polymorphisms (SNP) genotyped with the Affymetrix 6.0 chip, we performed a genome-wide sex-by-SNP interaction study in 931 Hispanics (mean age: 69±8 years, 61% women, mean IMT: 0.70±0.06 mm), followed by replication in 257 non-Hispanic blacks (mean age: 73±9 years, 62% women, mean IMT: 0.74±0.10 mm) and 153 non-Hispanic whites (mean age: 73±9 years, 50% women, mean IMT: 0.76±0.10 mm). Assuming an additive genetic effect for each SNP based on the minor allele number, we performed multiple linear regression analysis to test for sex-by-SNP interaction on the IMT while controlling for age and the top 3 principal components estimated to capture ancestry by EIGENSTRAT. Among 14 SNPs with an interaction of p<5.0E-6 in Hispanic discovery sample, replicated interactions were found for four SNPs in leucine, glutamate and lysine rich 1 (LEKR1) gene in non-Hispanic whites (p≤0.03) and for one SNP in polypeptide N-acetylgalactosaminyltransferase 10 (GALNT10) gene in non-Hispanic blacks (p=0.043). Specifically, for the top SNP rs7616559 in LEKR1 gene, the adjusted mean difference between men and women was 0.003 mm (p=0.67) for AA-carriers, 0.044 mm (p=2.1E-9) for AG carriers, and 0.064 mm (p=3.0E-5) for GG carriers in the combined sample. For SNP rs2081015 in GALTN10 gene, the adjusted mean difference between men and women was -0.017 mm (p=0.13) for TT-carriers, 0.022 mm (p=0.001) for TC carriers, and 0.051 mm (p=1.2E-10) for CC carriers in the combined sample. Genetic variants near LEKR1 gene have been associated with the measures of adiposity in newborns and variants near GALNT10 gene have been associated with body mass index. Given the consistent findings across different-ethnic groups, further studies are warranted to perform in-depth investigations of functional genetic variants in these regions.

2085S

The Kaiser Permanente/UCSF Genetic Epidemiology Research study on Adult Health and Aging: A blood pressure genome-scan in ~100,000 Subjects. *T. Hoffmann[1], A. Chakravarti[2], G. Ehret[2,3], C. Iribarren[4], Y. Banda[1], E. Jorgenson[4], M.N. Kvale[1], C. Schaefer[4], N. Risch[1,4].* 1) University of California San Francisco, San Francisco, CA; 2) John's Hopkins University, Baltimore, MD; 3) Geneva University Hospitals, Switzerland; 4) Division of Research, Kaiser Permanente, Northern California, Oakland, CA.

Blood pressure (BP) is quantitatively the major risk factor for cardiovascular disease. The Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort has detailed data on longitudinal blood pressure, prescription medication, and genotypes on ~675,000 markers for nearly all of its 100,000 participants (81% white, 7.5% Asian, 7% Latino, and 3.5% African American). Approximately 1.3 million systolic (SBP) and diastolic (DBP) blood pressure measures from electronic health records were used to derive long term average phenotypes and association tests with genotyped variants were run based on the directly genotyped markers.

We conducted a genome-wide association study among the subjects of European ancestry. All analyses were adjusted for age, age^2, sex, BMI, and the first ten principal components. Follow-up analysis was conducted in the other races/ethnicities. We compared the results of our association analysis of SBP to previously reported GWAS hits from the NHGRI GWAS catalog, and found that, at a p<0.0016 (0.05/32 SNPs), 23 SNPs replicated, 8 did not replicate, and 1 was not informative. Further we identified 3 novel loci at genome-wide significance (p<5×10^-8). When comparing to DBP, we found that, at a p<0.0016, 23 SNPs replicated, 6 did not replicate, and 1 was not informative. Further we identified 7 novel loci at genome-wide significance.

In summary, we replicate the great majority of BP SNPs listed in the NHGRI GWAS catalog, and identify 10 new common BP loci.

2086M

Single variant and burden analysis of low frequency variants for Fibrinogen, FVII, FVIII, and vWF. *J.E. Huffman[1,2], CHARGE Hemostasis Working Group.* 1) MRC Human Genetics Unit, MRC Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; 2) National Heart, Lung, and Blood Institute's Framingham Heart Study and Division of Intramural Research, National Heart, Lung, and Blood Institute, Bethesda, MD, USA.

Fibrinogen, coagulation factors VII (FVII) and VIII (FVIII, and von Willibrand factor (vWF) occupy key roles in blood coagulation. Plasma levels are associated with risk of arterial and venous thrombosis and fibrinogen is also a marker of inflammation. The CHARGE Hemostasis Working Group previously identified common variants associated with plasma levels of these factors. We now explore associations with rare and functionally relevant variants.

Individuals of European, African, East Asian and Hispanic ancestries were genotyped using the Illumina “Exome Chip” genotyping array and variants called using a common algorithm across cohorts. Association of rare variants with fibrinogen (n=76,316), FVII (n=25,372), FVIII (n=28,291), and vWF (n=23,272) were tested using both single-variant and burden methods. Burden tests included both unidirectional (T5 & T1) and bidirectional (SKAT) tests. These were restricted to include only missense, nonsense, or splice site single nucleotide variants. Fixed effects meta-analyses were used to combine results across studies using the seqMeta package for R. Conditional analyses were also undertaken for loci where common genetic variation was known to be associated with plasma levels.

Single variant associations were found within previously reported genes for fibrinogen (*FGG*, *FGB* & *HNF4A*), FVII (*F7*) and FVIII/vWF (*ABO*, *VWF* & *STAB2*). Conditioning on known common variants, we identified newly associated rare coding variants with independent associations. These included rs201909029 ($p=5.21\times10^{-13}$) in *FGB* and *FGG* SNPs rs148685782 ($p=2.30\times10^{-150}$) and rs145051028 ($p=4.84\times10^{-9}$) in addition to the previously reported association of rs6054 ($p=3.70\times10^{-42}$) in *FGB*. Significant rare variants tended to have larger effect sizes than previously reported common variants. In some instances, association of different rare variants within the same gene were noted when comparing ethnicity-specific results. Results of the gene-level burden tests were driven primarily by single variant associations rather than a burden of rare variants.

The investigation of rare, functional variants associated with circulating clotting factor levels can add to the knowledge of molecular pathways and mechanisms related to hemostatic disorders and their potential prevention or treatment.

2087S

Carotid intima-media thickness: a genome-wide association analysis among African Americans. *S.M. Tajuddin[1], M.A. Nalls[2], M.F. Keller[2], A.B. Zonderman[1], M.K. Evans[1].* 1) Laboratory of Epidemiology and Population Sciences, National Institutes of Health, Baltimore, MD; 2) Laboratory of Neurogenetics, National Institutes of Health, Bethesda, MD.

Although the age-adjusted death rate from coronary heart disease (CHD) continues to decline in the population overall, there remains significant morbidity and mortality disparities for African Americans (AAs). The atherosclerotic process of CHD leads to thickening of the intimal and medial layers of the common carotid artery. Carotid intima-media thickness (CIMT), measured by B-mode ultrasound, is a non-invasive assessment of subclinical atherosclerosis and has been shown to predict cardiovascular events. Genetic factors influence CIMT. Identification of genetic factors linked with CIMT may facilitate early detection of atherosclerosis and improved treatment strategies. Recent genome-wide association studies have identified genetic loci associated with CIMT in European ancestry and Hispanic populations. However, the association between genetic variants and CIMT has never been investigated among AAs. To identify genetic variants associated with CIMT in AAs, we conducted a genome-wide association analysis of CIMT in AAs in the Healthy Aging in Neighborhoods of Diversity across the Life Span (HANDLS) study, an epidemiological, longitudinal study of health disparities. CIMT in the left common carotid artery was measured by high-resolution B-mode ultrasound. We analyzed 16.2 million genotyped and 1000 Genomes Project imputed SNPs that passed stringent quality control criteria in 584 AA (55% men). We estimated beta coefficients and p values using multiple linear regression models adjusted for age, sex and first 10 principal components under additive genetic effect model. We identified eight SNPs in three novel loci (*MMAA*, *LINC00299*, and *CAMTA1*) associated with CIMT at genome-wide significance level of $P < 5 \times 10^{-8}$. The lead SNPs were *MMAA*-rs142277468 $P = 2.6 \times 10^{-9}$, *LINC00299*-rs12477055 $P = 2.7 \times 10^{-8}$, and *CAMTA1*-rs72863082 $P = 2.8 \times 10^{-8}$. We identified three genetic regions that are associated with CIMT in this African ancestry population. SNPs in *CAMTA1* and *LINC00299* have been implicated in plasma fatty acid levels and obesity related traits, respectively. *MMAA* is involved in cobalamin processing and transportation into the mitochondria and may have an effect on atherosclerosis through homocysteine metabolism. These findings may shed light on atherosclerosis development and provide a biomarker of susceptibility in AAs. Replication studies in other AA cohorts will be conducted to validate these findings.

2088M

Genetic determinants underlying hypertension in multi-ethnic populations. *N. Vasudeva[1], L. Wang[1,2], Z. Liu[2], P. Goldschmidt[3], M. Pericak-Vance[1,2], D. Seo[3], G. Beecham[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, FL., U.S.A; 2) Dr. John T. Macdonald Foundation, Department of Human Genetics, University of Miami, Miami, FL; 3) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL.

Hypertension is a major cardiovascular health risk that is well-established as a heritable trait. The environmental factors influencing it, as well as their complex interactions make it challenging to discover the genetic determinants affecting the trait. A cumulative effect of multiple variants has been believed to contribute to this polygenic trait. To dissect the genetic basis of this trait, we analyzed European, Hispanic and African ancestry samples from Miami Cardiovascular Registry (MCR). Genome-wide genotyping was performed on about 2000 subjects using an Affymetrix SNP array. The subjects were separated into European, Hispanic and African ancestry subgroups using Eigenstrat. Sample and SNP quality control were followed by single variant association test. To account of the effect of blood pressure lowering medications, we added 7% and 6% to systolic blood pressure (SBP) and diastolic blood pressure (DBP) measures, respectively, for each antihypertensive medication taken. Linear regression was used to analyze single variant association adjusting for covariates such as sex, age, age^2, anti-cholesterol medicines and diabetes. SNPs rs937421, rs7025928, rs11965507 and rs10488371 showed significant association with BP phenotypes. We further performed a gene-based association test using the SKAT R package. Significant association was observed in Hispanics for genes AURKAIP1 (p= 5.39E-06), FAM53C (p= 6.59E-06) for DBP and TSNAX-DISC1 (p= 6.05E-06) for mean arterial pressure (MAP). Various genes approached the genome-wide significant level in the European ancestry subgroup as well as African Americans. In order to find pathways connected to these large numbers of genes, we used web based tool WebGestalt. The results showed that in the European subgroup, cytokine-cytokine receptor interaction was significantly associated with SBP (p=5.83E-06) and RIG-I-like receptor signaling pathways with pulse pressure(PP); for Hispanics, metabolic pathways were significant for multiple phenotypes, with DBP being most prominent phenotype (p=5.06E-11); in African Americans metabolic pathways were also highly associated with SBP (p=5.15E-07). We will further analyze these genotypes and pathways using alternate methods such as VEGAS to better understand the genetic etiology of hypertension in our population.

Contribution of Global Copy Number Variants to Down Syndrome-associated Atrioventricular Septal Defects. *D. Ramachandran[1], J.G. Mulle[2], A.E. Locke[3], L.J. Bean[1], T.C. Rosser[1], P. Bose[1], K.J. Dooley[4], C.L. Cua[5], G.T. Capone[6], R.H. Reeves[7], C.L. Maslen[8], D.J. Cutler[1], S.L. Sherman[1], M.E. Zwick[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 3) Center for Statistical Genetics and Department of Biostatistics, University of Michigan School of Public Health, MI; 4) Sibley Heart Center Cardiology, Children's Hospital of Atlanta, GA; 5) Heart Center, Nationwide Children's Hospital, Columbus, OH; 6) Down Syndrome Clinic and Research Center, Kennedy Krieger Institute, Baltimore, MD; 7) Department of Physiology, McKusick Nathans Institute for Genetic Medicine, School Of Medicine, John Hopkins University, MD; 8) Knight Cardiovascular Institute, Oregon Health & Science University, Portland, OR.

Atrioventricular septal defects (AVSD), a severe congenital heart defect, occur in the general population in ~1 in 10,000 births. Nearly 20% of infants with Down Syndrome (DS) have an AVSD, representing an approximately 2000-fold increased risk compared to the euploid population. Our central hypothesis was that in the presence of an extra chromosome 21, otherwise benign copy number variants (CNVs) act to increase the risk of AVSD in individuals with DS. Here we sought to test two specific questions: (1) Do common CNVs of large effect contribute to the elevated risk of AVSD in the DS population? (2) Do rare CNVs increase the risk of AVSD in the DS population? We used the Affymetrix SNP 6.0 genotyping platform to comprehensively characterize CNVs in 452 ethnically matched individuals with DS, comprising of 210 cases (DS + complete AVSD) and 242 controls with a structurally normal heart (DS + NH). We implemented strict quality control filters to minimize false positive calls, including 3 algorithms to make the CNV calls (BEAST, GADA and GLAD). We also required each putative CNV call to contain > 20 SNPs within the interval. After excluding CNVs overlapping centromeres, we identified 541 deletions (253 in cases and 288 in controls) and 383 duplications (177 in cases and 206 in controls). Results from burden and region-wise analyses using PLINK revealed that despite the 2000 fold elevated risk, common CNVs of large effect (OR > 2.0) do not account for the increased risk observed in DS-associated AVSD. In contrast, cases do harbor a significantly elevated burden of large rare variants (> 100kb, < 1% frequency) ($p < 0.01$) and case deletions intersect genes more often than those observed in controls ($p < 0.007$). Gene enrichment analysis showed a trend for enrichment among deletions impacting the ciliome pathway in cases compared to controls. No significant differences were observed for large rare duplications between cases and controls. Our findings suggest that the etiology of AVSD is highly complex and does not arise from the action of a few common variants of large effect. Instead, our data support a multifactorial model, wherein large rare deletions play a significant role in elevating the risk of AVSD in a trisomic background. Our study further suggests an important role for ciliome genes in AVSD.

2090M

Identification of Loci associated with Bicuspid Aortic Valve (BAV). *S.C. Body[1], M. Heydarpour[1], J.G. Seidman[2], S. Prakash[3], D. Milewicz[3], Y. Bosse[4], G. Limongelli[5], the Bicuspid Aortic Valve Consortium (BAVCon).* 1) Anesthesia, Brigham & Womens Hosp, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) University of Texas, Houston, TX; 4) University of Laval, Quebec, Canada; 5) Monaldi Hospital, Naples, Italy.

OBJECTIVE: Bicuspid aortic valve (BAV) is observed in 0.6-1% of humans and is associated with premature aortic stenosis, aortic aneurysm and other congenital cardiac anomalies. BAV has been associated with high-penetrance rare mutations, mainly in NOTCH1, in a few families, but the majority of BAV is sporadic with unidentified inheritance. The embryologic molecular mechanisms causing BAV are unknown. The objective of this study was to identify pathway/genes associated with sporadic BAV. METHODS: We genotyped 456 Caucasian cases (339 males, 117 females) using Illumina Omni2.5. We used three dbGaP cohorts genotyped with either Omni2.5 or Omni5 arrays containing 1,869, 897, and 2,450 Caucasian controls respectively. Quality control and population stratification of the genotype data were performed in PLINK. An additive logistic regression model was performed for association analysis across all three GWAS studies accounting for gender and variants associated with aortic stenosis and aortic aneurysm in order to reduce confounding by presentation. We performed three analyses, one for each control group versus the cases, then pooled significant P-values (<1*10-5) for common SNPs (>5%) with the same direction for genetic marker effects (ORs). RESULTS: 22 SNPs in 12 regions with P<1*10-5 in all three GWA studies remained significant after correction for multiple testing. Five regions (1p21, 4q32, 5q14, 8p23, 12q22) contained SNPs of genome-wide significance (P<5*10-8) with odds ratios of 1.5-2.6. The most significant SNPs with high LD (r2>0.8) were identified on chromosome 8p23. CONCLUSION: Our findings suggest that several polymorphisms could explain the higher predisposition of BAV in Caucasians. Novel regions were identified on chromosomes 1,4,5,8,10,12,16, and 18, which have important role in heart development and can be good candidates for fine mapping and replication in other cohorts. In addition, prior work has demonstrated BAV-linked genes involved in cardiac development of other vertebrates (e.g. Notch1-deficient-mice, Gata5-null-mice). Such studies combined with our ability to delete genes in specific cells at specific developmental states in animal models will undoubtedly unravel numerous candidate Coronary Heart Disease causing genes that can be directly tested in human genetic studies. Conversely loci identify in human cohorts can be tested in animal models to confirm (or not) their causative link to disease. These findings are being replicated.

2091S

Relationship Between Plasma Betaine Levels and Cardiovascular Disease: Results of a Genome-Wide Association Study. *J. Hartiala[1], W.H. Tang[2], Z. Wang[2], S.L Hazen[2], H. Allayee[1].* 1) Department of Preventive Medicine, University of Southern California, Los Angeles, CA 90033; 2) Department of Cardiovascular Medicine, Cleveland Clinic, Cleveland, OH 44195.

We recently identified several metabolites generated through gut microbiome and hepatic-mediated metabolism of dietary choline and L-carnitine as novel risk factors for cardiovascular disease (CVD). Elevated levels of trimethyl amine N-oxide (TMAO) in particular were found to be pro-atherogenic in mice and humans but the role of betaine, which can also be generated from choline, in CVD is less clear. Following our recently published comparative genomics analysis of TMAO, we sought to identify the genetic determinants of plasma betaine levels. In stage 1, a GWAS with ~1900 subjects from the GeneBank study identified 4 loci on chromosome (chr) 1q32, 2q34, 5q14, and 16q24 that were significantly or suggestively associated with betaine levels. In stage 2 with ~2000 additional GeneBank subjects, 2 independent SNPs on chr 5q14 (rs617219 and rs16876503) and rs715 on chr 2q34 demonstrated association with betaine, which became even more significant in all ~4000 subjects (p=6.0E-9 - 9.0E-13). A weighted genetic risk score with these 3 SNPS also yielded highly significant association with betaine (p=1.1E-23). The SNPs on chr 5q14 are located near the BHMT gene (rs617219), which catalyzes the simultaneous conversion of betaine and homocysteine to dimethylglycine (DMG) and methionine, respectively, and the DMGDH gene (rs16876503), which further metabolizes DMG to sarcosine and subsequently glycine. Of these additional metabolites, rs617219 significantly lowered DMG levels (p=4.0E-4) whereas rs16876503 modestly increased methionine (p=0.04). By comparison, rs715 on chr 2q34 is located within the CPS1 gene, which is the rate-limiting enzyme in the urea cycle. In addition to the association with betaine, rs715 increased ornithine levels (p=9.0E-3) and decreased citrulline (p=3.0E-4), arginine (p=4.0E-3), and urea (p=0.07). These results suggest that rs715 reduces flux down the urea cycle by decreasing CPS1 activity and/or expression since the strongest effects were on the most proximal urea cycle metabolite (citrulline) with increasingly weaker effects on more distal metabolites (i.e. arginine and urea). Lastly, of the betaine-associated SNPs on chr 2q34 and 5q14, rs715 was significantly associated with decreased risk of CVD (OR=0.71, 95% CI 0.58-0.87; p=0.004) in all ~10,000 GeneBank subjects. Taken together, these studies provide evidence for a genetically mechanistic link between betaine metabolism, the urea cycle, and CVD in humans.

2092M

Genome-wide association study identifies novel susceptibility loci for venous thromboembolism in African Americans. *W. Hernandez[1], E.R. Gamazon[1], A. Konkashbaev[1], R.A. Kittles[2], L.H. Cavallari[3], M.A. Perera[1].* 1) The University of Chicago, Department of Medicine, Section of Genetic Medicine, Chicago, IL; 2) University of Illinois, Department of Medicine, Institute of Human Genetics, Chicago, IL; 3) University of Florida, Department of Pharmacotherapy and Translational Research, College of Pharmacy, Gainesville, FL.

Venous thromboembolism (VTE) is a chronic multifactorial disease encompassing deep vein thrombosis (DVT) and pulmonary embolism (PE). It is a major public health burden and the third most common life-threatening cardiovascular condition resulting in high rates of hospitalization and mortality. In the US, African Americans (AAs) have the highest incidence and mortality rates. Although studies suggest that VTE is highly heritable, few associations between VTE risk and genetic variants have been established. Furthermore, the role of these polymorphisms in the risk of VTE among AAs is conflicting at best. The lack of genetic susceptibility to VTE among AAs, in great part, may be due a combination of identifying susceptibility genetic variants in Caucasian cohorts and subsequently testing these variants in AAs, as well as, the very low frequency of these variants among AAs. In this study, we present preliminary findings from the first genome-wide association study (GWAS) and risk of VTE conducted exclusively on AAs (137 cases and 437 controls). Our results revealed 15 independent signals that reached a genome-wide significance level of 5.0×10-8. Five variants in PTGER3 (rs570021), PPP1R12B (rs705744), SLC22A3 (rs9364552), SLC39A11 (rs951284), and MGST1 (rs2975139) and eight intergenic variants (rs7503127, rs7669402, rs7729075, rs9276835, rs11219138, rs2535607, rs2749490, rs711831) were associated with increased risk of VTE (ORs= 2.2 - 2.6). Two variants, rs10234060 and rs711831, were found to decrease risk of VTE (OR=0.40 and 0.44, respectively). These ORs are larger than those previously identified in GWASs on VTE risk among Caucasians. In addition, we conducted bioinformatics analysis of the top signals to identify potential expression quantitative trait loci (eQTLs) utilizing whole blood from AAs. The risk variant, rs9364552 located in SLC22A3 (OR=2.3; P=4.30×10-8), was found to be a cis-eQTL (β=-0.19; P=0.02) for plasminogen (PLG) which is crucial in breaking down fibrin in blood clots. Individuals carrying the rs9364552 minor allele would express lower levels of PLG, consequently increasing their risk of VTE. Furthermore, SLC22A3 and PLG have been shown to affect lipoprotein(a) levels - an independent risk factor for VTE. Currently, we are in the process of validating these finding in an independent AA cohort of VTE. Our study provides new molecular insight into the underlying mechanism that may regulate VTE susceptibility in AAs.

2093S

Nervous system-related loci determining sex-difference in blood pressure reactivity to cold stress in both Chinese and Whites. *Q. Zhao[1], X. Kong[1,2], TN. Kelly[1], C. Li[1], D. Gu[3], J. He[1].* 1) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Endocrinology, China-Japan Friendship Hospital, Beijing, China; 3) State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center of Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

Exaggerated blood pressure (BP) response during the cold pressor test (CPT) has been suggested as a risk factor for developing cardiovascular disease. Women were reported to exhibit greater BP increase than men during the CPT in populations of different ethnicities. The aim of the study was to identify sex-specific genetic determinants for BP reactivity to cold stress. The discovery sample was from the Genetic Epidemiology Network of Salt Sensitivity (GenSalt) study, which was conducted among Han Chinese. During the CPT, BP was measured prior to and after the participants immersed their right hand in ice water for 1 minute. A total of 1,881 GenSalt participants completed the CPT and were genotyped using the Affymetrix SNP array 6.0. A genome-wide association analysis was conducted to examine the interaction effect of SNPs and sex on BP reactivity during the CPT. A total of 13 loci showed potential sex difference in the association with BP reactivity variables (P for interaction < 1.0×10^{-5}). These loci were further tested among 1,448 participants of European ancestry from the Coronary Artery Risk Development in Young Adults (CARDIA) study, in which a similar cold stress test was conducted. Five of the 13 loci (1p32.2, 2q33.1, 3q26.31, 5q15, and 13q33.3) identified in the GenSalt study showed potential transethnic replication in the CARDIA study (P for interaction < 0.1). Four of the five loci (1p32.2, 3q26.31, 5q15, and 13q33.3) include nervous system-related genes which have been implicated in neurological disorders, such as Parkinson's disease (*CDCP2* in 1p32.2 and *CAST* in 5q15), bipolar disorder (*TMEM212* in 3q26.31), and cerebral calcification (*COL4A1* in 13q33.3). Stratified analyses by sex for significant interactions between sex and SNPs were further conducted. For example, the index SNP rs3766457 of the locus 1p32.2 was associated with lower pulse pressure (PP) response in men but greater PP response in women (-2.64 vs. 1.48 mm Hg for each minor G allele) in the GenSalt study. Meanwhile, this SNP was associated with lower diastolic BP response in men but greater response in women (-2.42 vs. 4.02 mm Hg for each G allele) in the CARDIA study. In conclusion, our study provides the first evidence for the transethnic replication of sex-specific genetic factors for BP response to cold stress and implicates multiple potential nervous system-related genes in determining the sex difference in BP reactivity to stress.

2094M

Finding low-frequency causal genetic variants for lipids by genotyping subjects with extreme HDL-c levels. *W. Zhou[1], OL. Holmen[2,3], H. Zhang[1], J. Chen[1], M. Boehnke[4], GR. Abecasis[4], K. Hveem[2,5], CJ. Willer[1,6,7].* 1) Department of Internal Medicine, Division of Cardiology, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America; 2) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, 7600 Levanger, Norway; 3) St. Olav Hospital, Trondheim University Hospital, Trondheim, Norway; 4) Center for Statistical Genetics, Department of Biostatistics, University of Michigan School of Public Health, Ann Arbor, Michigan, 48109, United States of America; 5) Department of Medicine, Levanger Hospital, Nord-Trøndelag Health Trust, 7600 Levanger, Norway; 6) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, Michigan, 48109, United States of America; 7) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America.

Genome-wide association studies have identified more than 157 loci associated with lipid levels, which are treatable and heritable risk factors for cardiovascular diseases. Most of these variants are common with modest effect sizes. Missing heritability of blood lipid levels suggests less frequent (1 - 5% minor allele frequency) or rare (< 1% minor allele frequency) coding variants may exist for lipids. To detect low-frequency causal variants, samples with extreme phenotypes likely have increased power compared to population-based. We successfully genotyped 1,751 non-MI samples with extremely high HDL-c levels, 1,744 non-MI samples with extremely low HDL-c levels from the Norwegian HUNT-study using the Illumina HumanExome Beadchip, allowing for direct genotyping of 72,399 polymorphic coding variants. We evaluated the power of the extreme HDL samples (N=3,495) in comparison to a genotyped set of non-extreme samples (N = 3,495 from the same HUNT cohort) to detect the known HDL variants and genes. Single SNP association results for the 50 HDL known variants are more significant using extreme HDL samples than population-based samples (Pwilcox = 5.22×10^{-8}), as were the gene-based burden test results for the 11 known HDL genes (Pwilcox = 9.3×10^{-3}). Single SNP and gene-based association tests showed that no novel lipid loci were found with the extreme HDL-c samples, suggesting that even with extreme phenotypes, larger sample size or more complete genotypes from sequencing may be needed to detect novel loci.

High blood pressure (BP) is a major risk factor for cardiovascular diseases. We analyzed associations between the blood transcriptome and BP traits within large cohorts of the MetaXpress consortium by applying standardized protocols.

The study population included 4,533 individuals with available transcriptomics data from three German cohorts: Gutenberg Health Study (GHS), Cooperative Health Research in the Region of Augsburg (KORA F4) and Study of Health in Pomerania (SHIP-TREND) and one US cohort: Multi-Ethnic Study of Atherosclerosis (MESA). Expression levels were measured in monocyte (n=2,549) and whole blood cell (n=1,984) samples using Illumina HumanHT-12 BeadChip arrays. Associations with systolic BP (SBP), diastolic BP (DBP) and pulse pressure (PP) were computed by linear regression models adjusted for sex, age, BMI and technical covariates within each study. A meta-analysis was conducted within GHS and MESA using the inverse variance method. Significant associations (FDR≤0.05) were selected for replication in KORA F4 and SHIP-TREND. Genes with consistent effect directions in all four studies and p-values ≤ 0.05 in the replication cohorts were reported as candidate genes.

In total, transcripts of eight distinct genes were consistently associated with at least one of the traits SBP, PP or DBP in discovery and replication steps: *CEBPA*, *CRIP1*, *F12*, *LMNA*, *MYADM*, *TIPARP*, *TPPP3* and *TSC22D3*. Effect sizes were comparable between associations in monocytes and whole blood. In total, the candidate genes explained between 4-13%, 4-6% and 2-8% of inter-individual variance of SBP, DBP and PP, respectively.

This is the first study investigating the associations between BP traits and whole transcriptomes across different blood cell populations on a large scale. The comprehensive analyses highlight eight genes, correlated with BP.

Genetics of Plasma Lactate. *P. Balakrishnan[1], A. Tin[1], J. Pankow[2], E. Boerwinkle[3], R. Hoogeveen[4], J.H. Young[5], WH.L. Kao[1].* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) University of Minnesota School of Public Health, Minneapolis, MN 55454; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030; 4) Department of Medicine, Baylor College of Medicine, Baylor College of Medicine, Houston, TX 77030; 5) Department of Medicine, The Johns Hopkins University, School of Medicine, Baltimore, MD 21205.

Background: Type 2 diabetes affects 25.8 million of the U.S. population. Recent studies have shown that increased plasma lactate levels are associated with insulin resistance and type 2 diabetes. Plasma lactate is a measure of oxidative capacity, the ability to meet increased energy demand. The genetics of plasma lactate have not been well-characterized. **Materials and Methods:** We performed a genome-wide association study (GWAS) in the Atherosclerosis Risk in Communities (ARIC) study - an ongoing prospective epidemiological study conducted in four U.S. communities. Plasma lactate (mg/dl) was measured from blood collected at Visit 4, at which the participants' age ranged between 54-73. Single nucleotide polymorphisms (SNPs) were also genotyped from ARIC blood samples and imputation was done using the 1000 Genome (NCBI build 37 - hg 19) reference. Linear regression models of single nucleotide polymorphisms (SNPs) were assessed for association with log transformed plasma lactate, separately in European Americans and African Americans. Models were additionally adjusted for age at Visit 4, sex, ARIC center, body mass index, waist circumference and significant principal components of ancestry. The p-values from the European American GWAS SNPs with minor allele frequency >0.01 were used as input for pathway based analysis using MAGENTA. **Results:** Four SNPs reached genome-wide significance (P < 5*10-8) in the European Americans and were also associated in the African Americans based on locus specific threshold. The four SNPs are located within GCKR gene, involved in glucokinase inhibition, and PPP1R3B gene, involved in glycogen synthase inhibition. The vasoconstriction and vasodilation regulation pathway was the pathway most statistically significantly associated with plasma lactate. **Conclusions:** The genetics of plasma lactate may provide important clues regarding the pathogenesis of type 2 diabetes.

Identification of three novel genetic variations associated with electrocardiographic traits (QRS duration and PR interval) in East Asians. *J.E. Lim[1], K-W. Hong[2], J.W. Kim[3], Y. Tabara[4], H. Ueshima[5,6], T. Miki[7], F. Matsuda[4], Y.S. Cho[8], Y. Kim[2], B. Oh[1].* 1) Kyung Hee University, Seoul, South Korea; 2) Center for Genome Science, Korea Centers for Disease Control & Prevention, Division of Epidemiology and Health Index, Chungcheongbuk-do, South Korea; 3) Department of Internal Medicine, Inje University Ilsan Paik Hospital, Gyeonggi-do, South Korea; 4) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 5) Center for Epidemiologic Research in Asia, Shiga University of Medical Science, Otsu, Japan; 6) Department of Health Science, Shiga University of Medical Science, Otsu, Japan; 7) Department of Geriatric Medicine, Ehime University Graduate School of Medicine, Toon, Japan; 8) Department of Biomedical Science, Hallym University, Chuncheon, Gangwon-do, South Korea.

The electrocardiogram has several advantages in detecting cardiac arrhythmia - it is readily available, noninvasive, and cost-efficient. Recent genome-wide association studies have identified single nucleotide polymorphisms that are associated with electrocardiogram measures. We performed a genome-wide association study using Korea Association Resource data for the discovery phase (phase 1, n = 6,805) and 2 consecutive replication studies in Japanese populations (phase 2, n = 2,285; phase 3, n = 5,010) for QRS duration and PR interval. Three novel loci were identified: rs2483280 (PRDM16 locus) and rs335206 (PRDM6 locus) were associated with QRS duration, and rs17026156 (SLC8A1 locus) correlated with PR interval. PRDM16 was recently identified as a causative gene of left ventricular noncompaction and dilated cardiomyopathy in 1p36 deletion syndrome, which is characterized by heart failure, arrhythmia, and sudden cardiac death. Thus, our finding that a PRDM16 SNP is linked to QRS duration strongly implicates PRDM16 in cardiac function. In addition, C allele of rs17026156 increases PR interval (beta±se, 2.39±0.40 ms) and exist far more frequently in East Asians (0.46) than in Europeans and Africans (0.05 and 0.08, respectively).

Identify genetic risk factors for coronary collaterals in a genetically diverse population. *Z. Liu[1], L. Wang[1,2], N. Vasudeva[2], P.J. Goldschmidt-Clermont[3], M.A. Pericak-Vance[1,2], D.M. Seo[3], G.W. Beecham[1,2].* 1) Human Genetics, John T. Macdonald Foundation, University of Miami, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 3) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL.

Coronary artery disease (CAD) is the leading cause of death worldwide. Important risk factors for CAD have been identified, but they fail to explain why some occlusive CAD patients with fewer or no natural bypass collateral vessels have a lower rate of survival compared with patients with greater number of such vessels. Genetic components in combination with multiple other factors may play roles, but the genetic pre-determinant for developing coronary collateral vessels in patients is unclear, mostly due to study populations too small to represent all CAD patients. Under-represented populations, especially Hispanics, will provide additional information to study the genetic contribution to coronary collaterals formation. Toward this end, we ascertained 879 occlusive CAD patients from South Florida region and conducted a genome-wide association study. These patient samples represented the large diversity of populations in South Florida region, including Hispanic, African American and Caucasian populations. Each patient had coronary stenosis greater than 50% of at least one coronary artery. Among these occlusive CAD patients, 473 had collaterals and 406 did not. We genotyped patient samples on Affymetrix 6.0 platform and performed standard QC, followed by single genetic variant test using covariates of gender and principal components as previously identified. For single genetic variant test, SNPs rs16890371 (p = 5.58E-06), rs17497524 (p = 8.75E-06), rs10894957 (p = 8.86E-06) and rs4892107 (9.79E-06) showed top association with collateral binary trait. Furthermore, we performed gene-based test with VEGAS, and the top associated gene was C1QTNF9B (p= 2.00E-07), which passed Bonferroni corrected genome-wide significant threshold (2.8E-06); other top associated genes were SNAI3 (p= 5.31E-05), CTU2 (p = 1.53E-04), RNF166 (p = 1.56E-04) and PIEZO1 (p = 2.2E-04). In conclusion, we identified potential common SNPs and genes that are associated with collaterals in a genetically diverse population. We will further investigate genetic effects of rare variants in coronary collaterals. Studying the genetic components of coronary collaterals allows us to understand why there are differences between occlusive CAD patients of developing a sufficient collateral circulation, therefore make it possible to develop adjuvant treatment to increase CAD patient survival rate through manipulating collateral process.

2099S

Meta-analysis of Variants on the Exome Chip in 120,700 Individuals of European Ancestry Identifies Multiple Rare and Common Loci for Blood Pressure. *C. Liu[1], A.T. Kraja[2], J.A. Smith[3], J.A. Introduction: High blood pressure (BP) or hypertension is a major risk factor for cardiovascular disease. Previous genome-wide association studies (GWAS) have identified > 60 genetic loci for BP. However, most of the published variants are non-coding and explain a small proportion of BP heritability. Goal: To investigate the role of coding variation on interindividual variability in BP (systolic, diastolic, mean arterial, and pulse blood pressure). Methods: We genotyped ~250,000 mostly coding variants in 120,700 individuals of European ancestry using the Infinium HumanExome BeadChip. Association analyses were conducted using the seqMeta software in each of 15 participating studies and results were combined by fixed effect meta-analysis. Array-wide statistical significance was defined as $p < 5 \times 10\text{-}7$. Conditional analyses were performed to identify independent signals at known or novel loci. Results: Our analyses identified new associations of common variants (minor allele frequency or MAF > 5%) at known and novel loci, in addition to low-frequency (MAF 1- 5%) and rare (MAF < 1%) variants at novel loci. Significant novel associations ($p < 5\times10\text{-}7$) were discovered for common variants in several genes with influences on kidney function, erythrocyte measures, and cardiomyopathy: RGL3 (missense), PCNXL3 (intronic), TBX2 (intronic), TNNT3 (intronic), PHF19 (upstream), RABEPK (missense), and PRDM16 (missense). Among low-frequency and rare variants, novel associations were found at NPR1 (MAF 0.013, missense, $p = 8\times10\text{-}7$ DBP) and DBH (MAF 0.005, missense, $p = 7\times10\text{-}7$ MAP). Npr1 knockout has previously reported to result in higher BP in a mouse model, and Npr1 is a receptor for atrial and brain natriuretic peptides which regulate blood volume and pressure. In addition, we replicated 38 loci ($p < 7.0\times10\text{-}4$) reported in prior GWAS and candidate gene studies. Pathway analyses of top variants ($p < 1\times10\text{-}4$) showed enrichment for the angiotensin system. Several significant variants are in high LD with variants that reside in regulatory marks, which may affect promoter activity or distal regulation. Conclusion/Discussion: We have identified novel associations of low-frequency and rare variants, as well as common variants in coding genomic regions for BP phenotypes that may further elucidate novel biology related to BP regulation. Our findings suggest there are additional associations to be discovered by leveraging data from coding regions and low frequency variants.

2100M

GWAS of Serum (25(OH) Vitamin D levels in a Punjabi Sikh Diabetic Cohort. *B.R. Sapkota[1], G. Priamvada[1], A. Bjonnes[2], P.R. Blackett[1], R. Saxena[2], D.K. Sanghera[1].* 1) Department of Pediatrics, College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Broad Institute of Massachusetts Institute of Technology and Harvard, Cambridge, MA.

Vitamin D, 25-hydroxy-vitamin D [25(OH)D] deficiency is associated with multiple medical complications, including musculoskeletal, inflammatory, malignancy and cardiovascular risk. Earlier, we reported a high prevalence of 25(OH)D deficiency (<50nm/L) associated with a significant increase in cardiovascular risk factor including obesity, hypertension, and type 2 diabetes in Punjabi Sikhs from the Asian Indian Diabetic Heart Study (AIDHS); and 82% of diabetic patients were 25(OH)D deficient compared to 64% healthy controls. In this study, we investigated the relationship of serum 25(OH)D with cardiometabolic risk and performed the first GWAS and meta-analysis to identify gene variants influencing 25(OH)D deficiency in AIDHS. Our discovery GWAS of 1,616 individuals (842 cases and 774 controls) was followed by Stage 1 replication of 67 top signals ($P<10^{-5}$) in an additional Sikhs (n=2,386). On combined discovery and Stage 1 meta-analysis (n= 4,002), we identified a novel locus represented by *IVL* gene in association with serum 25(OHD) levels ($\beta = 0.10$, $p=3.1 \times 10^{-6}$) after adjustment with age, sex and type 2 diabetes status. These findings are currently being replicated in other independent larger datasets. Our results also confirmed a previously reported association with 25(OH)D represented by rs2282679 at the *GC* gene (4q12.13) with ($\beta = -0.13$, $p=3.0 \times 10^{-4}$) in Sikhs. The *IVL* gene, located on chromosome 1q21.3, encodes involucrin. Both *IVL* and *GC* genes are implicated in the synthesis of vitamin D. Genetic variation in the 25(OH) D pathway may have a significant impact in the observed deficiency of vitamin D, which could be synergistically contributing to increased cardiometabolic risk in this population. Taken together, the identification of a new locus in a vitamin D pathway gene for influencing serum 25(OH)D levels may have important clinical implications and should be replicated in other independent sample sets. This study was supported by NIH grants -R01DK082766 (NIDDK) and NOT-HG-11-009 (NHGRI), and VPR Bridge Grant (OUHSC).

A smoking stratified meta-analysis of peripheral arterial disease identifies associations and interactions with SNPs near genes implicated in nicotine dependence. *N.R. van Zuydam[1,2], M. de Andrade[3], G. Thorleifsson[4], E. Vlachopoulou[5], E. Ahlqvist[6], V. Salomaa[7], S. Gretarsdottir[4], H. Colhoun[2], I.J. Kullo[3], GoLEAD and SUMMIT.* 1) WTCHG, Oxford University, Oxford, Oxfordshire, United Kingdom; 2) Medical Research Institute, University of Dundee, UK; 3) College of Medicine, Mayo Clinic, Rochester MN, USA; 4) deCODE Genetics, Reykjavik, Iceland; 5) University of Helsinki, Finland; 6) Lund University, Malmö, Sweden; 7) National Institute for Health and Welfare, Helsinki, Finland,.

Peripheral arterial disease (PAD), a morbid complication of nicotine addiction, affects more than 200 million people worldwide. Smoking increases the risk of PAD up to 10 fold and there is evidence that there may be different pathways contributing to the disease in smokers compared to non-smokers, in whom the major risk factor is diabetes. There are two established loci for PAD from genome wide association studies: a genome wide significant (p<5e-8) signal near *CHRNA3* and another signal (p<5e-7) in the 9p21.3 region. The lack of additional associations may be due to the highly polygenic architecture of PAD. To identify variants specifically associated with PAD in smokers and non-smokers we performed a smoking status stratified meta-analysis and also performed a smoking interaction analysis to identify variants that may interact with smoking status to modify the risk of PAD. We combined summary statistics in a fixed effects meta-analysis for 2,356,286 SNPs from 4,544 PAD cases and 30,404 PAD controls - of whom 3,535 cases and 20,212 controls were smokers. We also performed an interaction analysis of allelic effects in smokers vs. non-smokers. The top SNP in smokers was rs1051730 (p=7.2e-7), near *CHRNA3*, that is established for PAD and is associated with nicotine dependence and smoking quantity. The previously reported signal in the 9p21.3 locus, represented by rs10757269, was also associated with PAD in smokers (OR=1.18, p=2.5e-6). The smoking interaction analysis highlighted signals that had large effect sizes in smokers but little or no effect in non-smokers. Rs2076156 (OR= 2.4, p=1.1e-4, phet=3.5e-6), near *BIK*, rs12593396 (OR=1.46, p=4.2e-6, phet=1.3e-5), near *ADAMTS17* and rs11214800 (OR=1.3, p=2.6e-4, phet= 2.7e-5), near *HRT3A* were associated in PAD in smokers and showed evidence for interaction with smoking status. The expression of *BIK* is directly affected by cigarette smoking, while SNPs near *ADAMTS17* have been shown to interact with smoking status to affect blood pressure and SNPs in *HRT3A* have been associated with smoking quantity. Our analyses stratified on smoking status highlight biologically plausible signals related to smoking and nicotine dependence. Such analyses may help to elucidate differences in disease aetiology in smokers compared to non-smokers.

2102M

A Comprehensive 1000 Genomes-based GWAS of Coronary Artery Disease. *H.-H. Won[1,2,3,4], A. Goel[5], M. Nikpay[6] on behalf of the CARDIoGRAMplusC4D Consortium.* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 2) Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA, USA; 3) Department of Medicine, Harvard Medical School, Boston, MA, USA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 5) Division of Cardiovascular Medicine, Radcliffe Department of Medicine, The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 6) Ruddy Canadian Cardiovascular Genetics Centre, University of Ottawa Heart Institute, Ottawa, Canada.

Enhanced coverage of genetic variation provided by a 1000 Genomes imputation training set may allow detection of additional common and uncommon genetic variants associated with coronary artery disease (CAD). The CARDIoGRAMplusC4D consortium has assembled 60,801 cases and 123,504 controls for a GWAS of CAD with 1000 Genomes imputed data. Forty-eight case-control studies contributed to the meta-analysis, 77% of European ancestry, 13% and 6% of South and East Asian ancestry with smaller numbers of Hispanic and African Americans. Cases were identified with an inclusive CAD phenotype (e.g. MI, ACS, chronic stable angina). After filtering very low frequency and poorly imputed variants, 9.4 million variants (91% SNPs, 9% indels) of which 29% were lower frequency variants ($0.005 < MAF < 0.05$) were available for meta-analysis. Significant associations ($p < 5 \times 10^{-8}$) with CAD were detected for 2,163 variants (8% indels) with a low false discovery rate (q-value $< 2.2 \times 10^{-4}$). These variants mapped to 42 loci, of which 33 had been previously reported with GWAS levels of significance. Key SNPs in *LPA* and *APOE* with low MAF (0.008 - 0.03) and moderate imputation quality (0.80 - 0.93) that had eluded previous GWAS showed strong associations. Nine novel loci were identified with imputation qualities ranging from 0.78 to 0.99 and MAF from 0.02 to 0.45. Conditional association analyses identified 88 variants in GWAS significant loci that explained 13% of CAD heritability; 85 variants in 73 loci (q-value < 0.05) explain a further 7% of CAD heritability. Thirteen percent of the jointly associated variants were indels compared to 9% of all the variants in the meta-analysis ($p = 0.04$). The variants preferentially clustered within or close to genes ($p = 1.3 \times 10^{-6}$); only two variants directly disrupt protein function (APOE and ZC3HC1). Ninety-two percent of the associated variants were common ($MAF > 0.05$) suggesting that low-frequency, high-penetrance variants explain little of the heritable risk of CAD. Our findings demonstrate the value of using a global imputation training set to integrate data from different ancestry groups and enhance coverage of low allele frequency and incompletely tagged variants.

Exome-wide association study of blood lipid levels and positive selection of lipids associated genes in Asian population. *H. Zhang[1], Y. Yang[2], W. Zhou[1], M. Yang[1], O.L. Holmen[3], K. Holmen[3], P. Sham[4], K.S.L. Lam[5], K. Mohlke[6], E. Chen[1], W. Gao[7], Y. Zhang[2], M. Xu[7], S. Ganesh[1,9], C.J. Willer[1,8,9].* 1) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, Michigan, USA; 2) First Hospital, Peking University, Beijing, China; 3) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 4) Centre for Genomic Sciences, Jockey Club Building for Interdisciplinary Research; State Key Laboratory of Brain and Cognitive Sciences, and Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China; 5) Department of Medicine, The University of Hong Kong, Hong Kong SAR, China; 6) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 7) Third Hospital, Peking University, Beijing, China; 8) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, Michigan, USA; 9) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, USA.

Cardiovascular disease (CVD) is the leading cause of death globally. Circulating blood lipids are heritable, treatable, risk factors for cardiovascular disease. Over the past six years, genome-wide association studies (GWAS) have identified 157 loci associated with plasma lipid levels. However, most of the GWAS were conducted on individuals of European descent, and so the degree to which knowledge gained from these studies is applicable to other populations has not been systematically investigated.

To have a better understanding of the global genetic variants associated with blood lipid levels, we conducted an exome-wide association study in samples from the Chinese population. In this study, we tried to answer three questions. (1) Whether the known lipids associated genes/variants were associated with blood lipids levels and have similar effect size in Asian samples? (2) Are there any novel genes/variants, especially low-frequency and rare variants, that are associated with blood lipid levels? (3) Whether the lipids-associated genes were affected by positive selection during evolution?

In the analysis, many of the known lipids associated loci/variants were also associated with blood lipids in our samples, and have similar effect size. Heritability analysis indicated that low-frequency and rare Asian-specific variants contribute a considerable proportion of the heritability, however, we could not identify any novel genes or variants that reached exome-wide significance. The rare variant, p.Leu3548Ile in *DNAH17* approached exome-wide significance ($P = 3 \times 10^{-7}$) but we could not identify sufficient copies of this variant in three additional East Asian studies to assess association in an independent cohort. We also identified several Asian-specific variants in known lipids associated loci (*APOA5*, *APOB* and *PCSK9*) that also reached genome-wide significant level. Using data from the 1000 Genomes Project, we found that lipid genes have a higher Fst between Asian and European populations than expected by chance. By estimating Fay and Wu's *H*, we also find these lipid genes tend to have a higher proportion of derived alleles in the Asian population. These suggested some lipids genes diverged quickly in Asian populations and may be driven by positive selection during evolution.

2104M

Genome-wide association analysis for chronic venous disease. *D. Ellinghaus[1], A. Fiebig[1], E. Ellinghaus[1], F. Lai[1], P. Krusche[2], N. Frings[2], C. Schreiber[3], S. Nikolaus[3], C. Gieger[4], W. Lieb[5], P. Rosenstiel[1], S. Schreiber[1,3], A. Chronic venous disease (CVD) is one of the most common vascular abnormalities, especially in Northern and Western Europe, with a prevalence of up to 20% in Northern and Western Europe. According to the CEAP guidelines, CVD comprises those clinical entities that are characterized by visible venous ecstasies but which are not associated with an identifiable mechanism of venous dysfunction. CVD represents a summary term comprising patients with either simple varicose veins (VV) or chronic vein insufficiency. The underlying etiology and pathophysiology of CVD are still poorly understood. A genetic component has been proposed for many years, strongly indicated by reports on familial clustering and twin studies. The narrow-sense heritability of VV and CVD has recently been estimated to equal 18.5%; and 17.3%, respectively, in a large sample of affected nuclear families from Germany. So far, no gene has been identified as a susceptibility factor for PVV. To further our understanding of the genetic etiology of CVD, we undertook the hitherto first genome-wide association study (GWAS) for this multifactorial condition. In total, 2,265 patients were recruited through local outpatient services in Germany. We performed genome-wide SNP genotyping of 323 unrelated German CVD cases and 4,619 healthy control individuals using Affymetrix SNP arrays, followed by replication in 1,942 cases and 3,101 controls from Germany. We identified two new susceptibility loci with genome-wide significant evidence of association ($p<5\times10^{-8}$), as well as one additional suggestive locus with $p<2\times10^{-7}$. From these analyses we are able to draw insight into the biological underpinnings of CVD.

Background: Large scale genome-wide association studies (GWAS) have identified over a hundred loci associated with blood lipid levels, and related cardiovascular traits in a cross-sectional setting. However, very few genetic association studies have focused on long-term changes in blood lipid levels. Methods and Results: Participants from the Northern Swedish GLACIER Study were genotyped with the MetaboChip array. Main effects of variants mapping to previously established lipid loci (n=9,898 SNPs) were estimated with linear regression models by fitting the lipid levels at follow-up as the dependent variables and conditioning on the corresponding baseline lipid measure (N=3,492 for total cholesterol change (ΔTC) and N=2,209 for triglyceride change (ΔTG)). We sought replication in three other Swedish studies (MDC, PIVUS, ULSAM; total N~4,000) and conducted an *in silico* look-up for the top ranking lipid-change associated variants in the CARDIoGRAMplusC4D Consortium (N~190,000) to explore whether these variants also associate with coronary artery disease (CAD). In total, 227 variants associated with either ΔTC or ΔTG in GLACIER ($P<0.01$). Of these 227 variants, 189 were only associated with longitudinal changes and not with baseline lipid levels ($P>0.05$). Four single nucleotide polymorphisms (SNPs) in or near two loci, *apolipoprotein A-V* (*APOA5*) and *spalt-like transcription factor 3* (*SALL3*) reached genome-wide significance ($P<5\times10^{-8}$) and one SNP in the proximity of *apolipoprotein B* (*APOB*) reached study-wide significance ($P<5\times10^{-6}$) for TG change in GLACIER. 27 variants (in 11 loci) had statistically significant ($P<0.05$) pooled effects for lipid changes after meta-analyzing the 4 cohorts' effect estimates; seven of these loci have not been discovered in previous cross-sectional meta-analyses. A novel genetic association with CAD was observed for rs2000999 in *haptoglobin-related protein* (*HPR*), which was associated with ΔTC ($P=5.1\times10^{-3}$) and CAD ($P=3.6\times10^{-4}$). Conclusion: In the GLACIER Study, we found 4 genome-wide significant hits for TG changes. Furthermore, through meta-analysis, we identified 11 regions associated with TC and TG changes and one novel locus, *HPR*, for CAD.

Chagas disease, due to Trypanosoma cruzi, occurs exclusively in the Americas, particularly in poor, rural areas of Mexico, Central America, and South America. An estimated 300,000 new cases and 50,000 fatilities occur per year. Chronic Chagas disease cardiomyopathy (CCC) is an inflammatory cardiomyopathy that affects approximately 30% of infected individuals. Familial aggregation of CCC suggests that there might be a genetic component to disease susceptibility. We hypothesize that expression of pathogenetically relevant genes and proteins in the myocardial tissue of CCC patients is controlled by genetic polymorphisms. Systems biology is an approach that aims to model and discover interactions and emergent properties of complex biological systems, which is addressed using quantitative measures and by rigorous integration of “omics” data. On heart biopsy samples, we performed a gene expression analysis and found 4142 differentially expressed genes between CCC patients and controls. Among these genes, there are immunoglobulins, cytokines, chemokines, integrins. There are also collagen, caspase and transcription factors. Several lncRNA were also differentially expressed such as MIAT that been previously associated to an increased risk of myocardial infarction. Several pathways were associated to disease such as: 1) Calcium Regulation in the Cardiac Cell 2) Striated Muscle Contraction 3) Arrhythmogenic right ventricular cardiomyopathy. The main genes were confirmed by single gene qPCR. Using IPA software, we performed a network/pathway analysis. We identified 5 main networks associated to heart function, apoptosis, and necrosis. In order to explain the gene expression variations we looked for miRNA on the same heart samples. We found 39 miRNAs differentially expressed between CCC and controls. There are good relationships between miRNA expression levels and targeted gene expression levels. For some of the gene described in our main networks the gene expression variation may be explained by the methylation mean of the promoter region. Statistical analyses were conducted to merge proteomic, gene expression miRNA and methylation data. On the main gene candidates, case control studies were set up to identify common variants associated to severe disease. On two nuclear families including several cases and asymptomatic controls, we are performing exome sequencing to identify rare variants shared only by the severe cases.

The genetic etiology is known in less than 20% of congenital heart disease (CHD). The objective of our study was to identify genes enriched for novel and rare damaging variants in pathways crucial for cardiovascular development. We performed whole exome sequencing (Agilent Sureselect V3, Illumina HiSeq) in 6 Caucasian families, with14 affected members with CHD, 9 non-affected members and 147 unrelated Caucasian CHD subjects. Gene and protein expression data of early expressing cardiac genes were obtained and genes with novel/rare variants on highly conserved locations in these genes that were predicted damaging were prioritized. Further analysis of these 56 prioritized genes using DAVID (GO-term enrichment analysis) identified strong functional interactions amongst 9 of these genes for extracellular matrix (ECM) function. Novel/rare pathogenic variants, inherited and de novo, in these 9 genes were seen in 12.7% of the CHD cases. 3 cases showed co-segregation of mutations in more than one gene. Expression knockdown of individual genes in zebrafish embryos caused abnormal cardiac phenotypes. More severe phenotypes were seen with concurrent knockdown of more than one gene supporting a multigenic etiology for CHD. Our study identifies novel variants in functionally interacting ECM genes that contribute individually or in combination to CHD.

2108M

Transcriptome-wide single-cell gene expression and genetic variation analyses of metabolic stress response in macrophages reveal functionally relevant genetic cues in atherosclerosis. *S. Sauer[1], C. Fischer[1], M. Metsger[1], S. Bauch[1], M. Boettcher[1], P. Grote[1], M. Kliem[1], A. Ibanez[2], R. Steinhoff[2], R. Zenobi[2].* 1) Max-Planck-Institute for Molecular Genetics, Berlin, Germany; 2) ETH Zurich, Zurich,. Switzerland.

Metabolic and cardiovascular diseases represent major health problems these days. Recent unbiased genome-wide (epi-) genetic variation and transcriptomics studies led to a number of potentially causative factors that require further study. Beyond possibly gaining mechanistic insights, mapping of disease-associated or correlated factors to molecular networks and functional pathways resulted in a comprehensive, holistic view of complex physiological homeostasis. Here, we show the potential of applying single-cell transcriptomics to discover characteristics and so far unexplored genetic modules involved in atherogenic and inflammation processes. Using single-cell RNA-sequencing and related approaches we analysed metabolically stressed macrophages and lipopolysaccharide-treated inflamed cells. Thereby, we could define and calculate the degree of noise and flexibility in cellular transcription of genetic information, suggesting genetic buffering in stressed cells to counteract environmental stress. Furthermore, by linking genetic modules observed by co-expression events in cell sub-populations with genetic variation data derived from unbiased association-studies we could validate and functionally integrate causative factors and pathways involved in atherosclerosis processes. For example, we identified transcriptional modules, which include well known functional categories (such as genes involved in fatty acid and cholesterol metabolism, immune response, cytokine activity, NOD-like receptor signaling pathway) and previously uncharacterized co-regulated gene groups (such as members of the ZNF gene family that are associated with inflammation, and other unexpected genes including various non-coding RNAs). Importantly, our results hint to networks based on the concerted action of several transcription factors targeting specific sites in the (variable) genome, which can be exploited to develop rationale individualized therapeutic intervention. In general, integrating genetic variation and powerful functional genomics analyses provides valuable insights in the mechanisms of genetic interaction to better understand disease-processes and susceptibility, and provides avenues to develop tailor-made disease-treatments.

2109S

Identification of pathway/genes associated with Bicuspid Aortic Valve in three Caucasian Cohorts. *M. Heydarpour[1], J.G. Seidman[2], S. Prakash[3], D. Milewicz[3], Y. Bosse[4], G. Limongelli[5], S.C. Body[1], the Bicuspid Aortic Valve Consortium (BAVCon).* 1) Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) University of Texas, Houston, TX; 4) University of Laval, Quebec, Canada; 5) Monaldi Hospital, Naples, Italy.

OBJECTIVE: Bicuspid aortic valve (BAV) is observed in 0.6-1% of humans and is associated with premature aortic stenosis, aortic aneurysm and other congenital cardiac anomalies. BAV has been associated with high-penetrance rare mutations in a few families, but the majority of BAV is sporadic with unidentified inheritance. The embryologic molecular mechanisms causing BAV are unknown. The objective of this study was to identify pathways associated with sporadic BAV. METHODS: We genotyped 456 adult US Caucasians with BAV (339 males, 117 females) using Illumina Omni2.5. 5,216 Caucasians from three dbGaP cohorts were used as controls and typed with either Omni2.5 or Omni5 arrays. Quality control of the genotype data were performed using PLINK. After QC, we examined 603,499 SNPs mapped to 500kbp regions covering 16,775 genes. We used i-GSEA4GWAS and ICSNPathway software (Zhang et al. 2010, 2011) to identify gene sets associated with BAV. This method integrates gene set enrichment, linkage disequilibrium analysis, functional SNP annotation and pathway-based analysis. Permutation test and False Discovery Rate (FDR) were used for multiple testing corrections. RESULTS: Of 1,843 gene sets selected using canonical pathways, 45 were associated with BAV (FDR<0.05). Four pathways - Small GTPase mediated signal transduction (SGMST), Ras protein signal transduction (RPST), Cell recognition (CR), and Regulation of G-protein coupled receptor protein signalling (RGPCRPS), were identified as candidate pathways for BAV. The top pathway SGMST contained 44 significant genes (FDR<0.001) of which, the SNP rs2842895 in the regulatory region (promoter) had high-LD (>0.8) with rs4585612. Both SNPs were present in the region of gene RREB1. Two other SNPs (rs3360 and rs9806942) near OPCML and RGS11 were also identified as candidate causal SNPs, respectively. CONCLUSION: We identified potential candidate genes for BAV in the SGMST, RPST, CR, and RGPCRPS pathways. Both genes RREB1 and OPCML have known role in cell-contact/cell-adhesion. The top candidate gene RREB1 is a zinc finger protein involved in Ras/Raf-mediated cell differentiation by enhancing calcitonin expression. RREB1 is essential to reduce cell-cell adhesion when epithelial cells are undergoing the dynamic changes for cell shape (Melani et al., 2008). RREB1 may be biologically related to BAV but further replication and biological investigations are required to understand this potential new mechanism leading to BAV.

2110M

The multi-tissue cis-eQTL landscape in coronary artery bypass grafting patients: the STockholm Atherogenesis & Gene Expression (STAGE) study. *K. Nguyen[1], C. Molony[1], R. Dobrin[2], H. Zhou[1], L. Chen[1], E. Schadt[2,3], D. Reilly[1], J. Björkegren[2,3,4].* 1) Department of Genetics & Pharmacogenomics, Early Development and Discovery Sciences, Merck Research Laboratories, Boston, MA; 2) Department of Genetics & Genomic Sciences, Institute of Genomics & Multiscale Biology, School of Medicine, Mount Sinai Hospital, New York, NY; 3) Clinical Gene Networks AB, Karolinska Science Park, Stockholm, Sweden; 4) Cardiovascular Genomics Group, Division of Vascular Biology, Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden.

Genome-wide association studies (GWAS) have identified well over a hundred loci showing genome-wide significance for association with cardiovascular and coronary artery disease (CAD). However, with the exception of few examples such as the *SORT1* locus, the mechanisms underlying these associations are not well understood. With the aim to better comprehend the relevance of genetic variation for CAD, we here dissect the consequences of single nucleotide polymorphisms (SNPs) on gene expression in carotid plaques and other CAD-relevant tissues. Blood and biological specimen from 100 patients who underwent coronary artery bypass grafting (CABG) surgeries were collected for genome-wide genotyping and expression profiling. We performed expression quantitative trait loci (eQTL) analysis using Matrix_EQTL of 7M *1000G*-imputed variants and 40K protein-coding probe sets in individual tissues and across 7 tissue types: atherosclerotic arterial wall (AAW, n=63), internal mammary artery (IMA, n=74), liver (n=72), skeletal muscle (n=74), whole blood (n=94), subcutaneous (n=60) and visceral (n=82) fat. We identified 370,871 unique eQTLs in 7,194 genes (FDR≤0.05), present in at least 1 tissue. Initial screening against the GWAS catalog among Caucasians yielded 489 GWAS SNP-anchoring eQTLs; in 60% of these (n=302), reported genes do not contain the corresponding eQTL gene. This shows that the biological functions of association loci are often obscure, and that eQTL studies are informative resources in unveiling additional insights in the association of complex phenotypes. To understand the roles of the identified eQTLs in coronary plaques in the 100 CABG patients in STAGE, we first restricted our attention to the top ~5% (FDR≤5×10^{-10}, n=19,333) that are putatively functional (contain SNPs in coding/regulatory or ncRNAs regions, n=7,157) and are not present in population negative controls (GTEx v.1) (335 genes in 7,076 eQTLs). Gene ontology enrichment analysis of the top cis-genes confirms the importance of metabolic/biosynthetic processes of lipids, lipoprotein and fatty acids (in liver, muscle and whole blood), and antigen processing and peptidase activities in the context of inflammatory response (in liver and visceral fat). This work provides an improved understanding of the underlying genetic mechanisms and multi-tissue eQTL landscape in CAD patients, paving the path forward to informed molecular validations for the disease biology.

2111S

Metabolomic profiling identifies markers of cardiac atrial septal defects. *H. Wang[1,4], D. Craig[3], C. Haynes[3], W. Kraus[3], S. Shah[2,3].* 1) Department of Surgery, Duke University Medical Center, Durham, NC; 2) Department of Medicine, Duke University Medical Center, Durham, NC; 3) Duke Molecular Physiology Institute, Duke University, Durham, NC; 4) Department of Computational Biology and Bioinformatics, Duke University, Durham, NC.

Atrial septal defect (ASD) is among the most common congenital heart malformations in adults. Although genetic variants have been found to be associated with ASD, the molecular etiology of the disease is not fully understood. Metabolic profiling of peripheral blood has been used in cardiovascular research to discover new risk factors and pathways associated with disease. We performed metabolomic profiling of adult patients in the CATHGEN biorepository at Duke University. Targeted, quantitative profiling was performed of 68 metabolites using flow injection tandem mass spectrometry (MS). Two groups of patients were profiled: 40 ASD cases and 40 non-ASD controls matched on sex, race and renal function. Principal component analysis and factor analysis identified a total of eight latent factors corresponding to highly correlated metabolite groups. Elevated levels of three factors were associated with ASD: long-chain dicarboxylacylcarnitines (factor 2, p = 0.045), short-chain dicarboxylacylcarnitines (factor 3, p = 0.01) and branched-chain amino acids (factor 6, p = 0.047). In multivariate logistic regression, factors 2 and 3 were independently associated with ASD, after adjusting for baseline medical conditions such as history of myocardial infarction, number of diseased coronary arteries and history of diabetes (factor 2, odds ratio 6.6; 95% CI 1.6 - 36.9, p = 0.02; factor 3, OR 2.19; 95% CI 1.14 - 4.68, p = 0.03). Using these two factors as predictors, probit regression with cross-validation using random resampling achieved a mean accuracy of 0.72, sensitivity of 0.70, precision of 0.76 and F1 score of 0.72. Both of these metabolite factors have been implicated in CAD and incident cardiovascular events, although neither had been profiled in ASD or other congenital heart diseases. Variances in these metabolites may reflect similar differences in mitochondrial fatty acid oxidation, modification in peroxisomal metabolism or endoplasmic reticulum stress that may occur with ASD.

2112M

A Gene Network approach to Rare Variant analysis. *T.G. Richardson[1], N.J. Timpson[1], C. Campbell[2], T.R. Gaunt[1].* 1) MRC Integrative Epidemiology Unit, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) Intelligent Systems Laboratory, University of Bristol, Bristol, United Kingdom.

Background: Current endeavours in rare variant analysis are typically underpowered when investigating signals from individual genes. We undertook a novel approach to rare variant analysis by utilising knowledge regarding interactions and relationships between sets of genes. Methods: Using the resource STRINGdb we identified 263,666 human protein-protein interactions that had experimental evidence and applied the ClusterOne algorithm to construct 2,099 Gene Networks. The variant effect predictor (VEP) was used enrich our analysis by identifying 116,621 unique variants in the UK10K sequence data predicted to be nonsynonymous. Variants within the same network were collapsed together and analysed with lipid traits using the sequence kernel association test (SKAT) after applying a threshold of 5% and 1% minor allele frequency. Results: Three networks provided evidence of association after correcting for multiple comparisons and were evaluated further using single gene analyses and permutation tests. The most statistically robust evidence found that variants from within 3 genes (PDE5A, MRVI1 and NPR1), whose products were known to interact, collectively contributed to an observed signal with LDLc levels (P = 5.30 x 10-6). Conclusion: We have undertaken a novel approach to rare variant analysis which examines the combined effect of variants from across genes which have been shown to interact according to experimental evidence. We identified networks which provide evidence of association with lipids traits which suggest further analysis of polygenic effects across networks and pathways should prove vital in better understanding the genetic architecture of complex disease.

2113S

WES reporting of mutations from cardiovascular "actionable" genes in clinical practice: a key role for UMD knowledgebases. *A. PINARD[1,2], N. HANNA[3,4], C. GUIEN[1,2], L. FAIVRE[5,6], G. JONDEAU[7,4], C. BOILEAU[3,4], C. BEROUD[1,2,8], G. COLLOD-BEROUD[1,2].* 1) Inserm UMR_S910, Marseille, France; 2) Aix Marseille Université, GMGF, 13385, Marseille, France; 3) Department of Genetics, Bichat University hospital, 46 rue Henri Huchard, 75018 Paris France; 4) Inserm U1148, Bichat University hospital, 46 rue Henri Huchard, 75018 Paris; 5) Centre de Référence Anomalies du Développement et Syndromes Malformatifs et FHU TRANSLAD, CHU Dijon, Dijon, France; 6) EA 4271 Génétique des Anomalies du Développement, Université de Bourgogne, Dijon, France; 7) Cardiology Department, Bichat University Hospital, 46 rue Henri Huchard, 75018 Paris; 8) APHM, Hopital d'Enfants de la Timone, Département de Génétique Médicale et de Biologie Cellulaire, 13385, Marseille, France.

High throughput next generation sequencing (NGS) such as whole exome sequencing (WES) are being rapidly integrated into clinical practice. The use of these techniques leads to unexpected findings for which decisions about the reporting to the patient need to be made. In the USA, the American College of Medical Genetics and Genomics (ACMG) recently published recommendations for the reporting of incidental findings in clinical WES and WGS for 58 "actionable" genes. Among these, seven are involved in Marfan Syndrome And Associated Pathologies (MSAAP) including familial thoracic aortic aneurysms and dissections and Loeys-Dietz syndromes associated with mutations in *FBN1, TGFBR1* and *2, ACTA2, SMAD3, MYH11* and *MYLK*. MSAAP are autosomal dominant disorders and are recommended to be reported in clinical practice because medical flollowup and treatment can improve survival and quality of life. In an effort to standardize information regarding mutations in the *FBN1* gene, we developed in 1995 a locus specific database with the generic system called Universal Mutation Database (UMD). Subsequently, databases for *TGFBR2* and *FBN2* genes were been created. All are now recognized as international references. To be exhaustive and facilitate NGS analysis, we have now developed databases for the *ACTA2, SMAD3, MYH11* and *MYLK* genes. They contain all known mutations collected from literature and through direct collaborations with diagnostic laboratories: *FBN1* (3200 entries), *TGFBR2* (300 entries) and the new *TGFBR1* (125 entries), *ACTA2* (203 entries), *SMAD3* (61 entries), *MYH11* (44 entries) and *MYLK* (13 entries). Each mutation is annotated at gene, protein and clinical levels. Several tools are also available for studying and extracting data of interest as well as complex algorithms to predict: pathogenicity of missense variations; consequences of variations on splicing signals, or to search for genotype-phenotype correlations. These databases are updated regularly and curated by experts. They are accessible at: http://www.umd.be/. Databases of variants are now essential in the context of NGS as more and more diagnostic laboratories worldwide are using these technologies without specific expertise for each gene. Relying on UMD knowledgebases, they could rapidly collect relevant information for data interpretation, report more accurate results and save time.

2114M

Sequencing of 2,000 Norwegians to evaluate genetic architecture of lipid and MI-associated variants. *C. Willer[1,2,3], W. Zhou[1], O. Holmen[4], H. Zhang[1], J. Chen[1], D. Hovelson[2], M. Boehnke[5], G. Abecasis[5], K. Hveem[4].* 1) Int Med & Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 5) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Genome-wide association scans have been successful at identifying novel loci and genes associated with blood lipid levels and coronary artery disease. However, these approaches have not adequately tested the role of low frequency variants. To attempt to identify low frequency variants with large effect on risk of myocardial infarction or impact on blood lipid levels, we performed low-pass whole genome sequencing of 2,000 individuals from Nord-Trondelag, Norway. We selected individuals with medical-record confirmed MI with early-onset (< 58 years for men and < 68 years for women). For each MI case, we selected one sex- and birth-year matched healthy control from 70,300 potential controls by excluding individuals with a variety of cardiovascular and metabolic conditions. We opted to perform low-pass whole genome sequencing for the following reasons; i. increased power relative to higher-depth whole genome sequencing in fewer samples, ii. utility of whole genome sequence data for imputation into GWAS samples relative to exome-sequence data and iii. to assess low frequency non-coding variation. Our first data freeze of 1,237 individuals (626 MI cases and 611 controls) did not identify any novel genes or genetic variants associated with lipids or MI, but did identify association at several known loci. Furthermore, we identified eight low-frequency non-coding variants (freq < 5%) with $P < 5\times10^{-7}$ (including chr4:76188636 near PARM1 with $P = 7\times10^{-8}$ with total cholesterol) that were not previously evaluated in large-scale GWAS studies and may represent novel low frequency large-effect loci.

2115S

Whole exome sequencing highlights the importance of the CRELD1 interactome in atrioventricular septal defect in Down syndrome. *C.M. Ackerman[1], H. Li[2], D. Klinedinst[2], R. Polk[2], S. Blackshaw[2], H. Corbitt[1], R.H. Reeves[2], C.L. Maslen[1].* 1) Knight Cardiovascular Institute, Oregon Health & Science University, Portland, OR; 2) Department of Physiology and the Institute for Genetic Medicine, School of Medicine, Johns Hopkins University, Baltimore, MD.

Atrioventricular septal defect (AVSD) is a congenital heart defect (CHD) frequently associated with Down syndrome (DS). Children with DS account for 65% of all cases of AVSD and have a 2000-fold increased risk of the defect. However, since half of all children with DS have a normal heart, trisomy 21 alone is insufficient to cause AVSD. Missense mutations in *CRELD1* are associated with AVSD in both euploid and DS populations and since disease-causing mutations tend to cluster in the same biochemical pathways, we hypothesized that AVSD-associated mutations would occur in genes within the CRELD1 interactome.

To define a CRELD1 interactome, we used a protein array to identify directly interacting proteins. We then assessed whole exome sequence data from cases and controls to test if rare variants in genes encoding proteins that interact with CRELD1 contribute to the risk of AVSD in DS. The study cohort was comprised of individuals with DS and a complete AVSD (cases) and individuals with DS and a normal echocardiogram (controls), including individuals of European Ancestry and African Americans. Missense variants were characterized as damaging, benign, or unknown based on PolyPhen2 and MutPred analyses.

Of the 33 genes we evaluated, 18 genes had at least one damaging rare variant. The majority of these genes have not been implicated in the pathogenesis of CHD, with the exception of *PTPN11*, a gene in which we previously reported mutations in individuals with non-syndromic AVSD. We detected 23 damaging variants in cases and only 3 in controls ($p<0.0001$), with the majority being missense variants. Other case-specific variants identified included one recurrent frameshift mutation in *RAB25* and a premature termination codon in *EDIL3*. There was no significant skewing of variants between genders, and inclusion of African American-specific variants did not falsely elevate the percentage of case-specific deleterious variants.

We observed that almost 17% of all cases of DS with AVSD had a damaging variant in a *CRELD1* pathway gene. The fact that we see mutations in the same genes in both euploid and DS with AVSD supports our hypothesis that the same genes involved in the pathogenesis of AVSD in DS, also contribute to AVSD in the euploid population. Further functional analysis of these *CRELD1* pathway variants will provide insight into the mechanisms that underlie heart defects during development.

Gene-centric association tests applied to cardiovascular disease using whole genome sequencing. *MAA. Almeida[1], J. Peralta[1,2], JW. Kent[1], TM. Teslovich[3], G. Jun[3], C. Fuchsberger[3], AR. Wood[4], A. Manning[5], TM. Frayling[4], P. Cingolani[6], TW. Blackwell[3], R. Sladek[7], TD. Dyer[1], AG. Commuzie[1], HHH. Goring[1], L. Almasy[1], MC. Mahaney[1], DM. Lehman[8], JE. Curran[1], G. Abecasis[3], R. Duggirala[1], J. Blangero[1].* 1) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Centre for Genetic Epidemiology and Biostatistics, University of Western Australia, WA, Australia; 3) University of Michigan, Ann Arbor, MI, USA; 4) University of Exeter, Exeter, United Kingdom; 5) Broad Institute, Boston, MA, USA; 6) McGill University, Montreal, Canada; 7) Montreal Diabetes Research Institute, Montreal, Canada; 8) University of Texas Health Center at San Antonio, San Antonio, TX, USA.

The advent of whole genome sequencing provides a unique opportunity to improve our understanding the genetic variation underlying complex diseases. As part of the T2D-GENES Consortium, we have directly sequenced 590 individuals (and accurately imputed another 448 members) from 20 large Mexican American pedigrees aiming the investigation of rare genetic variants contribution to the type 2 diabetes development. Those individuals are part of the SAFS (San Antonio Family Study) and have been extensively phenotyped during the 25 years of this project. The immense number of identified SNV imposes new statistical and analytical barriers that require the development of alternative approaches for screening of potential causal genes and pathways. We employed a variance component-based single degree-of-freedom test using an empirical gene-specific genetic relationship matrix (GRM) as the focal covariance kernel. The empirical gene-specific GRM (the GSGRM) utilizes any set of chosen variants identified in a gene or gene-pathway of interest and provides the correlation of the dosage vectors between individuals. The efficacy of this new focal kernel for explaining phenotypic variance is tested by the use of a single-degree freedom likelihood ratio test. Gene pathway definitions were obtained from the latest CytoScape database release and a GSGRM was estimated for each one of 1191 genes that constitute 9 CVD (Cardiovascular Diseases) related pathways. Each empirical kernels was tested against a set of CVD-related traits collected in the SAFS cohort. As might be expected, our top association was the LPA gene and the concentration of the apo(a) protein coded by this gene (p-value = 2.1×10-56); this is a known case of cys-regulation and serves as a positive control of our approach. We also observed a strong association between the gene PCSK9 and CVD itself (p-value = 8.2×10-5). The PCSK9 gene product plays a central role in cholesterol and fatty acid metabolism and is a major target for the new generation of anti-lipid drugs. Each variant in the gene was independently tested and two non-coding variants achieved genome-wide significance and a non-synonymous variant, rs11583680, located in first exon of this gene (p-value = 1.6×10-4) was also suggestive. Our results suggest that a pathway-filtered simple gene-based test may be useful for reducing the search space and aid the detection of specific functional variants influencing complex disease-related phenotypes.

Somatic Activating GNAQ Mutations are Frequent in Capillary Malformations (Port-Wine Stains). *M. Amyere[1], N. Revencu[2], A. Dompmartin[3], R. Healers[1], L. Boon[1,4], M. Vikkula[1].* 1) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Centre for Human Genetics, Cliniques Universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Department of Dermatology, Université de Caen Basse Normandie, CHU Caen, France; 4) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium.

Vascular malformations are localized defects of vascular development that are classified into capillary, venous, arterial, lymphatic, and combined anomalies. Capillary Malformation (CM) is the most common affecting cutaneous capillary vessels in 0.3% of newborns. These lesions can be localized or diffuse. CM most often occurs as an isolated and sporadic feature. Syndromic forms include Sturge-Weber syndrome, Klippel-Trenaunay syndrome and Parkes Weber syndrome. There is often associated soft tissue and/or bony overgrowth. In the autosomal dominant capillary malformation-arteriovenous malformation (CM-AVM), CMs increase in number with age. A third of the CM-AVM patients have an associated fast-flow anomaly, most often located in the head and neck region. CM-AVM is caused by haploinsufficiency, most likely combined with a tissular second-hit, p120-RasGAP, the protein product of RASA1. A series of Sturge-Weber syndrome and sporadic CMs were shown to harbor a non-synonymous somatic single-nucleotide variant in GNAQ, encoding guanine nucleotide binding protein. We assessed 33 fresh-frozen lesions by both Sanger sequencing on cDNA and allele-specific PCR on genomic DNA, for the presence of the c.548G>A (p.Arg183Gln) hot-spot mutation. Sixteen tissues with CMs; 5 lesions with Sturge-Weber-Syndrome; 4 lesions with CMs with overgrowth; 3 lesions with capillaro-veineuse malformation, 2 lesions with CM-AVM; 2 lesions with CM with dilated-vein and one lesion with hyperkeratotic cutaneous capillary venous malformation. A somatic mutation was detected in 18 lesions (54,5%); 5/5 (100%) of Sturge-Weber Syndrome lesions and 13/16 (81.2%) CMs. This mutation was not detected in the fifteen other lesions with other CM phenotypes (45.5%). This could be explained by the fact that normal cells can mask low-number mutant cells in the resected lesion. Targeted massive parallel sequencing of the complete coding sequences of GNAQ and RASA1 was therefore performed on the 16 negative lesions using Ion AmpliSeq Panel on PGM. Vertical coverage varied from 400x to 1550x. We did not find further evidence for the presence of the GNAQ hot-spot mutation, considering 1% as the limit for background. Whole exome sequencing is now performed in these negative tissues to identify additional causative genes. This should improve genetic classification and lead to better diagnosis, evaluation of genotype/phenotype correlation, and development of targeted therapies. (miikka.vikkula@uclouvain.be).

Molecular-genetic factors in normal and pathological angiogenesis. *I.I. Dimova[1], V.G. Djonov[2], A. Makanya[2], R. Hlushchuk[2], V. Stefanovic[3], M. Polenakovic[4], M.G. Mihailova-Hristova[1], R. Vazharova[5], L. Balabanski[5], S. Ivanov[5], D.I. Toncheva[1].* 1) Medical University Sofia, Sofia, Bulgaria; 2) Institute of Anatomy, University of Bern, Switzerland; 3) Faculty of Medicine, University of Nis; 4) Macedonian Academy of Sciences and Arts; 5) Laboratory Genomics, Malinov Hospital.

Angiogenesis is involved in many physiological processes, but also is a hallmark in the pathology of many diseases (cancer, ischemia, atherosclerosis, inflammatory diseases), in wound healing and in tissue regeneration. We aimed in studying the molecular-genetic mechanisms of angiogenesis in normal and pathological conditions. Chicken area vasculosa was used as a model for investigation of essential molecular pathways - Notch, ephrinB2/EphB4 and SDF-1/CXCR4 signaling. Glomerular sclerosis and interstitial fibrosis are characteristic angiogenic pathological changes in kidneys of patients with Balkan Endemic Nephropathy (BEN). DNA from blood samples of 22 patients was analyzed by NGS, searching for genes of predisposition. We demonstrated that Notch inhibition disturbed vessel stability and led to pericyte detachment followed by extravasation of mononuclear cells. The mononuclear cells contributed to formation of transluminal pillars with sustained intussusceptive angiogenesis resulting in a dense vascular plexus without concomitant vascular remodeling and maturation. Inhibition of ephrinB2 or EphB4 signaling induced some pericyte detachment and resulted in up-regulation of VEGFRs but with neither an angiogenic response nor recruitment of mononuclear cells. Notably, Tie-2 receptor was down-regulated, and the chemotactic factors SDF-1/CXCR4 were up-regulated only due to the Notch inhibition. Using NGS we found genetic variants with deleterious/damaging effects in three genes - CELA1, HSPG2 and KCNK5. These mutant genes in BEN patients encode proteins involved in basement membrane/extracellular matrix and vascular tone, tightly connected to process of angiogenesis. The studies contributed to elucidation of molecular mechanisms of normal angiogenesis and genetic factors predisposing to abnormal angiogenesis in glomerular sclerosis.

Genetic Variation of Scavenger Receptor Class B Type I (*SCARB1*) and Plasma Lipid Traits: An Association Study in a Nigerian Population. *V. Niemsiri[1], X. Wang[1], M.M. Barmada[1], C.H. Bunker[2], F.Y. Demirci[1], M.I. Kamboh[1].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Graduate School of Public Health, Pittsburgh, PA; 2) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

Abnormal lipid-lipoprotein levels are known to be the risk factors for cardiovascular disease. One of the genes involved in lipid metabolism is scavenger receptor class B type I (*SCARB1*), which has the main function in a selective uptake of cholesteryl esters in reverse cholesterol transport. Using Sanger sequencing, we examined 13 exons and exon-intron boundaries of *SCARB1* in 95 African Blacks from Nigeria having extreme high-density lipoprotein cholesterol (HDL-C) levels. Sequencing analysis revealed a total of 83 variants (MAF ≥5%, n = 32; MAF <5%, n = 51). Common tagSNPs (MAF ≥5%) and uncommon/rare variants identified by sequencing (n = 78), plus 69 additional common tagSNPs from HapMap project covering the entire gene and 2 additional relevant variants from the literature were genotyped in the entire Nigerian sample (n = 788). A total of 137 successfully genotyped variants were then analyzed for their associations with various lipid traits. The most significant associations were observed with HDL-C levels. Single-site analysis identified 20 common *SCARB1* variants significantly (P <0.05) associated with one or more lipid traits, of which the most significant was the rs11057851 SNP associated with HDL-C levels (P = 0.0043). Optimal sequence kernel association test (SKAT-O) revealed also a nominally significant association of rare variants (MAF ≤1%, n = 23) with HDL-C levels (P = 0.0475). In summary, our results suggest the genetic contribution of *SCARB1*—both common and rare variations—to lipid-lipoprotein levels (especially to HDL-C) and highlight the importance of this gene in lipid metabolism in humans.

Identification of novel genetic mutations causing familial hypercholesterolaemia among Saudi Arabian population. *F.A. AL-ALLAF[1,2], M. Athar[1,2], Z. Abduljaleel[1,2], A. Bouazzaoui[1,2], M.M. Taher[1,2], R. Own[1], A.F. AL-ALLAF[3], I. AboMansoor[1], Z. Azhar[1], F.A. BA HAMMAM[1,2], H. Abalkhail[4], A. Alashwal[4], S.S. Siddiqui[5].* 1) DEPARTMENT OF MEDICAL GENETICS, FACULTY OF MEDICINE, UMM AL-QURA UNIVERSITY, MAKKAH, Saudi Arabia; 2) Science and Technology Unit, Umm Al-Qura University, Makkah, Saudi Arabia; 3) Faculty of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 4) King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; 5) FACULTY OF DENTISTRY, UMM AL-QURA UNIVERSITY, MAKKAH, Saudi Arabia.

Familial hypercholesterolemia (FH) is a major risk factor for the development of Coronary heart diseases (CHD). The disease is hereditary in an autosomal dominant manner. Mutation(s) and/or deletion(s) in the LDL-receptor (LDLR) gene, in the apolipoprotein B-100 (ApoB) gene, or in the proprotein convertase subtilisin kexine 9 (PCSK9) gene are the most known causative mutations. The most accurate and unequivocal method for FH diagnosis is by molecular genetic testing of suspected cases and therefore this study aims to identify the genetic defects causing FH in Saudi population and to develop a diagnostic test for detecting such mutations. Forty four truly identified FH subjects were genetically screened for mutations in the LDLR, ApoB and PCSK9 genes through direct PCR-sequencing using ABI 3500 genetic analyzer. We identified four common mutations in coding sequences of the LDLR gene, one mutation in ApoB gene and three mutations in PCSK9 gene. Among the identified LDLR gene mutations, two have been reported previously and two are novel. In addition, a base substitution in the splice acceptor site of LDLR intron 11 and a second mutation was also observed in LDLR intron 11. We have also identified a single previously reported heterozygous mutation in ApoB gene. Similarly we found three mutations in PCSK9 gene which are also reported earlier. Moreover, two heterozygous mutations c.658-7C>T and c.799+3A>G in the PCSK9 gene intron 4 and 5 respectively, have also been identified. This knowledge is important for optimizing cholesterol lowering therapies and mutational analysis diagnostic test. In addition, these data contribute to the understanding of the molecular basis of FH in Saudi Arabia.

2121S

Whole Exome Sequencing of 350 LVOTO Cases Reveal Novel Candidate Genes for Congenital Cardiovascular Malformations. *J. Belmont[1,3], A. Li[2], N. Hanchard[1,3], M. Azamian[1], S. Fernbach[1], G. Zapata[3], P. Hernandez[3], D. Parekh[3], W. Franklin[3], D. Penny[3], C. Fraser[4], R. Gibbs[1], E. Boerwinkle[2].* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Div Epidemiology, School of Public Health, U Texas Health Sci Center, Houston, TX; 3) Dept Pediatrics, Baylor Col Med, Houston, TX; 4) Dept Surgery, Baylor Col Med, Houston, TX.

BACKGROUND: Congenital cardiovascular malformations (CVMs) occur in 5-8/1000 live births. Left Ventricular Outflow Tract Obstruction (LVOTO) defects, which include Hypoplastic Left Heart Syndrome (HLHS), Aortic Valve Stenosis (AS), Coarctation of the Aorta (CoA), Interrupted Aortic Arch Type A (IAAA) and Shone Complex, comprise 15-20% of severe CVMs. Genetic contributions to the causes of LVOTO defects are complex including chromosomal abnormalities, genomic disorders, and syndromes caused by single gene mutations. Familial clustering of cases and an increased risk of LVOTO in first degree relatives are consistent with single gene and oligogenic inheritance. The fact that most cases are sporadic also suggests a potential role for de novo mutations. METHODS AND RESULTS: We performed whole exome sequencing of 350 unrelated LVOTO cases without extracardiac malformations. Loss-of-function (LOF) variants (premature stop, splice, and frameshift indel) were prioritized using stringent criteria (depth >30x for nucleotide substitutions, >60x for indels) and compared to those observed in over 5000 ethnically-matched controls from the ARIC cohort sequenced using the same Illumina HiSeq platform. Novel LOF variants, not observed among controls, were highly overrepresented among genes with putative involvement in cardiac development, including 49 genes with overlapping cardiac phenotypes in model organisms (zebrafish, mouse); two known Mendelian genes previously implicated in congenital heart malformation (NF1, TBX20), and 1 gene previously hypothesized to be a candidate cardiac developmental gene. Targeted re-sequencing of these variants within cases and direct family members is currently ongoing to determine mode of inheritance and to validate genotypes. CONCLUSION: Our study implicates LOF mutations in a broad spectrum of known and postulated cardiac genes in the pathogenesis of LVOTO and illustrates the value of integrating an appropriately-matched control group, model organism bioinformatics, and a traditional family-based approach for discovering genes implicated in rare human disorders.

2122M

Low-frequency coding variation in *DNAH11* is associated with Sudden Cardiac Arrest among African Americans. *J.A. Brody[1], F. Asher[2], N. Bihlmeyer[2], X. Zhao[3], A. Mak[4], A.S. McCallion[2], T. Lumley[5], C.M. Sitlani[1], K. Rice[6], B.M. Psaty[1,7,8], R. Lemaitre[1], P.Y. Kwok[4], F.D. Kolodgie[3], D.S. Siscovick[1,7,9], N. Sotoodehnia[1,10].* 1) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, WA; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) CVPath Institute, Inc., Gaithersburg, MD; 4) Cardiovascular Research Institute and Institute for Human Genetics, University of California, San Francisco, CA; 5) Department of Statistics, University of Auckland, Auckland, New Zealand; 6) Department of Biostatistics, University of Washington, Seattle, WA; 7) Departments of Medicine and Epidemiology, University of Washington, Seattle, WA; 8) Group Health Research Institute, Seattle, WA; 9) New York Academy of Medicine, New York, NY; 10) Division of Cardiology, University of Washington, Seattle, WA.

Background: Sudden cardiac arrest (SCA) is a major public health concern, particularly among African Americans where risk of cardiac arrest is higher than that of the general population, and survival is poor. While environmental factors clearly contribute to SCA risk, familial aggregation studies and molecular genetics studies of inherited arrhythmias suggest that genetic factors confer susceptibility to SCA in the general population. **Methods**: We genotyped >240,00 common and low-frequency, nonsynonymous and splice-site variants with the Illumina HumanExome chip. Our study sample of African Americans consisted of 402 SCA cases and 4673 controls from the two cohort studies, Atherosclerosis Risk in Communities study and the Cardiovascular Health Study, and one case-control study of SCA; the Cardiac Arrest Blood Study (CABS). Associations were modeled using Cox-proportional hazards models for the cohort studies or logistic regression for the case-control study and were combined using fixed effects meta-analysis. Common variants (minor allele frequency [MAF] >1%) were tested individually and rare and common variants were jointly modeled within gene using the Sequence Kernel Association Test (SKAT). We then examined our findings among 2405 cases and 2431 controls of European ancestry from the CABS study. **Results**: Gene-based SKAT analyses identified Dynein, axonemal, heavy chain 11 (*DNAH11*) to be a novel gene associated with SCA among African Americans. The findings for *DNAH11* (p= 1.16E-6, cumulative MAF=249%) reached significance after Bonferroni correction for the number of genes examined (N=17,574). The gene test result was primarily driven by two missense variants (rs147478795, His2795Asp, MAF=1.6% and rs74667361, Cys2763Arg, MAF=2.0%) in high linkage disequilibrium (r2>.8). Rs147478795 (OR=4.34; 95% CI=2.43-6.25; p=7.95E-6) is likely to impact protein function as it was predicted to be deleterious by all four bioinformatic prediction algorithms examined. Among European descent individuals, rs147478795 is rare and was found in 1 case and no controls. The gene-based SKAT result showed no evidence of association in those of European ancestry (p=0.84, cumulative MAF=238%). Other mutations in *DNAH11* cause ciliary dyskinesia type 7, which is characterized by situs abnormalities including dextrocardia. **Conclusions**: Through analyses of low-frequency coding variation, we have discovered a novel gene associated with SCA among African Americans.

2123S

Whole genome sequencing and analysis of three hypoplastic left heart syndrome trios using DNA from buccal swabs collected through the National Birth Defects Prevention Study. *K.J. Buckingham[1], M. Beightol[2], J.D. Smith[2], J.X. Chong[1], C.T. Marvin[1], B.W. Paeper[2], K. Patterson[2], L.D. Botto[3], M.L. Feldkamp[3], D.A. Nickerson[2], J. Shendure[2], M.J. Bamshad[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Department of Pediatrics, University of Washington, Seattle, WA, USA; 2) Department of Genome Sciences, University of Washington, Seattle, WA, USA; 3) Department of Pediatrics, University of Utah, Salt Lake City, UT, USA; 4) Seattle Children's Hospital, Seattle, WA, USA.

Although identifying genes underlying Mendelian conditions has transformed our understanding of the genetic basis of human birth defects, the etiology for ~75% of birth defects remains unknown. To discover novel genes for isolated birth defects, we conducted a pilot study in which we performed whole genome sequencing (WGS) on three parent-child trios in which the newborn was diagnosed with hypoplastic left heart syndrome (HLHS). The samples and phenotypic information were collected as part of the National Birth Defects Prevention Study (NBDPS). As one of the largest studies of birth defects in the U.S., the NBDPS is potentially a rich resource for gene discovery. However the relatively low amount of DNA available for each participant (~1ug on average) presents a limitation in utilizing this cohort. To this end, we tested a protocol to generate high-quality WGS libraries from 225ng of genomic DNA extracted from NBDPS buccal swab specimens. Samples were sequenced to ~30X mean coverage without major modification to the WGS pipeline. We first analyzed the exome subset within the WGS data and identified novel biologically plausible candidate genes in each trio. In Trio 1 (HLHS, aortic atresia, mitral valve stenosis) we identified *de novo* missense mutations in *CABLES2* and *MVP*. *MVP* encodes major vault protein and directly interacts with PTPN11 protein. Mutations in *PTPN11* cause Noonan syndrome, which has been associated with HLHS in some cases. In Trio 2, (HLHS, atrial septal defect, mitral valve atresia), under a dominant model (a paternal uncle had HLHS), we found a frameshift mutation in *CMYA5*, which encodes cardiomyopathy associated 5 protein. A coding variant in *CMYA5* has been associated with variation in left ventricular wall thickness and cardiac hypertrophy. In Trio 3 (HLHS, aortic atresia, mitral valve stenosis, bilateral iris and retinal colobomas, partial agenesis of the corpus callosum), we identified a novel variant in *SOS1*, variants in which cause Noonan syndrome. While this finding suggests variants in *SOS1* could cause isolated CHD, this same variant was also found in a putatively unaffected parent for whom no phenotypic data were available. Next steps in the analysis of these trios will focus on non-coding variants and structural variants including CNVs. Collectively, our results demonstrate the feasibility of using samples of low quantity DNA combined with whole genome sequencing strategies for discovery of new genes underlying birth defects.

2124M

Rare variant association analysis for plasma lipids in coronary artery disease susceptibility loci. *H.K. Chheda[1], P.P. Palta[1], E.T. Tikkanen[1,6], S.M. McCarthy[2], V.S. Salomaa[3], R.D. Durbin[2], A.P. Palotie[1,4,5], T.A. Aittokallio[1], S.R. Ripatti[1,2,6].* 1) Institute for Molecular Medicine, Finland, Helsinki, Uusimaa, Finland; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 3) National Institute for Health and Welfare, Department of Chronic Disease Prevention, Helsinki, Finland; 4) Program in Medical and Population Genetics and Genetic Analysis Platform, The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Department of Medical Genetics, University of Helsinki and University Central Hospital, Helsinki, Finland; 6) Hjelt Institute, University of Helsinki, Helsinki, Finland.

Coronary artery disease (CAD) is the leading cause of deaths worldwide. Genome-wide association studies have identified multiple common variants associated with CAD and related traits. Some of these loci mediate their effects via risk factors such as lipids or hypertension. However, most of the common loci identified so far have a relatively small effect on the disease susceptibility. The exact molecular mechanisms behind most of these loci are also unknown. Therefore, we aimed at identifying rare and low frequency variants associated with plasma lipids and other metabolites in the known CAD loci. We analyzed low pass whole genome sequenced 1217 Finnish individuals from the FINRISK cohort with deep phenotypic data for CAD risk factors including metabolomic profiles using different platforms. We undertook the analysis using sequence kernel association test (SKAT) for variants with minor allele frequency less than 1% or 5%. We performed SKAT using two approaches; window-based (20 or 50 variants in each window) and genomic region- based (3kb regions). Our preliminary results show a higher burden of CAD loci on plasma lipid concentrations using both approaches. In the known CAD loci, we observed a combined proportion of 20-25% windows associated with high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), total cholesterol (TC) and triglycerides (TG). One such region upstream of HDAC9 gene on chromosome 7 showed significant association with TG (window-base approach: P= 9 x 10-5, genomic region-based approach: P= 2 x 10-4). Fine-mapping of this region identified 3 independent low frequency variants showing association with TG: rs150895469 (frequency: 0.8%, P=2 x 10-5); var_7_18328999 (frequency: 0.2%, P=7 x 10-4); rs117533313 (frequency: 0.1%, P=4 x 10-3). The lead SNP (rs150895469) was also imputed in 9946 individuals in an independent cohort and shown to be nominally associated with CAD (HR=1.92, 95% CI 1.06-3.49, P=0.03). We will are currently extending these analyses for other risk factors and datasets. The preliminary findings have provided us with higher-resolution insights into the genetic architecture of CAD-related traits, which may later lead to the identification of rare/low frequency causal variants for CAD. In conclusion, this study will help explain the molecular mechanisms behind the loci associated with CAD.

2125S

Identification of potentially pathogenic mutations in 9 candidate genes for bicuspid aortic valve using next-generation sequencing. *N. Dargis[1], M. Lamontagne[1], N. Gaudreault[1], L. Sbarra[1], C. Henry[1], P. Pibarot[1], P. Mathieu[1], Y. Bosse[1,2].* 1) Quebec Heart and Lung Institute, Quebec City, Quebec, Canada; 2) Department of molecular medicine, Laval University.

BACKGROUND : Bicuspid aortic valve (BAV) is the most frequent congenital heart disease. Affected individuals are at greater risk of developing aortic valve stenosis as well as other valvuloaortopathies. Despite the high prevalence of BAV, its etiology and genetic origins remain elusive. To improve our understanding of the genetic components contributing to the development and progression of BAV, we sought to identify and assess the pathogenicity of all genetic variants located in 9 candidate genes for BAV (*AXIN1, EGFR, ENG, GATA5, NKX2-5, NOS3, NOTCH1, PDIA2* and *TGFBR2*) in affected French Canadians using next-generation sequencing and in silico analyses. **METHODS :**Genomic DNA from 48 French Canadians affected with BAV confirmed at surgery and having no concomitant aortic insufficiency and/or aortic aneurysm was extracted from blood buffy coat. Targeted DNA sequencing was performed using the Ion Torrent™ Personal Genome Machine™ (PGM™) from Life Technologies™. We designed an Ion AmpliSeq™ custom panel of primers covering 1,000 bp of the promoter region, the entire coding sequence and both 3' and 5' untranslated regions (UTR) for each of the nine genes. Novel variants were validated by conventional Sanger sequencing and the pathogenicity of all variants was evaluated with the Combined Annotation Dependant Depletion (CADD) method. **RESULTS :** Sequencing revealed a total of 217 genetic variants, 38 of which were novel. Ten new variants were detected in the *NOTCH1* gene, including one novel missense mutation present in one patient (p.G152S, located in exon 4). This variant was evaluated as functionally damaging and deleterious. **CONCLUSION :** We identified 38 novel genetic variants within 9 candidate genes for BAV in 48 subjects affected with the disease. One novel mutation in *NOTCH1* is predicted to be damaging and deleterious. Further analyses will be required to determine the functional impact and evaluate the frequencies of these variants in French Canadians and other populations. Identifying causal mutations is essential to increase our knowledge of the molecular mechanisms underlying this frequent cardiac pathology, which could ultimately translate into earlier diagnosis, screening for families at risk, predicting disease progression and personalizing treatments.

Whole Exome Sequencing Reveals Rare, Truncating Variants in Nuclear Envelope Genes are Present in a Large Subset of Cardio-Genetic Patients. *G.T. Haskell[1], B.C. Jensen[3,4], D.S. Marchuk[1], C. Skrzynia[1], C. Bizon[2], K. Wilhelmsen[1,2], K.E. Weck[1,5], J.P. Evans[1], J.S. Berg[1].* 1) Department of Genetics, UNC-Chapel Hill, Chapel Hill, NC; 2) Renaissance Computing Institute, Chapel Hill, NC; 3) Division of Cardiology, UNC-Chapel Hill, Chapel Hill, NC; 4) McAllister Heart Institute, UNC-Chapel Hill, Chapel Hill, NC; 5) Department of Pathology and Laboratory Medicine, UNC-Chapel Hill, Chapel Hill, NC.

The NCGENES (North Carolina Genomic Evaluation by Next-Generation Exome Sequencing) clinical trial is applying whole exome sequencing (WES) in a bedside to bench approach, in order to evaluate the use of genome-scale sequencing to identify genomic determinants of a variety of genetic disorders, including hereditary cardiac conditions. Eighteen patients suspected of having a genetic form of cardiac disease have been enrolled, and WES sequence variants analyzed against a diagnostic list of ~75 known cardiac disease genes. The diagnostic yield for clearly positive results in this cohort was 16.7 percent. In patients with negative or uncertain diagnostic results, we analyzed other rare, predicted deleterious variants that might account for their conditions. Given that mutations in the nuclear envelope (NE) gene LMNA are a major genetic risk factor for severe cardiac disease, we were particularly interested in evaluating whether deleterious variants in other NE genes might contribute to cardiac disease as well. We used bioinformatics tools to systematically annotate a number of variant characteristics, including frequency in population databases and our own in-house WES database, as well as in silico pathogenicity predictions. We identified novel or extremely rare truncating variants in NE genes in 5 out of 14 patients. Three of these are nonsense or splice site variants in genes encoding nucleoporins, and one alters the splice donor site between intron 43 and exon 44 in SYNE1, a gene associated with Emery-Dreifuss Muscular Dystrophy, that is also important for mechanotransduction and normal heart function in mice. The SYNE1 variant was identified in a patient with dilated cardiomyopathy (DCM) who underwent heart transplant at age 15, and is present in his father, who also has advanced DCM. Many of the WES-identified NE genes are expressed in the developing as well as the adult heart, and we are evaluating whether these NE genes play a role in early cardiac development. Together, these data suggest the hypothesis that integrity of the nuclear envelope is particularly important for cardiac function and that alterations in this class of genes may be an important cause of genetic cardiac disease. Genome-scale sequencing technologies provide an especially attractive strategy for surveying clinically relevant variants in cardiac disease, and provide a rich source of data for discovery-based investigations aimed at identifying novel disease-associated variants.

Initial analysis of exome sequence from 410 individuals with familial or simplex dilated cardiomyopathy. *D.J Hedges[1,2], A. Morales[1,2], D. Kinnamon[1,2], D. Wheeler[1,2], J. Shendure[4], M. Bamshad[4], D. Nickerson[4], R. Hershberger[1,2,3], University of Washington Center for Mendelian Genomics.* 1) Dorothy M. Davis Heart and Lung Research Institute, The Ohio State University College of Medicine, Columbus OH; 2) Division of Human Genetics, The Ohio State University College of Medicine, Columbus, OH; 3) Division of Cardiovascular Medicine, The Ohio State University College of Medicine, Columbus, OH; 4) Department of Genome Sciences, University of Washington, Seattle WA.

PURPOSE: Dilated cardiomyopathy (DCM) is a leading cause of heart failure. Large DCM families have facilitated DCM gene discovery, and rare variants in 40 genes have been implicated to cause familial DCM. However, the extent that simplex DCM cases also have a genetic basis remains uncertain. To further understand the genetic architecture of DCM, we performed whole exome sequencing (WES) on 410 individuals from familial and simplex pedigrees to identify novel and known DCM-causing variants. Here we report our initial analysis of variants in established DCM genes. METHODS: WES was conducted on 410 affected individuals from 281 DCM pedigrees, 105 with simplex DCM (history reported as negative) and 177 with familial DCM (confirmed by medical records). Secondary sequence processing, variant calling, and downstream filtering and prioritization were performed with GATK (v.1.6) and GEMINI. All single nucleotide variants (SNVs) and indels predicted to alter protein sequence were selected from 40 published DCM loci. Further prioritization included: the absence or frequency <0.5% in the 1000 Genomes or Exome Sequencing Project datasets 2) a GERP score of >2, or region conserved (Phastcons). Where affected family members' samples were available, variants were prioritized by sharing among affected cases. Prioritized variants were adjudicated as per ClinVar: pathogenic (P), likely pathogenic (LP), or variant of uncertain significance (VUS), and confirmed by capillary sequencing. RESULTS: Following clinical adjudication of 177 familial pedigrees, 89 (51%) had one or more variants identified; classifying probands by their highest ranked adjudicated variant yielded: 5(3%) P, 40 (23%) LP, and 44 (25%) VUS. Of 105 simplex cases, 43 (41%) had one or more variants identified, and stratifying as above yielded 1 (1%) P, 5 (5%) LP, and 37 (35%) VUS). Estimates of probands (including nonfamilial) with adjudicated variants in known DCM genes were concordant with earlier studies: TTN (truncations) (20%), LMNA (4%), TNNT2 (4%), MYH7 (3%); DSP variants (8%) were increased compared to earlier reports. Interestingly, 88 cases (21%) carried two or more adjudicated variants in different genes: 2 (n=63), 3 (n=21), 4 (n=7) across the 40 DCM genes. CONCLUSION: These results suggest a proportion of simplex DCM cases have a genetic basis and that DCM has a more complex genetic basis than is commonly appreciated, all of which may impact clinical genetic testing.

2128M

Common variants of LDLR & PCSK9 genes associated with the risk and severity of Coronary Artery Disease in Iranian patients. *S.Hamid. Jamaldini[1], M. Babanejad[1], R. Mozaffari[1], N. Nikzat[2], KH. Jalalvand[2], A. Badiei[2], H. Sanaati[1], F. Shakerian[1], M. Afshari[3], K. Kahrizi[2], H. Najmabadi[2].* 1) Cardiogenetics Research Center, Shahid Rajaie Cardiovascular Medical & Research Center, Tehran, Iran; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 3) Research Center for Modeling of Health, Kerman University of Medical Sciences, Kerman, Iran.

Coronary artery disease (CAD) is the leading cause of mortality in the world and it is expected to be the first cause of death worldwide by 2020. Genome-wide association studies (GWAS) have identified several genetic variants associated with CAD in LDLR and PCSK9 genes. This study was evaluated the possible association of common polymorphisms at LDLR and PCSK9 genes with the risk and severity of CAD in the Iranian patients. Sequencing of all 18 exons of the LDLR gene and promoter region of the PCSK9 gene was performed in 202 Iranian patients angiographically confirmed CAD and 130 healthy controls. Sullivan's scoring system was used for determining the severity of CAD in cases. Our results showed that homozygote genotypes of rs1122608 (P<0.0001), rs4300767 (P<0.005) and rs10417578 (p<0.007) SNPs have strong protective effects on the CAD. In addition, we found that rs1122608 (GT or TT) was at higher risk of three vessel involvement compared to single vessels affecting (P=0.01). The only change in the coding region was c.1620 G>A in exon 11 of LDLR gene, which leads to a change in amino acid production (Gly>Glu). Moreover, according to the known databases this alteration probably is dangerous and benign, respectively. The results from our case-control study and other studies might be explained by genetic heterogeneity in the susceptibility of CAD and ethnic differences between Asians and Caucasians. Further investigation on other SNPs in these genes is warranted to validate our findings in Iranian population.

Targeted oligonucleotide-selective sequencing of 101 genes from 147 patients with dilated cardiomyopathy in Finland. *J.W. Koskenvuo[1,2], O. Akinrinade[3], L. Ollila[4], J. Tallila[2], H. Koillinen[5], M. Gentile[2], M. Kaartinen[4], T. Ojala[6], S. Myllykangas[2,7], T. Heliö[4], T.-P. Alastalo[2,3].* 1) University of Turku, Turku, Turku, Finland; 2) Blueprint Genetics, Helsinki, Finland; 3) Childrens Hospital Helsinki, University of Helsinki, Helsinki, Finland; 4) Department of Cardiology, University Hospital Helsinki, Finland; 5) Department of Genetics, University Hospital Helsinki, Finland; 6) Department of Pediatric Cardiology, University Hospital Helsinki, Finland; 7) Institute of Biomedicine, University of Helsinki, Helsinki, Finland.

The genetic basis of dilated cardiomyopathy (DCM) is recognized but still not widely utilized in diagnostics. Hundreds of mutations in coding exons of over 50 genes have been reported to associate with isolated DCM. We applied oligonucleotide-selective sequencing and custom data analysis and interpretation pipelines to identify pathogenic base substitutions and insertions and deletions in 101 genes associated with cardiomyopathies. Our sequencing panel covered coding exons, exon-intron boundaries and known variants in intronic regions of target genes. We genetically profiled 147 well-characterized DCM patients with average clinical follow-up of 8.7 years. On average, 99.1% of the targeted regions were covered >15x. We identified pathogenic or likely pathogenic variants in 50% of the familial and 27% of the sporadic cases. These included truncating TTN mutations affecting all transcripts that were identified in 21% of the familial and 13% of the sporadic cases. Family segregation analysis revealed that all tested truncating TTN mutations co-segregated with the DCM disease. We observed a trend of less atrial fibrillation, conduction abnormalities and pacemaker/ICD/CRT related therapies in patients with TTN mutations compared to patients with other mutations or patients without identified mutations. Other major findings in the analysis were mutations in genes encoding the nuclear lamina, the desmosome and the sarcomere. Mutation positive DCM patients and especially those with a LMNA mutation had significantly more atrial fibrillation when compared to mutation negative individuals. In conclusion, our analysis revealed high diagnostic yield in the familial form of DCM. It further confirms that truncating TTN mutations are a significant contributor to familial DCM. Authors disclosure: None: OA, LO, HK, MK, TO and TH. Minor: JT, MG, SM*, TPA* and JWK*. *Founders of Blueprint Genetics, which offers gene diagnostics for cardiomyopathies.

Association of rare variants in *LDLR*, *HMGCR*, *NAT2*, *ABCA1*, and *APOA1* with plasma lipid levels; initial results from the eMERGE PGx project. *I.J. Kullo[1], S.J. Bielinski[2], D.S. Carrell[3], S. Stallings[4], J. Pathak[2], A. Gordon[5], L. Rasmussen-Torvik[6], K.F. Dohney[7], S. Volpi[8], M.D. Ritchie[9], J.C. Denny[10], C.G. Chute[2], D.M. Roden[4], D.A. Nickerson[5], G.P. Jarvik[11], D.R. Crosslin[10].* 1) Division of Cardiovascular Diseases, Department of Medicine, Mayo Clinic, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Group Health Research Institute, Center for Health Studies, Seattle, WA; 4) Vanderbilt University Medical Center, Nashville, TN; 5) University of Washington, Seattle, WA; 6) Northwestern University Feinberg School of Medicine, Chicago, IL; 7) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore MD; 8) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 9) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 10) Departments of Biomedical Informatics and Medicine, Vanderbilt University, Nashville, TN; 11) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

Linking genome sequence data to the broad range of phenotypes in the electronic medical record (EMR) is a potential means of obtaining insights into the pathogenicity of rare variants. The Electronic Medical Records and Genomics (eMERGE) pharmacogenomics (PGx) project is using the next-generation PGRN-Seq capture reagent to sequence 84 drug response genes in 9,000 individuals across the network. In a preliminary analysis of the first 894 participants, we examined the association between rare variants in five candidate genes (*LDLR*, *HMGCR*, *NAT2*, *ABCA1*, and *APOA1*) that are implicated in lipid metabolism and plasma lipid levels (total cholesterol, LDL-C, HDL-C, and triglycerides) abstracted from the EMR at Group Health. For each trait, we ascertained the maximum level in the EMR for each participant. Of the 354 variants found in these 5 genes we identified 24 variants with evidence of high or moderate effects through *in silico* analyses using SnpEff and SeattleSeq annotation tools. For each functional variant, we assessed the differences in lipid levels between genotype groups. We describe the effect of one variant (C2177T) in *LDLR* on LDL-C levels in this cohort. The variant (rs45508991) leads to a THR/ILE amino acid change and was present in 12 participants (out of 894). Of these 12 patients, 25% were on statins vs. 42% in the remaining cohort. The mean LDL-C noted in the EMR in participants with the mutation was 128 mg/dL vs. 145 mg/dL in the remaining individuals. This was an unexpected finding. In review of the literature, ~15% of the *LDLR* mutation carriers have LDL-C levels below 75th percentile suggesting that certain mutations in *LDLR* may not affect receptor function. We believe that the C2177T mutation may belong to this 'non-pathogenic' category. Such information will be useful for variant annotation when interpreting *LDLR* sequence data. Our preliminary findings suggest that EMR-based studies may be helpful in confirming/assigning pathogenicity to rare variants identified by genome sequencing.

2131S

***TGFB3* pathogenic mutations cause MFS/LDS phenotypes and aortic aneurysms in 3 Japanese families.** *H. Morisaki[1,2], A. Ono[1,2], I. Yamanaka[1], R. Sultana[1], T. Oda[3], H. Tanaka[3], H. Sasaki[3], K. Minatoya[3], R. Matsukawa[4], T. Tsukube[4], N. Kubo[5], T. Morisaki[1,2].* 1) Bioscience and Genetics, National Cerebral and Cardiovascular Center Research Institute, Suita, OSAKA, Japan; 2) Medical Genetics, National Cerebral and Cardiovascular Center, Suita, OSAKA, Japan; 3) Vascular Surgery, National Cerebral and Cardiovascular Center, Suita, OSAKA, Japan; 4) Cardiovascular Surgery, Japanese Red Cross Kobe Hospital, Kobe, HYOGO, Japan; 5) Pediatrics, Urakawa Red Cross Hospital, Urakawa, HOKKAIDO, Japan.

To date, several genes have been identified to be responsible for hereditary aortopathies including systemic connective tissue disorders such as Marfan syndrome (MFS) and Loeys-Dietz syndrome (LDS). Some of these genetic mutations were found to cause high transforming growth factor (TGF)-β signaling. To identify new genes responsible for these diseases, 292 probands with MFS/LDS-like features negative in *FBN1*, *TGFBR1*, *TGFBR2*, *TGFB2*, or *SMAD3* mutations were subjected to exome sequencing. Three probands with family history of skeletal and/or aortic features resembling MFS/LDS were identified to have three novel mutations (p.N235fs, p.I322T, or p.R300W) in *TGFB3* gene. Case 1 was a 43y tall male with scoliosis, strabismus and a history of thoracic aortic dissection (Stanford A) at 41y with aortic root dilatation. He was treated with emergency total arch replacement followed by aortic root repair (David operation) at 43y. His mother was tall and slender, and diagnosed as MFS with a history of thoracic aortic dissection at 59y. Case 2 was a 56y tall male who had a Bentall operation for severe aortic root dilatation. His daughter and son were both tall and had chest deformities along with mild aortic root dilatation. Case 3 was a 3y female showing LDS features with arachnodactyly, hypertelorism, bifid uvula and translucent skin. Her father also had tall stature, hypertelorism and bifid uvula. Genetic analysis of family members revealed the *TGFB3* mutations segregated with phenotypes in all three cases. It was reported that *TGFB3* mutations cause familial arrhythmogenic right ventricular dysplasia and that *TGFB3* gene has an association with cleft lip and palate, hypertension, or ossification of the posterior longitudinal ligament of the spine. Murine model revealed that *Tgfb3* gene plays an important role in embryogenesis and palatogenesis. In addition, recently, it was reported that the patients with de novo *TGFB3* mutations showed MFS/LDS-like features with no or mild aortic involvement. This is the first report of *TGFB3* mutations found in familial cases with MFS/LDS-like features, and three of our patients required aortic root surgery. Based on these results, we conclude that *TGFB3* is essential not only for palatogenesis but also for systemic connective tissue disorders similar to MFS/LDS. Aortic aneurysms and dissections should be the important features of patients with *TGFB3* mutations.

2132M

Exome sequences and rare variant association for plasma lipids in over 18,900 individuals. *G.M. Peloso[1,2,3,4], J.A. Brody[5], J.R. Crosby[6,7], A. Isaacs[8], Y. Zhou[9,10], L.A. Lange[11], J.C. Genetic discovery using screens of common DNA sequence variants has identified many novel gene regions associated with plasma lipids but it has been challenging to pinpoint specific causal genes. Discovery using sequencing of protein-coding regions across the genome may overcome this barrier. Here, we test the hypothesis that exome sequencing in the population can identify novel genes associated with plasma levels of low-density lipoprotein cholesterol (LDL-C), triglycerides, high-density lipoprotein cholesterol (HDL-C), and/or total cholesterol. We sequenced the protein-coding regions (exome) of >17,000 genes from ~15,000 European ancestry (EA) and ~3,900 African American (AA) individuals and tested the association of plasma lipid levels with single rare coding variants or those aggregated within a gene. For gene-based tests, we implemented two methods - Sequence Kernel Association Test (SKAT) and burden - with various minor allele frequency thresholds. Functional classes of variants were aggregated into categories: loss-of-function (nonsense, splice-site and frameshift) and/or those predicted to be deleterious. seqMeta software was used for efficient gene-based meta-analysis, where each study computes association-specific statistics for each variant and genotypic covariance matrices within predefined gene regions. Score statistics and genotypic covariance matrices are combined across studies and used to construct the gene-based tests. With a sample size of 15,000 individuals, we had > 80% power to detect a gene with a cumulative minor allele frequency of 0.5% and a ½-SD unit effect at exome-wide statistical significance ($P < 2.5\times10^{-7}$). We found aggregated rare variant associations in many genes previously known to be associated with plasma lipids. For example, in EA individuals, LDL-C was associated with *LDLR* (beta=15 mg/dl; $p=2.7\times10^{-22}$ with Burden 0.1%), HDL-C was associated with *ABCA1* (beta=-4%; $p=2.4\times10^{-7}$ with Burden 1%), and triglycerides were associated with *APOC3* (beta=-37%; $p=6.4\times10^{-23}$ with Burden 1%). In AA individuals, LDL-C was associated with *PCSK9* ($p=6.7\times10^{-9}$ with SKAT 1%) and HDL-C was associated with *ABCA1* (beta=-8%; $p=4.8\times10^{-8}$ with Burden 1%). Surprisingly, despite analysis in over 18,000 individuals with exome sequences, our gene-based association analysis did not reveal any novel genes at exome-wide significance. These data highlight the challenges of rare variant association to identify novel genes for complex traits.

2133S

Rare mutations in cardiomyopathy genes are associated with takotsubo cardiomyopathy. *A.L. Siniard[1], P. Nakaji[2], J.J. Corneveaux[1], R.F. Richholt[1], R.P. Bruhns[1], E. Carlson[1], A. Courtright[1], K. Van Keuren-Jensen[1], J. Forseth[3], J.M. Zabramski[2], R.F. Spetzler[2], M.J. Huentelman[1], M.Y.S. Kalani[2].* 1) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 2) Division of Neurological Surgery, Barrow Neurological Institute/Saint Joseph's Hospital and Medical Center, Phoenix, Arizona; 3) Arizona Pulmonary Specialists, Phoenix, Arizona.

Takotsubo cardiomyopathy (TC), defined as transient cardiac malfunction with characteristic left ventricular (LV) wall motion abnormalities in the setting of normal coronary vasculature, is a poorly understood complication of cerebral aneurysm rupture that most commonly affects post-menopausal women. Little is known about the etiology of this condition; however, the clinical approaches for management of TC are largely supportive and reactive to the presentation of symptoms. In this study we utilized next generation exome sequencing analysis in an effort to define genetic variation associated with and responsible for this phenomenon. We performed exome sequencing on eight female patients diagnosed with TC after aneurysmal subarachnoid hemorrhage. Unless the variant was already present in ClinVar, filtering of the identified variants was performed to limit our investigation to those candidates that passed freebayes-derived haplotypic scoring, were rare (<0.5% MAF in NHLBI GO ESP) or novel (not observed in publicly available databases including 1000 genomes, NHLBI GO ESP, and an internal TGen database), were determined algorithmically to have high potential impact on the associated protein function (Combined Annotation Dependent Depletion, CADD, score >15), were within regions of high species conservation (PhyloP > 50%), and exist in genomic loci previously associated with cardiac dysfunction. Additionally, all candidate variants were verified to be present using Sanger sequencing chemistry. Exome sequencing and analysis revealed that 7 out of 8 patients with TC after aneurysmal subarachnoid hemorrhage were heterozygote carriers of predicted deleterious mutations in established cardiomyopathy genes including MYOZ2, SDHA, ANKRD23, MYLK2, PKP2, DSP, and TTR. Our study suggests that patients with TC following cerebral aneurysm rupture harbor deleterious mutations in established cardiomyopathy genes. We postulate that these patients likely live in a compensated state of cardiac dysfunction that manifests only after the myocardium is stressed by the adrenergic surge associated with aneurysm rupture or the stress associated with the aggressive hemodynamic treatment of cerebral vasospasm. It is possible that the clinical knowledge of the presence of these mutations would change the management of patients presenting with TC.

2134M

Screening of the *PRKG1* gene in a British cohort of Thoracic Aortic Aneurysm and Dissection (TAAD) patients. *Y.B.A. Wan[1], J.A. Aragon-Martin[1], L.J. Collins[1], D.C. Guo[4], A. Sagger[2], M. Jahangiri[3], D. Milewicz[4], A.H. Child[1].* 1) Cardiovascular & Cell Sciences Research Institute, St. George's Hospital, University of London, SW170RE, United Kingdom; 2) Clinical Genetics Unit, St George's University of London, Cranmer Terrace, SW170RE, London, UK; 3) Department of Cardiothoracic Surgery, St George's Healthcare NHS Trust, London, UK; 4) Department of Internal Medicine, University of Texas, USA.

Background: A mutation in the *PRKG1* gene, which encodes for the type I cGMP-dependent protein kinase (PKG-I, [OMIM 176894]) that was published in 2013, causes decreased contraction of the vascular smooth muscle cells. This in turn can increase risk of TAAD.

Method: A total of 101 UK patients (80M: 21F, mean age 53±13) with known TAAD who did not fulfill the revised Ghent criteria for Marfan syndrome, and with no demonstrable mutations in *FBN1*, *TGFB2*, *TGFBR1/2*, *ACTA2* and *SMAD3* genes were recruited to this study. These patients were screened for the whole gene and in particular the published variant c.530G>A (p.R177Q) in exon 3 of *PRKG1*, by bi-directional Sanger sequencing. The methodology was taken from the original paper (Recurrent gain-of-function mutation in PRKG1 causes thoracic aortic aneurysms and acute aortic dissections. Guo DC et al, Am J Hum Genet. 2013).

Results: Our TAAD cohort of 101 British samples did not carry the c.530G>A (p.R177Q) mutation in exon 3 of the *PRKG1* gene. However, 2 heterozygous synonymous mutations (c.477C>T/p.T159T and c.993T>C/p.V331V; NM_001098512) were found in 2 unrelated probands. These mutations were not reported on genome databases (1000 genomes and Exome Variant Server). In-silico (mutation t@ster) predicted these to be disease causing. Splice site tools (BDGP and ESE finder) were used to assess the pathogenicity of these mutations and the causativity remains to be proven.

Conclusion: This study was negative for the recurring mutation found in 3 families from a USA cohort. Family segregation studies will be performed for the two synonymous mutations in the two families to demonstrate that they could be linked to the disorder. Samples should then assayed to determine if it increases the activity of the kinase before the variant can be considered to be disease-causing. Further screening of novel single nucleotide variations through next generation exome sequencing data in our British cohort of TAAD patients is currently underway.

Exome sequencing identifies a homozygous splice site variation in ZBTB17 in arrhythmogenic ventricular dysplasia. *J. Wang[1,2], H. Lee[3], C. Silverstein[4], S. Nelson[1,3].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Medicine, UCLA, Los Angeles, CA; 3) Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 4) Medicine, Western University, Pomona, CA.

Background: Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is a genetic disorder of the myocardium characterized by progressive fibrofatty replacement that predisposes to ventricular tachycardia and sudden death. Although it classically affects the right ventricle, left and biventricular forms are increasingly recognized. A mutation in one of the 8 known genes, primarily encoding desmosomal proteins, is found in fewer than half of patients. We identified a family with onset of dilated cardiomyopathy in the 2nd or 3rd decade in four out of four siblings with progression to cardiac transplantation so far in three. Gross and histopathologic examination of the three explanted hearts demonstrated the characteristic fibrofatty replacement of ARVC/D involving predominantly the left ventricle. The family reported a high degree of consanguinity. Methods: To identify the molecular basis of these findings in the family, Clinical Exome Sequencing was carried out in the index patient. Exome variants were filtered for protein-altering rare heterozygous variants and homozygous variants to identify causative mutations. Mean oversampling of bases was 107X and at least 93.9% of the ~33.4 Mb of protein coding sequence defined by RefSeq was read to at least 10X depth. Illumina HumanOmniExpress BeadChip assay was performed on the living affected siblings to filter the candidate variants. Results: Within the shared linkage regions, three rare homozygous variants, predicted to cause missense, essential splice site, and premature stop codon changes, were identified in the index case and confirmed to be shared among the three affected siblings. Among the genes affected by the candidate variants, *ZBTB17* resides in a region that was previously implicated in dilated cardiomyopathy by association studies in European and Han Chinese populations. Conclusions: *ZBTB17* (zinc finger and BTB domain containing 17), also known as Miz-1, encodes a zinc finger protein involved in the regulation of c-myc. Our findings implicate *ZBTB17* as a new gene for ARVD/C and provide new evidence of a critical role for *ZBTB17* in cardiac function. The significance of the three variants shared by the affected siblings is to be established experimentally using animal models.

2136M

Identification of Novel Genes and Variants Associated with Hypertrophic Cardiomyopathy in Panel Negative Patients Through Targeted Sequencing of 450 Genes and Rare Variant Association Testing. *M.T. Wheeler[1,2,3], J.R. Homburger[1,4], F.E. Dewey[1,2,3], A. Pavlovic[1,2,3], H. Chaib[1,4], J.R. Priest[2,3,6], R.L. Goldfeder[1,5], D.M. Waggott[1], O. Soyinka[1], E.A. Ashley[1,2,3,4,5].* 1) Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 2) Stanford Center for Inherited Cardiovascular Disease, Stanford University School of Medicine, Stanford, CA; 3) Cardiovascular Institute, Stanford, CA; 4) Deparment of Genetics, Stanford University School of Medicine, Stanford, CA; 5) Program in Biomedical Informatics, Stanford University School of Medicine, Stanford, CA; 6) Department of Pediatrics, Stanford University School of Medicine, Stanford, CA.

Hypertrophic Cardiomyopathy (HCM) is a genetic disorder of the heart muscle leading to increased heart wall thickness and risk of sudden death. HCM is typically inherited in an autosomal dominant fashion. Clinical genetic testing for HCM patients sequences 8 to 17 genes to identify a causal variant. In about half of HCM patients who undergo clinical genetic testing, no known causal genetic variant is found. To better understand the genetic basis of HCM in these panel-negative patients, we performed targeted sequencing of 450 cardiac genes covering 3.3 Mbp in 58 unrelated HCM patients without known causal variants. We used Real Time Genomics (RTG) alignment and variant calling pipeline together with sequence to medical phenotypes (STMP) to align, call, and prioritize variants by comparison to publically available and cardiac-specific annotation data. We identified 126 extremely rare or novel exonic nonsynonymous and premature termination variants. Sanger sequencing validated novel stop variants in GJA5, CSRP3, and ATP1A4. To prioritize additional genes that may contribute to development of HCM, we performed gene-delimited rare variant association testing using the SKAT-O test. We compared our HCM patients against a cohort of 424 exome sequenced individuals without HCM. We identified new genes significantly associated with HCM case status including ILK (p = 9.9639 x 10^-18) and ADAMSTS9 (p = 1.8570 X 10^-5). To control for the potential confounding effect of ancestry, the results were replicated using a subset of the data set that contained only individuals of European ancestry. ILK has previously been implicated in dilated cardiomyopathy, suggesting that it is a strong biological candidate for affecting HCM. Through both functional annotation and burden testing we identify new candidate genes and variants that may play an important role in the genetic basis of HCM.

2137S

Whole exome sequencing of a family trio to identify potential genetic modifiers of *LMNA* arrhythmia and cardiomyopathy. *M. Zaragoza, S. Hakim, V. Hoang.* Pediatrics- Genetics & Genomics, University of California, Irvine, School of Medicine, Irvine, CA.

We identified a novel *LMNA* splice site mutation (c.357-2A>G) as the primary mutation associated with Sick Sinus Syndrome (SSS), Dilated Cardiomyopathy (DCM), and Sudden Cardiac Death (SCD) in a large family. To identify potential secondary factors, genetic "suppressors" or "enhancers" that may result in clinical variability within this family, we then focused on two affected members: a 71-year-old female and her 39-year-old daughter. The mother had bradycardia and atrial fibrillation at 49, sinus arrest at 52, and DCM at 61 while her daughter presented at 36 with bradycardia and ventricular arrhythmias. To identify potential modifiers associated with this phenotypic range, we conducted whole exome sequencing (WES) on the affected mother and daughter and the unaffected father. This produced 42 Gb of sequencing data in which we identified ~1 million unique variants for each parent and ~700,000 for the daughter. We then focused on the variants that were not shared by mother and daughter located in over 700 genes for ion channels, cardiac muscle contraction, *LMNA*-associated proteins (nuclear envelope proteins, transcription factors, chromatin-associated proteins), and *LMNA*-associated signal transduction (MAPK, mTOR, TGF Beta pathways). We validated the potential modifier variants by Sanger sequencing. We found seven potential "suppressors" including rare missense variants in the Lysosomal-associated membrane protein 2 (*LAMP2*), Mitogen-activated protein kinase 3 (*MAPK3*), and Retinoblastoma-like 2 (*RBL2*) genes. We found six potential genetic "enhancers" including a novel missense variant in the Unc-51-like kinase 3 (*ULK3*) gene and rare missense variants in the RNA binding motif protein 20 (*RBM20*) and Spectrin repeat containing nuclear envelope 1 (*SYNE1*) genes. In conclusion, we used WES to identify novel and rare variants in *LMNA* pathway-associated genes that serve as potential modifiers of SSS, DCM, and SCD. Gene expression and functional studies are planned. These studies may provide insight into the molecular mechanisms for the intrafamilial variability in *LMNA*-associated arrhythmia and cardiomyopathy. By taking advantage of the endogenous methods to alter disease; we hope that molecular targets may be discovered to develop new preventive strategies and treatments.

2138M

Timothy syndrome type 2 associated CACNA1C mutation G402S in a teenager with normal development presenting with ventricular fibrillation. *TP. Alastalo[1], A. Hiippala[1], J. Tallila[2], S. Myllykangas[3], JW. Koskenvuo[4].* 1) Padiatric Cardiology, University Hospital Helsinki, Helsinki, Finland; 2) Blueprint Genetics, Helsinki, Finland; 3) Institute of Biomedicine, University of Helsinki; 4) Research Center of Applied and Preventive Cardiovascular Medicine, University of Turku, Finland.

Timothy syndrome (TS) is a multiorgan disorder with prolonged QTc interval, congenital heart defects, syndactyly, typical facial features and neurodevelopmental problems. Ventricular tachyarrhythmia is the leading cause of death at early age. Classical TS type I results from a recurrent de novo CACNA1C mutation, G406R in exon 8A. An atypical form of TS, type 2, is caused by G406R and G402S mutations in the alternatively spliced exon 8. Only one individual for each exon 8 mutations has been described to date. In contrast to multiorgan disease caused by G406R either in exon 8A or 8, the G402S carrier manifested only an isolated cardiac phenotype with LQT and cardiac arrest. This isolated phenotype was suggested to result from somatic mosaicism. We describe a teenage patient resuscitated from ventricular fibrillation and treated with ICD. She has no other organ manifestations, no syndactyly, normal neurodevelopment and her QTc is <480ms. There is no family history of arrhythmias or sudden deaths. Targeted oligonucleotide-selective sequencing (OS-Seq) of channelopathy genes revealed a de novo substitution, G402S in exon 8 of CACNA1C. This is the third reported case of TS type 2. Direct sequencing of blood and oral mucosa derived DNA showed an identical mutation peak suggesting ubiquitous expression in different tissues. The phenotype of our patient and the previously described patient show an isolated arrhythmia disease with no other clinical manifestations of classical TS.

2139S

Rare potentially pathogenic variants in the congenital arrhythmia syndrome disease genes *SCN5A* and *KCNH2* are detected frequently but rarely associated with arrhythmia phenotypes in electronic health records. *S.L. Van Driest[1], S. Stallings[1], W.S. Bush[1,2], A. Gordon[3], D.R. Crosslin[3], G.P. Jarvik[3], D.S. Carrell[4], S.J. Bielinski[5], J.E. Olson[5], Z. Ye[5], I.J. Kullo[5], N.S. Abul-Husn[6], S.A. Roden[1].* 1) Vanderbilt University, Nashville, TN; 2) Case Western Reserve University, Cleveland, OH; 3) University of Washington, Seattle, WA; 4) Group Health Research Institute, Seattle, WA; 5) Mayo Clinic College of Medicine, Rochester, MN; 6) Icahn School of Medicine at Mount Sinai, New York, NY; 7) Children's Hospital of Philadelphia, Philadelphia, PA; 8) Northwestern University Feinberg School of Medicine, Chicago, IL; 9) Marshfield Clinic Research Foundation, Marshfield, WI; 10) The Pennsylvania State University, University Park, PA; 11) Johns Hopkins School of Medicine, Baltimore, MD; 12) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 13) Transgenomic, New Haven, CT; 14) GeneDx, Gaithersburg, MD.

The Electronic Medical Records and Genomics (eMERGE) consortium is using the next-generation PGRN-Seq platform to sequence 84 drug response genes in a diverse cohort of 9,000 individuals. Two of the 84 genes, *SCN5A* and *KCNH2*, encode ion channel subunits and harbor rare variants causing long QT syndrome and other arrhythmia phenotypes. Pathogenic variants in both are recommended for reporting as actionable incidental findings in recent American College of Medical Genetics and Genomics guidelines. In the initial 2,022 individuals sequenced, we identified 122 potentially pathogenic, rare (minor allele frequency < 1%), non-synonymous (nonsense, missense or splice site) variants. Five are currently designated as pathogenic for cardiac arrhythmia phenotypes in the ClinVar database. The 122 variants were submitted to 3 genomics laboratories with ion channel expertise (2 commercial and 1 academic) for assessment of pathogenicity. The number of variants assigned as pathogenic or likely pathogenic by each lab varied (lab 1: 16 variants; lab 2: 24; lab 3: 17). In all, 40 variants were designated as pathogenic or likely pathogenic by ≥ 1 lab, 9 by ≥ 2 labs, and only 4 by all 3 labs (rs199473166, rs137854618, rs199473603, and rs137854602, causing SCN5A I848F, D1275N, T1304M, and R1512W, respectively). To determine arrhythmia phenotypes for the 48/2,022 individuals with ≥ 1 of the 40 putatively-pathogenic variants, we reviewed electronic health record (EHR) data and ECG tracings (available in 33/48). None of the 48 had a family history of arrhythmia in the EHR. One individual with rs199473618 (SCN5A V1532I) had atrial fibrillation, a common arrhythmia. One individual with rs150264233 (SCN5A S1904L) had multiple instances of prolonged corrected QT interval (471-540 ms, normal < 440 ms), as well as normal corrected QT interval on many other ECGs. Four individuals had evidence of bundle branch block. No additional arrhythmia phenotypes were identified. We conclude that rare variants of undefined pathogenicity are often identified in these two arrhythmia syndrome genes. Expert curation of these variants resulted in inconsistent classifications. Among individuals with potentially pathogenic variants, arrhythmia phenotypes were rare. These data highlight the difficulty of rare variant interpretation and support a highly conservative approach to returning results of uncertain effect as "pathogenic," even in genes known to play a critical role in human disease.

2140M

Identification of histone modifier genes in 22q11DS patients with conotruncal heart defects by whole-exome sequencing. *T. Guo[1], J. Chung[1], D. McDonald-McGinn[2,6], W. Kates[3], T. Wang[4], R. Shprintzen[5], B. Emanuel[2,6], B. Morrow[1].* 1) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) Division of Human Genetics, Children's Hospital of Philadelphia and Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 3) Department of Psychiatry and Behavioral Sciences, and Program in Neuroscience, SUNY Upstate Medical University, Syracuse, New York; 4) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, New York; 5) Velo-Cardio-Facial Syndrome International Center, Department of Otolaryngology and Communication Science, SUNY Upstate Medical University, Syracuse, New York; 6) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

The 22q11.2 deletion syndrome (22q11DS, velo-cardio-facial/DiGeorge) is the most common microdeletion disorder, occurring in 1:4,000 births. The majority of patients have a similar deletion on chromosome 22q11.2. Approximately 60% of patients have varied conotruncal heart defects (CTDs), while 40% have normal cardiac anatomy. We hypothesized that novel (not previously reported) or rare (<1%) functional coding variants, could serve as genetic modifiers contributing to the risk of CTDs in 22q11DS patients. Genomic DNA samples from 186 22q11DS subjects including 91 cases with CTDs and 95 controls without CTDs were selected for whole exome sequence (WES) capture using the NimbleGen SeqCap EZ Exome Library V3.0, followed by Illumina HiSeq 2000 sequencing yielding 100-bp paired-end reads (NHLBI; Nickerson, U. Washington). A total of 77,836 coding variants were identified from the WES data. Among these, 10,621 are novel mutations not observed in the general population, and are predicted in silico to be pathogenic. Among these novel mutations, 98.8% are private with 127 in more than one sample. Novel mutations in FES (Feline sarcoma virus oncogene) and ZNF429 occurred in 3 cases but 0 controls. Novel mutations in ZNF559-ZNF177 (readthrough) and PDE4A (Phosphodiesterase 4A) occurred in 0 cases but 3 controls. Gene-based analysis using collapsing methods found three genes (JMJD1C, SPTBN5, and ZNF559-ZNF177) significantly associated with CTDs (gene based p=0.01). Of particular interest, JMJD1C had separate missense mutations in 6 of 91 cases. JMJD1C is a histone demethylase, playing a role in chromatin modification. When we searched for other mutations in genes associated with chromatin modification, we found two missense mutations in KDM3B and two others in KDM7A. Both genes encode lysine histone demethylases, supporting the idea that missense mutations in histone demethylases may contribute to CTDs in 22q11DS. Interestingly, de novo rare functional variants in histone modifying genes were found in WES data in the NIH congenital heart disease, PCGC cohort (PMID: 23665959). Among the 26 genes reported from the PCGC, we found a mutation in RNF20 (E3 ubiquitin ligase; histone H2B) in one of our cases. Overall, the two studies implicate histone-modifying genes either as causative or as modifiers in the etiology of CTDs. In addition, it expands the number of such genes that may be important for heart development in humans.

2141S

Use of high-throughput genetic sequencing to screen for copy number variation in hypertrophic cardiomyopathy. *C. Dalageorgou[1], L.R. Lopes[1], C. Murphy[2], P. Syrris[1], W.J. McKenna[1], V. Plagnol[2], P.M. Elliott[1].* 1) Institute of Cardiovascular Sciences, University College London, London, United Kingdom; 2) UCL Genetic Institute, University College London, London, United Kingdom.

The role of copy-number variation (CNV) as a cause or modifier of the hypertrophic cardiomyopathy (HCM) phenotype is poorly studied. This lack of knowledge is important as most diagnostic genetic laboratories have used Sanger sequencing when screening patients with the disease and are unable to detect CNV. The aim of this study was to use high-throughput sequence (HTS) data combined with a read-depth strategy, to screen for CNV in cardiac sarcomeric protein genes in a large consecutive cohort of patients with HCM. Five-hundred-and-five unrelated HCM patients were genotyped using a HTS approach for 41 cardiovascular genes. A previously validated read-depth strategy (ExomeDepth) was used to call CNVs from the sequencing data. Detected CNVs in 17 prioritized HCM associated genes were then validated by comparative genomic hybridization array. Eleven CNVs were identified in total. Four CNVs identified in 4 patients (0.8% of the cohort) were confirmed by aCGH: one large deletion in *MYBPC3*; one large duplication in *MYBPC3*, one large deletion in *PDLIM3* and one duplication of the entire *TNNT2* gene. The findings have immediate implications for the genetic testing and counselling of HCM patients. A patient considered as genotype-negative can in fact harbour a structural variation not detected by direct sequencing. As HTS gradually substitutes Sanger sequencing in the clinical context, bioinformatic strategies should be used to call CNVs, in parallel to single nucleotide variants and small insertion-deletions.

2142M

Gene expression profile of bicuspid and tricuspid aortic valves with and without calcification by RNA sequencing. *S. Guauque-Olarte[1], A. Droit[2], F. Hadji[1], N. Gaudreault[1], J.G. Seidman[3], S.C. Body[3], P. Pibarot[1], P. Mathieu[1], Y. Bossé[1,4].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Centre de Recherche du CHU de Québec, Laval University, Quebec, Canada; 3) Harvard Medical School, Boston, Massachusetts, USA;; 4) Department of Molecular Medicine, Laval University, Quebec, Canada.

Aortic valve stenosis (AS) is a cardiovascular disease that can be fatal in the absence of treatment. Individuals with a bicuspid aortic valve (BAV), the most common cardiovascular congenital abnormality, develop symptoms of AS 10 to 15 years earlier compared to those with a tricuspid valve. The molecular mechanisms leading to the premature development of AS in BAV patients are unknown. The objective of this study was to identify genes differentially expressed between calcified BAV and tricuspid valves with (TAVc) and without (TAVn) calcification using RNA sequencing. Ten human calcified BAV and nine TAVc were collected from male patients who underwent aortic valve replacement at the IUCPQ. All valves had the same degree of fibro-calcific remodeling. Ten TAVn were obtained from male patients who underwent heart transplantation. mRNA levels were measured using the Illumina HiSeq 2000 system. The alignment of paired-end reads and the comparison of gene expression among three groups of valves were performed using the TopHat-Cufflinks protocol. A q-value <0.05 was used as a significant threshold. Genes with FPKM <10 in two tissues compared were excluded. IPA was used to identify molecular functions enriched for genes differentially expressed. Thirty-one genes were up-regulated and 33 were down-regulated in BAV compared to TAVc, including 37 genes with fold change >2. The atherosclerosis (q=0.01), calcium signaling (q=1.95E-06), and phospholipases (q=7.76E-03) pathways were significantly enriched with differentially expressed genes. A total of 283 genes were up-regulated and 340 were down-regulated in BAV compared to TAVn, counting 288 genes with fold change >2. Compared to TAVn, 189 and 233 genes were up- and down-regulated in TAVc, respectively, including 248 genes with fold change >2. Tens of genes were newly identified to be differentially expressed among these groups of aortic valves. This is the first study analyzing the transcriptome of aortic valves by using RNA sequencing. AS causes significant changes in the expression profile of BAV and TAVc compared to normal valves. Pathways biologically relevant for AS were significantly enriched with differentially expressed genes. The role of these genes and pathways in the pathogenesis of AS in BAV patients requires further investigation. These results contribute to the search of new therapeutic targets with the potential to avoid or slow the development and/or progression of AS in patients with BAV and TAV.

2143S

Family-control analysis based on Hamming distance successfully prioritizes exome sequence variants in familial cardiomyopathy. *A. IMAI[1], J. Ott[2,3], J. Majewski[4], Y. Sakata[1], Y. Asano[1], S. Takashima[1,5].* 1) Cardiovascular Department, Osaka University Graduate School of Medicine, Suita, Japan; 2) Laboratory of Statistical Genetics, Rockefeller University, NY, US; 3) Institute of Psychology, Chinese Academy of Sciences, Beijing, China; 4) McGill University and Genome Québec Innovation Centre, Quebec, Canada; 5) Department of Medical Biochemistry, Osaka University Graduate School of Medicine, Suita, Japan.

Detecting causative genes for cardiomyopathy among hundreds of candidate variants is still challenging, especially in small pedigrees where conventional linkage analysis is underpowered or even uninformative. To overcome this problem, we developed a novel approach combining family data with population controls. The idea is that, due to linkage disequilibrium, a set of variants surrounding a disease locus should have different frequencies in affecteds and controls. Thus, we measure the distance between sets of variants in affected and unaffected individuals, where “distance” refers to the Hamming distance. At any variant surrounding a candidate variant, we distinguish between presence and absence of that variant. For a set of N such variants, the Hamming distance is the number n of variants differing between two individuals in terms of presence/absence. We then work with the Hamming distance ratio, HDR = n/N. We form pairs of all individuals and distinguish those pairs containing an affected family member (group 1) from pairs consisting only of controls (group 2). At a given candidate variant and surrounding variants, we calculate HDR for each pair of individuals and assess the difference in mean HDR values between groups 1 and 2 by a t statistic. In two hypertrophic cardiomyopathy families, known pathogenic mutations were previously detected: c.173G>A (p.R58Q) in the MYL2 gene (rs104894369), and c.746G>A (p.R249Q) in the MYH7 gene (rs3218713). Using current state-of-the-art approaches, we applied the usual filtering methods to select ~600 candidate variants from all variants obtained in exome sequencing. For one affected individual in a given small autosomal dominant family and 41 control individuals, we applied our approach. Not knowing how many variants should be included in our HDR calculation, we defined 8 regions (30-100KB) around a given candidate variant. For each region, a t statistic was computed whose maximum over the regions represents the test statistic, T, for a given candidate variant. We ranked candidate variants by their T statistic. For the two cardiomyopathy families, we were able to narrow down known disease variants to be up to the top 3% of all candidate variants. By contrast, HDR ranked 535th out of 631 variants for a TNNI3 *de novo* mutation in a restrictive cardiomyopathy pedigree. Our new statistical method for prioritizing disease regions will be useful for affected individuals in small autosomal dominant pedigrees.

2144M

Rare and common variation in *SCN10A* is associated with Brugada Syndrome. *E. Petropoulou[1], B.P. Prins[1], E. Savio-Galimberti[8], T. Yang[8], L. Crotti[4], J. Jabbari[3], M.J. Ackerman[7], R. Redon[6], P. Guicheney[5], M.S. Olesen[3], D. Darbar[8], C.R. Bezzina[2], E.R. Behr[1], Y. Jamshidi[1], Brugada Gene Discovery Group.* 1) Human Genetics Research Centre, St George's University of London, London, United Kingdom; 2) Academic Medical Center (AMC), Amsterdam, The Netherlands; 3) Laboratory for Molecular Cardiology, The Heart Centre, Copenhagen University Hospital , Copenhagen, Denmark; 4) Department of Molecular Medicine, Section of Cardiology, University of Pavia, Pavia, Italy; 5) ICAN Institute for Cardiometabolism and Nutrition, Université Paris 06, Pierre et Marie Curie, Paris, France; 6) Centre Hospitalier Universitaire (CHU) Nantes, France; 7) Mayo Clinic, Boston, MA, USA; 8) Vanderbilt University, Nashville, USA.

Introduction: Brugada syndrome (BrS) is a rare cardiac arrhythmia associated with mutations in *SCN5A*, which encodes the alpha subunit of the canonical cardiac sodium channel in ~20% of cases. BrS is associated with QRS prolongation, implying that slowed cardiac conduction is an important element of the phenotype. We hypothesized that genes in loci associated with QRS duration in the general population may harbor rare and/or common variation that contribute to the predisposition of BrS. **Methods:** A multicentre candidate gene study of 7 genes (*SCN10A*, *HAND1*, *PLN*, *CASQ2*, *TKT*, *TBχ3* and *TBχ5*) was carried out for 156 Caucasian *SCN5A* mutation-negative patients with BrS. The coding regions of the genes were sequenced, and variants categorised as pathogenic or benign when ≥3 bioinformatics tools (Polyphen2, SIFT, Grantham and GERP) predicted pathogenicity. Variant allele frequencies were compared with publicly available data (4,300 European Americans) from the NHLBI GO Exome Sequencing Project (ESP). Co-segregation analysis of putative pathogenic mutations was performed where DNA was available. Voltage-clamp experiments in ND7/23 cells were performed for the V1073A variant in *SCN10A*, which encodes the Nav1.8 sodium channel. **Results:** 49 variants were identified in the 7 genes; 23 were common single nucleotide polymorphisms (SNPs; minor allele frequency >1%). 9 variants were novel with 7 predicted as potentially pathogenic. Although co-segregation analysis was performed for 4 of the novel putative pathogenic variants, only G1299A in *SCN10A* showed co-segregation with disease alongside another novel *SCN10A* variant, I671V. There was a strong association of the common *SCN10A* variant V1073A (T>C) with BrS [frequency of T allele in BrS: 65.1% vs 40.1%, $p = 3.54\times10^{-19}$, odds ratio (95%) = 3.05 (2.37-3.91)] and voltage-clamp experiments showed a “gain-of-function” phenotype for this variant. **Conclusion:** Our study suggests that rare coding variants in the genes screened are not a major cause of BrS. The *SCN10A* common variant V1073A associated with BrS, whilst unlikely to explain the occurrence of BrS alone, confirms previous studies identifying an important role for common variation in *SCN10A* for BrS. Furthermore, we observed low specificity for predictions of likely pathogenicity when using a combination of in-silico prediction tools alone. This demonstrates that the performed in-vitro electrophysiology studies represented a valuable addition to predict pathogenicity.

2145S

Whole genome sequencing association study of ECG conduction traits. *B.P. Prins[1], F. Petropoulou[1], E. Zeggini[2], N. Soranzo[2], T.D. Spector[3], Y. Jamshidi[1], UK10K Consortium Cohorts Group.* 1) Cardiogenetics Lab, Cardiovascular and Cell Sciences Institute, St George’s University of London, London, United Kingdom; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 3) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom.

The UK10K project, funded by the Wellcome Trust, has completed whole genome sequencing (WGS) to ~6.7x coverage of 1,754 individuals from the TwinsUK study. Variants discovered through WGS, along with those from 1000 Genomes were imputed into the full cohort with genome-wide genotype data, increasing the sample size to 4,329, for which for 2,327 samples ECG measurements were available. We performed discovery analyses testing 9.2 million variants (MAF>1%) in a meta-analysis of sequenced and imputed variants for association with ECG conduction traits (PR interval, QT interval, QRS duration, and heart rate) and with the extremes of these traits. We identified 2 variants ($p < 5 \times 10^{-8}$) in known ECG trait-loci; a novel variant for PR interval and *SCN10A* (rs6599255, intronic, MAF 41.6%), and a known variant for QT interval and *NOS1AP* (rs12143842, 6 kb upstream, MAF 24.6%). We also identified 133 variants across 131 known and novel loci suggestively associated ($p < 1\times10^{-5}$) across the four ECG traits, some of which appear to be pleiotropic in nature. 60 variants were uncommon (<5% MAF), and 73 common (≥ 5% MAF). We are replicating these in independent cohorts with 1000 Genomes and UK10K imputed data, followed by direct genotyping of non-imputable variants. We performed molecular and cellular function enrichment analyses on a set of genes harbouring the identified variants, for which intergenic variants were assigned to their nearest gene and combined with genes already harbouring identified variants. We found significant enrichment ($p < 5\times10^{-2}$) for genes involved in sarcolemma function, calmodulin binding, voltage-gated channel activity and cytoskeletal protein binding. Using publicly available data from the ENCODE project on chromatin states, epigenetic modifications and sequence motifs, we show that some of these variants are likely to have functional consequences affecting regulatory elements. Currently rare variant-, and combined common-rare variant analyses are being performed using SKAT, where we collapsed variants in 57,820 gene sets based on GENCODE v19 definitions to test whether rare variation may be associated with ECG traits, and to dissect the contribution of common and rare variants to each ECG trait. These results will provide insights into how both rare and common variation are likely to contribute to the understanding of the genetic architecture of ECG traits, and are likely to explain a substantially larger fraction of the missing heritability.

Replication of a single nucleotide polymorphism variant in CETP gene associated with HDL level in the ClinSeq® Study. *H. Sung[1], T. Schwantes-An[1], B. Suktitipat[1], K. Lewis[2], D. Ng[2], S.G. Gonsalves[2], J.C. Mullikin[3,4], L.G. Biesecker[2], A.F. Wilson[1], National Institutes of Health Intramural Sequencing Center (NISC).* 1) Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, MD; 2) Medical Genomics and Metabolic Genetics Branch, NHGRI, NIH, Bethesda, MD; 3) Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, NHGRI, NIH, Bethesda, MD; 4) National Institutes of Health Intramural Sequencing Center (NISC), NHGRI, NIH, Bethesda, MD.

ClinSeq® is a large-scale medical sequencing study designed to investigate associations of rare sequence variants with traits related to Coronary Artery Disease (CAD). The study currently includes more than 1000 non-smoking participants between the ages of 45 to 65 with normal to severe coronary artery calcification scores. About 200 CAD-related traits were measured at the NIH Clinical Research Center in Bethesda, MD. Whole-exome sequencing was performed with the Agilent SureSelect 38Mb and 50Mb capture kits for 387 and 325 individuals, respectively, at the NIH Intramural Sequencing Center. Single nucleotide variants (SNVs) common to both capture regions with a call rate > 98% and minor allele frequency (MAF) > 1% were used to check for cryptic relatedness and for misspecified population stratification by multidimensional scaling analysis - 635 unrelated European Americans (EAs) remained. For each capture kit with EAs only, SNVs with at least one homozygote and a call rate greater or equal to 50% were included. The two capture regions with only SNVs in common were merged, yielding 439,807 SNVs. Of these SNVs, 74% and 46% had MAFs < 0.01 and < 0.001, respectively. The SNVs with MAF < 0.01 were collapsed into a single derived variant for each genomic region defined by hotspot blocks. Collapsed variants were coded as the proportion of minor allele occurring within each region; common variants were coded as the number of minor alleles (scaled from 0 to 1). Tests of association of each SNV with High Density Lipoprotein (HDL) level was performed on untransformed, log-transformed and rank-inverse transformed HDL with simple linear regression, adjusting for age, sex, BMI and medication. The SNV rs1532625 in the intron of CETP gene was found to have a significant association for all untransformed and transformed HDL traits at the level of 3.76e-07 after Bonferroni correction, replicating the study by Reilly et al. For all untransformed and transformed HDL traits, an additional three SNVs were found significant in the intron of the CETP (rs7205804), RBBP6 (rs3815906) and MCM5 (rs713618) at the level of 1e-05 and one SNV in the exon of PNMAL11 (rs111356009) at the level of 1e-04. CETP and RBBP6 genes are known to be associated with HDL and PNMAL1 gene with triglycerides.

Assessment of the implication of rare coding variants in familial and sporadic Fibromuscular Dysplasia. *N. Bouatia-Naji[1,2], SR. Kiando[1,2], PF. Plouin[2,3], MC. Barlassina[4], D. Cusi[5], P. Galan[6], M. Lathrop[7], X. Jeunemaitre[1,2,8].* 1) INSERM UMR970 PARCC, Paris, FRANCE; 2) Université Paris-Descartes, PRES Sorbonne Paris Cité, Paris FRANCE; 3) AP-HP, Department of Hypertension, Hôpital Européen Georges Pompidou, Paris, FRANCE; 4) Filarete Foundation, Genomic and Bioinformatics Unit ; Dept. of Medicine, Surgery and Dentistry, University of Milano, ITALY; 5) Graduate School of Nephrology, University of Milano, Division of Nephrology, San Paolo Hospital, Milano, ITALY; 6) Unité mixte de recherche 557 Inserm/Inra/Cnam/Paris13, FRANCE; 7) McGill University and Génome Québec Innovation Centre, Montréal, Québec, CANADA; 8) AP-HP, Refferal Center for Rare Vascular Diseases, Hôpital Européen Georges Pompidou, Paris, FRANCE.

Fibromuscular dysplasia (FMD) is an arterial disease characterized by non-atherosclerotic stenosis reported mostly in renal and extra-cranial carotid arteries. FMD predisposes to hypertension, renal ischemia and stroke, the first cause of disability worldwide. The genetics of fibromuscular dysplasia is under-investigated because of the lack of large families and cohorts due to the rarity of the disease and the complexity of the imaging-based diagnosis. The causes of FMD are unknown and it occurs predominantly in females with a prevalence of ~4/1000 for the clinical forms. There are strong arguments in favour of the genetic origin of FMD, based on documented and reported family history, although the precise estimation of its heritability is missing. FMD is probably a typical complex genetic disease and it is challenging to investigate because it is also a rare disease. Exome sequencing in 16 familial cases of FMD (five sibs and two sib-trios) generated 3,971 genes with at least one rare (MAF<0.01) and predicted functional variant. Inter-families analyses showed that no gene could explain the shared FMD status in at least three out of seven families. We also analysed 15 known causative genes of vascular diseases and/or connective tissue syndromes (e.g. FBN1, TGFB2 and COL3A1). None of these genes presented rare and putatively functional variants that could explain the FMD status in any of the seven families (intra-family analyses). Then, we aimed to follow-up 22 genes that were identified as harboring at least four rare variants and the 15 candidate genes in a larger sample of 259 FMD unrelated cases and 698 controls using genotyping data generated by the exome chip, an array enriched for rare and predicted functional variants. Neither gene-based association analyses of rare variants (MAF<0.01) using SKAT-O nor single SNP association of common SNPs by logistic regression (MAF>=0.05) support a role of the 37 genes tested (Ntotal=982 SNPs, including 264 common SNPs). These findings support strong genetic heterogeneity for FMD and encourage more powerful and comprehensive genomic approaches, such as genome-wide association studies, to decipher the genetic basis of FMD.

High Throughput Sequencing and Bioinformatic Analysis in Familial Congenital Heart Disease. *D. Corsmeier[1], S. Fitzgerald-Butt[2,5], G. Zender[2], M. Mori[3], L. Kelly[3], K. Walters[4], V. Vieland[4,5], H. El Hodiri[3,5], V. Garg[2,5], K. McBride[2,5], P. White[1,5].* 1) The Biomedical Genomics Core & The Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) The Center for Cardiovascular and Pulmonary Research, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) The Center for Molecular & Human Genetics, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 4) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 5) Department of Pediatrics, College of Medicine, The Ohio State University, Columbus, OH.

Congenital heart disease (CHD) is the most common type of birth defect, appearing in eight of one thousand live births. CHDs are a leading cause of death in infants and represent an increasing cause of adult morbidity and mortality. There is strong evidence for a large genetic component in the etiology of non-syndromic CHDs. As such, whole exome and whole genome sequencing will be invaluable in elucidating the underlying causal variants which lead to disease. In this study, high throughput sequencing approaches were utilized to identify genetic variants causing non-syndromic CHDs in families exhibiting Mendelian segregation of CHDs. Our subject cohort consists of over 800 affected cases and includes over 100 multiplex families. To date whole exome sequencing has been performed on several hundred of these samples using Agilent SureSelect Human All Exon V5 kits and the Illumina HiSeq platform. In selected cases for which preliminary results yielded no disease candidate mutations, more extensive sequencing methods were utilized including paired end and mate-paired whole genome sequencing. Bioinformatic analysis was performed using Churchill, the pipeline we developed for the discovery of human genetic variation. Churchill utilizes the Burrows Wheeler Aligner (BWA) and the Genome Analysis ToolKit (GATK) to perform sequence alignment and variant calling. The initial filtering and prioritization of variants, we used traditional heuristic methods based on existing variant databases (dbSNP, 1000 Genomes, NHLBI Exome Sequencing Project, HGMD). For bioinformatic and statistical validation, we explored other widely-used methods. These different methods yield highly consistent result sets from which we have been able to identify putative causal variants in these families and mark them for further validation and functional studies. These findings will provide a better understanding in the pathogenesis of CHD and can lead to improved diagnosis and novel preventive and therapeutic approaches.

Exome Sequencing Reveals Candidate Genes for Spontaneous Coronary Artery Dissection. *J.L. Theis, M.S. Tweet, J.M. Evans, R. Gulati, S.N. Hayes, T.M. Olson.* Mayo Clinic, Rochester, MN.

Spontaneous coronary artery dissection (SCAD) is an uncommon, idiopathic disorder that primarily affects young, otherwise healthy women. The pathophysiologic process involves an intimal dissection or intramural hematoma, which can obstruct blood flow and cause myocardial infarction and sudden death. A majority of patients has concomitant fibromuscular dysplasia (FMD), implicating a generalized arteriopathy. Postulating a genetic basis for sporadic SCAD, whole exome sequencing and comparative variant filtering of proband-parent trios was performed. The cohort for this pilot study was comprised of 28 unrelated patients with angiographically confirmed SCAD in the absence of a systemic connective tissue disorder (93% female; mean age 41 years). Exomes of each trio were uploaded into Ingenuity Variant Analysis™ software and filtered for rare (<1% minor allele frequency), predicted-deleterious coding variants. Modeling for de novo and recessive modes of inheritance yielded 150 unique candidate genes, none of which comprise commercial gene testing panels for thoracic aortic aneurysm and dissection. A short list of 8 prioritized candidate genes was generated based on presence in >2 trios (n=1), known coronary artery expression (n=2), or abnormal vascular phenotype associated with disruption of the murine ortholog (n=5). Each candidate gene harbored missense variants arising de novo (n=1) or inherited as recessive alleles (5, compound heterozygous; 2, homozygous). Two of these genes, each linked to SCAD associated with FMD, have been selected for mutation scanning of a cohort of 270 additional unrelated SCAD subjects by high throughput heteroduplex analysis. While our preliminary investigation has ruled out a common disease gene for SCAD, whole exome sequencing has identified plausible candidate genes, a first step toward deciphering molecular underpinnings of a disorder that may account for 40% of myocardial infarctions in women <50 years.

2150M

Feasibility of a Targeted Ion Torrent Next Generation Sequencing platform for Identification of Mutations Associated with Inherited Cardiac Arrhythmia Syndromes. *E. Burashnikov, R. Pfeiffer, G. Caceres, Y. Wu, C. Antzelevitch.* Molecular Genetics, Masonic Medical Research Laboratory, Utica, NY.

Introduction: Many unexplained sudden deaths are due to inherited cardiac arrhythmia syndromes such as Brugada Syndrome (BrS), Early Repolarization Syndrome (ERS), Short QT Syndrome (SQT) and idiopathic ventricular fibrillation (IVF). We sought to determine the suitability of screening a panel of 30 genes encoding sodium, calcium and potassium channels genes, including ATP-sensitive potassium channels, glycerol-3-phosphate dehydrogenase 1-like (GPD1L), genes previously associated with arrhythmia syndromes. We also included ankyrin 2 (ANK2), ryanodine receptor 2 (RYR2), ATP-binding cassette transporters (ABCC8, ABCC9), caveolin 3 (CAV3) and hes-related family gene (HEY2), as a potential causative contributors to these diseases. Methods: We employed an Ion Torrent Personal Genome Machine (Life Technologies) for Next Generation Sequencing and analyzed data with Ion Reporter Software (Life Technologies). Variants were annotated by Ingenuity Variant Analysis (Qiagen) and were confirmed by Sanger method on 3730 Automatic DNA Analyzer. Any variation with a frequency less than or equal to 0.5% was considered as a mutation, based on 1000 Genome Frequency. Libraries were constructed using Custom Ion Ampliseq to amplify all exons and intron borders of the targeted genes. Probands included in the study were predominantly SCN5A-negative. Results: Total of 121 probands were screened, among them 50 BrS, 42 ERS, 17 SQT and 12 cases IVF/VF. We identified mutations in 33 of 50 BrS probands screened, for a yield of 66%. Mutations in ANK2, calcium channel genes, SCN10A, SCN5A, and $I_{K\text{-}ATP}$ genes were found in 24, 20, 16, 8 and 18% of probands, respectively. In the ERS group, we identified mutations in 21 of 42 probands screened, for a yield of 50%. Mutations in ANK2, calcium channel genes, SCN10A, SCN5A, and $I_{K\text{-}ATP}$ genes were found in 17, 13, 14, 7 and 9% of probands, respectively. The SQT group had mutations in 13 of 17 probands screened, for a yield of 76%. Mutations in ANK2, CACNA1C, SCN10A, RYR2 and $I_{K\text{-}ATP}$ genes were found in 18, 24, 18, 24 and 12% of probands, respectively. In the IVF group, we uncovered mutations in 6 of 12 patients screened, for a yield of 50%. Mutations in ANK2, CACNA1C, SCN10A, SCN1B, RYR2, GPD1L and $I_{K\text{-}ATP}$ genes were 8% for each. Conclusions: Our study shows the feasibility of using a targeted Next Generation Sequencing approach for high throughput screening of SCD mutations. The study shows a yield of 50 to 76% for BrS, ERS, SQT and IVF probands.

Whole-Exome Sequencing in Multiplex Family Identifies Novel Risk Variants for Thrombotic Storm. *J.M. Vance[1], N.D. Dueker[1], A. Beecham[1], G. Beecham[1], P. Whitehead[1], S. Hahn[1], N. Hoffman[1], J.W. Lawson[2], D. Erkan[3], L.R. Brandao[4], A.H. James[5], M.J. Manco-Johnson[6], R. Kulkarni[7], C.S. Kitchens[2], T.L. Ortel[8], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of Florida, Gainesville, FL; 3) Hospital for Special Surgery, Weill Medical Center of Cornell University, Ithaca, NY 14850; 4) Paediatric Haemotology/Oncology, The Hospital for Sick Children, Toronto, ON; 5) Department. of OB/GYN, Duke University Medical Center, Durham, NC; 6) University of Colorado Denver and The Children's Hospital, Aurora, CO; 7) Pediatrics & Human Development, Michigan State University, East Lansing, MI; 8) Hematology, Duke University Medical Center, Durham, NC.

Thrombotic storm (TS) is a devastating and extremely rare disorder that occurs in a small subset of patients with venous thromboembolic disease. TS is characterized by patients exhibiting ≥ 2 of the following in a short period: 1) more than two acute arterial/venous thromboemboli, or thrombotic microangiopathy, 2) unusual location, 3) progressive/recent unexplained recurrence, or 4) refractory/atypical response to therapy. The causes of TS are currently unknown, but we hypothesized that rare genetic variants explain a proportion of the risk for TS. To identify candidate genetic variants we performed whole-exome sequencing (WES) on the only known TS multiplex family existing in the world. Within our multiplex TS family, 10 family members were WES including four sisters, 2 of which were TS affected and the other 2 unaffected. DNA was captured using the Agilent 50mb kit and sequenced using Illumina HiSeq2000. Alignment and genotype calling were performed with Burrows-Wheeler Aligner and Genome Analysis ToolKit. Using this WES data we filtered variants to identify those inherited under 3 different inheritance models; dominant, recessive, and co-dominant. For all analyses we included only those variants that met the following criteria; followed the specified inheritance model, found in the 2 affected sisters but not found in the 2 unaffected sisters, VQSLOD>-4, conserved, rare (minor allele frequency (MAF)<5%) and either missense, nonsense or splice site variants. Under a dominant model, we identified a novel variant located in zinc finger protein, FOG family member 1 (ZFPM1). ZFPM1 is an excellent TS candidate as the ZFPM1 protein interacts with GATA binding protein 1 (GATA1), a protein that plays a role in erythroid development. Previously identified mutations in GATA1 have been associated with X-linked dyserythropoietic anemia and thrombocytopenia. The variant we identified in our analysis was a missense variant predicted to be possibly damaging in PolyPhen-2. Under a recessive model, we identified two additional candidate variants; a stop-gained variant in keratin 37 (KRT37) and a missense variant in zinc finger protein 568 (ZNF568). In conclusion, through WES, we identified several loci that may play a role in the development of thrombotic storm, a complex disorder that has only recently been clinically defined and for whose cause is unknown.

Identification of rare exonic variants predisposing to early onset coronary heart disease in families from Northern Finland. *E. Nevala[1,2,10], S. Sebert[1,2], S. Kakko[2,3,4], M.J. Savolainen[2,3,4], M.R. Järvelin[1,2,5,6,7], A. Palotie[8,9], M. Männikkö[1,2,10], T. Kangas-Kontio[2,3,4].* 1) Institute of Health Sciences, Centre for Lifecourse Epidemiology, Faculty of Medicine, University of Oulu, Finland; 2) Biocenter Oulu, University of Oulu, Finland; 3) Institute of Clinical Medicine, Department of Internal Medicine, University of Oulu, Finland; 4) Clinical Research Center, Oulu University Hospital, Finland; 5) Department of Epidemiology and Biostatistics, MRC Health Protection Agency (HPA) Centre for Environment and Health, School of Public Health, Imperial College London, United Kingdom; 6) Unit of Primary Care, Oulu University Hospital, Finland; 7) Department of Children and Young People and Families, National Institute for Health and Welfare, University of Oulu, Finland; 8) Broad Institute of MIT and Harvard, Boston, Massachusetts, USA; 9) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 10) Faculty of Biochemistry and Molecular Medicine, Univeristy of Oulu, Finland.

Coronary heart disease (CHD) is the cause of every fourth death in the working-age population in Finland and the leading cause of death in the whole population. In our study we have altogether 60 extended families with over 500 subjects from an isolated and homogenous population of Northern Finland. The probands were diagnosed with early onset CHD (<55 years). To identify rare variants affecting the disease risk 51 most interesting subjects from 20 different families were selected for whole-exome sequencing (WES) on the basis of the severity of the phenotype or family history. We studied which SNPs with low occurrence (minor allele frequency < 0.05 in 1000 Genomes European population) and harmful functional prediction according to Sift, PolyPhen and Condel algorithms are co-inherited with the disease in each of the families separately. We identified per family on average 1) one variant located in CHD susceptibility genes found from OMIM database, 2) five variants in genes located nearby to the variants that have been associated with CHD in GWAS studies, and 3) five variants located in the linkage regions identified in our previously published linkage analysis. Furthermore, certain variants were shared between the families, and several genes had alternative variants in multiple families. There is intense discussion on disentangling the role of rare and common genetic variants in the etiology of complex diseases. Many studies attempting to identify the rare variants associated with the disease are large population based association studies whereas our study is designed to recognize inherited risk alleles. The discovered novel variants are located on promising genes and a more detailed analysis might provide new insights to molecular pathways responsible for the pathogenesis of CHD. Our family-data-based findings are now being confirmed by Sanger sequencing in the remaining study population and also in a large Northern Finland Birth Cohort.

Retrotransposons in Nonsyndromic Conotruncal Heart Defects. *D. Webber[1,2], S. MacLeod[1,2], S. Erickson[1,2], M. Li[1,2], L. Murphy[1,2], C. Hobbs[1,2].* 1) Pediatrics Department, College of Medicine, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Arkansas Children's Hospital Research Institute, Little Rock, AR.

Introduction: Congenital heart defects (CHDs) are a leading cause of infant morbidity and mortality. Research on CHDs has focused primarily on genomic variants within coding regions and has yet to investigate DNA transposable elements, which occupy nearly half of the human genome and are implicated in a wide range of structural and developmental conditions. We identified and characterized retrotransposon insertion polymorphisms (RIPs) among families affected by nonsyndromic conotruncal heart defects (CTDs). **Methods:** Participants were enrolled in the National Birth Defects Prevention Study at the Arkansas site between 1997 and 2007. We used probe hybridization enrichment and sequencing to map the position of human specific retrotransposons, including L1Hs and AluYb8/9, throughout the genomes of 88 case families ($n = 263$) affected by conotruncal heart defects and 40 unaffected control families ($n = 120$). Paired-end sequencing data was aligned to the reference genome with the Burrows-Wheeler Aligner (BWA), and non-reference RIPs were identified using RetroSeq. RIPs reported in dbRIP or 1000 Genomes were filtered out of the dataset in order to enrich for novel retrotransposon insertions, likely to be under selective pressure or to be a product of recent retrotransposition. **Results:** A similar proportion of novel RIPs were identified in case families compared to controls. Among cases, there were 26 novel RIPs in mothers, 37 in fathers, and 30 in infants. Nearly half (14/30) of the RIPs affecting case infants were located within introns, and the majority (21/30) were members of the LINE-1 family. Eight RIPs were observed in more than one case family, including an Alu retrotransposon within the *GLUD1* intron that was present in 5 case families and in no controls. Modeling suggest that this novel insertion introduces two canonical splice acceptor sites that are poised to disrupt the adjacent exon, which encodes a GTP binding domain previously implicated in familial hyperinsulinemic hypoglycemia 6 (HHF6; OMIM #606762). These findings are strengthened by gene ontology analysis among case infants, which showed significant enrichment ($P = .003$) of intronic RIPs in genes (*GLUD1, SLC30A8, PARK2*) involved in "regulation of insulin secretion." **Conclusion:** Proper glucose homeostasis is critical to cardiogenesis, and maternal diabetes and obesity are well-established risk factors for CHD. Results suggest that rare RIPs may influence glucose metabolism and risk of CTDs.

2154M

Cardiovascular Disease in Pediatric Patients with Ciliopathies. *S. Bowdin[1,2], N. Karp[1].* 1) Hospital for Sick Children, Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Pediatrics, University of Toronto, Canada.

Ciliopathies are a heterogeneous group of disorders caused by mutations in single genes, which alter proteins of the cilium-centrosome complex (CCC). As the primary cilia can play multiple roles and are ubiquitously distributed throughout the body, abnormal ciliary proteins can lead to multiple organ malformations and dysfunctions, including congenital heart disease. Published information on cardiovascular disease in patients with ciliopathies remains scarce , although the presence of significant cardiac disease is of cardinal importance to the clinical outcome. We conducted a retrospective review of the hospital charts and echocardiograms/electrocardiograms of 72 pediatric patients diagnosed with a ciliopathy syndrome, all of whom were cared for at the Hospital for Sick Children, in Toronto, Canada between 1983-2013. Each diagnosis of a ciliopathy was made on the basis of clinical phenotype, when possible confirmed by molecular genetic testing. A total of 23 out of 72 ciliopathy patients (32%) were found to have an abnormal echocardiogram. Five out of six patients with Alstrom syndrome had dilated cardiomyopathy as well as other structural cardiac anomalies and ECG findings . Six out of 39 patients with Bardet-Biedl syndrome, and 7 out of 19 patients with Joubert syndrome and related disorders, had structural cardiac anomalies and/ or rhythm disturbances. Three out of 6 patients with nephronophthisis had hypertension but none had structural cardiac defects. Seven patients with Leber Congenital Amaurosis, 1 patient with Senior-Loken syndrome, and 1 patient with Oral-Facial-Digital Syndrome type 1 had no documented cardiovascular disease. This data suggests that consideration should be given to a cardiovascular evaluation for all patients with a known or suspected ciliopathy. In the future, collection of prospective data may enable screening recommendations to be tailored to the patient's specific ciliopathy diagnosis .

Genotype and Phenotype Characteristics of Filipino Families with Familial Hypercholesterolemia and Novel LDL-R Gene Mutation. *E.C. Cutiongco de la Paz[1], R.G. Sy[2], K.N. Hernandez[1], E.B. Llanes[2], F.E. Punzalan[2], C.P. Cordero[3].* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila, Philippines; 2) Section of Cardiology, Department of Internal Medicine, College of Medicine-Philippine General Hospital, University of the Philippines Manila; 3) Institute of Clinical Epidemiology, College of Medicine, University of the Philippines Manila.

Familial hypercholesterolemia (FH) is a disorder of lipoprotein metabolism and is one of most common inherited disorders worldwide A diagnosis of FH is typically based on high plasma levels of total and LDL cholesterol, a family history of childhood-onset hypercholesterolemia, cholesterol deposition in extravascular tissues (e.g. tendon xanthomas, corneal arcus), and a personal and family history of premature CVD. However, there are no absolute predictive clinical criteria for FH diagnosis. Genetic testing is recommended in combination with clinical assessment to provide a more definitive diagnostic process. The LDL-R gene codes for the LDL receptor protein which is responsible for the uptake (and subsequent degradation) of serum LDL cholesterol via receptor-mediated endocytosis. Mutations in the LDL-R gene, can impair receptor synthesis or lead to the production of defective receptors. To date, 1,122 unique genetic variations have already been reported for the LDL-R gene and may be found in the online registry maintained by the Leiden Open (source) Variation Database (LOVD). Included here are the five novel mutations found by study involving selected Filipino FH patients: exon 3 G50R, exon 10 D147N, exon 13 I602V, intron 2 190+4 A>T 5' splice donor, and intron 8 1187-10 G>A 3' splice acceptor. Objectives: 1) To determine the presence of LDL-R gene mutation among first degree relatives of patients diagnosed with this genotype; 2) To describe the phenotype among these family members. Methodology: First degree relatives of the index patients identified with novel LDL-R mutations in the 2005 study of Punzalan et al. were recruited for the study. For each participant, clinical history and lipid profile were obtained and the presence/absence of the proband mutation determined via direct sequencing. The p values were calculated using the Kruskall-Wallis test. Results: A total of seven participants from four families were included, two (28.6%) males and five females (71.4%) with ages ranging from 16 to 60 years old and having a mean LDL level of 4.874 mmol/L. Calculated p values show significant association of elevated LDL- and total cholesterol levels as well as HDL ratio with the presence of an LDL-R mutation. Conclusion: Consistent with the known etiology of FH, elevated LDL cholesterol levels was found to be associated with mutations in the LDL-R gene.

Implantable cardioverter defibrillator (ICD) therapy in two founder arrhythmogenic right ventricular cardiomyopathy (ARVC) populations with mutations in TMEM43 (p.S358L) and PKP-2 (p.Q378X). When genotype matters. *K. Hodgkinson[1,3], P. Boland[2], A. Bullen[3], F. Curtis[3], A. Collier[3], S. Stuckless[1], T-L. Young[3], B. Fernandez[3], A.J. Howes[2], S. Connors[2].* 1) Clinical Epidemiology, Faculty of Medicine, Memorial University, Health Sciences Centre, St John's, NL, Canada; 2) Division of Cardiology, Faculty of Medicine, Memorial University, Health Sciences Centre, St. John's, NL, Canada; 3) Discipline of Genetics, Faculty of Medicine Memorial University, Health Sciences Centre, St. John's, NL, Canada.

Background: Arrhythmogenic right ventricular cardiomyopathy (ARVC) may lead to sudden cardiac death (SCD) due to ventricular tachycardia (VT) for which implantable cardioverter defibrillator (ICD) therapy is warranted. Determining when to provide primary ICD therapy in symptomless individuals is difficult. We assessed the efficacy of ICD therapy in two homogeneous founder cohorts with disease-causing mutations in PKP-2 (p.Q378X) and TMEM43 (p.S358L), the latter known for the significant difference in survival between mutation positive and negative individuals and the significantly worse disease in males than females. Affected status comprised mutation positive and/or clinically positive individuals. Unaffected status could only be defined as mutation negative. Methods: Genetic and clinical information was obtained from an existing database. Of 867 individuals at a priori 50% risk for TMEM43 (p.S358L), mutation status was known in 627 (398 affected). Of 117 individuals at a priori 50% risk for PKP-2 (p.Q378X), disease status was known in 61 (42 affected). The natural history to death in the PKP2 cohort was defined and outcomes following ICD in both cohorts assessed. Results: In 129 TMEM43 (p.S358L) mutation positive individuals with an ICD for primary prophylaxis, survival was significantly improved in both males ($p<0.001$, RR 9.31, 95% CI 3.34-26.00) and females ($p<0.001$, RR 3.57, 95% CI 1.34-9.54). In the PKP2 cohort, there was no survival difference between affected and unaffected individuals ($p=0.533$). Ten affected individuals had ICDs, nine for primary prophylaxis. One had VT requiring defibrillation. One SCD occurred after ICD explantation (implant infection). Six (67%) individuals had inappropriate ICD therapy encompassing 52 defibrillations. Discussion: In the missense TMEM43 (p.S358L) cohort there was a significant survival benefit following ICD. Individuals with the nonsense PKP-2 (p.Q378X) mutation had no difference in survival and thus no benefit from the ICD. However, they had an increased burden of inappropriate defibrillation. Conclusion: ICD therapy for individuals with the PKP-2 (p.Q378X) mutation should occur secondary to VT whereas primary ICD therapy is necessary for individuals with TMEM43 (p.S358L). This translational research supports the necessity for mutation-specific population studies to provide accurate natural history and clinical course information to help direct costs and lower patient burden.

Elevated risk of abnormal arterial remodeling in relatives of individuals with fibromuscular dysplasia. *A. Katz[1,3], M. Oberdoerster[2], S. Blackburn[2], D. Coleman[2], J. Stanley[2], A. Ruesch[1], J. Douglas[3], J. Li[3], S. Ganesh[1,3].* 1) Cardiovascular Medicine, University of Michigan, Ann Arbor, MI; 2) Vascular Surgery, University of Michigan, Ann Arbor, MI; 3) Human Genetics, University of Michigan, Ann Arbor, MI.

Fibromuscular dysplasia (FMD) is a rare disease of abnormal arterial remodeling, predominantly occurring in women (90%). While prior research has suggested a genetic etiology of FMD, little is known of vascular risk to family members of affected individuals. We hypothesized that compared to the general population, first degree relatives of individuals with FMD have a higher rate of diseases of abnormal arterial remodeling, manifesting as FMD with multi- or uni-focal stenosis, arterial aneurysm, and arterial dissection. Individuals with FMD were enrolled through care received at the University of Michigan and through self-referral to our study. Probands (N = 62) all had physician diagnosed FMD. Medical history of the family members was assessed for: (1) physician diagnosed FMD, (2) clinical signs of suspected but not formally diagnosed FMD, (3) aneurysm without evidence of FMD. Clinical signs of suspected FMD were stroke before the age of 55, hypertension diagnosed before age 30, renal artery stenosis, or sudden death without clear alternative etiology. Familial relative risk was calculated by comparing observed number of cases to expected number of cases among relatives of probands. Among all first degree relatives for which a medical history could be obtained (373; 120 parents, 153 full siblings, and 100 offspring), 2.7% had physician diagnosed FMD, 4.8% had clinically suspected FMD, and 3.5% had an aneurysm. Among female relatives, 5.5% (10/181) had physician diagnosed FMD, and 9.9% (18/181) had physician diagnosed or suspected FMD. Among probands' sisters, 6.3% (5/79) had physician diagnosed FMD. Using an estimate of 0.1% population prevalence of FMD, these data represent a crude unadjusted relative risk of 55 for female first degree relatives and 63 for sisters of FMD affecteds. Among probands' fathers, 11.7% (7/60) had been diagnosed with an abdominal aortic aneurysm (AAA). Using an estimate of 6% prevalence of AAA among men over 65 (from population screening studies), this represents a relative risk of 1.9. Our data indicate an elevated risk of arterial dysplasia in relatives of individuals with FMD, which supports the hypothesis that FMD is a heritable, systemic arteriopathy with variable clinical manifestations that may be specific to gender. These findings have potential clinical screening implications for family members of individuals with FMD. Further studies are needed to delineate the genetic basis and clinical presentations of FMD.

2158M

First 2 years of experience of an integrated multidisciplinary clinic for adults with aortopathies in a Canadian context. *A.M. Laberge[1,2], I. El Hamamsy[2], L. Robb[3], N. Poirier[2], P. Demers[2], F.P. Mongeon[3].* 1) Division of Medical Genetics, Dept of Pediatrics, CHU Sainte-Justine, Montreal, Canada; 2) Dept of Heart Surgery, Montreal Heart Institute, Montreal, Canada; 3) Dept of Medicine, Montreal Heart Institute, Montreal, Canada.

In 2012, the Montreal Heart Institute started an integrated multidisciplinary clinic for adults referred for suspicion of Marfan syndrome or other connective tissue disorders at risk of aortic disease. In this clinic, a specialized heart team (cardiologist specialized in adult congenital heart disease and heart surgeons specialized in aortic surgery) and a genetics team (medical geneticist, genetic counselor) see patients side-by-side. Patients with a family history of aortic disease or systemic features of Marfan syndrome are seen initially by both teams, unless a genetic diagnosis had previously been confirmed. Patients with presumed isolated aortic disease are seen first by the heart team, who determines if evaluation by the genetics team is needed. Special consultation corridors were established with a specialized orthopedist, ophthalmologist and physiatrist. A patient-centered, holistic approach is our standard of care. We report here our experience with this integrated multidisciplinary clinic over our first two years of activities. Between May 2012 and April 2014, 183 new patients were seen, from 146 different families. Reasons for referral included suspicion of Marfan syndrome (72), TAAD (56), suspicion of Loeys-Dietz syndrome (15), suspicion of Ehlers-Danlos syndrome (8), sudden death in the family (6) and various other reasons (26). All were seen by the heart team, 70 were seen by the geneticist for a dysmorphological exam. All had dedicated cardiovascular imaging in our center. Genetic tests were ordered for 35 patients. To date, genetic testing led to identification of mutations in FBN1 in eight patients and ACTA2 mutations in two families. Close links with the equivalent pediatric clinic and the prenatal genetics clinic at the affiliated mother and child university health center facilitated the evaluation of eight children of our adult patients. Most importantly, these close links allowed for the rapid evaluation of three pregnant women at risk of aortic disease and eight affected parents who had no active follow-up at the time their child was seen in the pediatric clinic. Our integrated multidisciplinary approach results in efficient access to specialized cardiac and genetic assessment and rapid management when required. Further follow-up is required to ascertain the value of such dedicated clinics in altering the natural history of these conditions.

Patterns of discordant phenotypes in familial congenital heart disease. *L.A. Larsen[1], S.G. Ellesøe[2], C.T. Workman[3], P. Bouvagnet[4], K. van Engelen[5], R. Hinton[6], V. Hjortdal[7], C.A. Loffredo[8], K. McBride[9], B.J.M. Mulder[10], A. Postma[11], L. Søndergaard[12], S. Brunak[2,3].* 1) Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 2) NNF Center for Protein Research, University of Copenhagen, Copenhagen, Denmark; 3) Center for Biological Sequence Analysis, Technical University of Denmark, Lyngby, Denmark; 4) Laboratoire Cardiogénétique, Hospices Civils de Lyon, Groupe Hospitalier Est, Bron, France; 5) Department of Clinical Genetics, Academic Medical Centre, Amsterdam, The Netherlands; 6) Division of Cardiology, The Heart Institute, Cincinnati Children's Hospital Medical Center; 7) Department of Cardiothoracic Surgery, Aarhus University Hospital, Skejby, Denmark; 8) Department of Oncology, Lombardi Cancer Center, Georgetown University, Washington, DC; 9) Center for Cardiovascular and Pulmonary Research, Nationwide Children's Hospital, Department of Pediatrics, Ohio State University, Columbus OH; 10) Department of Cardiology, Academic Medical Centre, Amsterdam, The Netherlands; 11) Department of Anatomy, Embryology & Physiology, Academic Medical Centre, Amsterdam, The Netherlands; 12) Department of Cardiology, Rigshospitalet, University Hospital of Copenhagen, Denmark.

Congenital heart disease (CHD) affects approximately 1% of live births. CHD may be caused by both genetic and environmental factors, but much of the molecular pathology remains to be elucidated. Observations of co-occurrence of specific heart defects in CHD families and in specific genetic syndromes suggest that some discordant heart defects may share susceptibility genes or pathways. Here, we have investigated the occurrence of concordant and discordant heart defects in a dataset of 4004 clinically diagnosed CHD cases, from 1175 families with at least two affected individuals per family (663 unpublished families, 512 previously published families). To investigate if specific discordant heart defects co-occur in families, we arranged the dataset into 62 anatomical subgroups of heart defects. Next, to determine the strength of association between pairs of anatomical subgroups, we calculated the log odds ratio of familial occurrence for each pair. Hierarchical clustering of the observed log odds ratios revealed specific patterns of occurrence of discordant heart defects within families, supporting a genetic relationship between specific cardiac phenotypes. The data show that defects typical for heterotaxy co-occur in families and suggest that left-sided defects rarely co-occur with right-sided defects. Targeted deletion of specific genes in mouse models often results in more than one type of heart defect, and for a specific subgroup of heart defects several overlapping susceptibility genes may exist in mouse models. We used published genotype-phenotype data from mouse models to investigate if the observed patterns of occurrence in families could be explained by shared susceptibility genes; we compared the pairwise discordance log odds ratios in families with pairwise subgroups of heart defects observed in mouse models, and we calculated the frequency of overlapping susceptibility genes between the pairs of phenotypes. The analysis revealed correlation between phenotype-pairs with high familial occurrence and phenotype-pairs with a large number of overlapping susceptibility genes in mice. For example; ventricular septal defects and interrupted aortic arch show high familial occurrence and in mouse models 14 susceptibility genes are overlapping between these two groups. In summary, we observed significant clustering of specific discordant CHD phenotypes within families and our data suggest that shared susceptibility genes may be an underlying mechanism.

Titin As a Gene for Conduction Defects With and Without Cardiomyopathy. *E. Smith[1], A. Mani[1,2].* 1) Program for Cardiovascular Genetics, Department of Internal Medicine/Section of Cardiology, Yale University School of Medicine, New Haven, CT; 2) Department of Genetics, Yale University School of Medicine, New Haven, CT.

Radical mutations in the gene Titin (TTN) have been associated with dilated cardiomyopathy. Mutations in this gene have been also reported to be associated with arrhythmogenic right ventricular cardiomyopathy, but not with isolated arrhythmia. We report three cases of sudden cardiac death due to ventricular fibrillation, where the underlying genetic causes have been narrowed down to a radical, protein altering TTN mutation. Case one is a young woman who had cardiac arrest due to ventricular fibrillation while driving a car. After resuscitation she underwent a single chamber implantable cardioverter defibrillator (ICD) placement. Post-arrest, she had several runs of non-sustained ventricular tachycardia and frequent bouts of premature ventricular excitations. Genetic testing by whole exome sequencing (WES) identified a TTN frameshift (p.G8858fs) mutation. She was later found to have mildly dilated left ventricle by echocardiography examination. The subject had family history of unspecified sudden death at young ages. Case two is a gentleman who had ventricular fibrillation at home. He had a history of paroxysmal atrial fibrillation. He too had a single chamber ICD implantation post-arrest. There is no history of cardiomyopathy or sudden death in the family. His genetic testing by WES revealed a TTN nonsense mutation (p.R18966X). He did not meet the criteria for dilated cardiomyopathy and instead had mild left ventricular hypertrophy. Case three is a woman who also had ventricular fibrillation while out with friends. Though she carried he diagnosis of hypertrophic cardiomyopathy post-arrest, serial echocardiograms did not corroborate this finding. An automatic implantable cardioverter defibrillator (AICD) was implanted post-arrest. Her family history was significant for young death in her maternal grandparents and great-grandfather. Genetic testing revealed a splice site substitution (c.28091-2A>C). These three isolated cases raise the possibility that radical TTN mutations may underlie malignant ventricular arrhythmia with and without cardiomyopathy, which constitutes a new phenotype for this gene. Further studies are needed to establish the association and to determine the mechanism.

Cystatin C and cardiovascular disease: a Mendelian randomization study. *S.W. van der Laan[1], T. Fall[2], J. van Setten[1,3], P.I.W. de Bakker[3,4], G. Pasterkamp[1], J. Ärnlöv[2], M.V. Holmes[5], F.W. Asselbergs[3,6,7,8] on behalf of the Cystatin C MR Consortium.* 1) Experimental Cardiology, UMC Utrecht, Utrecht, the Netherlands; 2) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Department of Medical Genetics, UMC Utrecht, Utrecht, the Netherlands; 4) Julius Center for Health Sciences and Primary Care, UMC Utrecht, Utrecht, the Netherlands; 5) Penn Medicine, University of Pennsylvania Health System, United States of America; 6) Institute of Cardiovascular Science, Faculty of Population Health Sciences, University College London, London, United Kingdom; 7) Durrer Center for Cardiogenetic Research, ICIN-Netherlands Heart Institute, Utrecht, the Netherlands; 8) Department of Cardiology, UMC Utrecht, Utrecht, the Netherlands.

Observational studies show a strong dose-rsponse association between circulating Cystatin C (encoded by *CST3*) and incident coronary heart disease (CHD), independent of traditional risk factors and renal function. This supports the hypothesis that circulating Cystatin C could represent a causal factor for CHD. However, residual confounding and reverse causality could be alternative explanations that are difficult to tease from observational studies. We sought to investigate the causal role of Cystatin C in CHD development by conducting a Mendelian randomization (MR) analysis using a common variant in the *CST3* locus.

We conducted a MR analysis in 43 studies including 219,219 individuals with 37,321 measures of Cystatin C and 41,162 CHD events. We used rs911119 (or a proxy, r^2>0.90) in the *CST3* locus (identified previously by GWAS) as a genetic instrument for MR analysis.

Cystatin C associated with risk of CHD in an observational analysis adjusted for age and sex (odds ratio [OR] 2.20; 95% confidence interval [CI]: 1.90, 2.57 per doubling of Cystatin C concentration; p=8.87×10^{-31}); additional adjustment for confounders (smoking, HDL-cholesterol, BMI, CKD-EPI, and systolic blood pressure) diminished the association (OR 1.60; 95%CI 1.34, 1.96 per doubling of Cystatin C concentration; p=9.09×10^{-7}). Rs911119 had a strong effect on circulating Cystatin C levels (-0.061; 95%CI -0.066, -0.057; p=4.49×10^{-149} per effect allele). However, the variant did not show significant association with risk of CHD (OR 1.01 (95%CI 0.99, 1.03; p=0.41).

In summary we replicated the association of Cystatin C with CHD risk and show a strong association of rs911119 with circulating Cystatin C. However, we find no evidence for a causal role of Cystatin C in the development of CHD.

2162M

Association of oxidative DNA damage with Folic acid metabolizing genes in Children with congenital septal defects. *S. Syed[1], K. Koneti[2], K. Kola[1], D. Dadala[3], G. Gundimeda[4], A. Akka[1], M. Mundluru[1].* 1) Institute of Genetics, Osmania University, Hyderabad, India; 2) Care Hospital, Banjara Hills, Hyderabad; 3) National Institute of Nutrition, Tarnaka, Hyderabad; 4) Indo american cancer hospital hyderabad.

Association of oxidative DNA damage with Folic acid metabolizing genes in Children with congenital septal defects Sunayana Begum Syed*, Nageswara Rao Koneti**, Srujana Kola*, Sujatha Dadala***, Sandhya Devi Gundimeda****, Jyothy Akka*, Hema Prasad Mundluru* * Institute of Genetics & Hospital for Genetic Disease, Osmania University, Begumpet, Hydreabad. **Care Hospital, Banjara Hills, Hyderabad. ***National Institute of Nutrition, Tarnaka, Hyderabad **** indo american cancer hospital, Hyderabad Background: Congenital Septal Defect (CSD) is the most common developmental anomalies, occurs 1 in 3000 live births with unknown disease etiology. The present study was designed to understand the possible etiological factors using FISH and comet assay for chromosomal and oxidative DNA damage. SNPs of folic acid metabolism and antioxidant genes MTHFR, MTRR, RFC and GST were studied by PCR-RFLP for the oxidative stress induced abnormal cardiac development during embryogenesis. Methods: The present study includes 162 children with CSD and their mothers and age matched controls (n=174). Blood samples were collected from Department of Pediatric Cardiology, Care hospital, Hyderabad with prior clearance from institutional ethics committee and written consent from parents. Lymphocytes were isolated for comet assay and FISH analysis. RBCs were used for the estimation of folic acid and Vitamin 12 levels. Inflammatory marker like C-reactive protein (CRP) was analyzed by ELISA for correlating with DNA damage. Genomic DNA was isolated for PCR based RFLP analysis of SNPs 677C>T, A66G, A80G, GSTM1 and GSTT1 genes. Results: Low RBC folate and high CRP levels were found in patients than the control group, demonstrating the severity of oxidative DNA damage. Fasting vitamin B12 levels in CSD patients and their mothers were significantly decreased than the control group. 22q11.2 micro deletions and significant DNA damage were observed in CSD patients. In MTHFR C677T the overall mutant T allele frequency was higher in patient. Similarly the frequencies of 'G/G' alleles of the genes MTRRA66G / RFC1A80G were also found to be 2 fold increased in CSD patients. Among the mothers of CSD children a 3 fold increase in frequencies of mutated 'T'/'G'/'G' allele was observed when compared to the controls. Conclusion: Elevated DNA damage, increased CRP levels and decreased folate, vitamin B12 indicates that oxidative stress plays an essential role in CSD.

2163S

Causal role of alcohol consumption in blood levels of lipids and hemostatic factors, and risks of coronary heart disease an ischemic stroke. *K. Vu[1], E. Boerwinkle[1,2], A.C. Morrison[1].* 1) School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 2) The Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA.

Background: Moderate alcohol use may reduce the risk of coronary heart disease (CHD) and ischemic stroke (IS) through an improved blood lipid profile and reduced hemostatic factor levels. However, the observed association may be confounded. Mendelian randomization (MR) can help to examine the causality of the association. Methods: The analysis involved 10,893 European American (EA) and 3,856 African American (AA) from the Atherosclerosis Risk of Communities (ARIC) study. Common and rare variants in alcohol metabolism genes, alcohol dehydrogenase (ADH), aldehyde dehydrogenase (ALDH), and cytochrome P450 (CYP2E1), were selected as the genetic instruments (25 in EA, 28 in AA). A stringent process was applied to examine the genetic instruments against MR assumptions and possible violations including linkage disequilibrium and pleiotropy. The instruments were combined into unweighted genetic scores. Alcohol use was measured by gram per week (g/wk). Lipids included triglycerides (TG), and high-density lipoprotein (HDL) and low-density lipoprotein (LDL) levels. Hemostatic factors included fibrinogen, factor VII, factor VIII, and von Willebrand factor (vWF). To examine for a possible J-shape effect of alcohol use, a sensitivity analysis excluding heavy drinkers (> 210 g/wk) was conducted. Results: In EA and AA, log alcohol use causally increased the log HDL levels (EA: β = 0.038, 95% CI: 0.001, 0.076; AA: β = 0.065, 95% CI: 0.026, 0.104), and reduced log factor VIII (EA: β = -0.039, 95% CI: -0.074, -0.003; AA: β = -0.031, 95% CI: -0.061, -0.001). A causal reduction in CHD incidence was also observed in EA (risk difference (RD) = -9.5%, 95% CI: -15.8%, -3.3%) and AA (RD = -4.8%, 95% CI: -7.4%, -2.3%). Among EA only, alcohol use causally reduced LDL levels (β = -5.715, 95% CI: -11.348, -0.082), TG (β = -0.100, 95% CI: -0.172, -0.028), and factor VII (β = -0.038, 95% CI: -0.072, -0.003). In AA, alcohol use causally reduced IS incidence (RD = -3.2%, 95% CI: -4.5%, -1.9%). No evidence was found for a causal link between alcohol use and fibrinogen and vWF. Only 5.9% EA and 4.2% AA were heavy drinkers and the sensitivity analysis yielded similar results. Conclusions: This study supports the causal role of moderate alcohol use in a raised blood level of HDL, reduced blood level of factor VIII, and reduced risk of CHD among EA and AA. The analysis also suggests a race-specific causal role of moderate alcohol use in a reduction of LDL, TG, factor VII, and risk of IS.

2164M

Mendelian randomisation study of alcohol and cardio-metabolic risk factors. *I.Y. Millwood[1], L. Li[2,3], R.G. Walters[1], W. Mei[1], D. Bennett[1], Y. Guo[2], Z. Bian[2], R. Peto[1], R. Collins[1], S. Parish[1], R. Clarke[1], Z. Chen[1], China Kadoorie Biobank collaborative group.* 1) Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU), Nuffield Department of Population Health, University of Oxford; 2) School of Public Health, Peking University Health Science Center, Beijing, China; 3) Chinese Academy of Medical Sciences, Dong Cheng District, Beijing, China.

Background: To explore the causal relationship between alcohol and cardio-metabolic risk factors in a large Chinese population, a Mendelian randomisation approach was taken using alcohol metabolising gene variants *ADH1B*2* and *ALDH2*2*. **Methods:** The study includes 82,155 men and women aged 30-79 years from the China Kadoorie Biobank prospective cohort, recruited in 2004-2008 from ten regions across China, with baseline data on alcohol consumption, physical measurements, random blood glucose and *ADH1B* (rs1229984) and *ALDH2* (rs671) genotypes. **Results:** 10,929 men (34%) and 1014 (2%) women were weekly drinkers, consuming mean (SE) 40.9 (0.3) and 16.7 (0.6) g alcohol/day, respectively. Allele frequency of *ADH1B*2* was 0.69 and *ALDH2*2* was 0.20, and both varied by region. For each acetaldehyde increasing allele, alcohol intake was lower by 3.4 (0.5) g/day (*ADH1B*2*) and 14.0 (0.9) g/day (*ALDH2*2*) in men, and by 1.8 (0.8) g/day (*ADH1B*2*) and 5.1 (1.6) g/day (*ALDH2*2*) in women, adjusted for age and region. Table 1 shows the association of reported alcohol consumption (adjusted for covariates) and alcohol predicted from a weighted genetic risk score (GRS) combining *ADH1B*2* and *ALDH2*2* (adjusted for age and region), with outcomes, in male weekly drinkers (**P<0.05, **P<0.0001). Results in female weekly drinkers were generally consistent, but not significant.

Beta (SE) 10g/d	SBP (mmHg)	DBP (mmHg)	BMI (kg/m2)	Waist:hip ratio	Waist (cm)	Body fat (%)	Glucose (mmol)
Reported-alc	0.59 (0.06)**	0.40 (0.03)**	0.01 (0.01)	0.001 (0.000)**	0.10 (0.03)**	0.04 (0.02)*	0.02 (0.01)*
GRS-alc	1.90 (0.32)**	1.61 (0.19)**	0.30 (0.05)**	0.009 (0.001)**	1.21 (0.15)**	0.79 (0.97)**	0.18 (0.04)**

Conclusion: Alcohol has a strong causal effect on blood pressure, with 10 g/day (≈one drink) increasing SBP by about 2 mmHg, and a modest adverse effect on glucose and measures of overall and central adiposity. Stronger effects seen using gene variants could reflect lifelong consumption patterns, and the limitations of self-reported questionnaire data.

2165S

Heritability and linkage study on heart rate variability in an isolated Arab population. *L. Munoz[1], M.O Hassan[2], V.S. Voruganti[3,4], D. Jaju[2], S. Albarwani[2], A. Aslani[1], R. Bayoumi[2], S. Al-Yahyaee[2], A.G. Comuzzie[4], B.Z. Alizadeh[1], I. Nolte[1], H. Snieder[1].* 1) Department of Epidemiology, University Medical Center Groningen, University of Groningen, The Netherlands; 2) College of Medicine and Health Sciences, Sultan Qaboos University, Muscat, Sultanate of Oman; 3) Department of Nutrition and UNC Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC, USA; 4) Department of Genetics, Texas Biomedical Research Institute, Texas, USA.

Background: Heart rate variability (HRV) is a reliable, non-invasive, economical reflection of many physiological and psychological factors regulating the normal heart rhythm. It is often used as an index of cardiac parasympathetic system activity. In the general population decreased HRV is an independent risk factor for morbidity and mortality. Individual differences of HRV can be attributed to genetic factors and are found to be more pronounced in subjects during stress tests. However, most published studies on the genetic influence on HRV have focused on subjects of European and African-Americans descent. In Oman Family Study (OFS) we aim to (a) estimate and quantify the contribution of genes to the variance of HRV; (b) calculate the overlap in genetic and environmental influences on HRV at rest and under stress using uni-and bivariate analyses; and (c) perform a multipoint variance component-based linkage analysis for all HRV parameters. Methods: The OFS consists of five large, multigenerational pedigrees of Arab families living in Willayat (state) of Nizwa. The strengths of the OFS are: (1) geographically isolated which provides a more homogeneous environmental exposure, (2) similar socio-economic status and health-related habits, (3) highly consanguineous, and (4) authenticity and accessibility of genealogical records. HRV variables (SDNN, RMSSD, HF, LF, VLF, and TP) and heart rate (HR) were measured from beat-to-beat heart rate data at rest and during physical (cold pressor test, CPT) and mental (word conflict test, WCT) stress tests for 1274 participants. Solar software was used to calculate the heritability estimates and to perform the linkage analyses. Results: Univariate and bivariate heritability (h2) estimates at rest and for the two stress tests were all highly significant ($p<0.05$). Linkage is currently being analyzed for all HRV measurements. Conclusions: In the OFS, additive genetic factors significantly influence all HRV parameters and especially HR. Heritability estimates at rest and during physical stress were lower than during mental stress, in particular for SDNN and RMSSD. Bivariate heritability analysis showed evidence that the same genetic factors that influence HRV at rest, influence HRV during both mental and physical stress tests.

2166M

The Familiality of Extreme Lipid Values. *S. Knight[1,2], J.B. Muhlestein[1,2], J.F. Carlquist[1], J.L. Anderson[1,2], B.D. Horne[1,2].* 1) Intermountain Medical Center, Murray, UT; 2) Department of Medicine, University of Utah, Salt Lake City, UT.

Background: It is estimated that ~40% of the variability in blood lipid values is heritable. However, little is known about the familiality of extreme lipid values, thus, we examined the familiality of extreme total cholesterol, low density lipoprotein cholesterol (LDL-C), high density lipoprotein cholesterol (HDL-C), and triglycerides. Methods: The Intermountain Genealogical Registry was used for this study. This registry contains the genealogy for over 700,000 patients in the Intermountain Healthcare (IHC) system. The extreme trait cases were defined as individuals who had at least 3 high/low value and at least 1 extreme value - Total cholesterol (high value ≥240 mg/dL & extreme value ≥300 mg/dL), LDL-C (≥160 mg/dL & ≥190 mg/dL), HDL-C (≤40 mg/dL & ≤20 mg/dL), and triglycerides (≥200 mg/dL & ≥500 mg/dL). We further restricted these cases to those that linked to a pedigree that has a minimum of 3 generations and 12 ancestors. For each extreme lipid trait, we generated a genealogy index of familiality (GIF), which is 10,000 times the average pairwise kinship of coefficient of cases. The significance of the GIF is assessed empirically using 1000 set of controls IHC patients with 3 generations and 12 ancestors. Results: The total numbers of extreme cases for the GIF analyses were 395 for cholesterol, 534 for LDL, 441 for HDL and 790 for triglycerides. The GIF for cholesterol was 0.3638, which was not significant compared to the matched controls (Average control set GIF = 0.448, p=1.00). However, the GIF for LDL-C (GIF=0.5035), HDL-C (GIF= 0.5127), triglyceride (GIF=0.6358) were all significant (all pvalues<0.01). The greatest contribution to the GIF for triglycerides and second greatest for LDL-C came from case pairs that were related by 2 meioses (e.g., siblings), while the greatest for HDL-C was case pairs that were separated by 6 meioses. This may indicate shared environmental factors contribute more to the heritability of triglycerides and LDL, than contribute to HDL-C. Conclusions: Extreme values of individual lipid traits (LDL-C, HDL-C, triglycerides) were familial, although extreme total cholesterol levels might not have a familial component. These results also suggest that shared environment may play a greater role in extreme LDL-C and triglycerides values, than they do in HDL-C.

2167S

Characteristics of Aortic Disease Associated with ACTA2 mutations. *E.S. Regalado[1], D. Guo[1], S. Prakash[1], T.A. Bensend[1], K. Flynn[1], A. Estrera[2], H. Safi[2], D. Liang[3], J. Hyland[4], A. DeBakey Department of Surgery, Baylor College of Medicine, the Texas Heart Institute, and Baylor St. Luke's Medical Center, Houston, TX, USA.

ACTA2 is the most frequently mutated gene causing familial thoracic aortic aneurysms and dissections and is responsible for up to 20% of cases. We characterized the aortic disease, management, and outcome associated with the first aortic event (defined as aortic dissection or aortic aneurysm repair) in a large case series of individuals (n=277) with 41 ACTA2 mutations. Aortic events occurred in 48% of the cohort, with the vast majority presenting with thoracic aortic dissections (88%) at variable ages ranging from 12 to 76 years and associated with a 25% mortality rate. Type A dissections were more common than type B dissections (54% versus 21%), but the median age of onset of type B dissections was significantly younger than type A dissections (27 vs. 36 years of age). Among individuals presenting with type A dissections, the maximum diameter ranged from 3.8- 9.5 cm, and one-third of these individuals had dissections at diameters <5.0 cm. Only 12% of aortic events were repair of ascending aortic aneurysms at diameters ranging from 4.2-6.5 cm (median 5.2 cm), with maximal diameter in the ascending aorta in half of the individuals. Overall cumulative risk of aortic event (i.e., penetrance) at age 85 years was only 0.76 (95% CI 0.64, 0.86). After adjustment for intra-familial correlation, gender, and race, mutations disrupting p.R179 and p.R258 were associated with higher penetrance of aortic events, whereas the mutations altering p.R185 and p.R118 showed significantly lower penetrance of aortic events. These findings demonstrate the following features of aortic disease caused by ACTA2 mutations differ from Marfan syndrome: higher rates of thoracic aortic dissections; higher prevalence of ascending aortic aneurysms involving the aortic root and/or aortic arch; decreased penetrance of aortic events for the majority of ACTA2 mutations; mutation-specific differences in penetrance and age of onset. The lack of syndromic features in ACTA2 patients most likely delays the diagnosis and proper management of aortic disease, therefore making these patients more likely to present with acute dissections. Integration of these data into genetic counseling and medical management as well as early identification of ACTA2 patients by genetic testing may reduce the extensive risk of aortic dissections. Future investigations will focus on identifying genetic and environmental modifiers in individuals with ACTA2 mutations and reducing the dissection rates in these patients.

Are short telomeres are cause or consequence of hypertension in spontaneously hypertensive mice? *C.L Chiu, N.L Hearn, D. Paine, N. Steiner, J.M Lind.* University of Western Sydney, School of Medicine, New South Wales, Australia.

Telomere length is widely considered as a marker of biological ageing. Clinical studies have reported associations between reduced telomere length and hypertension. However, the role of telomere length in the pathogenesis of hypertension, and whether reduced telomere length is a cause or consequence of disease, remains unknown. The aim of this study was to determine whether telomere shortening occurred prior to the onset of disease in spontaneously hypertensive mice. Spontaneously hypertensive Schlager mice (BPH/2J) and their normotensive controls (BPN/3J) were used in this study. Genomic DNA was extracted from kidney tissue of 4, 12 and 20 week old male BPH/2J and BPN/3J mice (n=10/group). Relative telomere length (T/S) was measured using quantitative PCR. Linear correlation estimates were performed to analyse telomere length over time within a strain. A general linear model with repeat measures testing was used to compare rate of telomere shortening between groups. A general linear model was used to compare relative telomere lengths and gene expression between groups. $P<0.05$ was considered significant. Age was inversely related to telomere length. In 4 week old pre-disease animals no difference in T/S was observed between BPH/2J and BPN/3J animals ($p=0.09$). The rate of telomere attrition between BPH/2J and BPN/3J was significantly different ($p=0.001$). At 12 and 20 weeks, established disease, BPH/2J animals had significantly shorter telomeres when compared to their age-matched controls (12 weeks $p<0.001$ and 20 weeks $p=0.004$). This is the first study to show that reduced telomere length occurs after the development hypertension, indicating that this is not the cause of hypertension in spontaneously hypertensive mice. Further studies are needed to determine the mechanisms which lead to the development of hypertension and the shortening of telomeres in these animals.

Biomolecular Sciences, University Carlo Bo, Urbino, Italy; 10) Erydel S.p.A, Urbino, Italy.

Background. Ataxia Teleangiectasia (AT) is a rare devastating neurodegenerative disease presenting with early onset ataxia, oculocutaneous teleangiectasias, immunodeficiency, radiosensitivity, and proneness to cancer. In a previous phase II study we showed that 6 monthly infusions of autologous erythrocytes loaded with dexamethasone (EryDex©) were effective in improving the neurological impairment in young AT patients. Here we report the results of the extension of this study for an additional 24 month-period. Methods. After the end of first trial, 4 subjects continued to be treated with monthly EryDex infusions for further 24 months and their clinical outcome was compared with that of 7 age-matched subjects who had stopped the treatment after the first 6 infusions. The protocol included serial assessment of ataxia (by International Cooperative Ataxia Rating Scale) and adaptive behavior (by Vineland Adaptive Behavior Scales), and clinical and laboratory tests revealing treatment- and steroid-dependent adverse effects, if present. Results. Patients in the extended study experienced a continuous neurological improvement with respect to their pre-treatment status while control subjects showed a progressive neurological deterioration (according to the natural history of the disease) after the discontinuation of the treatment. The delivery system we adopted proved to be safe and well-tolerated and none of the side effects usually associated with the chronic administration of corticosteroids was observed during the entire trial. Conclusion. These preliminary promising results call for a wide-scale controlled study on protracted treatment of AT patients with dexamethasone loaded erythrocytes.

2170M

Inta-nasal DDAVP administration for the prevention of massive subcutaneous hematoma in dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos Syndrome (DDEDS). *T. Kosho[1], M. Ishikawa[1], E. Kise[1], J. Takahashi[2], S. Yuzuriha[3], Y. Fukushima[1].* 1) Dept Med Gen, Shinshu Univ Sch Med, Matsumoto, Japan; 2) Department of Orthopedics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Plastic and Reconstructive Surgery, Shinshu University School of Medicine, Matsumoto, Japan.

Dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DDEDS), caused by recessive loss-of-function mutations in CHST14, is a recently delineated form of EDS [Dündar et al., 2009; Malfait et al., 2010; Miyake et al., 2010; Kosho et al., 2011], characterized by a unique set of clinical features consisting of progressive multisystem fragility-related manifestations (skin hyperextensibilty and fragility, progressive spinal and foot deformities, massive subcutaneous hematoma) and various malformations (facial features, congenital multiple contractures). Massive subcutaneous hematoma is the most serious complication for patients with DDEDS, which could cause significant reduction of ADL and QOL. In this report, we present experiences of three patients (7-years-old girl; 8-years-old girl; 13-years-old boy) suffering from recurrent serious hematomas and receiving intra-nasal spray of 1-desamino-8-D-arginine vasopressin (DDAVP), the only agent described to have efficacy in the control of bleeding in other types of EDS [Kimo and Becton, 1997]. First, clinical trial was performed before the therapy. Having 1 puff (300 micrograms) of DDAVP, vital signs were not changed excluding reduced urine output. Bleeding time was significantly decreased (3 to 1 minute; 4 to 2.2 minutes; 2.4 to 1 minute) with no change in PT, with mild decrease in APTT, and significant increase in activities of VIII factor and vWF. Then, they started to have intra-nasal DDAVP at an event that could cause a large hematoma. Although hematomas, typically, became large rapidly with severe pain, intra-nasal DDAVP relieved pain significantly as well as enlargement of hematomas in several minutes. The results showed efficacy of DDAVP for the prevention of massive hematoma and suggested the mechanism of this efficacy to be attributable not only to increased activities of VIII and vW factors but to rapid contraction effects of DDAVP for small arteries that might ruptured easily and not contracted normally.

2171S

Catatonia in Down syndrome; the overlooked, treatable cause of regression. *J.H. Miles[1], G. Yao[1], M. Ithman[1], A. Nassiri[2], N. Ghaziuddin[2].* 1) Dept Child Hlth, Med Gen Div, Thompson Ctr, Dept Psychiatry, Dept Biological Engineering, University of Missouri, Columbia, MO; 2) Dept Psychiatry, University of Michigan, Ann Arbor, MI.

Background: A significant minority of individuals with Down syndrome (DS) regress in motor, behavior, intellectual functioning, mood and activities of daily living during adolescence or as young adults. Catatonia, which produces these symptoms, is not considered in DS since clinicians who care for DS are generally unfamiliar with Catatonia outside Schizophrenia. Life threatening Catatonia associated with autonomic dysfunction can be triggered by neuroleptic medications used when patients are misdiagnosed. DS care guidelines don't reference Catatonia. **Objectives**: Alert physicians to Catatonia in DS and stimulate research on pathophysiology of catatonic regression. **Methods**: Five DS adolescents who experienced regression are reported. Extensive testing to rule out other causes of motor and cognitive regression was within normal limits. Based on the presence of multiple motor disturbances (slowing, grimacing, posturing), the adolescents were diagnosed with unspecified Catatonia and treated with anti-catatonic treatments (benzodiazepines/electroconvulsive therapy). One patient who had a Pupillary Light Reflex (PLR) study prior to developing Catatonia was followed with PLRs over his treatment course. **Results**: All five cases responded to initial treatment with a benzodiazepine, but required electroconvulsive therapy (ECT) to achieve remission. Longer duration Catatonia responded more slowly. All recovered baseline or near baseline functioning. A DS specific Diagnostic Protocol and Catatonia Improvement Scale were developed to standardize diagnosis and monitor treatment response over time. Changes in pupil constriction coincident with Catatonia implicate autonomic involvement. A survey of adolescents and young adults who attended one DS clinic as young children suggests a tentative prevalence of catatonic regression of 3%. **Conclusions**: We suspect Catatonia is a common, overlooked cause of unexplained deterioration in adolescents and young adults with DS. Being unaware of Catatonia in DS results in years of incapacitating illness and a risk of malignant catatonia, which may be induced by treatment with serotonergic or dopaminergic medications. Alerting geneticists to Catatonia in DS is crucial to prompt diagnosis, appropriate treatment, prevention of life threatening neuroleptic syndrome and discovering the frequency and course of this disorder. PLR evidence of autonomic dysregulation may suggest why individuals with DS are at risk for Catatonia.

2172M

To study anticancerous and antiproliferative effect of Zerumbone and Oridonin on HeLa cell lines. *N. Gill, A. Walia, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: The aim of present study was to evaluate anticancerous properties of Zerumbone (sesquiterpene phytochemical from a type of edible ginger) and Oridonin (a natural diterpenoid purified from Rabdosia rubescens, a Chinese herb) on HeLa cell lines (cervical cancer human origin). **Methodology:** HeLa cells were grown in DMEM medium supplemented with 10% FBS, 100 IU/mL Penicillin, 100μg/mL Streptomycin and Gentamycin at 37 °C in humid environment containing 5% CO2. HeLa cells were treated with different concentrations of Zerumbone and Oridonin (100 μmol/L, 50 μmol/L, 25 μmol/L, 20 μmol/L, 10 μmol/L, 5 μmol/L, 2.5 μmol/L). Cell viability and toxicity was assessed using the 3-(4, 5-dimethylthiazol-(2)-yl)-2, 5-diphenyl tetrazolium bromide (MTT) assay so to ascertain the dose effective against HeLa cell line. Morphological analysis, nuclear condensation, and fragmentation of chromatin in cells treated with different concentrations of Zerumbone and Oridonin were studied by confocal laser staining microscope using DAPI (4', 6-diamidino-2-phenylinodole), a nuclear stain. **Results:** The concentration-dependent cytotoxic activity of Zerumbone and Oridonin has been observed in HeLa cells. Zerumbone and Oridonin at a concentration of 20 μmol/L, 10 μmol/L, 5 μmol/L, 2.5 μmol/L after 24 hours showed decreased HeLa cells viability. On morphological examination, in contrast to control cells, the cells exposed to the lowest concentration of 2.5 μmol/L Oridonin and Zerumbone provoked apoptotic changes, such as cell shrinkage, nuclear fragmentation, and formation of apoptotic bodies. **Conclusion:** In the present study, we demonstrated by MTT assay and confocal studies that Zerumbone and Oridonin significantly inhibited HeLa cell growth and induced apoptosis in a dose-dependent manner.

2173S

Subjects treated with Migalastat continue to demonstrate stable renal function in a Phase 3 extension study of Fabry Disease. *D.G. Bichet[1], D.P. Germain[2], R. Giugliani[3], D. Hughes[4], R. Schiffmann[5], W. Wilcox[6], J. Castelli[7], E.R. Benjamin[7], J. Yu[7], J. Kirk[7], N. Skuban[7], J. Barth[7] On behalf of the FACETS study investigators.* 1) Hôpital du Sacré-Coeur, University of Montreal, Montreal, Quebec, Canada; 2) Hôpital Raymond Poincaré (AP-HP), University of Versailles - St. Quentin en Yvelines (UVSQ), Garches, France; 3) Medical Genetics Service, HCPA/UFRGS Porto Alegre, Brazil; 4) Royal Free Campus, University College London, London, UK; 5) Baylor Research Institute, Dallas, TX; 6) Department of Human Genetics, Emory University, Georgia; 7) Amicus Therapeutics, Cranbury, NJ.

Objectives: Fabry disease is caused by more than 800 different mutations in GLA, the gene encoding the lysosomal enzyme α -galactosidase A (α-Gal A), resulting in accumulation of globotriaosylceramide (GL-3 or Gb3) and serious morbidity and mortality. Migalastat (1-deoxygalactonojirimycin HCl, AT1001) is an orally-administered investigational pharmacological chaperone that selectively binds and stabilizes α-Gal A, leading to increased cellular levels and greater lysosomal activity. Renal function in the Phase 3 FACETS study (Study AT1001-011) was assessed over 18-24 months of treatment with migalastat using several different measures of glomerular filtration rate (GFR). After completing the FACETS study, subjects were offered continued treatment in a separate long term extension study (Study AT1001-041) where additional long-term GFR data were collected. **Methods:** The FACETS study included a 6-month double-blind placebo-controlled period (Stage 1), a 6-month open-label period (Stage 2), and a 12-month extension period. Sixty-seven subjects (24 males, 43 females) were randomized and 48 subjects (17 males, 31 females) entered long term extension Study AT1001-041. Fifty of the 67 randomized subjects had GLA mutations amenable to treatment with migalastat based on an in vitro human embryonic kidney cell assay. Analyses of eGFR (CKD-EPI, MDRD) were performed in subjects with amenable GLA mutations across both studies. **Results:** As previously reported for the FACETS study, GFR in subjects with amenable GLA mutations remained stable over 18-24 months of treatment, with mean annualized eGFR changes of -0.30 ± 0.66 (CKD-EPI eGFR) and +0.79 ± 1.03 (MDRD eGFR) mL/min/1.73m2/yr. Preliminary analysis indicates that renal function has continued to remain stable with an additional average of 6 months of treatment with migalastat in Study AT1001-041, with mean annualized eGFR changes over 24-30 months of +0.29 ± 0.64 (CKD-EPI eGFR) and +1.22 ± 0.87 (MDRD eGFR) mL/min/1.73m2/yr. **Conclusions:** Treatment with migalastat was associated with stable renal function in patients with Fabry disease and amenable GLA mutations over 24-30 months.

Development of a cell-based reporter assay suited for small-molecule drug discovery in FGF23-inducible HEK293 cells stably expressing Klotho. *S. Diener[1], K. Schorpp[2], B. Lorenz-Depiereux[1], K. Hadian[2], T.M. Strom[1,3].* 1) Institute of Human Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Bavaria, Germany; 2) Institute of Molecular Toxicology and Pharmacology, Assay Development and Screening Platform, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Bavaria, Germany; 3) Institute of Human Genetics, Klinikum Rechts der Isar der Technischen Universität München, Munich, Bavaria, Germany.

Fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis. It is of crucial importance in hereditary and acquired hypo- and hyperphosphatemic disorders. Moreover, FGF23 has emerged as a promising biomarker for the prediction of adverse clinical outcomes in patients with chronic kidney disease (CKD), as it might be related to mortality, cardiovascular abnormalities and disease progression. FGF23 is a bone-derived endocrine factor, which inhibits renal tubular phosphate reabsorption by activating receptor complexes composed of FGF receptor (FGFR) 1c and the coreceptor Klotho. As a major signalling pathway mitogen-activated protein kinase (MAPK) pathway is employed. For the investigation of FGF23 in an *in vitro* model we established FGF23-inducible HEK293 cells that stably express Klotho (HEK293-KL). The induction of HEK293-KL cells by FGF23 was shown by detecting the activation of MAPK pathway, which could be reduced by the use of two known small-molecule inhibitors of MAPK pathway: SU5402 and U0126. To identify novel small-molecule compounds that modulate FGF23/FGFR1c/Klotho signalling, we have developed a cell-based reporter assay that is suited for high-throughput screening (HTS). The assay is based on the AlphaScreen SureFire platform of Perkin Elmer to monitor the phosphorylation of endogenous extracellular signal-regulated kinase 1 and 2 (ERK1/2) in cellular lysates of HEK293-KL after the induction with FGF23 in the presence of small-molecule compounds. Since increased plasma concentrations of FGF23 are the main cause of many phosphatemic disorders, a modulation of its effect could be a potential strategy for drug discovery and new therapeutic approaches in disorders affecting phosphate homeostasis.

Phenylbutyrate increases pyruvate dehydrogenase complex activity in cells harboring a variety of defects. *R. Ferriero[1], A. Boutron[2], M. Brivet[2], D. Kerr[3], E. Morava[4], R.J. Rodenburg[5], L. Bonafé[6], M.R. Baumgartner[7], Y. Anikster[8], N.E. Braverman[9,10], N. Brunetti-Pierri[1,11].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Laboratoire de Biochimie, AP-HP Hôpital de Bicêtre, Le Kremlin Bicêtre, France; 3) Center for Inherited Disorders of Energy Metabolism, Case Western Reserve University, Cleveland, USA; 4) Hayward Genetics Center, Tulane University Medical School, New Orleans, USA; 5) Nijmegen Center for Mitochondrial Disorders, Department of Pediatrics, Radboud University Medical Center, Nijmegen, The Netherlands; 6) Center for Molecular Diseases, Lausanne University Hospital, Lausanne, Switzerland; 7) Division for Metabolic Diseases and Children's Research Center, University Children's Hospital, Zürich, Switzerland; 8) Metabolic Disease Unit, Edmond and Lily Safra Children's Hospital, Sheba Medical Center, Tel-Hashomer and Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 9) Department of Human Genetics, McGill University, Quebec, Canada; 10) Department of Pediatrics, Montreal Children's Hospital Montreal, Quebec, Canada; 11) Department of Translational Medicine, Federico II University of Naples, Italy.

Deficiency of pyruvate dehydrogenase complex (PDHC) is the most common genetic disorder leading to lactic acidosis. PDHC deficiency is genetically heterogenous and most patients have defects in the X-linked E1-α gene but defects in the other components of the complex encoded by *PDHB*, *PDHX*, *DLAT*, *DLD* genes or in the regulatory enzyme encoded by *PDP1* have also been found. Phenylbutyrate enhances PDHC enzymatic activity in vitro and in vivo by increasing the proportion of unphosphorylated enzyme through inhibition of pyruvate dehydrogenase kinases and thus, has potential for therapy of patients with PDHC deficiency. In the present study, we investigated response to phenylbutyrate of multiple cell lines harboring all known gene defects resulting in PDHC deficiency. Drug responses were correlated with genotypes and protein levels by Western blotting. Large deletions affecting *PDHA1* that result in lack of detectable protein were unresponsive to phenylbutyrate whereas increased PDHC activity was detected in most fibroblasts harboring *PDHA1* missense mutations. Mutations affecting the R349-α residue were directed to proteasome degradation and were consistently unresponsive to short-time drug incubation but longer incubation resulted in increased levels of enzyme activity and protein that may be due to an additional effect of phenylbutyrate as a molecular chaperone. PDHC enzyme activity was enhanced by phenylbutyrate in cells harboring missense mutations in *PDHB*, *PDHX*, *DLAT*, *DLD*, and *PDP1* genes. In the prospect of a clinical trial, the results of this study may allow prediction of in vivo response in patients with PDHC deficiency harboring a wide spectrum of molecular defects.

2176M

Rapamycin and Chloroquine: the in vitro and in vivo effects of autophagy-modifying drugs show unexpected results in valosin containing protein multisystem proteinopathy. *A. Nalbandian, K. Llewellyn, N. Walker, C. Nguyen, V. Katheria, A. Gomez, A. Dunnigan, P. Yazdi, V. Kimonis.* University of California, Irvine, Irvine, CA, Department of Pediatrics.

Mutations in the valosin containing protein (VCP) gene cause hereditary Inclusion body myopathy (hIBM) associated with Paget disease of bone (PDB), frontotemporal dementia (FTD), more recently termed multisystem proteinopathy (MSP). Affected individuals exhibit scapular winging and die from progressive muscle weakness, and cardiac and respiratory failure, typically in their 40s to 50s. Histologically, patients show the presence of rimmed vacuoles and TAR DNA-binding protein 43 (TDP-43)-positive large ubiquitinated inclusion bodies in the muscles. We have generated a VCPR155H/+; knock-in mouse model which recapitulates the disease phenotype and impaired autophagy typically observed in patients with VCP disease. Autophagy-modifying agents such as rapamycin and chloroquine at pharmacological doses have previously shown to alter the autophagic flux and autophagic signaling intermediates. Herein, we report results of administration of rapamycin, a specific inhibitor of the mechanistic target of rapamycin (mTOR) signaling pathway, in 19-month old VCPR155H/+ mice. Rapamycin-treated mice demonstrated significant improvement in muscle performance, quadriceps histological analysis, and rescue of defective autophagy by decreasing the protein expression levels of LC3-I/II, p62/SQSTM1, optineurin, ubiquitin, and TDP-43, and inhibiting the mTORC1 pathway substrates. Conversely, chloroquine-treated 19-month old VCPR155H/+ mice revealed progressive muscle weakness, cytoplasmic accumulation of TDP-43, ubiquitin-positive inclusion bodies and increased LC3-I/II, p62/SQSTM1, and optineurin expression levels. These findings suggest that targeting the mTOR pathway and restoring autophagic flux ameliorate an increasing list of disorders and can now include in VCP disease and related neurodegenerative multisystem proteinopathies.

2177S

Unfolded protein response induced by mutant alpha1-antitrypsin (AAT) activates JNK-MAPK pathway that modulates AAT levels and toxicity in AAT deficiency. *N. Pastore[1], B. Granese[1,2], C. Mueller[3], J. Teckman[4], N. Brunetti-Pierri[1,2].* 1) Telethon Institute of Genetics and Medicine, Italy; 2) Department of Translational Medicine, Naples, Italy; 3) Department of Pediatrics and Gene Therapy Center, UMass Medical School, Worcester, MA, USA; 4) Department of Pediatrics, Saint Louis University School of Medicine, Cardinal Glennon Children's Medical Center, Saint Louis, MO, USA.

Alpha-1-antitrypsin (AAT) deficiency is the most common genetic cause of liver disease in children and liver transplantation is the only available treatment in severe patients. The majority of patients carry a missense mutation (lysine for glutamate at amino acid position 342) in the AAT gene that alters protein folding. Mutant AAT is prone to polymerize and aggregate in the endoplasmic reticulum (ER) of hepatocytes, causing liver injury by a gain-of-toxic mechanism. Accumulation of these polymers results in release of ER calcium, NFκB activation, and apoptosis. The involvement of unfolded protein response (UPR) in AAT deficiency has been controversial. We observed that the PiZ mouse, a transgenic mouse model that expresses the mutant human AAT gene and recapitulate the features of human liver disease, has an age-dependent accumulation of mutant AAT that decreases with aging. UPR markers ATF6, PERK, IRE1, BiP, and GRP94 were all found to be overexpressed in younger PiZ mice with more abundant load of mutant AAT. Next, we injected PiZ mice with a recombinant serotype 8 adeno-associated virus (rAAV) vector that incorporate microRNA (miRNA) sequences targeting the AAT gene and resulting in mutant AAT knockdown in the liver. These mice displayed reduced activation of UPR as shown by decreased ATF6 and BiP protein levels thus confirming that UPR activation is dependent upon mutant AAT protein dosage at a given age. Finally, we observed that UPR induced by mutant AAT results in the activation of JNK-MAPK pathway in both PiZ mice and human liver samples from affected patients. Interestingly, inhibitors of this pathway decrease mutant AAT levels in a cell model of the disease, suggesting that these components might be new targets for mitigating AAT deficiency. Collectively, these data reveal new therapeutic entry points for treatment of AAT deficiency.

Case report: Efficacy of L-Citrulline supplementation in a patient with Mitochondrial Encephalopathy, Lactic Acidosis and Stroke-like episodes (MELAS) with behavioral disturbances and failure to thrive. *E. Alkhunaizi[1], A. Shuen[1], M. Lefrancois[2], M. Larose[3], C. Saint-Martin[4], W. Al-Hertani[1].* 1) Department of Medical Genetics, McGill University Health Centre, Montreal, QC, Canada; 2) Department of Nutrition, McGill University Health Centre, Montreal, QC, Canada; 3) Department of Psychiatry, McGill University Health Centre, Montreal, QC, Canada; 4) Department of Diagnostic Imaging, McGill University Health Centre, Montreal, QC, Canada.

MELAS (MELAS [MIM 540000]) is a mitochondrial multisystem condition that often manifests in childhood with seizures associated with stroke-like episodes and transient hemiparesis or cortical blindness and lactic acidosis. Therapeutic options for MELAS are limited at this time, and under trial. We report on an 8 year-old female of Sri Lankan origin, who presented with status epilepticus and found to have severe lactic acidosis (5-8.2 mmol/L). She subsequently developed mild to moderate bilateral sensorineural hearing loss. Her past medical history was significant for a seizure disorder, Wolff-Parkinson-White syndrome, failure to thrive and behavioral disturbances. Magnetic resonance imaging with spectroscopy (MRI/MRS) showed progressive increased T2 and FLAIR signal in multiple cortical and subcortical regions and presence of lactate peaks. She was later confirmed to have the most common MELAS mutation (m.3243A>G) in the *MT-TL1* (MTTL1 [MIM 590050]) gene. After her delayed diagnosis at 9 years of age, we started her on arginine supplementation (0.3mg/kg/day) for approximately one year. Her weight remained unchanged on the 0.1-3rd percentile and height on the 3rd percentile in that time period, and she continued to deteriorate in her behavior and mood as noted on neuropsychiatric assessment. One year later, as a trial we switched her to citrulline supplementation (0.3mg/kg/day) and a remarkable improvement in her neuropsychiatric function, especially mood and behavior, was noted by her parents. Furthermore, admissions for seizures and stroke-like episodes were less frequent. Finally her growth parameters increased up to the 15th-50th percentile for weight and 15th percentile for height, over a period of seven months, after initiation of citrulline. It is known that citrulline increases nitric oxide (NO) production more than arginine, and as published by El Hattab et. al., citrulline may potentially have a better therapeutic effect in MELAS, compared to arginine, with larger trials currently underway. This case report illustrates impressive improvement in clinical outcome and quality of life with citrulline supplementation in our MELAS patient.

2179S

Combination Therapy To Enhance Antisense Mediated Exon Skipping for Duchenne Muscular Dystrophy. *D.W. Wang[1], E.I. Mokhonova[1, 2, 3], L. Martinez[2, 3], D. Becerra[2, 3], M.J. Spencer[2, 3], S.F. Nelson[3, 4, 5, 6], M.C. Micheli[1, 3, 5].* 1) Microbiology Immunology and Molecular Genetics, University of California, Los Angeles, Los Angeles, CA., USA; 2) Neurology, David Geffen School of Medicine, University of California, Los Angeles; 3) Center for Duchenne Muscular Dystrophy, University of California Los Angeles, California, USA; 4) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, California, USA; 5) Molecular Biology Institute, University of California Los Angeles, California, USA; 6) Department of Pathology and Laboratory Medicine, University of California Los Angeles, California, USA.

Duchenne muscular dystrophy (DMD) is a lethal X-linked recessive disorder primarily caused by frameshifting deletions in the DMD gene that result in a loss of dystrophin protein expression. Antisense oligonucleotide-mediated exon skipping shows promise as a therapeutic approach by restoring the DMD reading frame and correcting dystrophin protein localization to the DGC. Using a small-molecule screen, our lab has previously found that dantrolene, an FDA approved compound used to treat malignant hyperthermia, increases antisense oligonucleotide-mediated exon skipping. Previous work has evaluated dantrolene synergy with antisense oligonucleotide (AO) in the context of twice daily intraperitonealy administered dantrolene. We tested if dantrolene administered via oral gavage or incorporated into mouse chow had a similar efficacy enhancement of Dmd exon 23 antisense oligonucleotide (PMOE23) skipping and dystrophin protein rescue. RNA was analyzed via qRT-PCR for amounts of skipped and full-length Dmd mRNA. Quantitative immunohistochemistry was performed to assess both rescued dystrophin levels as compared to wildtype control, as well as proper localization at the sarcolemma. We have thus assessed a series of alternate and more viable methods for dantrolene delivery with a large number of replicate 3 week experiments, and determined that dantrolene mixed in chow delivers optimal, stable and effective dosing. We further demonstrate that dantrolene administered with one half of the maximally effective dose of AO (greater than 100mg/kg) induces an equivalent amount of dystrophin as 100mg/kg per week AO or 300mg/kg per week AO. Thus, we have now determined route and method of dantrolene delivery that is compatible with long-term administration, and have established dosing of AO to assess both potential for enhancement of maximal effect and potential for dose saving effect in the upcoming 6 month treatment experiment. In addition to the animal studies, we aim to establish that dantrolene enhancement of exon skipping of human exon 51 occurs in multiple independent human induced myotubes. For this work, we have established protocols for skin punch fibroblast growth and transdifferentiation into myotubes. Seven skin punch biopsies have been obtained from patients with exon 51 skippable mutations, and 5 have been reprogrammed into iDRMs. We are assessing AVI4657 mediated skipping with and without dantrolene in myotubes generated from these iDRM cell lines.

2180M

Inhibition of AKT signaling in Proteus and PROS cells: A simple model for cancer therapeutics targeting the AKT/PI3K pathway. *L.G. Biesecker[1], M.J. Lindhurst[1], M.R. Yourick[1], D.T. Dransfield[2].* 1) NHGRI, NIH, Bethesda, MD; 2) ArQule, Inc., Woburn, MA.

The AKT/PI3K (phosphatidylinositol-3-kinase) signaling pathway is critical for cellular growth, survival, protein synthesis, and glucose metabolism. Mutations in several key genes that result in activation of this pathway have been implicated in disorders characterized by overgrowth and/or hypoglycemia and have been identified in numerous tumor samples. Identification of inhibitors that ameliorate the affects of these mutations is an important first step in the development of protocols to treat not only cancer, but also disorders such as Proteus syndrome (PS) and PROS (PIK3CA-related overgrowth spectrum). We tested a small molecule imidzopyridine pan-AKT inhibitor in skin fibroblasts harboring the *AKT1* p.Glu17Lys mutation isolated from several patients with PS. Cells treated for 24 hours with 31-500 nM with this compound grown in both serum-free and serum-containing medium had reduced levels of AKT phosphorylation, with levels at the higher three doses approaching those of quiescent wild-type cells. The inactivation of AKT, as measured by AKT phosphorylation, occurred rapidly as the levels were reduced 20-50 fold within two hours of addition of 125 nM of this inhibitor to the media. Similar results were found using fibroblasts containing *PIK3CA* p.His147Arg or p.His1047Leu mutations. *AKT1* mutation-positive cells treated with 625 nM of the inhibitor for 72 hours had a 25-40% reduction in cell viability compared to untreated cells, whereas mutation-negative cells only had a 0-20% decrease. These results indicate that basal AKT signaling in cells containing activating mutations in *AKT1* and *PIK3CA* can be inhibited in PS and PROS cells using an imidzopyridine inhibitor. Furthermore, our results suggest that reduced signaling can be achieved without complete disruption of cellular processes. This work has implications beyond PS and PROS as these mutations have been shown to be driver mutations in tumors. Because these cells harbor only a single mutation, as compared to the hundreds or thousands of mutations in tumors, they can be considered as single gene models of tumor therapy. Thus, the evaluation of such cells from patients with only a single mutation will simplify studies and allow investigators to assess the efficacy of a compound on a specific pathway without confounding effects resulting from additional driver and passenger mutations typically found in tumor cells.

Cycloheximide enhances skipping of mutated DMD exons synergistically with TG003. *A. Nishida[1], Y. Takeshima[2], T. Lee[3], T. Takarada[4], M. Matsuo[1].* 1) Medical Rehabilitation, Kobegakuin University, Kobe, Japan; 2) Department of Pediatrics, Hyogo Medical College, Nishinomiya, Japan; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 4) Department of Clinical Pharmacology, Kobe Pharmaceutical University, Kobe, Japan.

Duchenne muscular dystrophy (DMD) is a progressive and fatal muscle wasting disease. DMD is characterized by muscle dystrophin deficiency caused by mutations in the DMD gene. Exon skipping that produces in-frame functional DMD mRNA is the most plausible way to express dystrophin in DMD therapy. In our previous report, we showed that TG003, a chemical Clk1 inhibitor, enhances skipping of mutated DMD exons and the subsequent expression of dystrophin (Nishida et al. Nat Commun 2011). It has been questioned whether TG003-mediated exon skipping is potentiated. Here, we searched for chemicals that enhance skipping of 14 mutated DMD exons. Hybrid-minigenes inserting one of mutated exons were transfected into HeLa cells and resultant mini-gene product was analyzed RT-PCR amplification. We found that cycloheximide (CHX), a protein synthesis inhibitor, enhanced skipping of DMD exon 31 encoding a nonsense mutation (c.4303G>T). Other protein synthesis inhibitors, anisomycin and puromycin did not enhance skipping, but emetine did, indicating inhibitor-specific enhancement. As observed in TG003 treatment, CHX enhanced the skipping of mutated exons 27 and 39. CHX showed no effect on splicing of further 11 mutated or 14 wild-type DMD exons. CHX-mediated exon skipping was observed in the limited mutated exons that have been shown responsive to TG003 for exon skipping. This suggested that both TG003 and CHX enhance skipping of the mutated exons through common mechanism. Unexpectedly, the level of exon 31-skipping with TG003 was increased higher by combined treatment with CHX than the sum of increased levels with single chemical treatment. CHX was found to enhance the skipping of mutated exon 31 synergistically with TG003. This suggested that TG003 and CHX enhanced mutated exon 31 skipping in their own pathway. TG003 has been shown to increase full-length mRNA of the Clk1 gene which product phosphorylates SR protein. According TG003 treatment increased full-length Clk1 mRNA in HeLa cells. Remarkably, combination treatment of TG003 and CHX shifted the splicing completely to produce full-length mRNA only. This indicated that CHX modulates splicing of the Clk1 gene. CHX was shown to enhance skipping of mutated DMD exon 31 synergistically with TG003, and nominated as a leading compound to potentiate TG003-mediated exon skipping.

Treatment of *LMNA* Laminopathies with the Rapamycin Analog RAD001. *A.J. DuBose, N.M. Petrash, M.R. Erdos, F.S. Collins.* NHGRI, NIH, Bethesda, MD.

The lamina lies beneath the inner nuclear membrane (INM) and is composed of a meshwork of intermediate-sized filament proteins called lamins. The lamina is crucial for the structural support of the nucleus and interacts with INM proteins and chromatin. Two types of lamins make up the lamina - type A lamins and type B lamins. Through alternative splicing, *LMNA* encodes the four type A lamins, the major forms of which are lamin A and lamin C. Mutations in *LMNA* cause a wide array of disorders (laminopathies) including lipodystrophies, skeletal and cardiac myopathies, peripheral neuropathies, and accelerated aging syndromes.

Hutchinson-Gilford Progeria Syndrome (HGPS) is a rare premature aging disorder usually caused by a single nucleotide mutation in *LMNA*. This mutation activates a cryptic splice donor site causing abnormal mRNA splicing. As a result, an aberrant lamin A isoform called progerin is created. Progerin causes deleterious downstream effects including increased DNA damage, misregulation of gene expression, chromatin disorganization, altered histone modification, disruption of nuclear envelope proteins, replicative senescence, and blebbing (bulging of nucleus).

Rapamycin inhibits the mTOR pathway and thus triggers autophagy - a process that clears unnecessary proteins and organelles from cells. Treatment of HGPS fibroblasts with Rapamycin or RAD001 (Everolimus) has been previously shown to increase progerin clearance, delay cellular senescence, and reduce nuclear blebbing.

The purpose of this study is to expand investigation of RAD001 to other types of laminopathies. In addition to progerin, other mutant forms of Lamin A are known to cause defects in lamina function and could be removed by autophagy. We are examining the effects of RAD001 treatment on cells from patients with Hutchinson-Gilford Progeria Syndrome (HGPS), Atypical HGPS, Atypical Werner's Syndrome, and Emery-Dreifuss Muscular Dystrophy. We found that RAD001 increases autophagy, and some of the laminopathy cell lines show a decrease in nuclear blebbing. We hypothesize that RAD001 treatment will increase cell proliferation and rescue premature senescence.

2183S

Novel Cystine Derivatives as Potential Inhibitors of Cystine Stone Formation in Cystinuria. *A. Sahota[1], M. Yang[1], Y. Yanghui[2], H. Aloysius[2], H.M. Albanyan[2], L. Hu[2], J.A. Tischfield[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Dept Medicinal Chem, Ernest Mario Sch Pharmacy, Rutgers Univ, Piscataway, NJ.

Background: Cystinuria, caused by mutations in SLC3A1 or SLC7A9, is a common cause of urolithiasis in children. Slc3a1 knockout mice develop cystinuria and cystine stones in the bladder. Here we report the effects of two novel cystine derivatives (LH707 and LH708) on cystine solubility in vitro and in Slc3a1 knockout mice. The results were compared with cystine dimethyl ester (CDME), which is known to inhibit cystine crystal growth in vitro and cystine stone formation in knockout mice. **Methods:** The novel derivatives were designed to be absorbed through the intestine and are more resistant to esterases compared with CDME. The concentration of each derivative to double the solubility of cystine (EC2x) in aqueous solution was determined. The inhibitors were then administered by stomach tube to 2-3-month-old Slc3a1 knockout male mice daily for four weeks (200 μl of 3 mM solution in water). The bladders were dissected and the stones counted and weighed. In a second study, mice were prescreened for bladder stones by micro computed tomography and those with stones treated with LH708 and urine samples collected before and after treatment. Mutant and wild-type mice were treated with LH707 and LH708 for one week and the concentration of these compounds in the urine determined. **Results:** The EC2X for LH707, LH708 and CDME was 0.261, 0.856, and 6.37 μM, respectively. Thus, the new derivatives are 7.4 and 24.4 times more effective than CDME in the in vitro assay. The majority of stones in the LH708-treated group were less than 1 mm in the longest dimension, whereas stones in the LH707-treated group were distributed over a wider range. Only the concentration of cystine was increased in urine following LH708 treatment ($p = 0.033$). The concentration of LH708 in urine was higher than that of LH707 in wild-type or mutant mice and urine output was also greater in the LH708-treated mice (wild-type or mutant). **Conclusions:** Both LH707 and LH708 were detected in urine following treatment, indicating that these compounds were absorbed. LH708 showed better efficacy in inhibiting stone formation than LH707. The increase in cystine concentration in urine after treatment with LH708 supports our in vitro findings. The increase in concentration of LH708 in urine from mutant mice and the increase in urine output from these mice suggest that there may be enhanced transport of LH708 in mutant mice and that LH708 may have a diuretic effect in addition to inhibiting stone formation.

Towards treatment of Cantu syndrome. *G. van Haaften.* Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Utrecht, Netherlands.

The CantuTreat project aims to develop a novel therapeutic approach in treatment of Cantú syndrome. Cantú syndrome is a rare genetic disorder, affecting a small number of patients (currently 100 cases are known worldwide) who suffer from multiple symptoms including hypertrichosis, lymphedema, distinctive facial features and cardiac abnormalities. Cantú syndrome is caused by dominant gain-of-function mutations in the ATP-dependent potassium channel subunits ABCC9, and KCNJ8. This recent discovery offers a promising opportunity for therapeutic intervention. The IKATP potassium channel is a known pharmaceutical target: pharmaceutical correction of these channels by sulfonylurea drugs results in a nearly complete cure of patients with neonatal diabetes. In analogy, we intend to develop a sulfonylurea treatment for Cantú syndrome, combining in silico, in vitro and in vivo approaches. This novel treatment on the basis of existing pharmacology and approved drugs might prevent invasive clinical procedures such as heart surgery and frequent laser treatment, thus significantly improving the quality of life and life expectancy of the patients. CantuTreat brings together an international, multidisciplinary consortium for translational research into the development of a cost-effective treatment. The project unites the leading researchers and clinical experts in the field. Modelling and experimental testing of specific Cantú related mutations will further our understanding of the biology of the various symptoms. In addition we will build a global patient registry to generate a critical mass of patients in order to ensure a rapid progression towards clinical application when this preclinical study has finished. The translational approach towards a novel therapeutic strategy in this study could also serve as a blueprint for tackling related channelopathies.

Early intravenous enzyme replacement therapy improves white matter myelination in canine mucopolysaccharidosis I. *P. Dickson[1], J.M. Provenzale[2,3], S. Chen[2], I. Nestrasil[4], J. Yee[1], S.h. Kan[1], S.Q. Le[1], J. Jens[5], E. Snella[5], M.A. Guzman[6], C. Vite[7], E. Shapiro[4], N.M. Ellinwood[5].* 1) LA BioMed/Harbor-UCLA, Torrance, CA; 2) Duke University, Durham, NC; 3) Emory University, Atlanta, GA; 4) University of Minnesota, Minneapolis, MN; 5) Iowa State University, Ames, IA; 6) St. Louis University, St. Louis, MO; 7) University of Pennsylvania, Philadelphia, PA.

Diffusion tensor imaging studies in people with mucopolysaccharidosis I (MPS I) show reduced volume and reduced fractional anisotropy in the corpus callosum, which correlates with inattention on neurobehavioral tests. We have found decreased myelination in MPS I dogs as early as 6 weeks of age, and the fractional anisotropy of the corpus callosum varies with the amount of myelin basic protein in myelin extracts. We therefore studied the impact of enzyme replacement therapy (ERT) with recombinant human alpha-L-iduronidase on myelination. MPS I dogs received intrathecal (IT) ERT 0.05 mg/kg every 3 months and/or intravenous (IV) ERT 0.58-2.0 mg/kg weekly. Untreated MPS I and normal carriers were used as controls. The expression of several myelin-related genes was reduced in the corpus callosum of MPS I dogs compared to normal carriers. Expression of myelin-related genes improved in MPS I dogs treated with IT and/or IV ERT beginning at ≤30 days of age: the expression of myelin-related genes was normal in dogs treated with 0.58 mg/kg weekly IV ERT + IT ERT, and was greatly improved in dogs receiving 1.57 or 2.0 mg/kg weekly IV ERT without IT ERT. There was no improvement in myelin gene expression in dogs treated with IT ERT beginning at age 4m, although there was some improvement in fractional anisotropy, myelin basic protein levels, and myelin lipids. We have previously published improvement in brain lysosomal storage in MPS I dogs receiving early IV ERT. We suggest that small quantities of IV ERT cross the blood-brain barrier and that is sufficient to prevent some of the neuropathology of MPS I.

2186M

The impact of enzyme replacement therapy on immunity in Gaucher disease. *R. Limgala[1,2], C. Loanou[1], E. Komlodi-Pasztor[1], M. Plassmeyer[2], M. Ryherd[2], L. Austin[2], S. Lipinski[1], A. Hebert[1], M. Brown[2], O. Alpan[2], O. Goker-Alpan[1].* 1) Lysosomal Disorders Treatment Unit, O&O Alpan LLC, Fairfax, VA 22030; 2) Amerimmune, O&O Alpan, LLC, Fairfax, VA 22030.

Introduction: Gaucher disease (GD) is an autosomal recessive inherited disorder of metabolism caused by mutations in the GBA gene. Subsequent deficiency of the lysosomal enzyme glyucocerebrosidase results in accumulation of glycosphingolipids in macrophages. Patients with GD often present with an abnormal immune response that may be the result of cellular and/or humoral immune dysregulations. One of the most accepted therapies to treat GD is Enzyme replacement therapy (ERT). Here, we are examining the impact of ERT on immunity of GD patients. Cases and Methods: In an ongoing study (NCT01358188), the impact of ERT on the immunity was assessed in twenty-seven GD patients (19F/8M, mean age 40.2 yrs), five of whom were treatment-naïve at the start of the study. Flow cytometry based immunophenotyping was performed from peripheral blood samples obtained before and after ERT administration. Lymphocyte subsets, memory, NK, B and dendritic cell populations were assayed along with chemokine receptors and activation markers. Results: In a treatment naïve patient at baseline, prior to commencing ERT, CD4/CD8 ratio was less than 1 indicating immunosenescence, and transitional B-cells (characterized by CD21low expression) were markedly elevated suggesting a B-cell maturation defect. After establishment of stable-dose therapy, not only was the CD4/CD8 ratio reversed, but CD21 low cells were normalized, indicating improved B cell maturation. An increase in dendritic cells was also observed. Although the majority of subjects on long-term ERT exhibited normal ranges of lymphocyte subsets, in less than 20%, all of whom were diagnosed before the advent of ERT, the CD8 T-cell fraction was either elevated or expressed increased chemokine receptors like CXCR3, CCR6. Conclusions: Patients with GD can present with multiple immune abnormalities beyond the scope of activated macrophages resulting from accumulated sphingolipids. Our data suggest ERT or its effects may improve immunological parameters indicating the role of ERT on long-term outcome may extend beyond the known effects of decreasing organ size and improvement of hematological parameters.

2187S

An open-label, multicenter, ascending dose study of the tolerability and safety of recombinant human acid sphingomyelinase (rhASM) in patients with ASM deficiency (ASMD). *M.P. Wasserstein[1], S.A. Jones[2], H. Soran[2], G. Diaz[1], B. Thurberg[3], K. Culm-Merdek[3], A. Cunningham[3], T. Singh[3], A.C. Puga[3].* 1) Icahn School of Medicine at Mount Sinai, New York, NY, USA; 2) Manchester Centre for Genomic Medicine, St. Mary's Hospital, CMFT, University of Manchester, Manchester, UK; 3) Genzyme, a Sanofi company, Cambridge, MA, USA.

Background: Enzyme replacement therapy (ERT) with recombinant human acid sphingomyelinase (rhASM) is in clinical development for the treatment of the non-neurological manifestations of acid sphingomyelinase deficiency (ASMD). In a phase 1a single-ascending-dose study in adult patients, the maximum tolerated starting dose of rhASM was determined to be 0.6 mg/kg. Objectives: The primary objective of this phase 1b study was to determine the safety and tolerability of within-patient dose escalation of rhASM in five adult patients with Niemann-Pick Disease type B (NPD B), the non-neuronopathic form of ASMD. Each patient was to receive a starting dose of intravenous rhASM at 0.1 mg/kg and advance every two weeks according to a predetermined schedule to 3.0 mg/kg, or their maximum tolerated dose. The secondary objective was to study the pharmacokinetics, pharmacodynamics, and exploratory efficacy of rhASM administered intravenously every two weeks for 26 weeks. Methods: Study assessments included continuous adverse event (AE) reporting and periodic evaluations of safety, pharmacokinetics, pharmacodynamics, and exploratory efficacy. Safety biomarkers (e.g., C-reactive protein, bilirubin, IL-6, IL-8) were evaluated; plasma ceramide was used as a biomarker for the breakdown of sphingomyelin. Sphingomyelin content in liver was used as a pharmacodynamic endpoint. Results: The dose escalation regimen was well tolerated, with all patients reaching the maximum dose of 3.0 mg/kg. No serious or severe adverse events or deaths were reported. Related AEs consisted predominantly of infusion-associated reactions, the majority of which were mild and resolved without sequalae. A positive response to treatment with rhASM was observed in liver sphingomyelin content and several exploratory efficacy parameters, including spleen and liver volumes, pulmonary function testing, lung imaging, lipid profile, and quality of life assessments. Results will be presented. Conclusions: Within-patient dose escalation of rhASM was well tolerated. Repeat-dose safety and exploratory efficacy of rhASM support its continued development for the treatment of the non-neurological manifestations of ASMD. This study was funded by Genzyme, a Sanofi company.

2188M

A proprietary human acid α-glucosidase with high mannose 6-phosphate and its application in chaperone-advanced replacement therapy (CHART ™) as a potential next-generation treatment for Pompe disease. *S. Xu, R. Gotschall, M. Frascella, A. Garcia, R. Soska, Y. Lun, J. Feng, K. Chang, R. Khanna, H. Do, K. Valenzano.* Amicus Therapeutics, Cranbury, NJ.

Pompe disease is an inherited lysosomal storage disease that results from deficiency in acid α-glucosidase (GAA) activity. It is characterized by progressive accumulation of lysosomal glycogen in cardiac and skeletal muscles. The only treatment currently available is enzyme replacement therapy (ERT) using recombinant human GAA (rhGAA). The targeting and uptake of the exogenous enzyme into lysosomes requires the specialized carbohydrate, mannose-6-phosphate (M6P), which binds to cation-independent M6P receptors (CIMPR) at the cell surface for internalization. However, the quality and quantity of M6P present on existing rhGAA is not optimal, and may limit lysosomal uptake and clinical efficacy. While existing rhGAA products at 20 mg/kg or higher doses do achieve some clinical efficacy, unmet needs due to inadequate uptake and substrate reduction in key tissues still exist. Also the risk for developing immune response to rhGAA is high. Other drawbacks include long infusion times for patients and high demand for the manufacture of large quantities of rhGAA. We have developed a proprietary mammalian cell line and purification process that yields an rhGAA enzyme with significantly higher M6P content compared to existing products. This new rhGAA (designated as AT-B200) binds the intended CIMPR with high affinity in vitro, and is more efficiently internalized by skeletal muscle myoblasts. In the present study, AT-B200 was intravenously administered to *Gaa* KO mice using bi-weekly regimens, and achieved up to 75% reduction of accumulated glycogen in multiple skeletal muscles. Importantly, lower doses of AT-B200 (5 and 10 mg/kg) compared to Lumizyme® (20 mg/kg) showed similar or greater glycogen reduction in key skeletal muscles. At 20 mg/kg, AT-B200 showed significant superiority to Lumizyme, indicating that the higher M6P content in AT-B200 enables better drug targeting and substrate reduction in vivo. Moreover, co-administration of a pharmacological chaperone which was previously shown to improve the pharmacological properties of Pompe ERT via binding and stabilization resulted in a trend of further glycogen reduction in key skeletal muscles. Taken together, these data demonstrate that a well-targeted rhGAA mono-therapy leads to greater substrate reduction in KO mice, with additive benefits from the application of the CHART platform, thus warranting further investigation of this next-generation treatment for Pompe disease.

2189S

A Phase II Multicenter, Open-label Trial to Evaluate the Safety and Efficacy of Fabagal® (Agalsidase beta) in Patients with Fabry Disease. *H. Yoo[1], W.S. Kim[2], C.H. Lee[3], D.S. Kim[4], J.K. Jeon[5], H. Kook[6].* 1) Dept Pediatrics, Asan Medical Ctr, Seoul, KoreaKorea; 2) Dept Internal Med, Kyunghee Univ Hosp, Seoul, Korea; 3) Dept Internal Med, Hanyang Univ Hosp, Seoul, Korea; 4) Dept Neurology, Pusan Natl Univ Hosp, Pusan, Korea; 5) Dept Pediatrics, Pusan Natl Univ Hosp, Pusan, Korea; 6) Dept Pediatrics, Cheonnam Natl Univ Hosp, Hwasoon, Korea.

Background: Fabry disease is caused by a deficiency of α-galactosidase A (α-gal A), resulting in the accumulation of glycosphingolipids, mainly globotriaosylceramide (GL-3) in the vascular endothelial cells or tissues throughout the body. Fabagal® is a recombinant human α-gal A (agalsidase beta) produced from CHO cells through serum-free suspension culture. This study was planned to prove whether Fabagal® could be used as an enzyme replacement therapy for Fabry disease. We evaluated the efficacy and safety of enzyme replacement therapy (ERT) with Fabagal® in patients with Fabry disease. Methods: The study was a multicenter, open-label, and phase II study in Fabry disease patients for 24 weeks. A total of ten patients (7 male and 3 symptomatic female patients including 1 naiive patient) were enrolled (n = 10). The objective was to evaluate safety and efficacy during Fabagal® administration (1.0 mg/kg every 2 weeks) for 24 weeks. The primary endpoint of efficacy was to maintain the level of plasma GL-3 within normal range. The secondary endpoint variables were changes of urine GL-3, serum creatinine (Cr), plasma lysoGL-3 and urine lysoGL-3, echocardiographic findings, the score of Short Form McGill Pain Questionnaire & SF-36 Health Status Survey, and Subject symptom diary at 24 weeks of treatment compared to the baseline. Results: Nine of 10 enrolled patients completed the study (n = 9). Treatment with Fabagal® proved efficacious since plasma GL-3 level maintained within the normal range. Also urine GL-3 value was normalized after ERT with Fabagal® compared to the baseline. There were no significant changes of plasma lysoGL-3, urine lysoGL-3 (remained within normal range), echocardiographic findings and serum Cr level during the study period. As a result of the adverse event (AE) analysis, there was no serious adverse event or any drop out or death due to AEs. All AEs were resolved without any complications and none were related to Fabagal®. There was no significant infusion-associated reaction. Conclusions:This study proved the beneficial effect and safety of Fabagal® (agalsidase beta) that generates clinically significant decrease of GL-3 with no significant adverse drug reaction in Fabry disease patients. However, further study is needed in larger number of naiive patients for long-term period.

2190M

Choroid plexus-directed viral gene therapy for alpha-mannosidosis, a prototypical lysosomal storage disease. *E. Choi, S.G. Kaler.* Section on Translational Neuroscience; Molecular Medicine Program, NICHD/NIH, Bethesda, MD.

The choroid plexuses are highly vascularized structures that project into the cerebrospinal fluid (CSF) of the four cerebral ventricles. The specialized polarized epithelia of choroid plexuses produce CSF by transporting water and ions into the ventricles, and turn over at an extremely slow rate. We hypothesized that remodeling these epithelia to secrete a missing lysosomal enzyme by one-time administration of a recombinant AAV (rAAV) gene therapy vector into the cerebrospinal fluid could be an attractive and efficacious approach for long-term treatment of lysosomal storage diseases (LSD). Lysosomes function as the primary digestive units within cells and specific enzymes within lysosomes normally break down nutrients. Patients with LSDs cannot metabolize certain nutrients, resulting in diminished lifespans and reduced quality of life. There are no ideal therapeutic options presently available for the neurological manifestations of LSDs. Brain-directed recombinant enzyme replacement has shown promise for several LSDs but requires repeated instillations due to short enzyme half-lives. In contrast, rAAV-mediated gene transfer to the choroid plexus would enable continuous synthesis and secretion of missing lysosomal enzymes into the CSF and steady penetration to the cerebral cortex and cerebellum. To evaluate this hypothesis, we obtained a mouse model of alpha-mannosidosis in which a targeted disruption of the lysosomal acid α-mannosidase (LAMAN) gene is present. Using mice from our developing colony, we devised a genotyping assay that distinguishes wild type, heterozygous and homozygous animals. We cloned the human (hu) LAMAN cDNA into an adeno-associated virus serotype 5 (AAV5) shuttle plasmid and documented robust LAMAN expression in transfected HK293T cells. We next generated high titer rAAV5-huLAMAN expressing huLAMAN and administered 1×10e10 or 1×10e11 viral particles to homozygous affected mice by lateral ventricle injection on day 2. We documented efficient, dose-dependent viral transduction in the initial group of treated animals. Biochemical analyses and neurobehavioral testing in treated animals is in progress. We also established a NIH clinical protocol (14-CH-0106) to evaluate biomarkers in CSF of human subjects with alpha-mannosidosis for potential use in a future clinical trial. If the choroid plexus viral gene therapy approach were successful, the largest current barriers to health for patients with certain LSDs would be circumvented.

2191S

Genotoxicity after adeno-associated virus (AAV) gene therapy is dependent upon dose, treatment age and enhancer-promoter selection. *R.J. Chandler, M.C. LaFave, G.K. Varshney, A.G. Elkahloun, S.M. Burgess, C.P. Venditti.* Nat Human Genome Res Inst, National Institutes Hlth, Bethesda, MD.

AAV gene therapy has recently been approved for clinical use and shown to be efficacious and safe in a growing number of clinical trials. However, the safety of AAV as a gene therapy has been challenged by studies that documented hepatocellular carcinoma (HCC) after AAV gene delivery in mice. The association between AAV and HCC has been difficult to reconcile and is the subject of intense debate because numerous AAV studies have not reported toxicity. Here, we report a comprehensive study of HCC in a large number of mice following therapeutic AAV gene delivery. Using a sensitive high-throughput integration site-capture technique and global expressional analysis, we found that AAV integration into the Rian locus and the over-expression of a proximal gene, *Rtl1*, were associated with HCC. In addition, we identify a number of genes with differential expression that may be useful in the study, diagnosis and treatment of HCC. We demonstrate that AAV vector dose, enhancer-promoter selection, and the timing of gene delivery are critical factors in AAV-mediated insertional mutagenesis. Our results help define a mechanism underlying AAV-mediated genotoxicity and have important implications for the design of both safer AAV vectors and gene therapy studies.

Mutational and functional analysis of Glucose transporter 1 deficiency syndrome. *S. Nakamura[1], H. Osaka[1], S. Muramatsu[2], S. Aoki[1], E. F. Jimbo[1], T. Yamagata[1].* 1) Department of Pediatrics, Jichi Medical University, Shimotsuke-shi, Tochigi, Japan; 2) Department of Neurology, Jichi Medical University, Shimotsuke-shi, Tochigi, Japan.

Glucose transporter 1 deficiency syndrome (Glut-1 DS) is an autosomal dominant disorder caused by mutations in the SLC2A1 gene. The Glut-1 is expressed in the blood-brain barrier and responsible for hexose transport into the brain. The classic phenotypes with Glut-1 DS are infantile drug resistant seizures, intellectual disability (ID) and cerebellar ataxia. Seizures of Glut-1 DS can be treated with a ketogenic diet, but other symptoms persist. We detected a new mutation on SLC2A1 in a classical type patient on whom ketogenic diet was not effective. To aim more effective treatments of Glut-1 DS, we have been investigating the potentiality of gene therapy using AAV vector. As the first step, we established a functional system that monitor the ability of introduced SLC2A1 to transport glucose into cells. (Materials and methods) The patient was a 16-year old boy. He had frequent convulsion from early infancy and had severe ID. Ketogenic diet started from 6 years was not effective. After obtaining informed consent, we isolate DNA from a patient and sequenced the SLC2A1. Total RNA was also extracted and reverse transcribed to cDNA. For transfection study, we used SLC2A1 expression vector by Origene technologies (RC222696). We created plasmids with SLC2A1 mutation by ligation of oligonucleotide corresponding to R333W, A405D and c.906_907insG. To assess glucose transport, we transfected wild type and mutated SLC2A1 vectors into HEK293 cells, and 2-deoxyglucose (2DG) uptake was analyzed 48 hours after gene transfection. (Results) We identified a novel frame shift mutation, c.906_907insG in our patient. 2DG uptake increased in SLC2A1 gene expressing HEK293 cells than control vector transfected cells. 2DG uptake by mutated SLC2A1 vectors transfection to HEK293 cells decreased compared with wild type SLC2A1 vector or control vector transfection. (Discussion) Glut-1 DS is caused by haploinsufficiency of the SLC2A1 and expected to benefit from gene therapy without highly gene expression level. We could achieve the increase of 2DG uptake by wild type SLC2A1 gene transfection to HEK293 cells, which was not observed by the mutated SLC2A1. This system allows us to assess the 2DG uptake by vectors SLC2A1.

Online DuchenneConnect self-report data indicates Exon 44 skippable DMD patients have prolonged wheelchair-free survival. *J.W. Ulm[1,2], R.T. Wang[1,2], A. Eskin[1,2], S.F. Nelson[1,2,3].* 1) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles; 2) Center for Duchenne Muscular Dystrophy, University of California, Los Angeles; 3) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles.

Duchenne muscular dystrophy (DMD [MIM 310200]) is a debilitating and fatal human genetic disorder, resulting from frameshift mutations at the large *Dystrophin* gene locus on the X chromosome that disrupt the dystroglycan complex (DGC) in muscle tissue. Loss of dystrophin function causes a stereotypical clinical pattern of progressive lower-extremity proximal muscle weakness and depleted muscle mass, commencing usually prior to age 6, with muscle damage provoking inflammation and fibrosis. This leads eventually to wheelchair dependence (generally before adolescence) and eventually respiratory failure before the third decade. One treatment modality of significant interest is exon-skipping, which employs an antisense-mediated approach to bypass exons near disease-causing deletions while yielding a mostly intact transcript, thus restoring partial dystrophin function. DMD patients show significant heterogeneity in the age at which they lose the capacity for ambulation and become wheelchair-dependent (WCage), suggesting wide variation in the phenotypes ensuing from specific deletions and, therefore, in the impacts from skipping at different exons. At present, however, there is limited data available on which "skippable" exons would most likely give rise to an ameliorated phenotype, knowledge that would be of significant value in testing possible exon-skip protocols and in formulating eventual treatment regimens. In the work described here, we used online self-report data from the DuchenneConnect registry alongside gene characterization data from patients, grouping them according to which exon skip (based on their respective deletion mutations) would restore the *Dystrophin* transcript to being in-frame. We then considered the patients' particular skippable exons in the context of the reported severity of their phenotypes, focusing especially on their ages at loss of ambulation. We found that Exon 44 skippable patients demonstrated significant mitigations in severity compared to Exon 45, 50, 51, and 53 skippable patients and those with nonsense mutations, with statistically significant increases in WCage for the Exon 44 skippable group relative to other groupings (median 2 years at $p = 0.009$). These results support other studies of exon skippability and, given the comprehensive data and high statistical power of the DuchenneConnect registry, suggest that online self-report data can be of tangible value in guiding further research and treatment protocols.

TALEN-mediated Genome Modification Leads to Ablation of Intranuclear Foci in Neural Stem Cells Derived from Human Myotonic Dystrophy Type 1 iPS Cells. *G. Xia[1], Y. GAo[1], S. Jin[2], SH. Subramony[1], N. Terada[3], L. Ranum[2], M.S. Swanson[2], T. Ashizawa[1].* 1) Department of Neurology, University of Florida, College of Medicine, Gainesville, FL, USA; 2) Department of Molecular Genetics and Microbiology, College of Medicine, Gainesville, FL, USA; 3) Department of Pathology, Immunology & Laboratory Medicine, College of Medicine, Gainesville, FL, USA.

Objective: Myotonic dystrophy type 1 (DM1) is caused by expanded CTG repeats in 3'UTR of the DMPK gene. The advancement of iPS cell technology has introduced new possibilities for developing cell-based therapy. Correcting the mutation in DM1 iPS cells would be an important step towards autologous stem cell therapy. In this study, we developed an approach of in vitro gene editing to prevent production of mutant expanded CUG transcripts. Methods: Gene editing was performed in DM1 neural stem cells derived from human DM1 iPS cells. Integration of a cassette containing a selectable marker, SV40 polyA and bGH polyA sequences upstream of the DMPK 3'UTR CTG repeats was mediated by TALEN-induced double-strand break (DSB) and homologous recombination (HR). Cells that contained the insertion cassette were enriched by daGFP expression or puromycin resistance. The expression of mutant CUG repeats was monitored by foci formation using RNA fluorescence in situ hybridization (RNA-FISH). Results: The insertion cassette containing the selectable marker and polyA signals was successfully inserted into DMPK intron 9. The insertion resulted in the complete loss of intranuclear RNA foci. After removal of puromycin selectable marker by Cre recombinase, which leaves only poly A signals in the genome, cells continue to be foci-free. Conclusion: This study demonstrates that genome modification by integration of polyA signals upstream of CTG repeats prevents the production of toxic RNA mutant transcripts. This genome modification technique should overcome one of the major hurdles in the development of autologous cell replacement therapy for DM1.

Choroid plexus-directed gene therapy using an α-*N*-acetyl-glucosaminidase-IGF2 fusion protein in MPS IIIB mice. *S.H. Kan[1], S.Q. Le[1], K.N. Vondrak[1], M.R. Haddad[2], E.Y. Choi[2], A. Donsante[2], S.G. Kaler[2], P.I. Dickson[1].* 1) Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, USA; 2) Eunice Kennedy Shriver National Institute of Child Health and Development, National Institutes of Health, Bethesda, MD, USA.

Mucopolysaccharidosis type IIIB (MPS IIIB; Sanfilippo B) is an inherited neurodegenerative disorder for which no reliably treatment is currently available. The cause of MPS IIIB is deficiency of the lysosomal enzyme, α-*N*-acetyl-glucosaminidase (NAGLU) and accumulation of heparan sulfate glycosaminoglycans (GAG). Impediments to enzyme replacement therapy (ERT) include the short half-life, absence of mannose 6-phosphate (M6P), and poor blood-brain barrier penetration associated with recombinant human NAGLU. A modified human NAGLU fused to the receptor binding motif of insulin-like growth factor 2 (hNAGLU-IGF2) has been shown to enhance entry to MPS IIIB fibroblasts via M6P/IGF2 receptor-mediated endocytosis. In this study, we administered a recombinant adeno-associated virus, serotype 5 (AAV5) vector expressing rhNAGLU-IGF2 that targets the choroid plexus epithelia via lateral ventricle injection to deliver the deficient enzyme to the cerebrospinal fluid (CSF) of MPS IIIB mice.

We cloned the hNAGLU-IGF2 cDNA into an AAV vector plasmid and generated rAAV5 by the triple transfection method. NAGLU activity assay and western blots confirmed robust expression of the recombinant protein in HEK 293T cells. An *in vivo* pilot study was then performed in MPS IIIB mice by injecting 5×10^{10} vector genomes (v.g.) of rAAV5-rhNAGLU-IGF2 to the lateral ventricles of adult mice, or 5×10^{9} v.g. in neonatal mice. Mouse brains were analyzed 2 weeks after viral injection and compared with brains of untreated MPS IIIB and control (heterozygous) mice. NAGLU activity reached twice normal levels in the AAV5-treated brains. β-hexosaminidase activity, which is abnormally elevated in MPS IIIB, was significantly reduced in the AAV5-NAGLU-IGF2 treated brains. Histochemical evaluations confirmed NAGLU-IGF2 expression in the choroid plexus epithelia. NAGLU-IGF2 was also detected in brain parenchyma, even contralateral to the administered site, indicating delivery from the CSF. Evaluation of the efficacy of AAV5 gene therapy in preventing brain lysosomal storage and neurobehavioral abnormalities is in progress.

These preliminary results suggest that the combination of M6P/IGF2 receptor-mediated endocytosis and choroid plexus-targeted viral gene therapy may overcome the major obstacles associated with ERT for MPS IIIB and enable, sustained, and efficient distribution of NAGLU throughout the brain.

2196M

Glycogen storage disease type Ia mice receiving gene therapy are protected against age-induced obesity and insulin resistance. *GY. Kim[1], JH. Cho[1], YM. Lee[1], CJ. Pan[1], HS. Jun[1], BC. Mansfield[1,2], JY. Chou[1].* 1) Section on Cellular Differentiation, Program on Developmental Endocrinology and Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 2) Foundation Fighting Blindness, Columbia, MD.

Glycogen storage disease type Ia (GSD-Ia), characterized by impaired blood glucose homeostasis, fasting hypoglycemia, and hepatocellular adenoma (HCA), is caused by a deficiency in glucose-6-phosphatase-α (G6Pase-α or G6PC) activity. In a long-term, dose-ranging study, we showed that systemic administration of rAAV-G6PC, a recombinant AAV2/8 vector expressing G6Pase-α directed by the G6PC promoter/enhancer, delivered the G6Pase-α transgene to the liver of GSD-Ia mice. The old (70-90 week-old) rAAV-G6PC-treated GSD-Ia mice expressing 3-63% of normal hepatic G6Pase-α activity (AAV-mice) maintained glucose homeostasis, tolerated prolonged fasting, and showed no evidence of HCA. Interestingly, the AAV-mice exhibit better metabolic controls than their control littermates with fasting blood insulin levels closer to the normal values and a leaner phenotype. Mice overexpressing the transcription factor carbohydrate response element binding protein (ChREBP) in the liver exhibit improved glucose tolerance and are protected against insulin resistance, and ChREBP signaling is activated by G6P. The elevated levels of hepatic G6P in the AAV-mice suggests that ChREBP signaling would be activated. The AAV-mice also produced reduced levels of hepatic glucose, averaging 61-68% of the control littermates, suggesting that these AAV-mice lived under a chronic calorie restriction (CR). A hallmark of aging is mitochondrial dysfunction, and several longevity factors in the CR pathway have been identified that modulate mitochondrial function. These include: 1) the NADH shuttle systems that reoxidize cytosolic NADH produced by glycolysis, interconnecting glycolysis, lipogenesis, and mitochondrial oxidative phosphorylation; 2) intracellular levels of NAD^+ that are decreased in obesity and the aged; and 3) the AMP-activated protein kinase (AMPK)/peroxisome proliferator-activated receptor-γ coactivator 1α (PGC-1α) pathway, the major regulator of mitochondrial biogenesis in response to energy depletion. We now show that during aging, AAV-mice are protected against age-induced insulin resistance and obesity and that this correlates with: activation of ChREBP signaling; increases in glycerol-3-phosphate shuttle system expression; increases in NAD^+ concentrations; and activation of the AMPK/PGC-1α pathway in the liver of the AAV-mice, suggesting that reduced hepatic G6Pase-α activity is beneficial to longevity and a lean phenotype.

2197S

Developing Treatment for Neurofibromatosis. *A. Cosco, W. Salloom, A. Metzenberg, A. Metzenberg.* CSUN, 18111 Nordhoff Street, Northridge, CA 91330.

Neurofibromatosis type 1 (NF1) is a relatively frequent autosomal dominant disorder. The symptoms include neural tumors, which can affect vision if they occur in the area of the optic nerve. NF1 shows genetic heterogeneity, and different mutations in the NF1-GRD domain result in the NF1 phenotype. Furthermore, this disorder shows variable expressivity, in that different members of a single family may have a different set of symptoms. Tumor development occurs unexpectedly, making prevention difficult. The NF1 gene is a tumor suppressor, and encodes a protein called Neurofibromin. This protein has an arginine finger motif, and is able to aid in the hydrolysis of RAS-GTP to RAS-GDP. The faulty Neurofibromin protein is no longer able to enhance the intrinsic ability of RAS to turn itself off from a GTP bound state to a GDP bound state. The result may be that a permanently active RAS, leading to the development of tumors in the central and peripheral nerve systems. One possible preventive treatment for NF1 would involve gene therapy. We hypothesize that it is possible that a plasmid vector for this gene therapy would be preferable to a viral vector, because it would avoid the problems of inactivation of other genes by random insertion, and activation of the immune system. A plasmid was constructed using the One- Step Gibson cloning ligation technique, inserting the NF1-GRD domain into the vector. The construct was transfected into a cultured NF1-/- cell line derived from an individual with NF1, using Lipofectamine 2000. The effectiveness of the introduction of pEPito vector containing NF1-GRD was evaluated by estimating the level of active RAS in cells transfected with the construct, using an ELISA kit. The captured GTP-Ras was detected by an Anti-pan-Ras Antibody and HRP conjugated secondary antibody. A significant difference in RAS-GTP levels ($p<0.05$)between cells that were transfected vs non transfected cells suggests that the GAP domain of Neurofibromin was successfully transcribed and compliments the inability of these cells to inactivate RAS. These results support the idea that it would be possible to develop a gene therapy treatment for NF1 that would not cause certain side effects, and would cross the blood-brain barrier , allowing treatment for a disorder that affects the central nervous system, and can cause blindness.

2198M

Cell Reprogramming Technologies for the Treatment of Genetic Disorders of Myelin. *A. Lager[1], Z. Nevin[1], J. Heaney[2], P. Tesar[1,3].* 1) Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) New York Stem Cell Foundation, New York, NY.

Cellular therapies are a promising treatment modality for a variety of human myelin diseases. In previous work we describe reprogramming methods for generating functional oligodendrocyte progenitor cells (OPCs) from autologous sources (Najm & Lager et al Nat Biotech 2013). However, in cases of dysmyelinating diseases with genetic etiology (e.g. Pelizaeus-Merzbacher and Spastic Paraplegia Type 2), autologous cells harbor genetic abnormalities that preclude oligodendrocyte function. Here we present technology for generating functional OPCs from fibroblasts isolated from shiverer mice. Shiverer mice harbor a 20kb deletion in a locus containing myelin basic protein (MBP) and consequently lack compact myelin and exhibit severe motor deficits. We outline methods for correction of the MBP-shiverer allele in induced pluripotent stem cells (iPSCs). These methods utilize the CRISPR/Cas9 genome editing system for induction of homology-directed repair based on an exogenously supplied bacterial artificial chromosome that contains the MBP-wt allele. Gene corrected iPSCs will be differentiated into OPCs, and we hypothesize that introduction of gene-corrected shiverer OPCs back into the central nervous system of shiverer mice will allow myelination of hypomyelinated axons and behavioral improvements. This work will provide proof-of-concept for gene correction of large deletions by homologous recombination, with important clinical implications in treatment of microdeletion syndromes.

Rescue of lethal hypophosphatasia model mice by adeno-associated virus mediated muscle specific expression of bone targeted alkaline phosphatase. *A. Nakamura[1], O. Iijima[1], K. Miyake[1], A. Watanabe[1,2], Y. Hirai[1], H. Kinoshita[3], T. Noguchi[3], S. Abe[3], T. Okada[1], T. Shimada[1,2].* 1) Department of Biochemistry and Molecular Biology, Division of Gene Therapy Research Center for Advanced Medical Technology, Nippon Medical School, Tokyo, Japan; 2) Division of Clinical Genetics, Nippon Medical School Hospital, Tokyo, Japan; 3) Department of Anatomy, Tokyo Dental College, Tokyo, Japan.

[BACKGROUND] Hypophosphatasia (HPP) is a systemic skeletal disease, caused by the deficiency of tissue-nonspecific alkaline phosphatase (TNALP). The TNALP knockout (*AKP*2-/-) mice phenotypically mimic the severe infantile form of HPP and usually die by 3 weeks of age suffering epileptic seizures and apnea. Enzyme replacement therapy (ERT) is a potential approach, but repeated injection of large amounts of recombinant TNALP is required for clinical benefit. As an alternative approach, we have recently shown that *AKP*2-/- mice can be treated by a single intravenous injection of adeno-associated viral (AAV) vector expressing bone-targeted TNALP (TNALP-D10) in the neonatal period. However, the safety of a systemic injection of AAV into the neonates has not yet been established. In this study, to exploit a safe and clinically applicable protocol, we designed a new self-complementary type 8 AAV vector containing the muscle-specific muscle creatine kinase (MCK) promoter and examined the feasibility of muscle directed gene therapy for HPP. **[METHODS]** Self-complementary AAV8 expressing enhanced green fluorescence protein (scAAV8-MCK-EGFP) and TNALP-D10 (scAAV8-MCK-TNALP-D10) driven by the MCK promoter were generated and injected into the quadriceps femoris muscle of newborn C57BL6 (WT) or *AKP*2-/- mice. **[RESULTS and DISCUSSION]** Stringent muscle specificity of the MCK promoter was demonstrated after intramuscular (IM) injection of scAAV8-MCK-EGFP (5×10^{11} vector genome/mouse) into WT mice (n=3). Neonatal *AKP*2-/- mice (n=10) were treated with a single IM injection of scAAV8-MCK-TNALP-D10 (2.5×10^{12} vector genome/mouse). The plasma ALP activity was rapidly elevated and maintained at a therapeutic level (>1.0 unit/ml) for at least 3 months. The treated *AKP*2-/- mice grew well and survived over 3 months with healthy appearance (9/10), while untreated *AKP*2-/- mice died within 3 weeks ($P<0.001$). Improved mineralization of the knee joints was demonstrated on X-ray images and micro CT analysis. Ectopic calcification was not detected in treated mice. These results suggest that muscle directed gene therapy using scAAV8-TNALP-D10 would be safe and effective to cure the severe infantile form of HPP.

Functional genomic analysis of the interplay between the retrograde transport machinery and HIV-1 replication. *D. Dykxhoorn[1,2], S. Liu[1].* 1) John P. Hussman Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 2) Department of Microbiology and Immunology University of Miami Miller School of Medicine.

Human immunodeficiency virus (HIV) remains a global health concern affecting millions of individuals worldwide. By attacking the host's immune system, HIV leaves the infected individual susceptible to infection by a wide range of pathogens. Like all viruses, HIV-1 is dependent on host cell factors for successful infection, replication and release of progeny virus. Previously, a large-scale functional genomic screen was performed which identified over 230 novel factors, termed HIV-1 dependency factors (HDFs) whose silencing inhibited viral replication. Detailed analysis of these HDFs showed enrichment for factors involved in the trans-Golgi network (TGN), a pathway which had not been previously implicated in HIV replication. This included components of large multiprotein complexes that facilitate the recognition, docking and fusion of different vesicles as they are trafficked through the cell. The targeted silencing of these HDFs, including components of the conserved oligomeric golgi (COG) complex and the Golgi-associated retrograde protein/vesicular protein sorting fifty three (GARP/VFP) complexOur results show that the targeted silencing of components of COG complex each impaired HIV-1 replication in HIV-1-susceptible cell lines and primary monocyte-derived macrophages and inhibited replication against multiple strains of the virus. More detailed analysis of the different forms of the HIV-1 genome showed that the defect in HIV-1 replication occurred prior to late RT product formation, suggesting that these HDFs are required for very early steps in the HIV-1 life cycle. These results highlight a novel pathway required for HIV-1 replication and infection which may hold promise for the development of novel approaches to prevent HIV-1 transmission.

Toward Treatments for Genetically-Based Protein Misfolding Diseases Using Antisense Technology. *S. Guo[1], S. Booten[1], S. Murray[1], E. Ackermann[2], S. Hughes[2], M. McCaleb[1], B. Monia[1].* 1) Antisense Drug Discovery, Isis Pharmaceuticals, Carlsbad, CA; 2) Clinical Development, Isis Pharmaceuticals, Carlsbad, CA.

Protein misfolding diseases, also known as proteopathies, are a class of diseases that are caused by changes in protein conformation which often lead to gain of toxic function. Antisense technology utilizes RNase H mechanism to degrade RNA and subsequently remove unwanted protein products in the cell, potentially providing an optimal platform for the treatment of these diseases. We have evaluated potent antisense oligonucleotides (ASOs) for three genetically-based protein misfolding dsieases: 1) Transthyretin amyloidosis (ATTR), 2) Alpha-1 antitrypsin liver disease (AAT serpinopathy), and 3) autosomal dominant retinitis pigmentosa due to a mutation (P23H) in the rhodopsin gene. ISIS-TTR_{Rx} targets all mutant forms as well as wild type TTR mRNA for the treatment of ATTR. In a Phase 1 normal volunteer study, ISIS-TTR_{Rx} was well tolerated and achieved mean reductions in plasma TTR of ~75% at the 300mg dose level. This compound is currently being evaluated in a multicenter, double-blind, placebo-controlled Phase 3 trial in ATTR familial amyloid polyneuropathy patients. In a mouse model of AAT liver disease (PiZ mice), treatment with an antisense oligonucleotide targeted to the alpha-1 antitrypsin mRNA (AAT-ASO) prevented liver disease progression after short-term treatment; reversed liver disease after long-term treatment, and prevented liver disease in young animals. Furthermore, ASO treatment markedly decreased liver fibrosis in these mice. In addition to the reduction of peripheral targets like TTR and AAT which are mainly produced by liver, ASOs can be delivered directly into the eye via intravitreal injection and distribute to all the cell layers in the eye. P23H rhodopsin transgenic rats express both mutant mouse and normal rat rhodopsin, representing an excellent model of retinitis pigmentosa. We developed ASOs targeting the diseased allele (mouse mutant Rho), but not the normal endogenous allele in this model. Using allele-specific ASO, we demonstrated a slower progression of photoreceptor degeneration and improved electroretinography (ERG) measurements 30 days after a single intravitreal injection. Eyes injected with P23H ASO had a 128 ± 22% improved amplitude response and maintained more outer nuclear layers compared to PBS injected contralateral eyes. Our data demonstrate that antisense technology provides promising treatments for genetically-based protein misfolding diseases.

2202M

AUDITORY VERBAL THERAPY IN PEDIATRIC PATIENTS WITH CONGENITAL DISEASES. *M. Conde-Pacheco.* Audiology and Rehabilitation, Hospital para el Nino Poblano, Puebla, Puebla, Mexico.

The hearing, speech and language are essential parts in the development of a child, to speak and master the language the child needs to hear. If the hearing is the starting point of the main distinguishing characteristic of human beings that is language, their absence or reduction imply important consequences of the type; personal , family, social, educational and cultural, is closely linked to intelligence, thought and imagination. A child who does not hear, not only cannot learn to speak, but cannot appropriate the reading and writing that are the basis of cultural development. Language, in conclusion, is a fundamental requirement for a useful life. If the child's hearing loss is detected early, (considering that most children with this problem have residual hearing) and if this remnant increases with technological resources and appropriate auditory verbal therapy, these children can lead a normal life. The Ministry of Health of the State of Puebla has implemented in the Hospital para el Niño Poblano and other hospitals, health programs which include a program for the habilitation of hearing impaired children, this program includes; hearing screening in neonates, implantation of hearing aids or cochlear implants and conducting habilitation therapies. It is very important to mention that technological resources, (hearing aids or cochlear implant), are not solutions by themselves, are just only an opportunity for the child to live a normal life always and when the auditory is stimulated early, appropriately and continuously. These points are the objectives of the area of Auditory Verbal therapy inside the program to hearing impaired children in the HPNP. The Auditory Verbal Therapy provided in the HPNP, has as main objective the development of listening and speaking skills in children with hearing aids or cochlear implants. In conclusion, under all circumstances and mainly when the cochlear implant or the hearing aid were implanted late, auditory verbal therapy is essential to obtain the best development of the child. To obtain this is strictly required that the cochlear implant or the hearing aids are rightly adjusted or mapped, the child must hear at least a minimum range of frequencies. If due to different circumstances, the last point is not obtained, the development of the child will be unpredictable.

2203S

Combination therapy with artificial dermis, growth factors, and cell culture techniques for massive hematoma-induced skin necrosis in a patient with dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos Syndrome (DDEDS). *F. Nagai[1], S. Yano[2], K. Wakui[3], Y. Higuchi[4], S. Shimodaira[4], K. Fujita[1], M. Noguchi[1], K. Matsuo[2], T. Kosho[3], S. Yuzuriha[2].* 1) Department of Plastic Surgery, Nagano Children's Hospital, Azumino, Nagano, Japan; 2) Department of Plastic and Reconstructive Surgery, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 4) Cell Processing Center, Shinshu University Hospital.

Dermatan 4-O-sulfotransferase 1 (D4ST1)-deficient Ehlers-Danlos syndrome (DDEDS), caused by recessive loss-of-function mutations in CHST14, is a recently delineated form of EDS, characterized progressive multisystem fragility-related manifestations (skin hyperextensibilty and fragility, progressive spinal and foot deformities, massive subcutaneous hematoma) and various malformations (facial features, congenital multiple contractures) [Miyake et al., 2010; Kosho et al., 2011]. Massive hematoma is the most serious complication for patients with DDEDS. We present successful combination therapy with artificial dermis, growth factors, and cell culture techniques for massive hematoma-induced skin necrosis in an 18-year-old girl with DDEDS. She developed progressive necrosis of the skin and soft tissue throughout the left leg, resulting from massive subcutaneous hematoma occurring associated with manual reposition of the left hip dislocation caused by a traffic accident. She was referred to our hospital on day 33 after the injury to treat the necrosis. Autologous cultured dermis was generated by cultivating the patient's own fibroblasts and seeding them in artificial dermis before the first operation. The first operation, on day 43, included excision of all necrotic tissue and application of autologous cultured dermis prepared from her skin fibroblasts and artificial dermis. The second operation, on day 69, included application of split-thickness chip skin grafts taken from the right thigh and autologous cultured epithelia. The third operation, on day 109, included grafting small pieces of split-thickness skin from the right thigh again to cover skin ulcer. Intravenous hyperalimentation improved wound heeling and the tissue defect was completely epithelialized on day 230. She was able to walk without contracture in the knee joint in spite of immobility over 10 months. This is the first report of massive hematoma-induced skin necrosis as a potentially fatal complication of DDEDS and the successful treatment with application of autologous cell therapy and grafting techniques.

2204M

Feasibility of Exon-Skipping Therapy for Juvenile Neuronal Ceroid Lipofuscinosis. *M. Velinov[1,2], N. Dolzhanskaya[1].* 1) Human Genetics, NYS Institute for Basic Research in Developmental Disabilities, Staten island, NY; 2) Albert Einstein College of Medicine, Bronx, NY.

Rationale: Juvenile Neuronal Ceroid Lipofuscinosis (JNCL) is a progressive lethal, neurodegenerative disorder and is the most common type in the group of Neuronal Ceroid Lipofuscinoses. 95% of the JNCL patients carry a common 1 kb deletion in one or both alleles of gene CLN3. The deletion includes exons 7 and 8, and leads to reading frame shift and formation of truncated protein. No effective therapy for JNCL is available. Splicing out (skipping) of exon 9 may be induced in cells with the common CLN3 deletion using antisense oligonucleotides (AO). Such exon skipping would restore the correct reading frame and is expected to produce a modified protein with correct aminoacid sequence downstream of exon 9. Induction of exon skipping (ES) may lead to the increase of the CLN3 transcript in mutant cells by decreasing the nonsense-mediated decay. ES may also help restore some of the CLN3 protein function since the correct aminoacid sequence downstream of exon 9 would be restored. Such approach is currently used in a clinical trial for patients with Duchenne Muscular Dystrophy. **Exon skipping:** Exon splicing enhancer sequences within exon 9 were identified using the program ESEFinder. Four modified oligonucleotides with 2'-O-methyl modified bases on a phosphothiolate backbone, complementary to splicing enhancer sequences were synthesized. Fibroblast cell lines from patient, homozygous for the 1 kb deletion in CLN3 and phenotype of JNCL were plated 24 h prior transfection and were transfected with all four AO using Lipofectamine 2000 reagent. The cells were harvested 18 h after transfection. Total RNA was isolated and used for RT-PCR analysis. The AO transfection resulted in complete exon 9 skipping in the detectable mutant CLN3 transcript. These results were confirmed with sequencing of the RT-PCR product. . **Increase of the transcript level:** Total RNA extracted after AO treatment was used for real time quantitative RT-PCR. The total mutant transcript level increased with 30% after AO treatment compared to the non-treated mutant transcript. **Intranasal administration:** Two mouse-specific AO were labeled with immunofluorescent marker, and were applied intranasaly in a mouse model of JNCL. The intranasaly applied AO penetrated the blood brain barrier in detectable amounts, and were observed in the mouse neuronal cells. **Conclusions:** This prove of concept study showed that AO based ES therapy for JNCL may be feasible using intranasal application.

Improving the communication skills of Down Syndrome patients through speech therapy. *A. Umrigar[1], A. Musso[2], K. Foley[1], M. Banajee[2], F. Tsien[1].* 1) Department of Genetics, LSU Health Sciences Center, New Orleans, LA; 2) Department of Communication Disorders, LSU Health Sciences Center, New Orleans, LA.

Two major obstacles that Down Syndrome patients encounter in the process of communicating effectively are the craniofacial abnormalities and cognitive deficits associated with the syndrome. Physiological features, such as a small oral cavity, large tongue, high arched palate, and facial hypotonia impede the clear articulation of speech. In addition to the physical abnormalities, cognitive deficits further interfere with speech and comprehension. Early intervention in the forms of speech therapy and hearing loss treatments such as hearing aids are essential in overcoming these impediments and improving the communication skills of Down Syndrome patients. This study focuses on detailed communication evaluations of Down Syndrome patients enrolled in the Louisiana State University Health Sciences Center (LSUHSC) Speech Language Therapy program from 6 to more than 15 years. The patients' treatment plans and progress were examined weekly in order to determine the effect of speech therapy on the patient's comprehension and articulation of both verbal and written forms of communication. Patient improvement was monitored using the Goldman-Fristoe test of articulation, repetitive one word vocabulary test, expressive one word vocabulary test, and oral-motor/range of motion evaluation. In addition, these patients received audiological assessments. Concrete progress goals and objectives were constructed specific to each patient. All assessment methods demonstrated a significant improvement in effective communication skills, including progression from one-word to full sentences, vastly improved articulation, and communication in a group setting compared to those who did not receive any form of communication or speech therapy. It is therefore important for geneticists to recognize the improved quality of life benefits of communication intervention programs and refer Down Syndrome patients to speech pathologists.

2206M

The outcome of N-carbamylglutamate (Carbaglu®) therapy in a Korean patient with N-acetylglutamate synthase deficiency. *K. Woo[1], J. Choi[2], B. Lee[1,2], H. Yoo[1,2].* 1) Genome, Asan Medical Center, Seoul, South Korea; 2) Dept. Pediatrics, Asan Medical Center, Univ. Ulsan College of Medicine,Seroul, South Korea.

N-acetylglutamate synthase (NAGS) deficiency is a rare autosomal recessive disorder of the urea cycle. Affected individuals present with poor oral intake, vomiting, seizure, lethargy, and coma within a first few days of life. N-carbamylglutamate (Carbaglu®), a synthetic derivative of glutamic acid as well as a structural analogue of human N-acetylglutamate, is a treatment choice for NAGS deficiency. We report an 8-day-old boy with NAGS deficiency who has been treated with N-carbamylglutamate (Carbaglu®). The patient was born from non-consanguineous Korean parents with a birth weight of 3.4 kg after 40 weeks of gestation. At age 8 days, he showed poor oral intake and lethargy with hyperammonemia (800 μM), which was managed by peritoneal dialysis before referral to our institution. Plasma amino acid profiles revealed elevated glutamate (1117 μmol/L), low-normal arginine (51 μmol/L), ornitine (49 μmol/L), and low citrulline (7 μmol/L) levels. Urine orotic acid was normal (1.77 μmol/molCr; range 0.2-6 μmol/molCr). He has been placed on sodium benzoate, carnitine and citrulline therapy with protein restriction diet with presumptive diagnosis of carbamoyl phosphate synthase (CPS) deficiency. He was referred to our center at age 2 years. Genetic testing for CPS1 was negative. At age 7 years, the NAGS genes analysis using cDNA extracted from liver tissues identified compound heterozygote of p.V310A and p.H488Qfs*2, which were inherited from both parents. He showed mild mental retardation (IQ 51), epilepsy, and attention-deficit/hyperactivity disorder. Despite protein restriction and administration of nitrogen scavenger medicines, he presented recurrent hyperammonemia, stunted growth velocity, and poor weight gain. N-carbamylglutamate (Carbaglu®) replaced since age of 8.1 years, and he discontinued nitrogen scavenger drugs. After 4 months, he discontinued special formula and has been on liberal diet without protein restriction. During past 9 month, he has maintained plasma ammonia within normal range and showed normal prepubertal growth velocity. In conclusion, N-carbamylglutamate (Carbaglu®) has been effective for NAGS deficiency to maintain stable metabolic state and growth without any complications.

2207S

Modeling Autosomal Dominant Optic Atrophy in Induced Pluripotent Stem Cells (iPSCs) and Identifying the Potential Therapeutic Targets. *J. Chen[1], H. Riazifar[2], M. Guan[1], T. Huang[1].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 2) Department of Pediatrics, Division of Human Genetics, University of California, Irvine, CA, USA.

Purpose: Many retinal degenerative diseases are caused by loss of retinal ganglion cells (RGCs). Autosomal dominant optic atrophy (DOA) is the most common hereditary optic atrophy characterized by central vision loss and degeneration of RGCs. DOA is largely caused by mutations of a nuclear gene *OPA1*, which encodes an inner mitochondrial membrane protein. Currently, there is no effective treatment for these types of diseases. However, stem cell therapy holds great potential by replacing patient lost RGCs. Compared with embryonic stem cells, induced pluripotent stem cells (iPSCs) are derived from adult somatic cells, associated with fewer ethical concerns, and are less prone to immune rejection. In addition, these patient-derived iPSCs may serve as a cellular model, allowing us to closely study pathogenesis and therefore to identify potential therapeutic agents. **Methods:** In this study, we were able to generate specific iPSCs from the patient carrying an *OPA1* mutation and diagnosed with optic atrophy. We differentiated iPSCs into RGCs by using our established protocol. **Results:** We found that the mutation of *OPA1* in patients with optic atrophy led to significantly increased apoptosis and *OPA1*-iPSCs were not able to differentiate into RGCs. However, adding neuron induction medium or beta-estrogen into differentiation medium efficiently promoted *OPA1*-iPSC differentiation into RGCs. **Conclusions:** Our results suggest that apoptosis mediated by OPA1 mutations plays a very important role in DOA pathogenesis and both noggin and beta-estrogen could be potential therapeutic agents for *OPA1* mutations related optic atrophy.

2208M

Complete Huntingtin Haplotypes for Allele-Specific Silencing. *C. Kay[1], J.A. Collins[1], N.H. Skotte[1], A.L. Southwell[1], A. DiPardo[2], C. Ross[1], F. Squitieri[2], M.R. Hayden[1].* 1) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 2) Neurogenetics Unit and Rare Disease Centre, IRCCS Neuromed Pozzilli (IS), Italy.

BACKGROUND: The dominant CAG repeat expansion causing Huntington disease (HD [MIM 143100]) occurs on specific haplotypes of the *HTT* gene. In humans, at least 2300 polymorphisms occur across *HTT* and offer potential targets for allele-specific silencing of the mutant transcript encoding the CAG expansion. The organization of all *HTT* polymorphisms into gene-spanning haplotypes, and the portion of the HD patient population treatable by selective silencing of disease-associated haplotypes, is unclear and needed to guide allele-specific *HTT* silencing strategies.

AIMS: Our study sought to identify all genetic variants occurring on the most common HD-associated haplotypes, A1 and A2, and determine the frequency of these haplotypes among distinct HD patient populations of European ancestry. We additionally sought to demonstrate selective *HTT* silencing using novel HD-associated polymorphisms identified by this work.

RESULTS: Using whole-genome sequencing from the 1000 Genomes Project, and direct genotyping of diverse HD patient cohorts from Canada, Sweden, France, and Italy, we assemble complete haplotypes for all known common variants (>5%) in *HTT*. The most common HD-associated haplotype, A1, is uniquely defined by three transcribed polymorphisms; the second most common HD haplotype, A2, is uniquely defined by five intragenic polymorphisms. A1 is most heterozygous in Northern European patient populations, where HD is most common, whereas A2 is most heterozygous in Southern European patients. Using antisense oligonucleotides (ASOs) targeting a novel A1-defining polymorphism, we silence mutant A1 *HTT* mRNA and protein in patient-derived cells, maintaining wild-type *HTT* expression at untreated levels.

CONCLUSIONS: Across populations of European ancestry, silencing the A1 haplotype may offer allele-specific therapy in approximately half of HD patients. Our results suggest that targeting the A2 haplotype may allow selective *HTT* silencing in an additional quarter of patients across all four populations, and over half of HD patients in Italy. In combination, antisense reagents silencing A1 and A2 may offer selective silencing of mutant *HTT* in >70% of HD patients.

2209S

iPS-cell derived basal keratinocytes and melanocytes to study severe monogenic genodermatoses in patient-specific 3D tissue systems. *K.M. Eckl[1], D.M. de Lima Cunha[1,2], R. Plank[1,2], R. Casper[2], H. Traupe[3], M. Rauch[1], M.K. Gupta[4], T. Saric[4], H.C. Hennies[1,2].* 1) Ctr. for Dermatogenetics, Div. of Human Genetics, Innsbruck Medical University, Innsbruck, Austria; 2) Ctr. for Dermatogenetics, Cologne Ctr. for Genomics, Univ. of Cologne; 3) Dept. of Dermatology, University Hospital Münster, Germany; 4) Inst. for Neurophysiology, Medical Center, Univ. of Cologne, Cologne, Germany.

Induced pluripotent stem (iPS) cells from a somatic source like dermal fibroblasts from a patient with a known severe, often fatal, but always rare genodermatosis are a unique and excellent tool to study the pathomechanism during neuro-ectodermal differentiation, melanocyte development and epidermal commitment and finally epidermal stratification. In contrast to primary keratinocytes and melanocytes, genetic modification of iPS cells can be easily performed and allows stable gene correction and fast in-vitro gene-therapy approaches. Up to date, for most genodermatoses, like neurofibromatosis 1 (NF-1), congenital ichthyosis (autosomal recessive congenital ichthyosis, ARCI), and Cole disease, therapy is only symptomatic and rarely sufficient. Although genetically and functionally well characterised, patient-specific, individualized therapies have so far not been generated for all of these disorders. Lately we published 3D skin models for different monogenic and severe genodermatoses. These models can be used for the development of protein replacement therapeutics (PRT). To overcome the shortage of cells for large-scale patient-specific skin modelling, keratinocytes and melanocytes can be differentiated from patient iPS cells and incorporated into the 3D skin model. We established a protocol to differentiate diseased and healthy iPS cells into the neuro-ectodermal fate (p63 positive cells) using a feeder-free culture system. Our protocol is based on a defined medium, which is supplemented with BMP4, retinoic acid, and ascorbic acid. At specific time points during the 30-40 days of differentiation enhancers of the Wnt/β-catenin pathway are additionally supplemented. Neuroectodermal cells are then specifically differentiated in either keratinocytes or melanocytes. For melanocyte differentiation cells are passaged daily in the presence of a melanocyte-specific, defined medium which is further supplemented. During keratinocyte differentiation we observe first keratin 18 expression (day 12), then around day 30 a strong keratin 14 expression indicating basal keratinocytes; at day 30 at least 50% of all keratinocytes are positive for CD104. iPS cell-derived melanocytes are positive for Mel5, Tryp1 and Mart1. Only iPS-cell derived keratinocytes and melanocytes allow us to generate patient-specific 3D tissue models in larger quantities, which will be essential to assess drugs for these orphan diseases and pave the way for individualized therapies.

2210M

A Fine Balance of Dietary Lipids Improves a Murine Model of VCP-associated Disease. *K.J Llewellyn, A. Nalbandian, N. Walker, J. Tang, A. Gomez, V. Kimonis.* Pediatrics, 2501C Hewitt Hall, Irvine, CA.

Despite intense investigations, the discovery of effective novel advancements/therapies and the disease mechanisms underlying Valosin containing protein (VCP)-associated myopathies and neurodegenerative disorders remain elusive. VCP diseases, caused by mutations in the VCP gene, are a clinically and genetically heterogeneous group of disorders with manifestations varying from hereditary inclusion body myopathy, Paget's disease of bone, frontotemporal dementia (IBMPFD), amyotrophic lateral sclerosis (ALS), and other neurodegenerative changes. Affected individuals exhibit scapular winging and progressive muscle weakness and die from cardiac and respiratory failure. Histologically, patients display rimmed vacuoles and TAR DNA Binding Protein-43 (TDP-43)-positive ubiquitinated inclusion bodies in muscles. Currently, there are no effective treatments for patients with VCP-related myopathies. VCP mouse models carrying the common R155H mutation include several of the clinical features typical of human diseases. Here, we examined the effects of varying dietary lipid percentages on VCPR155H/+and wild type (WT) mice from birth till 9 months of age. Disease progression was monitored and analyzed using survival curves, pathological and immunohistochemical methods. Mice on the 9% lipid-enriched diet demonstrated an improvement in muscle strength measurements, histology, and autophagy signaling pathway when compared to mice on normal diet. In this report, we demonstrate VCP mice fed increasing lipid diets of 12%, 15%, 30%, and 48% showed no improvement in muscle pathology or the autophagy cascade, suggesting that significantly increased lipid diets only depict a detrimental effect in mice. Thus, a balanced lipid supplementation suggests a promising translational therapeutic strategy for patients with VCP-associated neurodegenerative diseases.

2211S

Development of autologous myogenic stem cell therapy for carriers of a heteroplasmic mtDNA mutation: a proof of principle study in m.3243A>G mutation carriers. *F. van Tienen[1,2], E. Timmer[1,2], M. Quattrocelli[3], M. Sampaolesi[3], I. De Coo[4], H. Smeets[1,2,5].* 1) Clinical Genetics, MaastrichtUMC, Maastricht, Netherlands; 2) Research School GROW, MaastrichtUMC, Maastricht, Netherlands; 3) Interdepartmental Stem Cell institute, KU Leuven, Leuven, Belgium; 4) Dept Neurology, Erasmus UMC, Rotterdam, Netherlands; 5) Research School CARIM, MaastrichtUMC, Maastricht, Netherlands.

Mitochondrial diseases due to heteroplasmic mitochondrial DNA (mtDNA) mutations are severe multisystem disorders (frequency 1/5,000), caused by defects in oxidative phosphorylation (OXPHOS). Severe progressive myopathy and exercise intolerance occur in >50% of the mtDNA disorders with a variety of other clinical manifestations and seriously affect the quality of life and well-being. Effective therapy is currently unavailable. We hypothesize that inducing muscle regeneration by transplantation of mtDNA-mutation free autologous myogenic stem cells (pericytes/mesoangioblasts -MABs) can compensate for the OXPHOS defect and may reverse myopathy and exercise intolerance, resulting in increased mobility and quality of life for heteroplasmic mtDNA mutation carriers. MABs are currently the only myogenic precursors that fulfill all requirements for being used in this therapeutic strategy and a phase I/II clinical trial using allogeneic MABs is currently ongoing in DMD patients. The key characteristic of our project is transplantation of the patients' own MABs that have been freed of the mtDNA mutation. This approach allows targeting all proximal muscles safely without adverse reactions to the transplant and the use of immunosuppressive agents. To this end, we have succeeded in generating mutation-free MABs from m.3243A>G carriers (with adult onset myopathy and a mutation load in skeletal muscle ranging from 15% to 93%) in sufficient amounts for initial local treatment. The in vitro growth rate and myogenic differentiation capacity (ranging between 20%-57%) of these mutation-free MABs were comparable with MABs derived from healthy controls and their in vivo myogenic capacity was subsequently verified in immunodeficient mice. The next step is to perform a proof of principle clinical study to demonstrate the local effect of transplantation of mutation-free autologous MABs, injected in the leg of m.3243A>G carriers. Muscle regeneration, mutation load and OXPHOS capacity will be determined. From this study, we expect to get a clear insight in the potential of this exciting new therapeutic approach, warranting further steps into a systemic clinical trial.

2212M

Online Self-Report Data for Duchenne Muscular Dystrophy: observations of current natural history and explorations of therapeutic responses. *A. Eskin[1], R. Wang[1], J. Ulm[1], C. Silverstein[2], I. Jankovic[1], A. Lu[1], V. Miller[3], R. Cantor[1], N. Li[4], R. Elashoff[4], A. Martin[5], H. Peay[5], S. Nelson[1,6].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Department of Internal Medicine, College of Osteopathic Medicine of the Pacific, Western University of Health Sciences, Pomona California and the Western Diabetes Institute, Western University of Health Sciences, Pomona, CA; 3) PatientCrossroads, San Mateo, California; 4) Department of Biomathematics, David Geffen School of Medicine, University of California, Los Angeles; 5) Parent Project Muscular Dystrophy, Hackensack, NJ; 6) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles.

To assess the utility of online patient self-report outcomes in a rare disease, we attempted to observe the well established therapeutic benefit of corticosteroids for Duchenne muscular dystrophy. First, we assessed how comparable an online self report registry for Duchenne, called DuchenneConnect, compared to prior natural history data in regard to age at diagnosis, mutation spectrum, and age at loss of ambulation. Second, we assessed the correlation of reported corticosteroids usage with reported age at fulltime wheelchair use in Duchenne muscular dystrophy (DMD) only using data from 1,057 males from DuchenneConnect. Because registrants reported differences in steroid and other medication usage, as well as age and ambulation status, we could explore these data for correlations with age at loss of ambulation. Using multivariate analysis, current steroid usage was the most significant and largest independent predictor of improved wheelchair-free survival. Thus, these online data were sufficient for the retrospective observation that current steroid use by patients with DMD is associated with a delay in loss of ambulation (a key functional endpoint difficult to assess in traditional study designs). Interestingly, reported use of Vitamin D, CoEnzyme Q10, insurance status, and age at diagnosis after 4 years were also significant, but smaller, independent predictors of longer wheelchair-free survival. This study demonstrates the utility of DuchenneConnect data to observe therapeutic differences, and highlights needs for improvement in quality and quantity of patient-report data, which may allow exploration of drug/therapeutic practice combinations impractical to study in clinical trial settings. Further, with the low barrier to participation, we anticipate substantial growth in the dataset in the coming years.

2213S

Prevention and reversal of transcriptional changes in an induced model of spinal muscular atrophy by administration of an antisense oligonucleotide promoting inclusion of *SMN2* exon 7. *J.F. Staropoli[1], H. Li[1], S.J. Chun[2], N. Allaire[1], P. Cullen[1], A. Thai[1], C. Fleet[1], F. Bennett[2], A. Krainer[3], D. Kerr[1], A. McCampbell[1], F. Rigo[2], J. Carulli[1].* 1) Biogen Idec, Boston, MA; 2) ISIS Pharmaceuticals, Carlsbad, CA; 3) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Spinal muscular atrophy, the leading genetic cause of infant mortality, is a neuromuscular disease characterized by progressive loss of alpha-motor neurons in the anterior horn of the spinal cord. It is caused by disruption of the *SMN1* gene and insufficient compensation of its function by the neighboring, nearly identical paralogous gene *SMN2*, which harbors a splicing silencer element in intron 7 that suppresses inclusion of exon 7 critical for production of full-length SMN protein. Antisense oligonucleotide (ASO)-mediated blockade of the splicing silencer was previously shown to promote inclusion of *SMN2* exon 7 in multiple mouse models of SMA and to mediate phenotypic rescue. To date, however, the molecular signature of this rescue has not been defined. Here we characterize the transcriptional changes that occur in an induced model of type III SMA and the substantial prevention or reversal of those changes in CNS tissue upon intracerebroventricular administration of an ASO promoting inclusion of exon 7. We further show that the timing of ASO administration is correlated with prevention or reversal of specific subsets of transcriptional changes. Collectively, these changes represent potential biomarkers of SMN depletion and therapeutic response to SMN repletion.

2214M

A hemizygous *GYG2* mutation in Japanese siblings showing Leigh syndrome without marked elevation of lactate and pyruvate. *E. Imagawa[1], H. Osaka[2], A. Yamashita[3], M. Shiina[4], E. Takahashi[5], H. Sugie[6], M. Nakashima[1], Y. Tsurusaki[1], H. Saitsu[1], K. Ogata[4], N. Matsumoto[1], N. Miyake[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Division of Neurology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Molecular Biology, Yokohama City University School of Medicine, Yokohama, Japan; 4) Department of Biochemistry, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 5) Division of Infection and Immunology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 6) Department of Pediatrics, Jichi Medical University, Tochigi, Japan.

Leigh syndrome (LS: MIM#256000) is a progressive neurodegenerative disorder characterized by unique, bilateral neuropathological findings in brainstem, basal ganglia, cerebellum and spinal cord. The estimated incidence of LS is 1:40,000 live births. LS is genetically heterogeneous and the majority of the causative genes affecting mitochondrial malfunction. However, the genetic causes in the majority patients still remain unsolved. Here, we present male sibling affected with LS showing developmental delay, convulsion, athetoid movements, nystagmus, hypotonia, spasticity, increased deep tendon reflex, ketonemia, and bilateral lesion of basal ganglia (caudate nuclei, globus pallidus, and putamen), but no marked elevation of lactate and pyruvate. To identify their genetic cause, we performed genetic analysis using whole exome sequencing. Based on the hypothesis of autosomal recessive and X-linked recessive models, we identified only one hemizygous missense mutation (c.665G>C, p.Trp222Ser) in glycogenin-2 (*GYG2*, isoform a: NM_001079855) in both affected siblings. The heterozygous change was identified in their mother, which is consistent with the X-linked recessive trait. *GYG2* is located at Xp22.33 and encodes glycogenin-2 (GYG2) which plays an important role in the initiation of glycogen synthesis. Based on the structural modeling based on its homologue, glycogenin-1 (GYG1), the alteration from hydrophobic Trp222 to hydrophilic Ser222 may lead to structural instability and create a cavity around the mutated Ser222 residue possibly resulting in protein malfunctioning. Furthermore, *in vitro* experiments showed mutant GYG2 expressed in COS-1 cells was unable to undergo the self-glucosylation observed in wild-type GYG2. We proposed a pathomechanism of the GYG2 impairment in this family based on the canonical pathway of glycogen metabolism. LS is known as one of metabolic disorders that impaired mitochondrial function resulting an energy depletion. In present patients, the central nervous system was dominantly affected. This predominance could be explained by high glucose consumption as the primary energy source in brain. In conclusion, these data highlight the possible link between mutation in *GYG2* and LS. Further studies are needed to conclude whether GYG2 abnormality leads to atypical LS.

2215T

Role of ACBD3 protein in the mitochondrial energy metabolism. *M. Tesarova[1], H. Kratochvilova[1], M. Rodinova[1], V. Stranecky[2], H. Hartmannova[2], A. Vondrackova[1], J. Spacilova[1], M. Hulkova[1], H. Hansikova[1], T. Honzik[1], J. Zeman[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic.

A homozygous mutation c.460A>G in ACBD3 gene was found by whole-exome sequencing in patient with mitochondrial encephalomyopathy and combined deficiency of respiratory-chain complexes. ACBD3 encodes a 60 kDa acyl-coenzyme A binding domain containing 3 protein (also known as PAP7 or GCP60) localized in the Golgi apparatus, endoplasmic reticulum, and mitochondria. ACBD3 protein plays an important role in many cellular processes (lipid metabolism, membrane transport, neuronal division, embryogenesis, steroidogenesis, structure of the Golgi apparatus, apoptosis, iron homeostasis). In mitochondria, ACBD3 protein is a part of the complex (140-200kDa) mediating cholesterol transport into the organelle. An integral part of this complex is VDAC protein (Porin) which forms freely permeable pores in the outer mitochondrial membrane and further associates with ANT protein (adenine nucleotide transporter) in the inner mitochondrial membrane. ANT is an ADP/ATP carrier that controls a pool of mitochondrial adenine nucleotides required for mtDNA maintenance. The aim of the study is characterize the consequences of stably down-regulated expression of ACBD3 protein on the biogenesis and functions of OXPHOS complexes in HEK293 to elucidate its role in the pathogenesis of the patient's phenotype. The first results show that deficit of ACBD3 protein leads to the decrease of amount and activity of complex IV and decrease of selected subunits of complex IV. Supported by research projects IGA NT/13114-4, IGA NT/11186-5, RVO-VFN64165/2012, and GAUK 1308214.

2216M

Encephalopathy and urea cycle disorder after gastric bypass in a heterozygous G209S short chain acyl-CoA dehydrogenase gene carrier. *H. Wang[1,2], A. Singh[3], N. Shimizu[1], V. Patel[1].* 1) Department of Surgery, Metabolic Support Service, Brigham and Women's Hospital, 75 Francis Street, Boston, MA 02115; 2) Department of Medical Genetics, Mayo Clinic, 200 First Street SW, Rochester, MN 55905; 3) Department of Surgery, Thomas Jefferson University Hospital, Philadelphia, PA 19107.

INTRODUTION: There is growing evidence of urea cycle disorder (UCD) recognized in adult. Encephalopathy after gastric bypass has been reported increasingly and fetal hyperammonia related encephalopathy has been reported in several cases. Among of them only two cases were reported to have investigated and identified UCD as a culprit of encephalopathy. We describe a UCD whose phenotypic expression became manifest with the stress of malnutrition in an adult bariatric patient. CASE : A 47 year old morbidly obese female with no history of chronic liver disease status post gastric bypass surgery eight years ago presents with altered mental status requiring intubation and ventilatory support. Her post surgical course is notable for severe malnutrition over the preceding 4 months. Admission labs revealed a markedly elevated NH3 139ug/dL peaking at 276 [normal range 40-80] and multiple micronutrient deficiencies. Head MRI is normal. Therapy was initiated with an ammonia scavenger, ammunol and TPN nutrition support. Metabolic panel showed urine orotic acid 2.8 mmol/molCr (0.4-1.2), alanine 184umol/L (240-600), arginine 30umol/L (40-160), citrulline 5umol/L (10-60), glutamine 366umol/L (410-700), isoleucine 0umol/L (30-130), methionine 11 umol/L (17-53), serine 36umol/L (60-200), tyrosine 9umol/L (30-120), valine 44umol/L (140-350). Ornithine, carnitine and acylcarnitine levels were normal. With the exception of low glutamine and alanine, the biochemical findings were consistent with ornithine transcarbamylase (OTC) deficiency. The patient recovered after aggressive treatment. Further molecular genetic analysis did not reveal a detectable mutation in the OTC gene. However, a heterozygous G209S (GGC>AGC) in exon 6 of the acyl-CoA dehydrogenase (ACAD) gene (NM_000017.2) disease-associated variant was identified. DISCUSSION: Mutations in the ACAD gene are associated with short-chain acyl-CoA dehydrogenase (SCAD) deficiency, an autosomal recessive disorder. Only those patients homozygous or compound heterozygous for the mutation are considered to be at risk with most carriers remaining asymptomatic. SCAD-deficient mice show depressed mRNA expression and enzyme activity for urea cycle enzymes carbamyl phosphate synthetase I (CPS) and OTC. The risk of this mutation confers to this patient has not yet been clearly defined but exemplifies the need to suspect UCD in severely malnourished bariatric patients with acute onset of encephalopathy and hyperammonia.

2217T

Persistent elevations in C3 and C5OH, heralding signs for an underlying mitochondiral defect: Neurogenic weakness with ataxia and retinitis pigmentosa (NARP). *N. Hauser.* Medical Genetics Dept, Childrens Hospital Central California, Madera, CA.

INTRODUCTION Mitochondrial diseases are a heterogeneous group of disorders, particularly those caused by defects in mitochondrial DNA. These disorders can affect single or multiple organs and can present with varied symptoms. Here, a patient was eventually diagnosed with NARP who presented with mild biochemical abnormalities, poor coordination and speech delay. PATIENT CASE Patient was a 3.5yrs old male referred for speech delay. Additional concerns were clumsiness and decreased endurance. Metabolic testing revealed mild elevations in C3 2.42uM (0.11-1.25), C5-OH 0.23uM (0-0.06), CK 368U/L (<160),] lactic acid 2.8mmol/L (0-2.2), alanine 796 umol/L (157-481umol/L) and urine 3OH-butyric, 3OH-isovaleric and octanoic acids. Basic chemistries showed persistently low CO2 17mmol/L (21-33mmol/L). Lymphocyte carboxylases performed were normal. Family history revealed an older full sibling who passed away in Mexico at 7 days of age from a cardiomyopathy. Subsequent metabolic studies continued to reveal the same mild abnormalities. Six weeks prior to his death at age 5 years, the patient showed signs of decreasing endurance, worsening balance, strabismus and increasing sleepiness and fatigue. These symptoms increased in severity until the patient presented to the Emergency Room with encephalopathy and inability to walk. Muscle biopsy was performed; the mitochondrial respiratory chain was evaluated (Buffalo, NY) and showed no abnormalities of any of the mitochondrial complexes. The pathology on the muscle biopsy showed a variety of mild abnormalities including pale cytochrome C oxidase staining, mild mitochondrial cytopathy, Z-band streaming, cap-like filamentous inclusions, and mild type I fiber predominance. The patient rapidly progressed to coma, respiratory failure, and passed away. Mitochondrial genome sequencing (GeneDx) revealed a homoplasmic mutation m.8993T>G associated with Neurogenic weakness with ataxia and retinitis pigmentosa (NARP). CONCLUSION Mitochondrial disorders can present with varying abnormalities. Our patient had signs of acidosis, elevations in C3 and C5-OH, not typically associated with NARP. Investigations into conditions causing C3 and C5-OH elevations were negative, leaving us to conclude the C3 and C5-OH elevations are connected to the m.8993T>G mutation. Research to determine the precise biochemical interactions between the mitochondrial effects of the m.8993T>G mutation and the two acylcarnitine abnormalities are needed.

2218M

Evidence of secondary mitochondrial dysfunction in patients with organic acidemias. *G.M. Enns[1], T. Moore[2], A. Le[2], M.K. Shah[1], K. Cusmano-Ozog[1,3], A.K. Niemi[1], T.M. Cowan[1].* 1) Pediatrics, Stanford University, Stanford, CA; 2) Pathology, Stanford University, Stanford, CA; 3) Genetics and Metabolism, CNMC, Washington, DC.

Growing evidence suggests that organic acidemias are accompanied by secondary mitochondrial dysfunction, decreased energy production, and oxidative stress. We previously reported that reduced and oxidized glutathione (GSH and GSSG), as measured in whole blood by LC-MS/MS, are useful biomarkers of mitochondrial dysfunction, and that patients with primary mitochondrial disorders show significant redox imbalance which further worsens during periods of metabolic crisis. Here we extend these findings to the organic acidemias, and provide direct evidence that these disorders are associated with secondary mitochondrial dysfunction. Whole blood GSH and GSSG levels were evaluated in 105 samples from 37 organic acidemia patients (29 methylmalonic acidemia, 5 propionic acidemia, 3 isovaleric acidemia). All patients were evaluated at least once during outpatient clinic visits (i.e., clinically stable), and 7 were also tested while hospitalized for metabolic decompensation. Redox potential was calculated using the Nernst equation, and compared to the mean redox potential from 59 healthy controls (-260 mV ± 6.4). Statistical comparisons were conducted using Student's t test, with significance set at $p<0.05$. As a group, organic acidemia patients showed significant redox imbalance (redox potential -250 mV ± 6.8, $p<0.0001$) with an increased level of oxidation of ~10 mV compared to controls. This was seen in all three organic acidemias studied, with no significant differences noted between the groups. Patients experiencing a metabolic crisis had significantly more oxidized redox potential (-245 mV ± 3.5) than those who were clinically stable (-250 mV ± 6.9; $p=0.036$). These results support the idea that measurements of blood GSH and GSSG may give insights into the contribution of oxidative stress and mitochondrial dysfunction to the pathophysiology of organic acidemias.

2219T

A newborn with persistent mild elevations of succinylacetone in bloodspot, plasma and urine, with an identified homozygous variant in the *GSTZ1* gene. *W. Al-Hertani[1], L. You[1], K. Phommarinh[1], S. Yak[1], S. El Tarazi[3], M-T. Berthier[4], Y. Giguère[4], T. Gagnon[2], D. Cyr[2], P.J. Waters[2].* 1) Department of Medical Genetics, McGill University Health Centre, Montreal, QC, Canada; 2) Biochemical Genetics Laboratory, Medical Genetics Service, Centre hospitalier universitaire de Sherbrooke (CHUS), Sherbrooke, QC, Canada; 3) Department of Pediatrics, McGill University Health Centre, Montreal, QC, Canada; 4) Quebec Newborn Bloodspot Screening Program, Service de Biochimie, CHU de Québec, Quebec City, QC, Canada.

Case report: The proband is a Native Canadian female, born to non-consanguineous parents. At age 18 days, she was referred as screen-positive for tyrosinemia, following slightly elevated succinylacetone (SUAC) in bloodspot (age 40 hours): hydrazine method, 1.19 micromol/l, cutoff 0.67; enzymatic method 3.53, cutoff 2.50. Meanwhile, a urine organic acid profile at age 6 days (test requested independently, for unrelated reasons) revealed mild SUAC elevation. SUAC results obtained using stable isotope dilution GC-MS on samples collected between age 4 days and 4 weeks were: in plasma, 1282, 689, 617 nanomol/L (reference < 24); in urine, 776, 766, 604 micromol/mol creatinine (reference < 34). While unambiguously elevated, and persistent, these values were approximately 1000-fold lower than typical of patients with tyrosinemia type 1. Tyrosine and phenylalanine, normal on the newborn bloodspot, remained normal in plasma during follow-up, as did the remainder of the plasma amino acid profile. At age 2 months, she is doing well clinically. Initial minimal elevations of transaminases have been resolving spontaneously. Abdominal ultrasound and ophthalmological examination were within normal limits, as were coagulation factors. Sequencing of the *FAH* gene did not show any deleterious mutations or variants. Considering the clinical course together with biochemical and molecular findings, a diagnosis of tyrosinemia type 1 is highly unlikely. Despite no reported human phenotype in the literature, we considered the possibility that reduced activity of maleylacetoacetate isomerase, due to hypomorphic variants in the *GSTZ1/MAAI* gene (J Clin Pharmacol 2012;52:837-849), as the most likely potential etiology for the persistent elevation of SUAC in this infant. Interestingly, molecular analysis in our patient, did reveal a homozygous variant of uncertain significance in exon 7 of the *GSTZ1* gene; c.449C>T (p.Ala150Val), predicted to be pathogenic by SIFT and Mutation Taster. Parental analysis is currently under way.

2220M

Novel mutations in human lipase A gene. *J. Huang, Z. Wu, C.R. Scott.* Dept Pediatrics, Univ Washington, Seattle, WA.

Lysosomal acid lipase (LAL) is a lysosomal enzyme that is involved in intracellular lipid metabolism. Deficiency of the LAL enzyme results in accumulation of cholesterol esters and triglycerides in most tissues of the body, and causes Wolman disease and cholesteryl ester storage disease (CESD). Wolman disease is fatal within the first year of life due to severe hepatomegaly, persistent diarrhea and failure to thrive, while CESD is a milder disease that is characterized by hyperlipidemia and hepatomegaly that can be observed in childhood or develop in adulthood. LAL deficiency is an inherited genetic condition, caused by mutation in the lipase A (LIPA) gene that encodes the LAL enzyme. Spanning about 40 kb with 10 exons and coding 400 amino acids, the LIPA gene is located on the long arm of chromosome 10 between positions 23.2 and 23.3. So far more than 40 mutations in the LIPA gene have been reported, including missense, nonsense, splice site, small deletion/insertions and large deletions. We have examined twenty specimens worldwide with LAL deficiency for mutation analysis of the LIPA gene, performing bi-directional sequence analysis of coding exons and corresponding intron/exon boundaries on genomic DNA. Among mutations we identified, the common mutation c.894 G>A is about 20% of alleles; and four novel mutations have never been reported previously. These new mutations include: (1) missense mutation c.67G→A (p.G23R), (2) missense mutation c.266T→C (p.L89P), (3) small deletion TGCCAACAGCAGCCT in c.297-311, and (4) missense mutation c.421G→C (p.A141P). Interestingly, the mutation c.421G→C has only been detected in specimens from persons of Asian ethnicity.

Inherited GPI anchor deficiency: biochemical, molecular, and clinical presentation of a patient with *PIGW* mutations. *T. Chiyonobu[1], N. Inoue[2], M. Morimoto[1], T. Kinoshita[3], Y. Murakami[3].* 1) Pediatrics, Kyoto Prefectural University of Medicine, Kyoto, Japan; 2) Molecular Genetics, Osaka Medical Center for Cancer, Osaka, Japan; 3) Immunoregulation, Research Institute for Microbial Diseases, Osaka University, Osaka, Japan.

Background: Glycosylphosphatidylinositol (GPI) is a glycolipid that anchors 150 or more kinds of proteins to the human cell surface. Recently, inherited GPI anchor deficiencies (IGDs) were reported which cause developmental delay often accompanied by epilepsy, facial dysmorphism and multiple anomalies. There are 26 known genes involved in the biosynthesis and remodeling of GPI anchored proteins (GPI-APs). IGDs due to germline mutations in nine of these genes (*PIGA*, *PIGM*, *PIGN*, *PIGV*, *PIGL*, *PIGO*, *PIGT*, *PGAP2* and *PGAP3*) have been reported so far. Additionally, elevated levels of serum alkaline phosphatase (ALP), one of the GPI-APs, is commonly seen in IGDs caused by mutations in *PIGV*, *PIGO*, *PGAP2*, and *PGAP3*, and these deficiencies are termed hyperphosphatasia with mental retardation syndrome (HPMRS). Here we report the first patient with mutations in *PIGW*, which is involved in the addition of the acyl-chain to inositol in an early step of GPI biosynthesis. Patient and Results: The patient was the second child from healthy non-consanguineous Japanese parents. Severe developmental delay was evident from early infancy. At 7 months old, he developed clusters of tonic spasms with hypsarrhythmic pattern in EEG and was diagnosed as having West syndrome, a type of infantile epileptic encephalopathy. Brain MRI disclosed symmetric lesions in the basal ganglia and brainstem. Laboratory investigations including metabolic disorder screening were normal but the serum ALP was constantly elevated at around 2000 U/L. Because he showed severe developmental delay with dysmorphic facial features (broad nasal bridge and tented upper lip) and hyperphosphatasia, characteristics often seen in IGDs, we tested for GPI deficiency. Flow cytometry using blood granulocytes from the patient revealed reduced surface expression of GPI-APs. He was identified to be compound heterozygous for Thr71Pro and Met167Val mutations in *PIGW* by targeted sequencing. Functional analysis using the PIGW deficient CHO cells revealed that both mutations affect the PIGW activity. Conclusions: Hypomorphic mutations in *PIGW* cause infantile epileptic encephalopathy and HPMRS. The characteristic findings in brain MRI may be a diagnostic clue, and flow cytometric analysis of blood cells is effective in screening IGD.

2222M

Structural modeling and bioinformatics analysis of Acid Alpha-Glucosidase in Colombian patients with p.[G576S; E689K] polymorphism associated with p.W746C mutation. *J. Gonzalez Santos[1], LP. Barragán-Osorio[2], S. Bustos-Hémer[2], P. Ayala[2], R. García-Robles[3,4], F. Suarez-Obando[2].* 1) Nutrición y bioquímica, Pontificia Universidad Javeriana, Bogota, Colombia; 2) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá D.C., Colombia; 3) Instituto de Investigación en nutrición, genética y metabolismo. Universidad del Bosque, Bogotá, Colombia; 4) Genzyme de Colombia S.A.

Introduction: Pompe disease is caused by pathogenic sequence variations in the Acid α-Glucosidase gene (GAA) causing lysosome glycogen accumulation. SNPs c.1726G>A (p.G576S) and c.2065G>A (p.E689K) were predicted to cause pseudodeficiency of GAA. Substitution p.E689K reduces GAA activity by 50%; at most. Substitution p.G576S reduces GAA activity to clinical spectrum ranges. Objective: to assess the effects of p.[G576S; E689K] and their association with mutation p.W746C found in 2 Colombian patients. Methods: Three-dimensional model of human GAA based on the N-terminal Subunit of Human Maltase-Glucoamylase complex with Acarbose (MGA PDB 2QMJ) template. Energy minimization was performed. Physicochemical properties were validated with ProtParam. Quality/Reliability of stereo chemical parameters of the homology model was confirmed with Qmean6, GROMOS and Ramachandran plot. Alignments were calculated with ClustalW and Muscle. Conserved amino acids were obtained as a consensus of MultiDisp, Consurf and ConSeq. Solvent accessible surface area value (ASA) was determined with PYMOL. The mutant model was superimposed on the wild type structure to determine the influence of amino acid replacement in the 3D structure on the basis of the total root-mean-square distance (RMSD). Results: Amino acid identity between GAA and the template was 44%. Both proteins belong to the glycosyl hydrolases family 31 in which the structure is conserved and shares similar binding site, overcoming the low sequence identity. GAA and GMA are hydrophilic with similar composition of negative and positive residues. Stereo-chemical quality of the predicted model showed 85.7%; of residues in favored regions, 8.4%; in allowed regions and 5.9%; in outlier regions. The conservation analysis recognized a highly conserved amino acid position G576, in a lesser extent to E689. The preliminary ASA measurement indicated that both polymorphisms and W7466C mutations are buried. Wild type predicted model value, significantly differs from the mutant model (27125.766 $Å^2$ and 30854.953 $Å^2$, respectively). The Superposition of the two models reveals that G576 is located inside the barrel structure and G576S substitution change the side chains of the Aα4-helix. E689 is located at N-terminus of Aα8-helix where the side chain is fully exposed. The superposition RMSD value was 0.84 Å.

2223T

Familial hypermangenesemia among Egyptian families: further delineation of the phenotype and management. *M.S. Zaki[1], MS. Abdel-hamid[2], H. Hossni[3], MY. Issa[1], A. El-Safty[4], A. Oraby[5].* 1) Clinical Genetics Department, National Research Centre , Cairo, Egypt, Dokki, Cairo, Egypt; 2) Human Molecular Genetics Department, National Research Centre, Cairo, Egypt; 3) National Institute of Neuromotor System, Cairo, Egypt; 4) Toxicology Department, Cairo University, Cairo, Egypt; 5) Pediatrics Department, Cairo University, Cairo, Egypt.

Familial hypermanganesemia or inherited manganism is a rare metabolic error caused by recessive mutations in SLC30A10 gene. This gene is functioning to maintain homeostatic control of intestinal absorption and biliary excretion of manganese through responsible for manganese transporter. Manganese accumulates in the liver, muscle, bloodstream, and brain, specifically the basal ganglia resulting in extrapyramidal manifestations, polycythemia and liver cirrhosis. We describe 7 patients from 3 unrelated consanguineous families with cardinal manifestations of manganism. They were five males and 2 females and their aged ranged from 1 4/12y to 18 years old. Six patients (Family 1(4 sibs), 2 (2 sibs)) presented with slowly regression of walking around the age of 2 9/12, manifested as recurrent falling due to limb dystonia. Interestingly, one patient (Family 3) had sudden acute dystonia of lower limbs with inability to walk at the age of 1 year and 5 months with suspicious of inflammatory etiology but the weak response to intravenous immunoglobulin together with the striking neuroimaging pointed to this metabolic error. All affecteds had polycythemia with hemoglobin concentration ranged from 17 -21 g/dl and blood manganese level was above 2000 nmol/L. Elevated liver enzymes with no sign of cirrhosis were in the older 2 sibs in family 1 (17 and 15 ys old), however normal enzymes were in the older affected in family 2 in spite of reaching 18 years old and was still ambulant. Brain MRI showed the typical picture of manganese deposition in basal ganglia classically on T1-weighted images, with affection of midbrain and the tegmentum of the pons as well as the middle cerebellar peduncle with no corresponding abnormality on T2-weighted scans. Molecular analysis for these 3 families revealed novel mutations in SLC30A10 gene in 2 of them. We designated oral treatment with 2,3 dimercaptosuccinic acid (DMSA), iron supplementation and levodopa that showed satisfactory preliminary results in chelating manganese with remarkable improvement of biochemical markers in all and alleviation of clinical manifestations in the younger probands. This report represents further delineation of familial hypermanganesemia. It emphasizes the importance of considering this treatable metabolic error in any patient presenting with acute or insidious dystonia and polycythemia.

2224M

Abnormal phospholipid metabolism due to variants in *PCYT1A* causes spondylometaphyseal dysplasia with cone-rod dystrophy. *J. Jurgens[1], N. Sobreira[1], J. Hoover-Fong[1], P. Modaff[2], G. Yamamoto[3], W. Baratela[3], D. Bertola[3], F. Collins[4], J. Christodoulou[4], M.B. Bober[5], R. Pauli[2], D. Valle[1].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pediatrics, University of Wisconsin-Madison, Madison, WI; 3) Unidade de Genética, Instituto da Criança, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; 4) Western Sydney Genetics Program, Children's Hospital at Westmead, Sydney and Disciplines of Pediatrics & Child Health and Genetic Medicine, Sydney Medical School, University of Sydney, New South Wales, Australia; 5) Division of Medical Genetics, Department of Pediatrics, A.I. duPont Hospital for Children, Wilmington, DE.

Spondylometaphyseal dysplasia with cone-rod dystrophy (SMD-CRD) is a rare, autosomal recessive condition characterized by short stature, bowing and metaphyseal flaring of the long bones, rhizomelic shortening, platyspondyly, scoliosis, and early-onset progressive degeneration of cone and rod photoreceptors. By whole exome sequencing and Sanger sequencing, Hoover-Fong et al. (2014) identified novel homozygous or compound heterozygous variants in *PCYT1A* in 6 unrelated probands. Independently, Yamamoto et al. (2014) described two novel homozygous *PCYT1A* variants, p.Glu129Lys and p.Ser323Argfs*38, in two unrelated SMD-CRD probands. Here, we used Sanger sequencing to identify homozygous or compound heterozygous variants in *PCYT1A* in four additional unrelated individuals with SMD-CRD. We detected a single homozygous variant (p.Ala99Val) in 2 unrelated probands and found a separate homozygous variant (p.Tyr240His) in a third unrelated proband. In the fourth proband, we detected the compound heterozygous variants p.Ser323Argfs*38/p.S114T. *PCYT1A* encodes CTP:phosphocholine cytidydyltransferase α (CCTα), an enzyme which catalyzes the rate-limiting step in de novo phosphatidylcholine biosynthesis by the Kennedy pathway. Phosphatidylcholine is the predominant membrane phospholipid in mammalian cells. Western blot analysis of CCTα expression in cultured skin fibroblasts of 3 unrelated individuals with SMD-CRD shows that the protein levels vary among SMD-CRD patients. When compared to controls, p.Ala99Val homozygotes show a 30% reduction in protein levels; p.Glu129Lys homozygotes show a 70% reduction; and patients homozygous for a 1-bp frameshifting insertion (p.Ser323Argfs*38) show no protein levels. Preliminary northern blot analysis of RNA isolated from the same fibroblast cells suggests that phosphatidylethanolamine N-methyltransferase (*PEMT*) mRNA levels are increased in patients as compared to controls. Based on these results, we hypothesize that patient cells may be compensating for their deficiency in phosphatidylcholine synthesis by upregulating the PEMT pathway, which converts phosphatidylethanolamine into phosphatidylcholine. We suggest that abnormal phospholipid metabolism is a largely unexplored cause of progressive retinal degeneration with or without accompanying skeletal abnormalities.

Mutation spectrum of six genes in Chinese phenylketonuria patients obtained through next-generation sequencing. *Y. Gu[1], K. Lu[2], G. Yang[2], Z. Cen[2], Y. Li[2], L. Lin[2], J. Hao[2], Z. Yang[2], J. Peng[2], S. Cui[2], J. Huang[2].* 1) Lianyungang Maternal and Child Health Hospital, Lianyungang, China; 2) Chinese National Human Genome Center at Shanghai Shanghai, CHINA.

Background: The identification of gene variants plays an important role in the diagnosis of genetic diseases. Methodology/Principal Findings: To develop a rapid method for the diagnosis of phenylketonuria (PKU) and tetrahydrobiopterin (BH4) deficiency, we designed a multiplex, PCR-based primer panel to amplify all the exons and flanking regions (50 bp average) of six PKU-associated genes (PAH, PTS, GCH1, QDPR, PCBD1 and GFRP). The Ion Torrent Personal Genome Machine (PGM) System was used to detect mutations in all the exons of these six genes. We tested 93 DNA samples from blood specimens from 35 patients and their parents (32 families) and 26 normal adult individuals. Using strict bioinformatic criteria, this sequencing data provided, on average, 99.14% coverage of the 108 exons at more than 70-fold depth. We found 23 well-documented variants in the PAH gene and six novel mutations in the PAH and PTS genes. A detailed analysis of the mutation spectrum of these patients is described in this study. Conclusions/Significance: These results were confirmed by Sanger sequencing. In conclusion, benchtop next-generation sequencing technology can be used to detect mutations in monogenic diseases and can detect both point mutations and indels with high sensitivity, fidelity and throughput at a lower cost than conventional methods in clinical applications.

2226M

Functional Characterization of RYR1 Sequence Variants Associated with Malignant Hyperthermia Susceptibility Identified through Exome Sequencing. *S.G. Gonsalves[1, 2], C.E. Kasper[2], S. Perry[2], S.M. Muldoon[3], L.G. Biesecker[1].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 2) Uniformed Services University of the Health Sciences, Graduate School of Nursing, Bethesda, Maryland, USA; 3) Uniformed Services University of the Health Sciences, School of Medicine, Department of Anesthesiology, Bethesda, Maryland, USA.

Malignant hyperthermia susceptibility (MHS) is a life-threatening, inherited disorder of muscle calcium metabolism, triggered by anesthetics and depolarizing muscle relaxants. Exome sequence (ES) data from ClinSeq® were screened to identify putative pathogenic MHS variants in the RYR1 and CACNA1S genes. To study the effects of RYR1 variants on channel function, we selected benign and pathogenic variants for comparison—using an in-vitro assay measuring calcium release from participant-derived Epstein-Barr virus immortalized B-lymphocytes—to determine if incidental MHS-associated variants identified from ES showed abnormal calcium release from lymphoblasts. Annotation of 870 exomes for RYR1 and CACNA1S variants used an algorithm that filtered results based on genotype quality, allele frequency, mutation type, and information from mutation databases. Sixty-three RYR1 and 41 CACNA1S variants passed the quality and frequency metrics and were scored on a four-point pathogenicity scale (2-5). Three RYR1 class 5 (p.RArg614C, p.S1728F, p.D3986E) and one class 3 (variant of uncertain significance) p.R1667C, were selected for functional testing. Pharmacological sensitivity of the RyR receptor type-1 in EBV-immortalized B-lymphocytes derived from four ClinSeq® participants were tested and compared to MH-negative controls. RYR1 p.R614C (with published functional data) was selected as a positive control. B-lymphoblastoid cell lines were used to study the transient peak calcium release induced by the ryanodine receptor agonist 4-chloro-m-cresol (4-CMC). Calcium release (area under curve) was averaged from 12 replicates. Differences in calcium release between cell lines were analyzed by t-test. EBV-lymphocytes from class 5 variants showed increased sensitivity of calcium release to 4-CmC compared to normal controls. Elevated calcium release was observed in RYR1 p.R614C and p.D3986E, (*$P<0.05$) at progressive doses (0.4 mM, 0.6 mM and 1.0 mM) of 4-CMC. RYR1 S1728F showed increased levels compared to wild type (WT), but did not achieve statistical significance. RYR1 p.R1667C was similar to WT. Two class 5 MHS variants showed significantly altered calcium release. Although this assay is time consuming and impractical for large-scale screening of putative MH-susceptibility variants, variant RYR1 function can be successfully assayed using a biochemical assay on participant-derived EBV-lymphocytes, without resorting to muscle biopsy for ex-vivo contraction testing.

2227T

Screening for Lysosomal Storage Disorders using an integrated enzymatic and molecular approach. *O. Bodamer[1], G. Ghaffari[1], P. Noriega[2], C. Hung[1], B. Illagan[1], A. Hosseini[1], B. Johnson[1].* 1) University of Miami, Miami, FL; 2) Genzyme-Sanofi Inc, Mexico City, Mexico.

Background: Lysosomal storage disorders (LSDs) comprise a heterogeneous group of genetic conditions that affect lysosomal metabolism. The clinical phenotype typically follows a clinical continuum of progressive multi-organ involvement. Effective therapies including enzyme replacement therapy (ERT) are available for a subset of LSDs including Fabry, Pompe, Gaucher diseases, MPS I and MPS II. Additional therapies are under development. Timely diagnosis and initiation of ERT is vital to reduce and/or prevent disease morbidity. Methods: We have validated an integrated diagnostic approach utilizing enzyme testing and second tier molecular testing on dried blood spots (DBS) for 6 LSDs including Fabry, Pompe, Gaucher, Niemann Pick Type A/B, Krabbe diseases and MPS I. Samples were collected from at-risk patients based on clinical phenotype suspicious for LSD from larger tertiary referral centers in Mexico. Enzyme analysis in DBS was done by tandem mass spectrometry followed by direct sequencing in samples with low enzyme activities. Results: 3206 samples were received for enzyme testing and 820 samples for direct sequencing of the GLA gene in females. 223 samples (7%) were reflexed to molecular testing based on low enzyme activities. 3/22 (14%) of samples were diagnostic for Pompe disease, 4/19 (21%) were diagnostic for Gaucher disease, 6/11 (55%) were positive for MPS I, 9/171 (5.2%) were diagnostic for Fabry disease and 12/820 (1.4%) of females tested for Fabry disease carried a heterozygous GLA mutation. Conclusion: The use of an integrated diagnostic approach for the above LSDs in DBS allows timely and inexpensive diagnosis of at-risk patients. The refinement of the clinic phenotype that prompts testing for LSDs will lead to further reduction of unnecessary testing.

2228M

Lysosomal acid lipase activity in dried blood spots from patients initially suspected of Gaucher disease. *V.G. Pereira[1], C.F. Chaves[1], J.U.S. Yamamoto[1], A.M. Martins[2], V. D'Almeida[1].* 1) Department of Psychobiology, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Department of Pediatrics, Universidade Federal de São Paulo, São Paulo, Brazil.

Lysosomal acid lipase (LAL) deficiency is an autosomal recessive condition, which leads to the accumulation of cholesteryl esters and triglycerides in most tissues, causing two different lysosomal storage disorders: Wolman disease (WD) and Cholesterol ester storage disease (CESD). WD is the most severe form of the disease, leading to death before one year of age, while CESD presents a more attenuated clinical course, with highly variable phenotypes. Hepatic alterations are a common symptom between lysosomal storage disorders, mainly in CESD, Gaucher and Niemman-Pick diseases. Therefore, differential diagnosis is essential for proper treatment. In this sense, patients initially suspected of Gaucher disease, whose biochemical diagnosis had not been confirmed, may represent a high-risk population for LAL deficiency (LALD). The aim of this study was to determine LAL activity in dried blood spots (DBS) referred to Laboratório de Erros Inatos do Metabolismo/UNIFESP - Brazil with an initial suspicion of Gaucher disease, which had beta-glicosidase activity within the normal range (Gaucher-negative), as a screening for LALD patients. LAL activity was determined by a fluorimetric assay. Until now, 110 Gaucher-negative samples were analyzed and mean LAL activity observed was 45.28 pmol/punch/h (standard error = 4.17), median = 33.99 pmol/punch/h, ranging from 0 to 299 pmol/punch/h. From these samples, 38 (~35%) of them presented LAL activity below the normal range, which had been previously determined in our laboratory (> 24 pmol/punch/h). These samples were then analyzed separately; in this group, mean LAL activity was 12.82 pmol/punch/h (standard error = 1.23), median = 12.97 pmol/punch/h, ranging from 0 to 23.91 pmol/punch/h. All the physicians responsible for patients in the group with low LAL activity were contacted and a new DBS was requested to confirm the diagnosis, to exclude the possible interference of reduced LAL activity due to long storage periods (all DBS samples used in this study were kept at 4°C through a maximum period of one year). Although we still have not received these new DBS to confirm LALD, the high rate of LAL activity below the normal range found in our study suggests that Gaucher-negative samples indeed represent a high-risk population to screen for LALD patients. In addition, Gaucher-negative patients should also have LAL activity determined as differential diagnosis. Funding: FAPESP, CAPES, IGEIM and AFIP.

2229T

Novel strategy for the diagnosis of late onset Pompe disease using next generation sequencing technologies. *S. Levesque[1], E. Gravel[1], S.L. Austin[2], S. Gravel[1], J. Keutzer[3], C. Auray-Blais[1], P.S. Kishnani[2].* 1) Department of Pediatrics, Division of Medical Genetics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, QC, Canada; 2) Departments of Pediatrics, Division of Medical Genetics, Duke University Medical Center, Durham, NC, USA; 3) Genzyme Corporation, a Sanofi company, Cambridge, MA, USA.

Background: Pompe disease is a rare lysosomal storage disorder caused by acid alpha-glucosidase enzyme deficiency, and is characterized by progressive lysosomal glycogen accumulation especially in muscles. Studies have shown that early diagnosis followed with prompt initiation of enzyme replacement therapy may maximize clinical benefits. However, early diagnosis remains challenging, especially in the actual adult cohort owing to the lack of universal screening. Despite published guidelines to educate clinicians, testing for Pompe is often overlooked owing to its low frequency. Next generation sequencing (NGS) might solve this issue given that it can analyse at once a large number of genes causing diseases with overlapping phenotypes. **Method:** We designed a NGS assay in order to analyze the coding sequences and splice site junctions of *GAA*, mutated in Pompe disease, along with 78 genes causing neuromuscular disorders with overlapping phenotypes. Analytical validity was then determined using DNA from 20 Pompe patients with known variations and the reference cell line NA12878. Enrichment of target sequences was performed using a custom in-solution oligonucleotide probes library (SeqCapEz®, Nimblegen), followed by NGS on the Illumina MiSeq® platform. Variations were detected with our bioinformatics pipeline based on BWA and GATK. **Result:** We obtained a median coverage of ~90X (sequences per base) per sample, with only 0.3% of all exons showing less than 20X. All *GAA* exons were successfully covered with >20X. The NGS assay showed a sensitivity of 100% (95% C.I. 98-100%) for the *GAA* gene, based on the analysis of 197 known single nucleotide variations and indels in Pompe patients (42 different variations). In addition, recurrent deletion of exon 18 was correctly detected by read depth analysis in 5/5 Pompe patients. Sensitivity of the assay across all selected genes was similar with 100% (95% C.I. 99%-100%), as determined by comparison between observed variations and 373 expected variations in NA12878. Specificity was determined to 98% (95% C.I. 95-99%), for 208 variations found in exons and splice site junctions of selected genes in the NA12878 cell line. **Conclusion:** We were successful in designing a highly sensitive and specific NGS assay for Pompe disease and related genetic disorders. NGS of patients presenting with a neuromuscular disorder of unknown etiology from neuromuscular clinics is in progress and results will be presented.

2230M

Molecular testing of 163 patients with Morquio A syndrome (mucopolysaccharidosis IVA; MPS IVA): 39 novel *GALNS* gene mutations. *M. Hegde[1], A. Morrone[2,3], K.L. Tylee[4], M. Al-Sayed[5], A.C. Morquio A syndrome is an autosomal recessive lysosomal storage disorder caused by deficiency of N-acetylgalactosamine-6-sulfatase (GALNS) encoded by the *GALNS* gene. Mutations occur throughout *GALNS* and often are identified only in one patient/family, complicating mutation detection and interpretation. 7 laboratories reported mutations in *GALNS* from Morquio A patients and 2 clinicians directly reported molecular results. Individuals received a diagnosis of Morquio A prior to and independent of molecular results. *GALNS* mutations were checked against reported SNPs. Molecular testing of 163 Morquio A patients identified 99 separate changes, of which 39 are previously unpublished, novel *GALNS* mutations associated with Morquio A: p.Val16Glu, p.Leu36Arg, p.Asp40Asn, p.Val48Gly, p.Glu51Lys, p.Pro81Leu, p.Ala84Glu, p.Leu91Pro, p.Gly116Val, p.His145Tyr, p.Phe156-Leu, p.His166Arg, p.Gly201Glu, p.Leu214Pro, p.Phe216Ser, p.Thr235Lys, p.Ser264Thr, p.Asn289Asp, p.Arg380Gly, p.Gly415Val, p.Ile416Thr, p.Pro420Arg, p.Ala492Thr, p.Gly500Ser, p.Cys507Phe, p.Glu126Ter, p.Trp141Ter, p.Tyr209Ter, p.Arg251Ter, p.Pro357ArgfsTer21, p.Leu372SerfsTer6, p.Tyr385Ter, p.Gln414Ter, p.Val427SerfsTer13, p.Glu477_Gln485del, Complex del-dup (duplication from intron 5-intron 9, deletion in intron 10), c.120+1g>c, c.405_422+1del, c.758+4a>t. We also identified 26 SNPs. Reporting Morquio A-associated *GALNS* mutations improves genetic counseling and diagnosis capability. We recommend also to molecularly test both parents. While molecular testing provides useful diagnostic and genetic counseling information, enzyme activity testing of GALNS, along with other enzymes, remains the standard for diagnosis of Morquio A.

2231T

Menkes disease: the importance of precise diagnosis with molecular analysis in neonatal period. *C. Kim[1], L. Costa[1], S. Pegler[1], R. Lellis[2], V. Krebs[1], T. Morgan[3], R. Honjo[1], D. Bertola[1].* 1) Dept Pediatrics, Inst da Crianca, Hospital das Clínicas - Universidade de São Paulo - Sao Paulo, SP, Brazil; 2) Dept. Pathology - Hospital das Clínicas - Universidade de São Paulo - São Paulo - Brazil; 3) Department of Womens and Children's Health, Dunedin School of Medicine, University of Otago, Dunedin NEW ZEALAND.

Menkes disease (MD) is a congenital disorder in copper metabolism, caused by mutations in ATP7A. It is characterized by physical and neurological alterations. In neonatal period these alterations can be nonspecific, what makes the precocious diagnosis a challenge. Clinical includes: developmental delay, hypotonia, seizures, hair abnormalities and connective tissue disorders. Diagnosis can be suspected when there are low levels of ceruloplasmine and serum copper, but they can be in low levels even in normal newborns. Molecular analysis confirms the diagnosis. Precocious treatment is mandatory with copper histidine for clinical improvement. We report a familial case of MD with molecular confirmation. The proband was the second child of a healthy mother, with a history of eye twitching since 1mo2d.The physical exam of our proband showed: weight of 4080g (15%), length 52.8 cm (15%) and OFC of 40cm (> 97%), steely, kinky, sparse hair, divergent strabismus, pudgy cheeks. The mother had the first son, from different partner, who died at 3mo21d with a clinical diagnosis of MD. Laboratorial exams showed low serum ceruloplasmin <2mg/dL (reference range from 20-60 mg/dL) and copper <8 μg/dL (reference range from 70-160 μg/dL) confirming clinical diagnosis of MD. Treatment with copper histidine was indicated immediately but it was instituted only at 2mo27d. The reason for delay was the time demanded for the preparation. He did not presented clinical or neurology improvements and died at 6mo. Mother had another pregnancy (with the same partner), a male fetus was identified and copper histidine was manufactured. He was born healthy, biochemical markers were diminished and treatment was instituted since 3d and he presented no neurological symptoms. Molecular analysis was performed the proband was hemizygous for a mutation in ATP7A (c.1668-1680del, predicted to lead to the frameshift p.Ile556Metfs*11). Mother is heterozygous for the same mutation. The third son did not have the mutation and consequently treatment was discontinued. We support the clinical relevance of molecular confirmation for diagnosis and genetic counseling, once clinical findings in the neonatal period are nonspecific and early treatment must be indicated. Molecular confirmation in our case was indispensable for the correct diagnosis of MD, once biochemical markers are nonspecific of copper deficiency.

2232M

Mitochondrial Heteroplasmy and Clinical Variability in a MELAS Family. *K. McClelland[1, 2], K. Weisiger[2], T. Huang[3], J. Youngblom[1], C. Lee[2], N. Barasa[3], C.A. Valencia[3], S. Packman[2].* 1) California State University, Stanislaus; 2) University of California, San Francisco; 3) University of Cincinnati.

Genetic counseling and prognosis in patients with mitochondrial disorders is challenging due to highly variable expression and penetrance. One source of variability is the existence of heteroplasmy; the co-occurrence of wild-type and mutant mitochondrial DNA [mtDNA] within a cell. Heteroplasmy levels can differ both between individuals and between different tissue types in the same individual. Manifestation of pathology in a given tissue, is, in fact considered to depend on that tissue's threshold for mtDNA mutation load. While a relationship between mutation load and disease expression has been shown in in vitro studies, current literature is conflicting on the utilization of heteroplasmy for predictive and prognostic counseling. In the present work, we asked whether there was a correlation between mutation load, as measured in urine sediment cells, and clinical manifestations in an extended Hispanic family with the mA3243G MELAS [mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes] mutation. This study examined 23 maternal relatives of a patient diagnosed with MELAS for the presence of clinical symptoms, physical findings and degree of heteroplasmy in urine sediment cells. For the molecular analyses and assessment of percent heteroplasmy, mitochondrial DNA was isolated from cells in urine samples and the mA3243G mtDNA mutation was detected by real time PCR. Presence and number of clinical symptoms [patient reports] and physical findings [examination by SP and CL] were compared to percentage of mtDNA A3243G mutation detected in urine sediment cells for each individual. This study found that 65% of family members self-reported MELAS-associated symptoms, and 52% had physical findings, both neurologic and other systemic. A significant correlation was found between age and number of MELAS-associated symptoms, as well as age and number of physical findings. In contrast to a number of reported studies, no significant correlation was found between levels of mutation load measured in urine and the number of symptoms or physical findings. We conclude that urine sediment cell heteroplasmy analysis is not a uniformly effective test to predict clinical phenotype in individuals, or small sample sizes that carry the mA3243G mutation.

Morquio A syndrome (mucopolysaccharidosis IVA; MPS IVA): A review of 277 gene mutations curated in a new *GALNS* locus-specific database. *N. Miller[1], A. Morrone[2,3], A. Caciotti[2,3], R. Atwood[4], K. Davidson[1], C. Du[4], P. Francis-Lyon[5], P. Harmatz[6], M. Mealiffe[1], S. Mooney[4], T.R. Oron[4], A. Ryles[5], K.A. Zawadzki[7].* 1) BioMarin Pharmaceutical Inc., Novato, CA, USA; 2) Molec and Cell Biol Lab, Pediatric Neurology Unit and Laboratories, Meyer Child Hosp, Florence, Italy; 3) Dept of Neurosciences, Psychology, Pharmacology and Child Health, Univ of Florence, Florence, Italy; 4) The Buck Institute for Research on Aging, Novato, CA, USA; 5) Dept of Computer Science, Univ of San Francisco, San Francisco, CA, USA; 6) UCSF Benioff Children's Hospital Oakland, Oakland, CA, USA; 7) Health Interactions Inc., San Francisco, CA, USA.

Morquio A is caused by deficient activity of N-acetylgalactosamine-6-sulfatase (GALNS) resulting from mutations in *GALNS. GALNS* mutations are numerous and heterogeneous. To aid detection and interpretation of mutations, we summarize published mutations from 541 Morquio A patients, together with 81 published mutations not described as genotypes from individual Morquio A patients, and report a new public-access *GALNS* locus-specific database. 277 unique *GALNS* mutations were identified from 1091 alleles. Most alleles reported from patients (79%) are missense. Even the most frequent mutations are uncommon. The three most common alleles (R386C, I113F, G301C) together only represent 14% of alleles. Significant geographical and/or ethnic origin-based allele frequency variability exists. 11% of alleles are insertions/deletions, 6% intronic, 4% nonsense. Most Morquio A-associated mutations have only been reported 1-2 times. 48% of patients are homozygous for a *GALNS* mutation, 39% heterozygous, and 13% have only one mutation detected. Mutation detection and genotype-phenotype challenges are in part due to the heterogeneity of *GALNS* mutations and lack of multiple families with the same mutations. Parental testing is encouraged. Reporting new alleles facilitates distinguishing pathogenic from benign mutations. The standard for Morquio A diagnosis is still deficient GALNS enzyme activity measured in leukocytes or fibroblasts, together with normal control enzyme activities.

2234M

Expanding the toolbox for the diagnosis of mitochondrial disorders. *L. Kremer[1,2], G. Pichler[3], T. Schwarzmayr[1,2], T. Haack[1,2], T. Wieland[1,2], T. Strom[1,2], M. Mann[3], T. Meitinger[1,2], H. Prokisch[1,2].* 1) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 2) Institute of Human Genetics, Technische Universität München, Munich, Germany; 3) Max Planck Institute of Biochemistry, Martinsried, Germany.

Despite good progress in the field, many disease causing mutations in patients with mitochondrial disorders still have to be identified. We recently applied whole exome sequencing (WES) in 400 unrelated individuals with juvenile-onset mitochondrial disorder. In 50% of the patients we were unable to identify the disease causing mutation and hence additional tools are needed to promote the identification of the disease gene for the remaining 50% of cases. Sequencing of trios will expand the screening for de novo mutations, while whole genome sequencing (WGS) approaches will ease the discovery of additional DNA variation not seen by WES. However, the interpretation of the consequences of rare variants remains a challenge. To this end, we established a collection of more than 200 fibroblast cell lines from patients with mitochondrial disorders, WES and respiratory chain complex investigation for a quantitative proteome study. The combined determination of DNA variation and protein steady state levels in a cell line expressing impaired energy metabolism will advance the identification of DNA variants important for protein stability and turnover involved in the etiology of the disease. For quantitative proteomics, we are developing a protocol for a fast and comprehensive analysis based on a limited number of cells. We are using the coding variants from the exome data to predict a cell line specific proteome and we are also considering allele specific detection of peptides. Testing different HPLC gradient separation times, we were able to quantify up to 8 000 proteins (out of 10 000 expected to be expressed in fibroblast cells). Starting with controls and characterized fibroblast cell lines from patients with known diagnosis, we applied 3 different algorithms to verify the approach: A) A principle component analysis allowed a clear distinction between patient and control cell lines. B) Hierarchical cluster analysis of 18 samples followed by pathway enrichment analysis discovered a disease specific profile in FBXL4 patients. C) Case by case analysis revealed not only the absence of NDUFB3 in a cell line harboring mutations in NDUFB3 but also a significant reduction of the respiratory chain complex I subunits. Currently, we are analyzing the first set of unsolved patient cell lines as well as the impact of frequent variants on the corresponding protein level.

2235T

Novel mutation in BCKDHA gene in Iranian population. *m. abiri[1], M.R. Noori Daluie[1], M.R. Alaee[3], A. Sotoodeh[1], S. zeinali[2,4].* 1) Tehran university of medical sciences, Iran; 2) 2Pasteur Institute of Iran, Tehran, Iran; 3) 3Shahid Behesti University of Medical Sciences, Tehran, Iran; 4) Medical Genetics Laboratory, Kawsar Human Genetics Research Center, Tehran, Iran.

Novel mutation in BCKDHA gene in Iranian population M, 1 Noori Daluie M.R, 3 Alaee M.R, 1Sotoodeh A, 2, 4 zienali S 1,2 Abiri 1Tehran University of Medical Sciences, Tehran, Iran. 2Pasteur Institute of Iran, Tehran, Iran. 3Shahid Behesti University of Medical Sciences, Tehran, Iran. 4 Medical Genetics Laboratory, Kawsar Human Genetics Research Center, Tehran, Iran. Abstract: Maple syrup urine disease (MSUD) is a rare inherited metabolic disorder that inherited as an autosomal recessive disorder. The defect is in branched-chain alpha-keto acid dehydrogenase, the enzyme required for the catabolism of branched chain amino acids (valin, Leucin, Isoleucin). MSUD is clinically and genetically heterogeneous disorder. Affected neonates show a distinctive maple sugar odor in earwax, sweat, and urine, poor appetite, irritability and developmental delay. If untreated can lead to seizures, coma, and death. It is estimated MSUD affects 1 in 185,000 infants worldwide, but this estimation can be higher in countries with high rate of consanguineous marriage. Mutation in several gene can cause the disease, including BCKDHA, BCKDHB, DBT, DLD. In this study, we report evaluation of 20 MSUD families with 20 affected individuals from different parts of Iran. Homozygosity mapping with the help of STR markers showed the probable mutated gene. The Analysis followed by amplification of all exons and flanking intronic sequences. The next was bidirectional sequencing of the amplified sequences. Investigation of the mentioned genes in all families are ongoing and here we report a new mutation in a twin which is the outcome of a consanguineous marriage. The patient is an 8 years old boy with developmental delay and severe mental retardation. Homozygosity mapping showed the probable mutation is in BCKDHA gene. Direct sequencing of the exons and intron/exon boundaries showed homozygous deletion of a T in Cd 234 of the mentioned gene. Our results show that the parents are heterozygous carrier of the disease. The spectrum of the mutations underlying MSUD would expand by these previously unpublished mutations in the BCKDHA gene. The identified mutation forms the basis to confirm the clinical diagnosis by genetic testing, provided the availability of Prenatal Diagnosis and pre-genetic implantation Diagnosis for demanding families. Also it helps to identify heterozygous carriers to reduce the burden of MSUD in Iran.

2236M

Two children with Phenylketonuria with normal tetrahydrobiopterin biochemical testing and normal Phenylalanine Hydroxylase gene testing. *P.M. James[1], C. Candeleria[1], M. Colville[1], M. Kennedy[1], H.L. Levy[2].* 1) Divison of Genetics, Phoenix Children's Hospital, Phoenix, AZ; 2) Divison of Genetics and Metabolism, Boston Children's Hospital, Boston, MA.

We report two girls with biochemically confirmed hyperphenylalaninemia who do not have detectable mutations of the Phenylalanine Hydroxylase (PAH) gene. The first girl was seen at age 16 months for developmental delay, hyperactivity, microcephaly; her plasma phenylalanine (Phe) level was 1620umol/L (27mg/dL). Urine pterins were normal x2; the 1st biopterin 39.5%, and the 2nd 67.7% (nl 18-69%). RBC dihydropteridine reductase activity was 1.2 nmol/min/mg Hgb, the 2nd 1.3 nmol/min/mg Hb (nl 0.8-3.9 nmol/min/mg Hb). She was placed on a low Phe diet and responded rapidly. Within 36 hours her plasma Phe level decreased to 274umol/L (4.5mg/dL) , subsequently on a Phe intake of 400-600 mg/day she maintained plasma Phe levels ranging 18-150umol/L (0.3-2.5mg/dL). Thus, her Phe tolerance was that of mild PKU. PAH gene sequencing performed on two different dates by two laboratories was non-informative. Investigating the possibility she had BH4 deficiency despite the normal pterin results she was given a BH4 challenge. Fed a normal diet for 4 days, then given BH4 5mg PO, there was no reduction in plasma Phe level. CSF neurotransmitters were normal. Retrospective study revealed her Phe level on newborn screening at 24 hrs of age was <2mg/dL. The original newborn specimen was retrieved from storage and retested, again showing a normal Phe level of <2 mg/dL. The second girl of African American heritage was found on newborn screening to have a Phe level of 3.6mg/dL at dol1; 7.1mg/dL at dol22 with plasma Phe level of 471umol/L (7.8 mg/dL). She was started on a Phe restricted diet of 83mg/kg/d and maintained plasma Phe levels from 3.3-4.9mg/dL. Lost to follow-up, she presented at 4 and ½ years of age with severe Kwashiorkor, developmental delay, blond hair, short stature (<2sd), and cardiomyopathy. Her plasma Phe on admission was 0.4mg/dL, tyrosine 0.05mg/dL, and albumin 0.6gm/dL. She developed re-feeding syndrome, max plasma Phe was 12.5mg/dL. PAH gene sequencing with del/dup was non-informative. Urine biopterin was 48% (nl 49-74%), and RBC dihydropteridine reductase activity was 4.74 nmol/min/disc (nl 1.96-7.51). Five months post hospitalization she is regaining milestones on a high protein and moderate Phe restricted diet with plasma Phe 2.1-5.3mg/dL. These girls represents the only instances of PKU known to be true negatives in over 50 years of PKU screening in New England and Arizona. Consequently, we suspect they represent a new variant of hyperphenylalaninemia.

2237T

Molecular characterization of homocysteine metabolism in North Indian cohort with Hyperhomocysteinemia. *A. Lomash, S. kumar, S. pandey, A. singh, M. goyal, SK. polipalli, S. kapoor.* Division of Genetics, Department of Pediatrics, MAMC, New-Delhi, , India.

Objective: The current study was conducted to elucidate whether the elevated Hcy levels are associated with the mutations in the MTHFR(A1298C & C677T),TYMS(6bp I/D) & HLA-G(14bp I/D) gene in a North Indian Cohort in the patient with hyperhomocysteinemia Materials and Methods: Fasting plasma total homocysteine concentration were measured using RP-HPLC & Genetic polymorphisms in MTHFR (A1298C & C677T), TYMS (6bp Ins/Del) & HLA-G (14bp Ins/Del) gene were determined by using PCR-RFLP, SSP & ARMS-PCR method & p value <0.05 were considered significant. Result: Forty five subjects with elevated Homocyteine levels were detected with a mean homocysteine value (26.1+2.7 umol/L) out of 180 referral cases and characterize into Pediatric, Adolescent & Adult age group. Stroke & Ectopia Lentis were the commonest reason behind Pediatric (70% & 10%) & adolescent age group (80% & 20%) respectively. The frequencies of the AA, AC, CC genotype of MTHFR (A1298C) in cases v/s controls were 12.5%, 75%,12.5% and 75%, 25% 0%. The frequencies of the CC,CT,TT genotype of MTHFR (C677T) in cases v/s controls were 60%,40% and 75% & 25% respectively. The frequency of 6bp Ins/Ins,Del/Del &Ins/Del polymorphism in TS 3'UTR of TYMS gene in cases vs controls were 17.7%,51.1%,31.1% and 15.5%,28.8%,55.5%..The frequency of 14bp Ins/Ins,Del/Del &Ins/Del polymorphism of HLA-G in cases vs controls were 31.1%,22.2%,46% and 11.1%,31.1%,57.7%. Conclusion: Study explains that elevated homocysteine concentration may be a significant contributor & positively associated with the presence of stroke in patient with pediatrics & adolescent age group. Molecular evaluation show that homozygous Del/Del genotype(P value = 0.0332) of TS 3'UTR (6bp Ins/Del) of TYMS gene & homozygous Ins/Ins genotype(P value = 0.0251) of the HLA-G 14-bp Ins/Del polymorphism respectively is more common in patients with genotypes A1298C & C677T & it appears to confer significant susceptibility to the development of Hyperhomocysteinemia.

2238M

Identification of a Mutation in a Novel Gene Causing a Chédiak-Higashi Syndrome-Like Phenotype. *J.C. Roney[1], M. Gunay-Aygun[1], D. Gul[2], T. Vilboux[1], D.M. Maynard[1], C. Toro[1], W.J. Introne[1], J.C. Mullikin[3,4], M. Huizing[1], W.A. Gahl[1], A.R. Cullinane[1].* 1) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD, USA; 2) Gülhane Military Medical Academy, Department of Medical Genetics, Ankara, Turkey; 3) Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, NHGRI, NIH, Bethesda, MD, USA; 4) NIH Intramural Sequencing Center, NHGRI, NIH, Rockville, MD, USA.

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by partial albinism, recurrent infections, a mild bleeding tendency, and a later onset neurological dysfunction with features that include learning difficulties, cerebellar dysfunction, polyneuropathies, and L-DOPA responsive Parkinsonism. Diagnosis of CHS is based on identification of enlarged granules on peripheral blood smear and enlarged lysosomes and lysosome related organelles in many cell types. Previously, CHS was only known to be caused by mutations in the lysosomal trafficking regulator gene (*LYST*) that encodes a cytosolic protein proposed to function in the regulation of lysosomal size and trafficking. However, there are patients with CHS who do not have mutations in *LYST*, suggesting that mutations in other genes could also result in the disorder. Here we describe a set of twins of consanguineous background who presented with hepatosplenomegaly and were diagnosed with CHS based on typical inclusions in peripheral leukocytes and in precursor cells in the bone marrow. Their subsequent clinical course was dominated by severe global developmental delay and refractory epilepsy; at age 6 years they were non-verbal and unable to sit unsupported. Cellular analysis showed enlarged lysosomes that clustered perinuclearly in both patients' fibroblasts. Whole exome sequencing of one of these patients revealed no mutations in *LYST*, but identified a homozygous 1bp deletion in *WDR91*, representing a novel gene causing a CHS-like phenotype. The same mutation was identified in the affected sibling by Sanger sequencing, and segregated with disease status within the family. *WDR91* encodes WD40 Repeat 91 protein that contains several WD40 domains similar to LYST. These domains fold into a beta-propeller structure known to form a platform that mediates protein-protein interactions. Consistent with the severity of the mutation, WDR91 protein expression is completely absent in the two affected individuals and likely accounts for their CHS-like phenotype. Identification of other CHS patients with *WDR91* mutations will help us understand if WDR91-related CHS causes the severe neurological phenotype observed in these siblings.

2239T

Molecular Characterisation of known & novel mutations in Congenital Adrenal Hyperplasia patients (CYP21A2 gene) : Genetic & diagnostic implications. *r. khajuria[1], r. prasad[1], r. walia[2], a. bhansali[2].* 1) biochemistry, PGIMER,Chandigarh, chandigarh, chandigarh, India; 2) endocrinology,-PGIMER,Chandigarh India.

Congenital Adrenal Hyperplasia (CAH) is autosomal recessive disease, with a wide range of clinical manifestations from severe classical form to late onset form. Most cases of CAH, the inherited inability to synthesize cortisol, aldosterone with subsequent overproduction of androgens, are caused by mutations in steroid 21 Hydroxylase genetic analysis. As a complement to hormonal measurements, mutation analysis of CYP21A2 gene is potentially important tool in diagnosis of steroid 21 Hydroxylase defiency as well as genetic counselling. Our aim was to determine the frequency of common CYP21A2 gene mutations and identify novel mutations. Clinical and hormonal evaluations were used to categorize the patients in Salt Wasting (SW), Simple Virilizing (SV) and Non Classical (NC) forms. About 95 % of mutant alleles have apparently been transferred from linked pseudogene (CYP21P) to active gene (CYP21A2).Molecular analysis of CYP21A2 was performed in 50 patients for detection of common mutations viz gene deletion,Q318X,R356W,V281L,E6 cluster,i2g, ins T in exon 7 or L307 frameshift mutation, P267L by PCR, ACRS, restriction method and finally confirmed by sequencing . Polymorphisms viz D183E & S268T were identified in 50 patients and 50 control by DNA RFLP and sequencing. Novel mutations were identified by SSCP technique and subsequently sequencing of amplified product. Disease causing mutations were identified in patients comprising SW(n=14), SV(n=22) and NC(n=14). Single gene deletion was found with frequency of 18.4 % in SW, SV patients whereas homozygosity was found with 7.9% in these cases. Frequency of other known mutations were to be present at R356W mutation (20 %), Q318x (11 %) ,V281L (25 %), i2g (36 %), L307 (10 %) and P267L (4 %). D183E and S268T polymorphisms are also present in our population . The genotypic frequency of S268T polymorphism was present with 0.42% in normal and 0.86% in patients. H365N, F306V, P357P, D234D are novel mutations in CYP21A2 gene. Each novel mutation was present at frequency of 2 %. This is a comprehensive study showing compound heterozygosity in majority of our CAH population.

Molecular Analysis of two Indian Mucolipidosis-II (ML-II) patients and Identification of One Novel Mutation in GNPTAB gene. *M. Mistri[1], J. Sheth[1], K. Godbole[2], F. Sheth[1], N. Makadia[3].* 1) Biochemical and Molecular Genetics, FRIGE's Institute of Human Genetics, Ahmedabad, Satellite, India; 2) Department of Genetic Medicine, Deenanath Mangeshkar Hospital & Research Center, Pune, India; 3) N. M. Virani Wockhardt Hospital, Rajkot, Gujarat, India.

Mucolipidosis II (MLII or I-cell disease MIM# 252500) is an autosomal recessive genetic disorder resulting from defects in the membrane-bound enzyme UDPGlcNAc-1-phosphotransferase due to mutation in GNPTAB gene (MIM# 607840) which plays a key role in lysosomal enzyme trafficking. As per HGMD database, 135 mutations have been reported from different ethnic groups, although the disease causing mutations are not known in Indian population except one or two cases. In present study, mutation study for GNPTAB gene in 2 Indian patients with increased appropriate lysosomal enzyme level in plasma was address to ML -II. Mutation study was performed using direct sequence analysis. Both the patients were found to have 2 different mutations that includes novel homozygous missense mutation c.1144 A>C (p.T382P) in one patient and known small homozygous deletion c.3503_3504delTC (p.L1168QfsX5) in another patient, which is frequently observed in various populations with high carrier rate. This homozygous mutation was observed in two unrelated patients with non-consanguineous parentage. In silico analysis further confirmed the pathogenic effect of the novel mutations occurring at highly evolutionarily conserved domain residues in the protein, leading to conformational changes. This novel mutation also provides the new insights into the molecular basis of the disease that can be utilized for the molecular diagnosis, which will be helpful in offering precise genetic counseling, carrier detection followed by prenatal diagnosis.

Guadalajara, Jalisco, México; 3) Unidad de Investigación Médica en Bioquímica Centro Médico Nacional, "Siglo XXI" IMSS. Av Cuauhtémoc 330, Ciudad de México, México.

Introduction: In chitotriosidase (CHIT1), a biomarker used in Gaucher disease, 24bp duplication is the most frequent polymorphism at CHIT1 and results in deficient enzymatic activity compromising its use as biomarker. In this study we wanted to determine the allelic and genotypic frequency of dup 24bp on six Mexican Amerindian populations. Material and methods: 692 samples were analized: Purepechas (49), Tarahumaras (97), Huicholes (97), Mayan (139), Tenek (97) and Nahuas (213). DNA extraction and PCR was done as published elsewhere. Statistical analysis was done by direct counting of genotype and allele frequencies and HWE were using a chi-square and Markov chain by Arlequin 3.5. Results: We found the dup 24bp (CHIT1) in distributions observed in Table 1. All groups were in HWE. The allele frequency of dup 24bp was higher than expected in all analyzed groups compared with Mexican mestizo. Molecular and Functional Characterization of Mucopolysaccharidosis Type VI in Indian population. *U. Anusha, S. Jamal Md Nurul Jain, B. Ashwin Dalal.* Centre for DNA Fingerprinting and Diagnostics, Hyderabad, Andhra Pradesh, India.

Mucopolysaccharidosis type VI (MPS VI) is a rare, autosomal recessive lysosomal storage disorder caused by deficiency of the enzyme N-Acetyl Galactosamine-4-sulfatase resulting from mutations in the Aryl Sulfatase B (ARSB) gene. In the present study, molecular and functional characterization of the ARSB gene was done for twenty three patients and their families who were enzymatically confirmed to have Mucopolysaccharidosis type VI. A total of fifteen mutations were identified, of which eleven were novel mutations: p.D53N, p.L98R, p.Y103SfsX9, p.F166fsX18, p.I220fsX5, p.I350F, p.W353X, p.H393R, p.S403Yfs, p.P445L, p.W450L, and p.W450C and three were known mutations (p.D54N, p.A237D and p.S320R). All the novel sequence variants were confirmed not to be polymorphic variants by performing sequencing in 50 normal individuals from the same ethnic population. Age of onset, clinical progression and enzyme activity levels in each patient were studied, to look for genotype-phenotype correlations. Haplotype analysis performed for five different families with the recurring mutation W450C, was suggestive of founder effect. Sequence and structural analysis of the ARSB protein using standard software was carried out for determining the impact of detected mutations on the function of the ARSB protein. Functional characterization of all the mutant cDNA constructs were done by transient expression in cultured COS-7 cells and Aryl Sulfatase B enzyme activity was measured in cell extracts. Summary: Many novel mutations which were unique to Indian population were identified in the present study. This is the first study describing mutations in MPS VI cases from India and also provides some insights into the genotype-phenotype correlation in MPS VI. Keywords: Mucopolysaccharidosis type VI, ARSB gene, mutations, functional characterization, genotype-phenotype correlation, ARSB protein structural analysis.

Antioxidant enzymes gene expression in Fabry Disease along the circadian rhythm. *A.C. Barris-Oliveira, V. D'Almeida.* Department of Psychobiology, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil.

Fabry disease (FD) is caused by a mutation in the *GLA* gene, located in the X chromosome, which leads to a deficiency in the α-galactosidase A and thus, globotriaosylceramide storage in lysosomes. The symptoms of this disease are not completely explained by the lipid storage and pathophysiological changes observed in this disorder have been correlated with the activation of secondary pathways, as oxidative stress. Our group has already investigated the erythrocytes levels of antioxidant enzymes in FD patients, and has observed higher catalase (*CAT*) activity levels and also, higher levels of total glutathione. The generation of reactive oxygen species and their removal have already been described as processes that vary along the day, following a circadian rhythm. The objective was to investigate gene expression of the antioxidant enzymes: superoxide dismutase (*SOD1*), glutathione peroxidase (*GPX1*) and *CAT* in FD and control fibroblast cultures along a circadian rhythm. Four fibroblast cultures were used, divided equally in FD and control cultures, from female and male individuals. To induce the circadian rhythm, it was used the serum shock protocol with DMEM 50% fetal bovine serum for 2 hours. The RNAs, extracted at the following times: T1, T4, T10, T16, T22 and T28, were further converted in cDNA and used for qPCR. The genes expressions were plotted in graphics in relation to *36B4*, used as endogenous control gene. Comparing the cell cultures from Fabry Disease Woman (FDW) with Control Woman (CW), *SOD1*, *GPX1* and *CAT* showed similar circadian patterns of expression, and there were statistical differences for *SOD1* at T28, for *GPX1* at T10, T16 and T22, and for *CAT* at T16; besides, the amplitude of expression from CW seemed higher. Comparing the cultures from Fabry Disease Man (FDM) with Control Man (CM), the circadian patterns of expression looked different for all genes, and there were statistical differences for *CAT* at T4, T16 and T28; moreover, FDM presented lower amplitude of expression. Comparing CW and CM for all genes, the circadian expressions followed similar patterns, but CW tended to have higher amplitude of expression, as expected. With the data obtained, we conclude that FD cells show a variable gene expression of antioxidant enzymes along the circadian rhythm, and this variation differs between FDW and FDM, adding information to the study of pathophysiological differences between FD male and female patients. Characterization of NPC1 expression on mRNA and protein levels in a cohort of Niemann-Pick type C disease type 1 (NPC1; MIM #257220) patients. *M. Hrebicek[1], F. Majer[1], D. Musalkova[1], M. Reboun[1], I. Maresova[1], G. Storkanova[1], H. Vlaskova[2], O. Luksan[1], M. Jirsa[2], L. Dvorakova[1].* 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University and General University Hospital, Prague, Czech Republic; 2) Institute for Clinical and Experimental Medicine Prague, Czech Republic.

NPC1 expression in skin fibroblast cell lines were characterized at mRNA and protein levels in a subset of a cohort of 45 patients carrying various combinations of *NPC1* pathogenic variations. Total NPC1 protein expression levels were semi-quantitated by protein immunoblot analysis of fibroblast lysates. Steady state amounts of immunoreactive NPC1 were lower when compared to controls (80% - 10%). In all tested cell lines carrying at least 1 missense *NPC1* variant treatment with proteasome inhibitor bortezomib increased NPC1 amounts, while chemical chaperones (glycerol, 4-phenylbutyrate) and low temperature lead to increases only in some of them.

NPC1 allelic RNA expression ratios were determined in 23 patients by next generation sequencing of RT-PCR products, or in 11 patients by RT-PCR/RFLP followed by fragmentation analysis. In 15 patients carrying two missense mutations the expression from both alleles was generally balanced, with the exception of p.V950G/p.P1007A, in which the ratio was 70/30. From 5 patients carrying a combination of a missense mutation and a small deletion or duplication the ratios were skewed in favor of the missense allele (> 89/11) in three, while in two others the ratios suggested balanced mRNA expression. We have also analyzed 2 kb of *NPC1* promoter region in 62 control alleles and found six common polymorphisms comprising five probable haplotypes. We did not identify any rare variants potentially altering *NPC1* transcription in the patients.

Thus far, the results suggest that the *NPC1* missense mutations generally allow for residual protein synthesis, which may be increased by treatment with chemical chaperones in some cases. Support: IGA MZ CR NT12239-5/201, PRVOUK-P24/LF1/3, MHCZ-DRO-VFN64165.

Enzyme activity values and Pseudodeficiency Findings of arylsulfatase A and α-glucosidase in a Mexican Population. *A. Juárez[1,2], S. Mendoza[2], A. Porras[1,2], T. Da Silva[1,2], E. García[2].* 1) Instituto de Genética Humana "Enrique Corona Rivera" , Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Bioquímica IB, División de Genética, Centro de Investigación Biomédica de Occidente, Guadalajara, Jalisco, México.

Introduction . Lysosomal storage diseases (LSD) are a group of disorders caused by the buildup of molecules due to genetic defects of lysosomal acid hydrolases or receptor, activator, membrane or conveyor proteins. Each condition is derived from the accumulation of one or more specific substrates . There are enzymes involved in LSD that have significantly decreased enzyme activity in general population; this condition is known as pseudodeficiency and is due to the presence of residual alleles. However, individuals with these alleles show no clinical manifestations. The present investigation was performed to determine the presence of reduced enzyme activity of arylsulfatase A (EC 3.1.6.8) and α -glucosidase (EC 3.2.1.20), deficient enzymes in Metachromatic Leukodystrophy and type II Glycogenosis (Pompe disease), in a Mexican population. Material and methods. A cross-sectional study was conducted in 50 individuals of Mexican population (without any clinical manifestation), of which, prior informed consent, leukocytes were extracted from peripheral blood. Subsequently, the proteins were determined by Lowry method, and determination of enzyme activity was performed by spectrophotometric method in arylsulfatase A and fluorometric in α-glucosidase. The following reference values were considered: for arylsulfatase A: 3.0 ± 2.3 nmol / mg of protein / min and for α-glucosidase: 0.1365 ± 0.56 nmol / mg protein / hr. Candidates to the presence of pseudodeficiency alleles were evaluated by sequencing in order to identify polymorphisms associated with this condition; in *ARSA*: c.1049A> G (rs2071421) and c * 96A> G and in *GAA*: c.1726G> A (rs1800307) and c.2056G> A (rs78653500). Results and discussion. Only two individuals had reduced enzymatic activity for α-glucosidase (less than 50% relative to the control range) and were confirmed by molecular study; both presented c.1726G> A and c.2056G> A polymorphisms. No cases were detected for arylsulfatase A. Conclusions. We show for the first time, the presence of pseudodeficiency in Pompe in our population (heterozygous state); the essay confirms that the biochemical study on leukocytes is reliable to detect potential cases of pseudodeficiency and alert to think of them when suspected cases are studied (cases with clinical picture of Pompe disease). This study creates the basis for further study as determine the frequency of pseudodeficiency in Mexican population.

2246M

Unexpected manifestations of Gaucher disease during enzyme replacement therapy. *YM. Kim[1], CK. Cheon[1], DH. Shin[2], SB. Park[3], GH. Kim[4], HW. Yoo[4].* 1) 1Department of Pediatrics, College of Medicine, Pusan National University Children's Hospital, Yangsan , South Korea; 2) Department of Pathology, College of Medicine, Pusan National University Yangsan Hospital, Yangsan, Korea; 3) Departement of Internal Medicine, College of Medicine, Pusan National University Yangsan Hospital, Yangsan, Korea; 4) Medical genetic center, Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, Korea.

Background: Gaucher disease (GD) is caused by the deficiency of glucocerebrosidase. This enzyme helps break down fatty substances in the body, and when the enzyme is deficient, fatty substances build up in parts of the body and cause damage. In many individuals with GD, especially Type I, enzyme replacement therapy (ERT) can reduce the enlargement of the liver and spleen and improve anemia and thrombocytopenia. Recently, we encountered a 35 year-old man with GD manifested gastrointestinal involvement during ERT. Case: The patient was monozygote twin and both were diagnosed with GD by bone marrow biopsy showing marked increase in foamy histiocytes and lipid laden macrophages at 9 years old. They took a splenectomy at 10 years old. ERT was begun in the subject at the age of 24. They visited tour hospital 3 years ago and have been treated with ERT as dosage of 60units/kg administered every other week. Their biomarkers including angiotensin converting enzyme and acid phosphatase were decreased but osteolytic bone lesions still remained and he was suffered from bone pain at that time. Whole body magnetic resonance imaging (MRI) showed severe bone necrosis in right hip and both tibia and liver was not enlarged. The subject complained of dyspepsia and difficulty of ingestion of any pills 3 years ago. He performed esophagogastroduodenoscopy (EGD) from another hospital and the result revealed normal. He continued complaining of dyspepsia despite medication with proton pump inhibitor. A follow-up EGD showed multiple nodular yellowish lesions on duodenum by gastrofibroscopy. Gastric biopsy was done and pathologic finding showed that nodular lesions consisted of Gaucher cell infiltrations. We increased the dose of cerezyme from 60IU/kg to 80IU/kg and performed genetic testing. Direct sequencing of GBAgene showed the compound heterozygous mutations, c.259C>T (p.R48W) and c. 5118G>A (p.R257Q). The mutations (R48W and R257Q) are known as rare mutations. The R48W regarded as mild mutation was reported in non-neuronopathic GD manifesting bone disease, whereas R257Q was previously reported in both acute neuronopathic and non-neuronopathic GD. We increased the dose of cerezyme from 60IU/kg to 80IU/kg and are planning to repeat gastroduodenoscopy 6 months later. Conclusion: As ERT might change the natural course of GD during ERT, close monitoring of adverse events and sharing the patient's course during ERT would be required.

2247T

Characterization of the Beta-Galactosidase Protein Isolated from Brain of Normal Sheep and from a Unique Ovine Model of GM1-Gangliosidosis. *D.A. Nevin, A.J. Ahern-Rindell.* Biology, University of Portland, Portland, OR.

Background: β-galactosidase (β-gal) is a lysosomal hydrolase that catalyzes the removal of terminal β-linked galactose moieties from glycoconjugates. Human β-gal is encoded by the *GLB*1 gene and synthesized as an 88 kDa precursor that is processed into a mature 64 kDa enzyme within the lysosome. Patients with mutations in the *GLB*1 gene develop GM1-Gangliosidosis (GM1 [MIM 230500]), a Lysosomal Storage Disorder (LSD) recognized by a decrease in β-gal activity and the buildup of GM1-ganglioside. Several animal models of GM1 are used to research this disorder. This study aims to characterize a unique ovine model of GM1 presenting with dual activity deficiencies of β-gal and alpha-neuraminidase (α-neur). These enzymes associate and are stabilized within the Lysosomal Multienzyme Complex (LMC), a structure responsible for facilitating step-wise substrate degradation in the lysosome. We hypothesize that a missense mutation in the *GLB*1 gene alters the structure of β-gal and compromises the formation of the LMC, producing a secondary deficiency in α-neur activity. **Methods**: Brain tissues were homogenized in lysis buffer containing protease inhibitors, centrifuged, and supernatant collected. Western blotting was used to determine the size of β-gal in ovine brain. Protein lysates were denatured and size-separated using SDS-PAGE. Ovine β-gal was detected using a feline-stimulated antibody that cross-reacted. A glyceraldehyde-3-phosphate dehydrogenase antibody was used as a protocol control (~38 kDa band) and followed by film capture of chemiluminescence. **Results**: Approximately 28, 72, and 79 kDa bands were consistently detected in normal and *GM1* sheep brain. **Conclusion**: Previously in our lab, a 64 kDa β-gal was isolated from normal and GM1-affected sheep fibroblasts. Subsequently, we found a G714T DNA sequence variation causing a C229F missense mutation in exon 6 of the *GLB*1 gene. These findings support our hypothesis that the disease-causing mutation alters the structure of β-gal, but not its size. Preliminary results suggest that tissue-specific protein expression plays a pronounced role in the size of β-gal. Post-translational modifications and/or the presence of β-gal isoforms may explain this size variation. Further analysis of this unique GM1 ovine model is imperative to characterize the specific interactions of the LMC components, to discover the underlying molecular mechanism of this disorder, and to create an effective therapeutic treatment for GM1.

Galactose Supplementation Improves Glycosylation in PGM1-CDG. *T.E. Gadomski, K.J. Scott, G. Preston, R.O. Crandall, L.A. Pro, T. Kozicz, E. Morava.* Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA.

Congenital disorders of glycosylation (CDGs) are phenotypically diverse genetic syndromes caused by impaired glycoprotein synthesis. Phosphoglucomutase 1 deficiency (PGM1-CDG; MIM 612941) is a newly discovered and possibly treatable CDG characterized by decreased protein glycosylation, hypoglycemia, abnormal liver function, muscle involvement and endocrine dysfunction. Intercellular cell adhesion molecule 1 (ICAM-1) serves as a useful biomarker for the measurement of cell surface glycosylation. Dietary galactose supplementation is a promising experimental therapy for PGM1-CDG. We present the cases of two female patients, Patients 1 and 2, ages 16 and 19 respectively, who presented with rhabdomyolysis, hypogonadotropic hypogonadism and hypoglycemic episodes. Each patient was diagnosed with PGM1-CDG. Fibroblasts from both patients were cultured and stained for ICAM-1 to measure glycosylation. In vitro galactose complementation assays with repeat ICAM-1 staining were then performed on fibroblasts to assess for improved glycosylation. ICAM-1 staining in fibroblasts from both patients revealed decreased glycosylation compared to a control cell line. Western blot analysis showed decreased PGM1 protein expression in both patients and each patient had decreased PGM1 enzyme activity. Galactose complementation and subsequent ICAM-1 staining revealed a restoration of glycosylation in fibroblasts from both patients. Non-ischemic exercise testing in Patient 2 demonstrated an abnormal lactic acid elevation curve, suggesting a predominantly muscular phenotype with abnormal glycogen release in response to exercise challenge. Following one year of oral galactose supplementation, Patient 1 demonstrated significant improvement in liver and endocrine function and her hypoglycemia resolved. Patient 2 recently started taking oral galactose and showed transferrin restoration after only five weeks. In summary, *PGM1* defect is an intriguing inborn error of metabolism showing a combined phenotype of insufficient glycogen breakdown and abnormal glycosylation. Both of our patients showed abnormal glycosylation and impaired glycogen mobilization but their different presentations demonstrate the phenotypic heterogeneity of PGM1-CDG. As galactose therapy appears to be a promising dietary intervention for normalizing protein glycosylation, future directions include targeted screening for PGM1-CDG and further clinical studies to evaluate the success of oral galactose supplementation.

2249T

MORQUIO SYNDROME: NEW HETEROZYGOUS MUTATION OF THE GALNS GENE IN TWO SIBLINGS FROM SOUTH-WEST COLOMBIA. *M.F. Hernandez-Amariz[1], F. Ruíz-Botero[1], S. Eichler[2], H. Pachajoa[3].* 1) Centro de Investigaciones en Anomalías Congénitas y Enfermedades Raras (CIACER), Universidad Icesi, Cali, Colombia; 2) Centogene. Rostock, Germany; 3) Fundación Clínica Valle del Lili, Cali, Colombia.

Introduction: Mucopolysaccharidosis type IV A, or Morquio syndrome, is an autosomal recessive lysosomal storage disorder that is caused by mutations on the GALNS gene, leading to a deficiency of N-acetylgalactosamine-6-sulfatase enzyme which is encoded by this gene, resulting in the accumulation of keratan sulfate and condroitin sulfate in certain tissues. It is expressed as generalized skeletal dysplasia with corneal clouding, resulting in short stature, pectus carinatum, platyspondylia, odontoid hypoplasia, kyphoscoliosis, and genu valgum. Cardiovascular and respiratory systems can also be affected. This phenotype has a broad variability associated to the more than 180 mutations that have been reported. Until recently there was no effective therapy for treating the disease aside from a multidisciplinary approach, and this year was approved the enzymatic replacement therapy. Objective: to report the case of two siblings identifying a new mutation. Methods: 9 and 6 six year old brothers with clinical characteristic of severe Morquio syndrome, deficit of enzymatic activity of GALNS enzyme, GALNS gene was analyzed by PCR and exome sequencing. Results: two mutations were found, a previously reported one in exon 3 (c.280C>T p.R94C) and a new heterozygous variant in exon 9 (c.998G>A p.G333D), with software analysis predicting it as probably damaging. Conclusion: These brothers have received an approach by a multidisciplinary team including pediatrician, orthopedist, geneticist, endocrinologist, neurosurgeon, physiatrist and neuropsychologist and the starting of enzymatic replacement therapy is being considered. This multidisciplinary approach is recommended for the best control of the disease.

Identification of genetic mutations in Malaysian patients with fructose-1,6-bisphosphatase deficiency. *L.H. Ngu[1], A.A. Nor Azimah[2], H.Y. Leong[1], B.C. Chen[1], H. Muzhirah[1], M.Y. Zabedah[3], H. Anasufiza[3], Y.K. Chor[4], Y. Yusnita[2].* 1) Genetics Department, Hospital Kuala Lumpur, Jalan Pahang, 50586 Kuala Lumpur, Malaysia; 2) Molecular Diagnostics and Protein Unit, Specialised Diagnostics Centre, Institute for Medical Research, Jalan Pahang, 50586 Kuala Lumpur, Malaysia; 3) Biochemistry unit, Specialised Diagnostics Centre, Institute for Medical Research, Jalan Pahang, 50586 Kuala Lumpur, Malaysia; 4) Paediatric Department, Sarawak General Hospital, Jalan Hospital, 93586 Kuching, Malaysia.

Fructose 1,6-bisphosphatase (FBPase) deficiency (MIM #229700) is an autosomal recessively inherited disorder of gluconeogenesis. Patients present notably with recurrent episodes of hypoglycaemia, ketosis and lactic acidosis, which can be fatal if not treated appropriately. Urinary analysis in acute samples may reveal increased glycerol and glycerol phosphate. However these biochemical diagnostic markers rapidly normalized following treatment and can be easily missed. FBPase (EC3.1.3.11) is encoded by *FBP1* (NM_000507.3) gene on chromosome 9q22.2-q22.3. Genetic analysis of *FBP1* is useful in diagnosing FBPase deficiency, avoiding the need of invasive liver biopsy. Although more than 20 *FBP1* gene mutations have been published, there has been limited investigation into the genetics of this disorder in Malaysian patients. We studied 5 patients (2 males, 3 females) from 4 unrelated families with clinical symptoms and laboratory findings consistent with FBPase deficiency. All of them have recurrent episodes of ketotic hypoglycaemia since infancy. Urinary glycerol and glycerol phosphate were only detected in 2 patients. Bidirectional sequencing of all seven *FBP1* coding exons plus approximately 50 base pairs of flanking noncoding intronic DNA on either side of each exon is performed using genomic DNA. Five mutations were identified in these families. In two siblings from consanguineous parents, we identified a previously reported homozygous missense mutation in exon 7, c.778G>A [p.(Gly260Arg)]. Three other unrelated patients from non-consanguineous parents have novel mutations discovered. One of them has a homozygous missense mutation in exon 5, c.472C>T [p.(Arg158Trp)]. One patient has a heterozygous deletion c.392delT [p.(Val131Glyfs*71)] in exon 4 in association with a heterozygous splice site mutation at c.568-2A>C in intron 5. Another patient has a homozygous deletion at c.603delG [p.(Val201Valfs*3)] in exon 6. This mutation causes a frame-shifting change after Valine-201 and creating a new reading frame that ends at a stop at position 3. All the newly identified mutations in the *FBP1* gene were not found in normal controls in our population and are predicted to result in loss of FBPase activities. Following their genetic diagnosis, adequate management aimed at avoiding fasting periods, particularly during febrile episodes have been initiated for these patients and yielded good outcome to date.

Molecular Spectrum of HFE Gene Mutations in Patients Referred for HFE Molecular Analysis: A Single Center Study. *F. Ozkinay[1], A. Aykut[2], T. Atik[1], M. Tombuloglu[3], H. Onay[2].* 1) Dept Pediatrics, Ege Univ, Izmir, Turkey; 2) Dept Medical Genetics Ege Univ, Izmir, Turkey; 3) Dept Internal Medicine , Ege Univ, Izmir, Turkey.

Hereditary hemochromatosis is a relatively common autosomal recessive disorder caused by the high absorption and deposition of iron in major organs. This leads to organ dysfunction, and eventually arthritis, cirrhosis, cardiomyopathy, diabetes mellitus, hypogonadism and hepatocellular cancers. Early diagnosis and treatment are of utmost importance in the prevention of end stage organ damage. In more than 90% of hereditary hemochromatosis patients, HFE gene mutations have been responsible for the clinical manifestations. The aim of this retrospective study is to investigate the frequencies of common mutations found in individuals referred for HFE gene molecular analysis to a single genetic center in the Aegean region of Turkey. A total of 230 individuals were tested for HFE mutations between the years 2005 and 2014-June 1. The HFE common polymorphisms (H63D, C282Y, S65C, Q283P, E168Q, E168X, W169X, P160delC, Q127H, H63H, V59M, and V53M) were studied using polymerase chain reaction. Of 230 patients studied for HFE mutations, 73% were found to have no mutation and 27% had mutations either homozygously or heterozygously. Three distinct mutation (C282Y, H63D, S65C) and five different genotypes, with the exception of mutation free genotype, were detected in the group studied. Although no one was homozygous for C282Y mutation, one patient was heterozygous and another compound heterozgyous for this mutation. Five patients (2.1%) were homozygous for H63D mutation, with another fifty three patients (23%) showing heterozygosity for it. One patient had the genotype H63D/C282Y and one patient was heterozygous for S65C mutation. Among the mutant alleles H63D was the most prevalent allele with a frequency of 94.1%. In conclusion; C282Y mutation of HFE gene, which causes severe form of hemachromatosis and is common in Northern Europe, was not found to be frequent in our hemochromatosis patients. The most frequent hemochromatosis causing HFE gene mutation in our population was found to be H63D mutation.

2252M

An infant with hyperhomocysteinemia, methylmalonic aciduria, and an atypical cellular distribution of protein-bound cobalamin. *M. Pupavac[1], F. Petrella[1], D. Watkins[1], S. Fahiminiya[1,2], J. Muenzer[3], J. Majewski[1,2], D. Rosenblatt[1].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) University of North Carolina, Chapel Hill, North Carolina, USA.

In mammalian cells, derivatives of vitamin B12 (cobalamin, Cbl) are required as cofactors for two enzymes. Adenosylcobalamin (AdoCbl) is required in the mitochondria as a cofactor to methylmalonyl CoA mutase (MCM), and methylcobalamin (MeCbl) is required in the cytoplasm as a cofactor to methionine synthase (MS). Inborn errors of Cbl metabolism can present with elevations of methylmalonic acid and/or homocysteine in the blood and urine. A sixteen-month-old boy of Hispanic ethnicity was investigated because of elevated serum methylmalonic acid and homocysteine levels. Additional clinical findings included cardiac defects (ventral septal defect, long QT syndrome), cleft palate, hypospadias, hyperbilirubinemia, intractable epilepsy, and global developmental delay. There was no family history of similar findings. Cultured patient fibroblasts showed decreased function of both MCM and MS, and decreased synthesis of AdoCbl and MeCbl from exogenous [^{57}Co]cyanocobalamin. Crude subcellular fractionation demonstrated that most internalized radiolabelled Cbl was found in a fraction containing mitochondria, lysosomes and possibly other membrane-bound cellular compartments. The radiolabel in control fibroblasts was predominantly in the cytoplasmic fraction. Size exclusion chromatography of radiolabelled patient fibroblast extracts showed that the majority of labelled Cbl eluted bound to transcobalamin (TC). The majority of label in control fibroblasts was present bound to MCM and MS. Somatic cell complementation analysis suggested that the disorder in this patient was not any known inborn error of cobalamin metabolism. Whole exome sequencing did not identify causal mutations in any gene known to play a role in Cbl metabolism. However, candidate causal variants have been identified in several genes not previously implicated in Cbl metabolism. Family and functional studies are being performed to validate the candidate variants.

2253T

Insightful investigation of mtDNA integrity in affected tissues of patients with mitochondrial disorders. *J. Wang, J. Lin, X. Tian, V.W. Zhang, E.S. Schmitt, LJ. Wong.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Introduction: Mitochondrial biogenesis and maintenance defects are due to mutations in a group of nuclear genes, including TK2, SUCLA2, RRM2B, SUCLG1, DGUOK, MPV17, TYMP, POLG, POLG2, C10orf2, and OPA1. Affected tissues usually showed mitochondrial DNA (mtDNA) depletion, multiple deletions, or point mutations. MtDNA multiple deletions are known to be associated with mutations in nuclear genes involved in mtDNA biosynthesis. Investigation of mtDNA alterations in affected tissues can reveal impacts of nuclear gene defects on mtDNA integrity and their correlation with clinical phenotype. Methods: The mitochondrial genome is amplified by long range PCR followed by massively parallel sequencing (MPS) to assess mtDNA point mutations, large deletion and multiple deletions. MtDNA content was examined by Real Time-qPCR. Nuclear gene was analyzed by target gene capture/MPS or Sanger sequencing. Results: In a total of 34 patients with nuclear gene mutations, mtDNA deletion or multiple deletions in muscle or liver were detected in 25 patients (73.5%). Ten patients with mutations in MPV17, DGUOK, TK2, SUCLG1 or POLG, had mtDNA depletion in the affected tissues, and presented with encephalohepatopathy or encephalomyopathy at young age (1 month to 4 years). Multiple deletions were detected in 11 patients with mutations in RRM2B, POLG, C10orf2 or OPA1. These patients presented with myopathy at adulthood (17 to 78 years old, mean 46). Four patients with encephalomyopathy (4 to 66 years old) and mutations in TK2, RRM2B or POLG had mtDNA depletion and multiple deletions. The number of low heteroplasmic variants is significantly increased compared with that of age and tissue matched individuals without mutations in the above mentioned genes. Conclusions: MtDNA multiple deletions and depletion are secondary defects to defects in nuclear genes responsible for mtDNA biosynthesis and maintenance. Mutations in the POLG, TK2 or RRM2B gene can cause both mtDNA depletion and multiple deletions. Mutations in the MPV17, DGUOK or SUCLG1 gene are mostly associated with mtDNA depletion in patients with early onset of encephalopathy or hepatopathy, whereas autosomal dominantly inherited mutations in C10orf2, POLG or OPA1 are associated with multiple deletions without mtDNA depletion. This study provides insights into the mtDNA integrity and its correlation with nuclear gene mutations and phenotypes. MtDNA depletion and/or deletions in affected tissues may guide molecular diagnosis.

2254M

X-chromosome inactivation in females heterozygotes for Fabry disease. *L. ECHEVARRIA[1], K. BENISTAN[1], A. TOUSSAINT[2], O. DUBOURG[3], A.A. HAGEGE[4], D. ELADARI[5], F. JABBOUR[6], I. DETRAIT[7], C. BELDJORD[2], P. DE MAZANCOURT[7], D.P. GERMAIN[1,7].* 1) Medical Genetics, University of Versailles, Garches, France; 2) Molecular biology, CHU Cochin, Paris, France; 3) Cardiology, CHU Ambroise Paré, Boulogne-Billancourt, France; 4) Cardiology, HEGP, Paris, France; 5) Physiology, HEGP, Paris, France; 6) Biochemistry, CHU Raymond Poincare, Garches, France; 7) EA 2493, UFR des Sciences de la Santé, Montigny, France.

Background: Fabry disease (FD) is an X-linked genetic disorder caused by the deficient activity of lysosomal α-galactosidase A. Inheritance is X-linked so that while males are usually severely affected, female patients range from asymptomatic to clinical disease equal to that of males. The underlying reasons for this phenotypic variability in female patients are still poorly understood. **Aims**: To evaluate the existence of X-inactivation in females with FD, its variability or concordance between tissues, and its potential contribution to clinical phenotype. **Patients and methods**: 56 female patients were enrolled in the study. Extensive clinical work-up was carried out and two validated scores assessed global clinical severity. Kidney function was evaluated using measured GFR, while magnetic resonance imaging (MRI) evaluated left ventricular mass index, left posterior wall thickness and interventricular septum thickness. Alpha-galactosidase A residual activity was measured in leukocytes. X-inactivation status was analysed using DNA methylation studies at the Hpa II sites in the highly polymorphic CAG repeat in the first exon of the androgen receptor gene in four different tissues (leukocytes, mouth smears, skin biopsies and urine sediment). **Results**: Disease severity increased with age. Skewed or highly skewed X-inactivation was found in 29 percent of the study population and a significant correlation between the direction and degree of skewing of X chromosome inactivation and residual α-galactosidase A activities, global severity scores of FD, progression of cardiomyopathy and deterioration of kidney function was evidenced. **Discussion**: This study shows that X chromosome inactivation is a key factor in determining the clinical phenotype of females affected with Fabry disease. Our findings support the inclusion of X chromosome inactivation studies as a tool to predict the natural history of the disease and as a decision making criteria for enzyme replacement therapy in female patients.

Multiple gene variants cause a phenocopy for Lysinuric Protein Intolerance: A case report. *S. Lipinski[1], A. Hebert[1], O. Alpan[2], S. Pattison[3], A. Tolun[3], S. Huguenin[3], E. Haverfield[4], J. Neidich[4], O. Goker-Alpan[1].* 1) Genetics Unit, O and O Alpan, LLC, Fairfax, VA; 2) Allergy and Immunology Unit, O and O Alpan, LLC, Fairfax, VA; 3) Laboratory Corporation of America® Holdings, Reseaerch Triangle Park, NC; 4) GeneDx, Gaithersburg, MD.

Absorption of amino acids from the renal tubular lumen and small intestine are mediated by solute carrier transport proteins. Cystinuria is a common selective renal aminoaciduria clinically associated with urolithiasis. The protein product of SLC3A1 in cystinuria is involved in cystine and dibasic amino acid exchange for neutral amino acids at the luminal membrane. Lysinuric protein intolerance (LPI), caused by mutations in SLC7A7, is the result of defective dibasic amino acid transport at the basolateral membrane which leads to poor intestinal absorption and urinary loss of dibasic amino acids. Biochemically, LPI is characterized by circulating deficiency of arginine and ornithine, which is thought to lead to classical symptoms of post-prandial hyperammonemia, protein intolerance and orotic aciduria. The metabolic defect in LPI can be partially corrected by supplementation with citrulline, while cystinuria is managed by preventing formation of kidney stones by hydration and urinary alkalization. An 11 year-old female presented with severe abdominal pain, diarrhea, rash, multiple fractures and osteoporosis (Z-score -2.7). There were pain and tingling sensations in the hands and muscle weakness after exercise. Fasting metabolic evaluation revealed elevations of dibasic amino acids in the urine: Cystine 2016.2 umol/g (0.0-141.45), Ornithine 354.8 umol/g (0.0-66.6), Lysine 4330.6 umol/g (0.0-562.2) and Arginine 430.0 umol/g (0.0-69.4), a pattern most consistent with cystinuria. Plasma amino acids were normal. A post-prandial (protein loaded) ammonia and urine orotic acid/creatinine ratio were elevated, 187 ug/dL(19-87) and 1.98 mmol/mol Crt (0.11 - 1.07), respectively, and were considered inconsistent with the classical biochemical and clinical picture of cystinuria. Although protein restriction and citrulline supplementation normalized the ammonia level, the patient continued with abdominal pain. Whole Exome Sequencing revealed homozygosity for the known pathogenic M467T variant in the SLC3A1 gene, consistent with cystinuria. Additional variants possibly related to the mixed phenotype included a S712X heterozygous mutation in the enterokinase (TMPRSS15) gene, homozygosity for the T196I variant in the lysine hydroxylase 2 (PLOD2) gene, and the H599R variant in the sodium channel (SCN4A) gene. The clinical presentation is suggestive of an alternate amino acid transport single gene disorder and could be a phenocopy resultant of multiple gene variants.

2256M

Clinical and molecular characterization of Korean patients with glycogen storage type 1a. *J. Lee[1], G. Kim[1], Y. Kim[2], J. Kim[2], B. Lee[1,2], H. Yoo[1,2].* 1) Medical Genetics Center, Asan Medical Center, Seoul, South Korea; 2) Dept. Pediatrics, Asan Medical Center, Seoul, South Korea.

Glycogen storage disease (GSD) Ia is caused by mutations in the G6PC gene. This condition is characterized by hepatomegaly, doll-like face, hypoglycemia, lactic acidosis, dyslipidemia and hyperuricemia. The aim of the study was to characterize clinical and molecular features and evaluate late complications in of Korean patients with GSD Ia. Thirty Korean patients (18 males and 12 females) from 26 unrelated families were diagnosed based on genetic and biochemical data between 1999 and 2013. Their medical records have been reviewed retrospectively. The mean age at diagnosis was 8.8 ± 9.9 years (range, 8 month to 42 years) and the follow-up period was 11.0 ± 7.0 years (2.4-43 years). Most patients (60%) presented with hepatomegaly and hypoglycemia during infancy. Dyslipidemia (80%) and frequent epistaxis (37%) were common findings as well. Serum lactic acid and uric acid levels at diagnosis were 27.44 ± 32.3 μmol/L and 7.91±2.4 mg/dL, respectively. Serum cholesterol and triglyceride levels were high (mean level: 222.8 ± 56.1 and 639.8 ± 507.1 mg/dL, respectively) as well. In genetic analysis, c.648G>T was the most common (45/52 alleles, 86.5%), followed by p.G122D (2 alleles), p.G222R (1 allele), p.S326P (1 allele), p.R83H (1 allele), p.F51S (1 allele) and p.Y128* (1 allele). Allopurinol and uncooked cornstarch were given to all patients. Fourteen patients (46.7%) received fibrates or HMG-CoA reductase inhibitors for hyperlipidemia. Iron supplementation was required in six patients (20%). Of 16 adults patients (10 males and 6 females), 11 patients (68.8%) had multiple hepatic adenoma and 7 patients (43.7%) had osteoporosis. In addition, 9 patients (56.3%) showed renal problems including microalbuminuria, gross hematuria, medullary calcinosis, ureter stones or renal insufficiency. Four patients (25%) suffered from gout despite preventive allopurinol medication. Two patients (12.5%) had pulmonary hypertension. The final adult heights were 156.1 cm (-2.94 SDS) in males and 155.5 cm (-1.02 SDS) in females. In conclusion, the most common mutation in Korean patients with GSG Ia was c.648G>T, suggesting founder effect. DNA analysis for this mutation is efficient for confirmatory diagnosis rather than liver biopsy or biochemical analysis.

Two new unrelated cases of Pyrroline-5-carboxylate synthase -new founder effect? *Y. Trakadis, M. Berry, S. Fox, A. Khan, C. St Martin, J. Morel, D. Buhas.* McGill U., Montreal, Canada.

Objectives: Pyrroline-5-carboxylate synthase catalyzes the biosynthesis of proline, ornithine and arginine. Its deficiency (P5CSD) is characterized by neurological and connective tissue abnormalities. 11 cases have been reported, with abnormal amino acids profile in only two families. Two new cases will be described here. **Methods**: A literature and chart review. **Results**: Both patients (B.A. and B.M.) are of Innuit origin and carry the same novel mutation in ALDH18A1 (homozygous c.544A>G). The two families are non-consanguineous and unrelated. B.M. has had a history of irritability, tremor and hypotonia since birth. He developed bilateral cataracts at 8 months. Plasma amino acids showed low Proline, Arginine, Citrulline and Ornithine, suggestive of P5CS deficiency. ALDH18A1 sequencing confirmed the diagnosis. At 2 years old he still had jittering episodes, mild developmental delay, short stature, and feeding problems. His brain MRI demonstrated an unusual T2 hyperintensity in the pons and bilateral widening of the temporal / insular CSF space. B.A. presented at 10 months old with bilateral subcapsular cataracts and recurrent vomiting. She had mild dysmorphic features and stretchy skin. The low level of Citrulline and Arginine, as well as, the low/normal Proline and Ornithine levels were evoking a defect in their synthesis, which was confirmed molecularly. At 17 months old she had hypotonia, joint/skin laxity and pes planus. Her brain MRI showed arterial tortuosity. **Conclusions**: Although rare, P5CSD should be in the differential diagnosis of metabolic causes for early cataracts. A founder effect may exist in the Innuit population of Quebec.

Phosphoglycerate kinase-1 (PGK-1) deficiency presenting as neonatal onset hemolytic anemia, rhabdomyolysis, and mild developmental delay. *Y. Watanabe[1,2], S. Ozono[1], T. Fukuda[3], H. Sugie[4], S. Yano[5], T. Matsuishi[1,2].* 1) Dept Pediatrics and Child health, Kurume Univ, Kurume, Japan; 2) Research Institute of GC/MS, Kurume Univ, Kurume, Japan; 3) Dept Pediatrics, Hamamatsu Univ, Shizuoka, Japan; 4) Dept Pediatrics, Jichi Medical Univ, Tochigi, Japan; 5) Genetics/Pediatrics, USC, Los Angeles, CA, United States.

Background: Phosphoglycerate kinase-1 (PGK-1) deficiency is an X-linked recessive condition and caused by mutation in the PGK1 gene. Highly variable clinical symptoms including hemolytic anemia, myopathy, seizures, developmental delay and renal failure as well as variable age of onset (infancy to adult) are known in this condition. Case report: The patient was a 2nd child born to a non-consanguineous Japanese couple (38 wk, 3410 g). Apgar scores were 81 and 95. He developed jaundice on the 1st day of his life (total bilirubin 12.1 mg/dl) requiring phototherapy and exchange transfusion. At age 9 months, he was referred to us for a chronic indirect hyperbilirubinemia and hemolytic anemia (Hb 8~9 g/dl). At age 15 months, he was hospitalized for acute onset generalized muscle weakness, worsening anemia, and myoglobinuria which were preceded by a fever. Laboratory studies showed anemia (Hb 5.4g/dL, MCV 95fL), increased reticulocytes (202‰), hyperbilirubinemia (TB 1.9mg/dL, DB 0.2mg/dL), high plasma levels of AST 163 (U/L), CK (4490 U/L), and LDH 1147 (U/L), and abnormal urinalysis with hematuria and myoglobulinuria. Peripheral blood smear showed RBC of variable size and shape. He received RBC transfusion and antibiotics for 8 days, and was discharged home. The activity of PGK-1 in RBC was found to be deficient confirming the diagnosis. Discussion: Neurologic involvement is associated in approximately 50% of patients with PGK-1 deficiency. The presented case has motor and speech delay. The mechanism of neurologic involvement is unclear although glutaminergic synaptic metabolism is thought to be disrupted by PGK-1 deficiency. The patient has been followed with MCT supplementation and has not developed another severe episode of hemolysis or rhabdomyolysis for six months.

NORRBOTTNIAN VARIANT OF GAUCHER DISEASE IN SOUTHER ITALY: LONG TERM FOLLOW-UP. *M. Grisolia[1], S. Simona[1], F. Ceravolo[1], E. Pascale[1], M. Filocamo[2], P. Strisciuglio[3], D. Concolino[1].* 1) Pediatrics, University "Magna Graecia", Catanzaro, Italy; 2) Centro di diagnostica genetica e biochimica delle malattie metaboliche, Istituto G. Gaslini, Genoa, Italy; 3) Depatment of Pediatrics, University Federico II, Naples, Italy.

The Norrbottnian type of Gaucher disease has been described many years ago, as due to a unique mutation which may have happened in or before the 16th century in northern Sweden and is a well defined nosological entity with a characteristic course of clinical manifestations. We report the results of a long-term follow-up of four patients affected by Gaucher disease type III. The patients, originating from South of Italy, present with clinical features and progression of disease, in particular for the skeletal involvement, comparable with the “Norrbottnian” Swedish phenotype. The patients (3M, 1F), median age 38,2 years (range 32-49 years) belonging to three different families, had been diagnosed at a median age of 3,4 years (range 1,1-8 years). The clinical manifestations at diagnosis were hepatosplenomegaly, thrombocytopenia, anemia and growth retardation. The [L444P]+[L444P] genotype was confirmed in all of them. Bone involvement consisting, primarily of bone pain, bone crisis, osteopenia and bone abnormalities (such as Erlenmeyer flask deformity) detected by X-ray, was present in all four patients. With age a progressive kyphoscoliosis, due to wedging of vertebral bodies, occurred in all patients together with a restrictive ventilatory defect. All of the four patients had cognitive delay and other neurological manifestations began to appear at a median age of six years (range 4-10 years), as horizontal gaze, intentional tremor, seizures for one patient and depression for two different patients. The patients started Enzyme Replacement Therapy (ERT) at a median age of 16,2 years (range 11-23 years) and were assessed during the years of treatment with regular clinical observations, biochemical tests and psychometric testing. The duration of ERT was associated with significant improvements in platelet count, haemoglobin, liver and spleen volumes, while neurological involvement seemed no to benefit of ERT so as skeletal manifestations.

GM2-gangliosidosis, AB variant: clinical, ophthalmological, MRI and molecular findings. *D. Renaud[1, 2, 3], M. Brodsky[1, 2, 4].* 1) Neurology, Mayo Clinic, Rochester, MN; 2) Pediatrics, Mayo Clinic, Rochester, MN; 3) Medical Genetics, Mayo Clinic, Rochester, MN; 4) Ophthalmology, Mayo Clinic, Rochester, MN.

GM2-gangliosidosis, AB variant is a very rare form of GM2-gangliosidosis due to a deficiency of GM2 activator protein, associated with autosomal recessive mutations in GM2A. Less than 10 patients, confirmed by molecular analysis, have been described in the literature. A 12 month old Hmong girl presented to the Neurometabolic clinic for evaluation of global developmental delay, hypotonia and cherry red spots. The parents are not known to be consanguineous. Her examination was remarkable for hypotonia with hyperreflexia and excessive startling. The head circumference was normal. An extensive neurometabolic evaluation was negative. Developmental regression began at 14 months of age. Retinal examination at 16 months of age disclosed 4+ cherry red / black spots with “heaped up” whitish infiltrate surrounding both foveae but no evidence of optic atrophy or peripheral retinal abnormalities. Repeat MRI scan at 17 months of age revealed delayed but interval myelination associated with abnormal signal intensity of the bilateral thalami presenting as T2 hyperintensity of the posterior thalami in the region of the pulvinar nuclei and T2 hypointensity in the anterior thalami. Sequencing of the GM2A gene revealed a homozygous c.160 G>T mutation, predicted to result in a premature protein termination p. Glu54*.

The role of inflammation in vascular disease in the MPS I canine model. *M. Vera[1], S. Le[1], S. Kan[1], P. Dickson[1], R. Wang[2].* 1) Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 2) CHOC Children's, Orange, CA.

Inflammation has come to be appreciated as an important pathophysiologic mechanism in the mucopolysaccharidoses (MPS). Inflammatory markers and pathways have been identified in the joints and cardiovascular systems in several MPS animal models. Undoubtedly, inflammation causes a significant portion of the morbidities and progressive decline suffered by MPS patients. Arterial disease has been well described in mucopolysaccharidosis type I (MPS I) and consists of intimal-medial thickening with proliferation of vascular smooth muscle cells and extracellular matrix remodeling. Evidence of inflammatory pathways involving Toll-like receptor 4 (TLR4) and transforming growth factor beta (TGFβ) signaling have been observed in these arterial lesions, though the inciting events stimulating these pathways have not been identified. In this report we have studied the role of macrophages as effector cells in the initiation of the vascular disease phenotype. Our model hypothesizes that macrophages are recruited to sites of vascular endothelial damage or dysfunction caused by lysosomal storage where they secrete cytokines that stimulate an inflammatory cascade.

2262M

A Novel mutation in the Methylenetetrahydrofolate Reductase (MTHFR) gene in a Turkish child: A Case Report. *M. ARSLAN[1], S. VURUCU[1], H.I AYDIN[2], B. ÜNAY[1], R. AKIN[1].* 1) GULHANE MILITARY MEDICAL SCHOOL, DEPARTMENT OF CHILD NEUROLOGY, ANKARA, Turkey; 2) TURGUT ÖZAL UNIVERSITY, DEPARTMENT OF PEDIATRIC METABOLISM DISEASES, ANKARA, Turkey.

Severe methylenetetrahydrofolate reductase deficiency is an autosomal recessive metabolic disorder of folate metabolism causing elevated levels of homocysteine and decreased levels of methionine. A 12-year-old boy with nonspecific developmental delay was admitted to our clinic with a 2-week of history of inability to walk, muscle weakness, speech disorder, confusion, and visual hallucinations. The patient was found to have high serum homocysteine and low-normal serum methionine, cerebral and cerebellar atrophy. Molecular genetic analysis identified homozygous p. F564V (c.1690T>G) MTHFR mutation in the patient.

2263T

Hypophosphatasia: a case report. *R. Ortega, J. Prieto.* Pontificia Universidad Javeriana, Bogotá, Colombia.

Introduction: Hypophosphatasia is a rare inborn error of metabolism that is characterized clinically by defective bone mineralization and biochemically by deficient activity of the tissue-nonspecific isoenzyme of alkaline phosphatase in serum and in tissues 1. Clinical expression is variable ranging from stillbirth without mineralized bone to pathologic fractures developing only late in adulthood2. Has been classified into six subtypes: perinatal lethal, prenatal benigna, infantile, childhood, adulthood, odontohypophosphatasia. The biochemical diagnosis is based on the determination of low serum alkaline phosphatase and serum or urine increased phosphoethanolamine, pyridoxal 5'-phosphate and inorganic pyrophosphate3, and molecular diagnosis with gene sequencing of ALPL. Case Report: Patient with short stature evident from 10 months of age, associated with severe chest deformity, marked and progressive genu valgus frontal bossing. At 2 years of life lost teeth that have not yet been replaced starts. Radiographs show metaphyseal dysplasia, generalized demineralization, and cranial synostosis. Serum calcium: 10.3 mg / dl. Chromatography of amino acids, protein, parathyroid hormone, phosphorus, renal function, cerebral MRI, IQ and karyotype were normal. Alkaline phosphatase 30u / L. Finding of elevated calcium and alkaline phosphatase suggest low child hypophosphatasia.To complete the study we request sequence analysis of gen ALPL that report a homozygous mutation c.892G>A (pGlu298Lys). Discussion: This patient has a phenotype that suggests inborn error of metabolism that is confirmed by biochemical analysis suggesting hypophosphatasia. The sequence analysis identified a c.892G>A change in the ALPL gene. This mutation has been previously reported in a Japanese patient. 1. P S Henthorn and M P Whyte. Autoimmune thrombocytopenia in a patient with Hunter Syndrome: a rare association. *A. Rufus, J. Flores, B. Croke, K. Fernandez, P. Sandiford, R. Antony.* Department of Pediatrics, University of Illinois College of Medicine, Peoria, IL.

Background:Individuals with Hunter syndrome develop coarse facial features, hepatosplenomegaly, cardiovascular disease, skeletal dysplasia, pulmonary disease, neurocognitive deficits and deafness from about 2 years with phenotypic variation. Hematological complications of Hunter syndrome are typically mild thrombocytopenia and neutropenia. We describe our experience managing a patient with Hunter syndrome with severe autoimmune thrombocytopenia/anemia. Case Report: A 4 year old boy with Hunter syndrome presented with fever, fatigue, poor oral intake and decreased urine output. Initial hematological indices: WBC 4600/microlitre, Hemoglobin 5.3g/dl, Platelet count 7000/microlitre, and ANC 1940/microlitre. Parvovirus B19, varicella, EBV, and CMV studies were negative. Blood and bone marrow studies (pancytopenia, dyserythropoiesis, no abnormal cell lines and no hemophagocytosis) ruled out hematological malignancy and HLH. Pericardial effusion was assumed to be viral or secondary to anemia. Despite multiple platelet transfusions his Hemoglobin (<6 g/dl) and platelet count (<10000/microlitre) failed to increment. Direct Antiglobulin Test positivity and antiplatelet antibody positivity led us to a working diagnosis of autoimmune hemolytic anemia and thrombocytopenia. IVIG (1gm/kg) did not have a beneficial effect so prednisone 15 mg q8 was commenced. The patient then developed acute intracranial hemorrhage and pulmonary hemorrhage necessitating oscillatory ventilation. Steroid dose was increased to IV methylprednisolone (MP) 12mg/kg/day and daily plasmapheresis was commenced (continued for 11 days) .Platelet infusions, Keppra, Labetalol and Clonidine were used for supportive care. His PICU course/ platelet count were as follows: Day 3: Platelets = 94000 (MP 2 mg/kg/day), Day 13: Platelets = 195000 and Hemoglobin 10.2 (MP 1mg/kg/day). Day 17: EVD/Ventilation discontinued. Day 45: MP stopped. On stopping the MP his platelet count slowly dropped to 147000 so MP restarted (30 mg Q8h) and IVIG 400mg/kg/day was administered for 4 days. This permitted us to wean and discontinue the MP by day 82. (Platelet =253000). Weekly enzyme replacement therapy was then commenced and patient's platelet counts has been consistently above 150000.Conclusion: With this report of the first case of Hunter syndrome associated with autoimmune thrombocytopenia we hope to add to the body of knowledge regarding the management of hematological complications of Hunter syndrome.

Bone Health in Children and Adults with Isolated Methylmalonic Acidemia. *J.L. Fraser, J.L. Sloan, E. Harrington, I. Manoli, C.P. Venditti.* National Human Genome Research Institute, NIH, Bethesda, MD.

Methylmalonic acidemia (MMA) causes multisystemic disease, characterized by both acute metabolic crisis and chronic, progressive end-organ damage, and requires lifelong therapy with protein-restricted diets. In our natural history cohort of patients with mut, cblA, and cblB MMA, we have observed patients with pathologic fractures and marked osteopenia/osteoporosis. We sought to explore the clinical features and potential biomarkers associated with decreased bone density in untransplanted MMA patients, as well as the effect of liver/kidney transplantation on bone health in our smaller transplantation cohort. A subset of patients enrolled in our MMA natural history protocol with *mut* (N=31), *cblA* (N=5), and *cblB* (N=8) MMA underwent whole body dual-energy X-ray absorptiometry (DXA) and comprehensive laboratory evaluation. Age and race-based DXA Z-scores were obtained and adjusted for patient height. These values were then used to query the relationships between bone health and body mass, electrolytes, minerals, vitamins, plasma amino acids, MMA-related metabolites, hematological indices, and renal function. Bone mineral density (BMD) Z-scores without adjustment for height suggest that two-thirds of our *mut* MMA cohort had a bone mineral density <-1.5 (osteopenia/osteoporosis). When adjusted for height, 40% of our cohort had BMD Z-score <-1.5, and the mean Z-score value with and without height correction was significantly different. Renal disease was a key determinant of growth retardation. After height correction, alkaline phosphatase levels, the percentages of neutrophils and lymphocytes, HDL cholesterol, triglyceride levels, and markers of oxidative stress, including F2 isoprostanes and oxidized LDL, but not serum MMA concentrations, remained associated with differences in BMD. The patients with the worst bone health (pathologic fractures, osteoporosis, height-adjusted BMD <-2.5) had essential amino acid deficiencies, significant growth retardation, and were more metabolically fragile. Transplanted patients showed improvement in bone health after liver/kidney transplant. Patients with MMA are at high risk for decreased BMD, poor bone health, and pathological fractures. Routine screening for bone mineral density using DXA with height adjustment of the resulting BMD Z-score should help identify patients who require more aggressive therapeutic intervention and reduce morbidity from associated renal disease, pathologic fractures, and poor bone health.

2266M

Optic nerve atrophy in methylmalonic acidemia (MMA): natural history, pathological findings and experience with anti-oxidant therapy. *I. Manoli[1], W.M. Zein[2], J.L. Sloan[1], E. Harrington[1], Y. Wang[3], J. Zhang[3], B.P. Brooks[2], A. Hamosh[4], C.C. Chan[3], C.P. Venditti[1].* 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 2) Ophthalmic Genetics & Visual Function Branch, NEI, NIH, Bethesda, MD; 3) Immunopathology Section, NEI, NIH, Bethesday, MD; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Optic nerve atrophy (ONA) is increasingly recognized as a complication of isolated MMA, caused by a deficiency of the mitochondrial enzyme methylmalonyl-CoA mutase (MUT). Multisystem manifestations include growth failure, pancreatitis and renal disease, but patients can also suffer acute neurological events such as bilateral globus pallidi strokes and ONA. The natural history and disease pathophysiology remain unknown. 26 patients with isolated MMA (17 *mut*, 4 *cblA* and 5 *cblB*, including 3 with organ transplant) underwent ophthalmologic evaluations, including serial optical coherence tomography (OCT), through a dedicated natural history protocol. A total of 56 OCT studies were performed, with 12 patients contributing 2-15 serial measures. Of 77 patients with isolated MMA evaluated, 10 mut patients (6M, 4F) presented with symptoms of acute or subacute visual loss. Age of presentation ranged from 7 to 27 years. Visual loss was bilateral but asymmetric and 8 patients were legally blind. Thinning of the retinal nerve fiber layer (RNFL) preceded symptomatic presentation in 2 patients. There were no apparent environmental triggers shared between patients, and MR imaging variably revealed thin optic nerves. Ophthalmic pathology, assessed by light and electron microscopy using autopsy samples from a 14.5y old mut patient with normal visual acuity, showed thinning of the macular outer nuclear layer, peripheral retinal gliosis and abnormal mitochondrial ultrastructure of enlargement, edema, and degeneration in the photoreceptor inner segment, the retinal ganglion cell and vascular endothelium, as well as corneal epithelium and keratocyte but not the retinal pigment epithelial cell. Coenzyme Q10, vitamin E, idebenone and intravenous N-acetylcysteine were employed with variable success in 5 of the patients. Thinning of the RNFL progressed with near complete loss of vision in all over the ensuing years. Our experience suggests that 1) ONA is a complication of isolated MMA and patients should undergo periodic eye exams, to include OCT, for pre-symptomatic diagnosis; 2) cell-intrinsic mitochondrial morphological changes in the retina, similar to what has been observed in the proximal tubule epithelial cells in the kidney, suggests that cellular autonomy may underlie the ONA in isolated MMA; 3) antioxidants, improved metabolic control and possibly organ transplantation may not prevent progression of disease, but can ameliorate the rate of loss of visual function.

2267T

Ophthalmic manifestations of Cobalamin C disease occur independent of metabolic control and prenatal treatment. *B. Brooks[1, 2], A.H. Thompson[1], N. Carrillo-Carrasco[3], J. Sloan[2], I. Manoli[2], W.M. Zein[1], C.P. Venditti[2].* 1) National Eye Institute, NIH, Bethesda, MD; 2) National Human Genome Research Institute, NIH, Bethesda, MD; 3) National Center for Advancing Translational Sciences, NIH, Bethesda, MD.

Cobalamin C (*cblC*) disease, an inborn error of intracellular vitamin B12 metabolism, is caused by mutations in the MMACHC gene and leads to impaired intracellular synthesis of adenosyl- and methylcobalamin, which produces both methylmalonic acidemia (MMA) and hyperhomocysteinemia. To examine the clinical course of ocular manifestations of *cblC* in relation to genotype and metabolic parameters over time we conducted a retrospective, observational case series study at the NIH Clinical Center. The 25 *cblC* patients ranged in age from 2 to 27 years at last ophthalmic visit, and follow-up ranged from 0 months to 83 months. There were a total of 69 visits; 14 patients were seen more than once, for a median follow-up duration of 36 months. Nystagmus was present in 64% of patients and strabismus 36%. Despite significant elevation of plasma homocysteine, lens dislocation was never observed. The median visual acuity at last ophthalmic visit of the 18 patients with measurable acuity was 1.15 LogMAR (20/280). Retinopathy with a prominent macular component was present in 72% of patients, with MMACHC c.271dupA homozygotes (14) showing the most extensive degeneration. Retinopathy was accompanied by optic nerve pallor and vascular changes in 68% and 44% of patients, respectively. Empiric treatment with prenatal vitamin B12 in two cases resulted in children with less cognitive dysfunction and better visual function than their affected older sibling. The retinopathy, while delayed in its progression compared to that of the older sibling, nonetheless progressed. These data suggest that maternal prenatal vitamin B12 therapy may be palliative, but does not prevent ocular symptoms or eventual ocular progression. Our longitudinal study reports the ocular status of the largest group of patients with *cblC* systematically examined at a single facility over an extended period of time. There are general differences in the progression and severity of macular degeneration, optic nerve pallor, and vascular attenuation between homozygous c.271dupA patients and compound heterozygote genotypes. Tempo and chronicity of the ophthalmic manifestations appear to be unrelated to metabolic status. The effects of prenatal treatment, the presence of patients with severe ocular disease in infancy, and the presence of comorbid developmental abnormalities (microcephaly, cardiac non-compaction), re-enforce that *cblC* disease displays a developmental as well as a degenerative phenotype.

2268M

GENOTYPE-PHENOTYPE CORRELATION IN FABRY PATIENTS DETECTED BY LYSOSOMAL NEWBORN SCREENING. *J. Navarrete[1], D. Cervantes[1], A. Limon[2], R. Del Valle[3], R. Delgado[4], A. Rivera[5].* 1) Dept Gen, Hosp Sur PEMEX, Mexico City, Mexico; 2) Pediatrics Division, Hosp Sur PEMEX, Mexico CIty, Mexico; 3) Gerencia Medicina Preventiva, Subdireccion Servicios de Salud PEMEX; 4) Pediatrics Division, Hosp Reg Villahermosa, Tab, Mexico; 5) Faculty of Medicine, Universidad Anahuac, Mexico city, Mexico.

The goal of newborn screening is an early detection of inborn errors of metabolism diseases. In Mexico we began newborn screening since 1977 with very few inborn errors of metabolism such as phenylketonuria, galactosemia, congenital hypothyroidism, sickle cell anemia and cystic fibrosis. Petróleos Mexicanos is a big governamental institution with approximately ten thousand workers and their families. Since 2005 a larger screening has been done to all newborns in this institution through all the country. We test for most aminoacidopathies including acidurias, hemoglobinopathies, G6PD deficiency, adrenal hyperplasia, cystic fibrosis, and biotinidase deficiency; since August 2021 we included primary immunodeficiencies, Gaucher disease, Niemann-Pick (A/B) disease, Pompe disease, Krabbe disease, Fabry disease, and MPS 1. We analyzed our results from August 2012 to May 2014. We have found 4 newborns with Fabry disease confirmed with enzyme activity and moleuclar analysis; and 4 patients with Pompe disease, three were pseudodeficiencies and ones was late onset presentation. Since the most lysosomal prevalent disease in our cohort was Fabry disease, we describe our findings and compared them with other populations, and we make a close follow up of all newborns with pathological mutations and study and analyze their families. We also look for biomarkers of the disease so we can start treatment depending of the mutation and the course of the disease as soon as possible.

Biochemical, Molecular and Clinical Heterogeneity in Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency. The Atlantic Canadian Experience. *J. Gillis[1 2], S. Dyack[1 2], D. Skidmore[1 2], H. McDonald[1], J. Farrell[1], M. Chapman[1], N. Kureshi[1].* 1) Dept Medical Genetics, IWK Health Centre, Halifax, NS, Canada; 2) Dalhousie University, Halifax, NS, Canada.

Very long-chain acyl-CoA dehydrogenase deficiency (VLCADD, MIM #201475) is a recognized rare genetic disorder of fatty acid metabolism caused by mutations in the gene ACADVL. The disorder is classified into three forms depending on the time of onset and severity of illness. VLCADD demonstrates autosomal recessive disease inheritance. Accurate diagnosis and early detection are crucial for favourable clinical outcomes for these patients and for this reason VLCADD is now part of most expanded newborn screening (NBS) programs including the Atlantic Canadian provinces (Nova Scotia, New Brunswick and Prince Edward Island). Diagnosis is established through; acylcarnitine analysis by MS-MS of plasma or a dried blood spot specimen, molecular genetic analysis and measurement of residual enzyme activity in lymphocytes. However, very little remains known of the clinical course of this highly variable condition and there are no established guidelines for management. Since screening began in the Maritimes a decade ago, we have ascertained more true positive cases than expected, demonstrating a greater prevalence for the condition. We have identified novel and deleterious mutations in those ascertained via NBS, as well as in those born prior to NBS for VLCADD and clinically symptomatic; notably we have identified a novel splice-site variant in patients of Acadian ancestry. Our primary objective is to characterize the biochemical, molecular and clinical phenotype of patients with a diagnosis of VLCADD, including those identified via NBS in the Atlantic Maritime provinces. We have identified 17 patients known to our clinic ranging in age from birth to 25 years. Despite their asymptomatic presentation those ascertained on NBS were found to have two deleterious mutations and low level of residual enzyme activity (REA) on follow up analysis. Review of clinical data showed that ≤10% REA correlates with development of symptoms in our patients including; significant hypoglycemia, myopathy, cardiomyopathy and death. Moreover our data also suggest that Individuals with REA within 10-15% are also at risk to develop symptoms. Our study indicates that our current NBS method is sensitive and adequate to identify infants with VLCADD and that acylcarnitine profile on NBS may possibly predict biochemical phenotype correlated to REA and allow for earlier risk assessment for cardiac, hepatic and metabolic complications associated with this condition.

GAL-1-P levels and GALT Gene mutations in infants following abnormal newborn screening for galactosemia in South Florida. *S.A. Hosseini, C. Hung, B.J. Ilagan, G. Ghaffari, B. Johnson, O. Bodamer.* Division of Clinical and Translational Genetics, Dr. John T. MacDonald Foundation, Department of Human Genetics, University of Miami, Miller School of Medicine, Miami, FL 33136.

Background: Galactose-1-phosphate uridyltransferase (GALT) deficiency (OMIM# 230400, Galactosemia) is an autosomal recessive inherited condition with an incidence of 1 in 30,000 to 60,000 newborn infants. Galactosemia is one of the 29 core conditions for newborn screening in the United States. No data are available for confirmatory testing in South Florida. Methods: We received blood samples from 42 infants following an abnormal newborn screening for low GALT activity from August 2012 until May 2014. All infants were born in the State of Florida and screened through the State Newborn Screening Laboratory in Jacksonville. Confirmatory testing samples were analyzed at the Clinical Biochemical and Molecular Diagnostic Laboratories, Department of Human Genetics at the University of Miami for erythrocyte galactose-1-phosphate (GAL-1-P) levels and for GALT gene sequencing, respectively. Standard laboratory protocols were employed. The laboratories are CLIA and CAP certified and participate in proficiency testing. Results: 16 infants had the D/G genotype (GAL-1-P: mean +/- SD; 21.8 mg/dL +/- 16.6), 18 infants were carriers for either D or G variants (GAL-1-P: 7.1mg/dL +/- 10.4), and 8 were without detectable mutation (GAL-1-P levels ranged from >1 to 1.4 mg/dl). GAL-1-P levels were significantly different between infants without mutation, carriers, and D/G infants ($p<0.005$). The Duarte variant c.940A>G (p.Asn314Asp) in cis with the promoter GTCA deletion (c.-116_-119delGTCA) as present on 25% of alleles. 22% of alleles carried the pathogenic mutations c.404C>T (p.Ser135Leu) or c.563A>G (p.Gln188Arg). Two alleles carried the LA variant c.940A>G (p.Asn314Asp) without, GTCA promoter deletion. We did not observe any infants with classic galactosemia. Discussion and conclusions: Confirmatory testing following abnormal newborn screening for galactosemia is straightforward provided GAL-1P can be analyzed within a few hours followed by timely molecular testing.

2271T

Implications for newborn screening by sequencing. *Y. Zou[1,2], S.E. Brenner[1].* 1) University of California, Berkeley, CA; 2) Fudan University, Shanghai, China.

Fatty acid oxidation disorders (FAOD), amino acid disorders (AAD) and organic acid disorders (OAD) are three groups of inherited metabolic disorders with an aggregate population frequency of roughly 1.4-5.0 per 10,000. These comprise several rare diseases that lead to severe morbidity or mortality if untreated. Therefore newborns are routinely screened, primarily using tandem mass spectrometry (MS/MS), to identify metabolites that are diagnostic of disease. With improvements in sequencing technology, it is becoming possible to imagine that whole genome/exome sequencing approaches may be applied in newborn screening. In this case, it will be necessary to identify the pathogenic variants in the genes responsible for these diseases.

As a foundation for such studies, we have examined the landscape of variants in 63 genes known to be associated with FAOD, AAD and OAD. As these diseases are believed to be recessive, we explored homozygous and compound heterozygous protein-altering variants in individuals whose genomes were sequenced as part of the 1000 genomes project. We observed that more than 800 protein-altering variants with minor allele frequency (MAF≤0.01 are present, and 76 protein-altering variants show homozygous (20 variants) or compound heterozygous (56 variants) state in at least one person. Several genes have higher homozygous frequency than expected from Hardy-Weinberg equilibrium. We found one homozygous or compound heterozygous protein-altering mutation with MAF≤0.01 in a FAOD, AAD or OAD related gene in 17, 28, and 19 people, respectively, among 1092 individuals. PolyPhen2 predicts that approximate 20% of homozygous protein-altering variants (4 variants) and 23% of compound heterozygous protein-altering variants (13 variants) are pathogenic. Moreover, based on the annotation of Human Gene Mutation Database (HGMD), 5 of 20 homozygous protein-altering variants observed in healthy people were validated to be linked to severe metabolic disorders like phenylketonuria or carnitine palmitoyltransferase II deficiency. As these greatly exceed the population incidence of these diseases, we infer that the vast majority of rare variation in these genes, including that flagged as pathogenic by either computational methods or databases, is likely benign. These findings indicate that it will be challenging to identify causal variants in screening the newborn defects of metabolic disorders by genomic sequencing technology.

Newborn screening and the incidences of inherited metabolic and endocrine disorders in the Arab Middle East. *A.M. Kinrich[1], P.A. Sanchez-Lara[2].* 1) Keck School of Medicine of University of Southern California, Los Angeles, CA; 2) Children's Hospital Los Angeles, Keck School of Medicine of University of Southern California, Los Angeles, CA.

The Middle East and North Africa (MENA) is home to over 300 million people spanning 17 countries and 4000 miles, with over 7 million annual births and some of the highest rates of consanguinity in the world. Several studies suggest that the incidences of inherited metabolic and endocrine disorders in MENA are higher than in Western countries. Early detection and treatment of these conditions can reduce morbidity and mortality, but newborn screening (NBS) can be sparsely performed in parts of these regions. We provide descriptive analysis of the national incidences of metabolic and endocrine disorders and assess the availability of NBS programs in each MENA country. Data was gathered from the Center for Transmission Genetics in Arabs database, indexed articles in PubMed, and through contact with regional experts. Newborn screening programs were categorized by number of conditions tested and how much of the population was screened in each country. Incidence rates were qualitatively compared to published incident rates of Californian neonates of Middle Eastern descent (Feuchtbaum et al 2012). NBS programs in the region were found to vary widely: seven wealthier countries with lower annual birth rates achieved nearly universal screening for a number of conditions, although these populations represented only 12.2% of MENA births. Two countries had limited national screening programs, and eight developing countries with higher annual birth rates had no universal screening program, which together comprised 87.8% of annual births in the region. Incidence rates were identified for 66 inherited endocrine and metabolic disorders in 10 of 17 MENA countries. Rates of disease were found to be higher in MENA countries than in Californian neonates of Middle Eastern descent. Published data on MENA NBS programs are insufficient—only a small number of MENA countries, accounting for 12.2% of regional births, have widespread neonatal genetic screening for multiple disorders. In most of the region, screening is limited to a few conditions in select portions of the population. As a consequence of insufficient access, the incidences of heritable diseases are likely underestimated in the MENA region. There is significant benefit in expanding national NBS programs in the MENA countries to avoid preventable morbidity and mortality associated with untreated inherited endocrine and metabolic disorders.

Providing more education to parents about newborn screening: not harmful and probably beneficial. *B.J. Wilson[1], B.K. Potter[1], J.C. Carroll[2], J. Little[1], D. Castle[3], P. Chakraborty[4,5], S. Craigie[1], H. Etchegary[6], L. Lemyre[7], F.A. Miller[8], G.A. Wells[1], J. Milburn[4], R. Rennicks White[9,10], G. Tawagi[9], M. Walker[9,10,11], CIHR Emerging Team in Genomics in Screening.* 1) Epidemiology & Community Med, University of Ottawa, Ottawa, ON, Canada; 2) Department of Family & Community Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 3) ESRC Innogen Centre, University of Edinburgh, Edinburgh, UK; 4) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Department of Pediatrics, University of Ottawa, ON, Canada; 6) Clinical Epidemiology, Memorial University Newfoundland, St John's, NL, Canada; 7) School of Psychology & Institute of Population Health, University of Ottawa, ON, Canada; 8) Institute of Health Policy, Management and Evaluation, University of Toronto, ON, Canada; 9) Department of Obstetrics, Gynecology and Newborn Care, The Ottawa Hospital, ON, Canada; 10) Clinical Epidemiology Program, Ottawa Hospital Research Institute, ON, Canada; 11) Department of Obstetrics and Gynecology, University of Ottawa, ON, Canada.

Background: Effective parental education about newborn screening (NBS) is important even where screening is mandated. Potential benefits include promoting trust, mitigating anxiety about the NBS process and possible outcomes, and emphasizing the importance of follow up where needed. However, concerns are sometimes expressed that more comprehensive education may lead to parental anxiety and lower acceptance rates in consent-based programs. Published expert opinions suggest key NBS educational messages, but empirical evaluations are lacking. This study formally examined the effect of specific NBS education content on parents' decision-making. **Objectives:** To measure the effect of specific educational messages on pregnant women's decisional conflict about NBS. **Methods:** Women with low-risk pregnancies were recruited from routine second trimester ultrasound clinics in Ottawa, Ontario. Using a factorial survey, they were randomized to receive different combinations of messages: possibility of false positive/negative results; pain from the heel-prick; possibility for results of unclear clinical significance; storage/secondary use of bloodspots; and the nature of parental consent. In total, 32 (2^5) discrete message combinations were assessed. The primary outcome was the mean score on the validated Decisional Conflict Scale (DCS) (1-100, higher scores indicating higher decisional conflict). Secondary analyses explored associations with respondent characteristics, their understanding of key messages, and cognitive burden. **Results:** We received responses from 494 participants. The mean (95% CI) DCS score was 27 (25-29). We observed statistically significant differences in DCS score between recipients and non-recipients of two test messages. The heel-prick pain message ($p<0.01$) and the storage/secondary use of bloodspots message ($p<0.05$) were associated with lower DCS scores. Specific knowledge questions were more likely to be answered correctly if the participant had received the corresponding message. The mean DCS score declined significantly with increasing number of messages received (test for linear trend, $p<0.01$). **Conclusions:** The results suggest that providing information does not compromise NBS decision-making, and may enhance it. This study has high internal validity, but needs to be replicated in more diverse populations, using a broader set of outcomes. The factorial survey design is a useful approach in this context.

2274M

Evaluation of Behavior, Executive Function, Neurotransmitter Function and Genomic Expression in PKU "Nonresponders" to Sapropterin. *H.C. Andersson[1,2], A. Cunningham[1,2], K. Crivelly[1], Y. Li[2], D. Goldstein[3], T.J. Chen[1,2].* 1) Hayward Gen Ctr, Tulane Univ Med Sch, New Orleans, LA; 2) Dept. Pediatrics, Tulane Univ Med Sch, New Orleans, LA; 3) NINDS, NIH, Bethesda, MD.

Oral sapropterin (BH4) has been part of PKU care since FDA-approval in 2007. Sapropterin enhances residual metabolism of phenylalanine hydroxylase and 40-50% of PKU patients experience decreases in plasma phenylalanine (PHE). Anecdotal reports exist of patients who have not experienced changes in plasma PHE but have been noted to, or have reported, improved attention and mental clarity. Behavior, metabolic effects and gene expression has not been studied in PKU patients who were nonresponsive to sapropterin. We have studied 17 classical PKU patients (ages 8-39y) previously shown to be non-responders (NR) to Kuvan® and 4 patients subsequently shown to be responders (R). Prior to receiving Kuvan®, patients completed behavioral inventories of executive functioning and adaptive function (BASC, BRIEF), submitted 24-hour urine for catechol analysis and had gene expression arrays performed at baseline and after 4 weeks of Kuvan® (20mg/kg). Plasma amino acids during with the trial confirmed non-responsiveness to Kuvan®. Dietary diaries were used to assess stability of dietary PHE. RESULTS: On BASC, 2/10 NR patients and 1/1 R patient demonstrated significant improvement on multiple measures to normal score from significantly abnormal; 10 adults were too old for (BASC validated only to 21y). Only one patient demonstrated worsening on one measure. On BRIEF, 3/16 NR patients and 2/3 R patients showed significant improvement on multiple measures; 1/16 NR patient worsening on a single measure. Urine catechols showed no consistent pattern among NR or R patients. Gene expression arrays showed 171 diverse genes among NR patients which showed ≥1.5-fold up-/downregulation and R patients showed 316 diverse genes ≥1.5-fold up-/downregulation. Numerous canonical gene pathways not known to be directly involved in PHE metabolism were involved. In summary, a few NR patients demonstrated a clear effect of Kuvan® on behavior, suggesting a possible neurocognitive benefit of sapropterin beyond its effect to mediate PAH gene function.

TREATMENT OF PHENYLKETONURIA WITH A NEW FORMULA CONTAINING LNAA. *D. Concolino[1], I. Mascaro[1], M.T. Moricca[1], G. Bonapace[1], k. Matalon[2], P.V Patel[3], R. Matalon[3], P. Strisciuglio[4].* 1) Pediatrics, University "Magna Graecia", Catanzaro, Italy; 2) Health and Human Performance, University of Houston, TX; 3) Deptment of Pediatrics, University Texas Medical Branch, Galveston, TX; 4) Deptment of Pediatrics, University of Naples, Italy.

Background and objectives: Phenylketonuria is an autosomal recessive disease caused by deficient activity of phenylalanine hydroxylase. A low phenylalanine diet is used to treat PKU. The diet is very restrictive and dietary adherence decreases as patients get older. A new formula (PheLNAA) has been tested in this study with the purpose to improve compliance and lower blood phenylalanine. Patients and Methods: The formula has been tested for nitrogen balance and is nutritionally complete. It is fortified with more nutritional additives that can be deficient in PKU diet, such as B12, Biotin, DHA, Lutein and increased levels of Large Neutral Amino Acids to help lower blood Phe. The new formula has been tested on 12 classic PKU patients with a loading test of 4 weeks and the patients who initially responded to treatment continued the PheLNAA administration for an additional five months. Results: Fifty-eight percent of patients had a significant decline in blood Phe concentration from baseline throughout the study. The PheLNAA was well tolerated with excellent compliance and without illnesses or side effects. Conclusion: The new formula is suitable for PKU treatment and offers the PKU clinic a new choice for treatment specially in affected adolescence.

Optimizing treatment for neonatal hyperammonmia. *P.A. Levy.* Pediatrics, Children's Hospital at Montefiore, Bronx, NY. Albert EInstein College of Medicine.

Treatment of hyperammonemia in the neonate is at best problematic. Many factors complicate treatment. Discovering the hyperammonemia requires a good degree of suspicion. Current treatment requires removal of ammonia by Renal Replacement Therapy (RRT), either by hemodialysis or CVVH (continuous veno-venous hemofiltration). Confounding the treatment is the size of the patient (neonate) who usually weigh between 2.5 and 3 kg, and the placement of catheters suitable for dialysis. “The optimal RRT prescription for neonatal hyperammonemia remains unknown,” as was concluded by Spinale, et al, in a recent article in Pediatric Nephrology (2013). We decided to poll nephrologists as to their approach to RRT for hyperammonemia in a neonate. An informal telephone poll was conducted. Nephrologists were asked their approach to treating a 3 kg neonate with hyperammonemia. Findings: 1.The start of therapy was cited as the important factor for successful outcome 2. Catheter placement whether by ICU staff, interventional radiology or Pediatric surgery was not as much of a concern as was the speed with which the line could be placed so RRT could begin. 3. Catheter size was generally agreed to be a 7 French for this size infant. 4. Area of placement was optimally felt to be the internal jugular in most cases, but again speed of access would override the area of placement. 5. Hemodialysis vs CVVH: The division here seemed to depend on the experience of the nephrologists. Those more comfortable with hemodialysis preferred that mode of ammonia removal, while other felt that higher flows with CVVH could achieve similar results and was more easily accomplished with CVVH. Standardization of treatment is difficult because it depends on the preferences and experience of the treating nephrologist and factors related to each institution.

Melatonin and Dopamine as Biomarkers to Optimize Treatment in Phenylketonuria: Effects of Tryptophan and Tyrosine Supplementation. *S. Yano[1], K. Moseley[1], C. Azen[2].* 1) Genetics/Pediatrics, University of Southern California, Los Angeles, CA; 2) Clinical and Translational Science Institute, University of Southern California, Los Angeles, CA.

Objective: To determine if additional supplementation of tryptophan (Trp) and tyrosine (Tyr) improve serotonin and dopamine metabolism in individuals with phenylketonuria (PKU) treated with large neutral amino acid (LNAA) tablets. Study design: Ten adult individuals with PKU participated in a randomized double-blind placebo controlled crossover study consisting of three 3-week phases: washout, treatment with LNAA tablets plus supplementation with either Trp and Tyr tablets or placebo, and LNAA tablets plus the alternate supplementation. An overnight protocol to measure blood melatonin, a serotonin metabolite in the pinealocytes, and urine 6-sulfatoxymelatonin and dopamine in first void urine specimens was conducted after each phase. Results: Serum melatonin and urine 6-sulfatoxymelatonin and dopamine levels were increased in the LNAA phase (LNAA plus placebo) compared to the washout phase. Serum melatonin and urine 6-sulfatoxymelatonin did not increase in the active phase (LNAA plus Trp+Tyr) compared to the LNAA phase, although plasma Trp/LNAA ratios were increased compared to the LNAA phase. Among 7 subjects whose plasma Trp/LNAA ratios were above 0.03, a negative correlation between urine 6-sulfatoxymelatonin and plasma Phe levels was observed ($r = -0.072$). Urine dopamine levels and plasma Tyr/LNAA ratios were increased in the active phase compared to the LNAA phase. Conclusion: Melatonin levels did not increase with the larger dose of Trp supplementation although dopamine levels were increased corresponding to the larger dose of Tyr supplementation. Serotonin synthesis appears to be suppressed by high Phe levels at the Trp Hydroxylase level.

2278M

Induction of immune tolerance in MPS I patients initiating enzyme replacement therapy with Aldurazyme. *G.F. Cox[1], R. Giugliani[2], P.V. Novikov[3], S. Richards[1], Y. Xue[1].* 1) Genzyme, a Sanofi company, Cambridge, MA; 2) Medical Genetics Service/HCPA, Department of Genetics UFRGS and INAGEMP, Porto Alegre, RS, Brazil; 3) Department of Clinical Genetics, Moscow Research Institute for Pediatrics and Children Surgery, Moscow, Russia.

Objectives: Mucopolysaccharidosis I (MPS I) is a rare autosomal genetic disorder caused by deficiency of the lysosomal enzyme α-L-iduronidase and the subsequent accumulation of its substrates, the glucosaminoglycans (GAGs) dermatan and heparan sulfates. This results in progressive and debilitating multi-organ disease. Enzyme replacement therapy with laronidase (Aldurazyme®) is approved for the treatment of patients with MPS I. Studies in MPS I dogs have shown that antibodies to laronidase affect its biodistribution and ability to clear glycosaminoglycans (GAGs). In patients with MPS I, high antibody titers correlate with less urinary GAG reduction, but not with clinical response. This study was designed to determine whether an immunosuppressive regimen that induced immune tolerance in dogs could be used in patients with MPS I. Methods: This open-label clinical trial (NCT 00741338) in patients with severe MPS I (≤ 5 years of age) included a Tolerance Induction Period (TIP) followed by an Immune Challenge Period (ICP). The immunosuppressive regimen consisted of cyclosporine A (CsA), azathioprine, and low-dose weekly Aldurazyme (0.058 mg/kg). Following gradual discontinuation of immunosuppressants, patients received full-dose Aldurazyme (0.58 mg/kg) for a total of 24 weeks. Immune tolerance was defined as an anti-laronidase IgG antibody titer ≤1:3,200 at the end of the ICP. A sequential adaptive design allowed for modification of the immune tolerance regimen in a second patient cohort if the initial regimen was unsuccessful (<2 of 3 patients immune tolerant). Safety evaluations focused on signs of infection or organ toxicity, blood pressure elevation, and bone marrow suppression. Results: None of the 3 patients in Cohort 1 and 1 of 3 patients in Cohort 2 achieved immune tolerance. A second patient in Cohort 2 maintained a low IgG titer after 17 weeks of full-dose Aldurazyme, but discontinued the study due to infusion-associated reactions and was considered a treatment failure. CsA levels were variable and required frequent monitoring and dose titration. There were no deaths or other significant adverse events. Conclusions: The results of the study are inconclusive. The risk, benefit, and feasibility of immune tolerance induction should be reconsidered in patients with MPS I. This study was supported by the Genzyme/BioMarin Joint Venture.

2279T

Effects of pre-symptomatic initiation of enzyme replacement therapy for infantile-onset Pompe disease. *M. Kosuga[1], M. Tajika[2], Y. Miwa[2], K. Fujimaki[2], T. Matsuoka[2], K. Soga[2], Y. Umeda[2], S. Uemura[3], T. Fukuda[4], H. Sugie[5], T. Okuyama[1].* 1) Department of Clinical Laboratory Medicine, National Center for Child Health and Development, Tokyo, Japan; 2) Showa University Northern Yokohama Hospital, Children's Medical Center, Yokohama, Japan; 3) Showa University Northern Yokohama Hospital, Cardiovascular Center, Yokohama ,Japan; 4) Hamamatsu University School of Medicine, Department of Pediatrics, Shizuoka, Japan; 5) Jichi Children's Medical Center, Tochigi, Japan.

Pompe disease is an autosomal recessive lysosomal glycogen storage disease caused by a deficiency of acid α-glucosidase. Infantile-onset Pompe (IPD) disease is characterized by progressive cardiomegaly, skeletal muscle weakness, delay of motor function and respiratory insufficiency, and die before the first 1 year of life. Enzyme replacement therapy (ERT) has been shown to improve symptoms and life expectancy of IPD patients when it starts at early (pre-symptomatic) stage. We report on two siblings with IPD in this study. The siblings initiated ERT at 4 months (older sister) and 12 days (younger sister) of age, and we compared their outcomes after 6 and 3 years of treatment respectively. At the start of treatment, the older sister showed typical symptoms of IPD. Now she is 7 years old, bedridden and needs the invasive ventilation due to progressive muscular weakness. Younger sister was initiated ERT at 12 days after birth without any symptoms of IPD. She acquired natural motor development and has no symptoms of IPD at 3 years old. These results show that early ERT initiated at pre-symptomatic IPD is effective in preventing disease progression of IPD. Early diagnosis and ERT introduction can result in better clinical outcomes. Therefore, newborn screening is necessary to allow IPD patients to be treated as early as possible.

Expression and purification of human recombinant α-*N*-acetylglucosamine-6-sulphatase. *S. Le, S. Kan, R. Dokko, P. Dickson.* Dept Med Gen, LA Biomed Harbor-UCLA, Torrance, CA.

Mucopolysaccharidosis type III (MPS III, Sanfilippo syndrome) is a heritable lysosomal disorder of heparan sulfate degradation, divided into four types (A-D), depending on the enzyme deficiency. All four MPS III types are characterized by severe neurologic problems and relatively mild somatic syndromes. MPS IIID (Sanfilippo D syndrome) one of the rarest Sanfilippo syndrome and is caused by the deficiency of GNS (α-N-acetylglucosamine-6-sulfatase; EC 3.1.6.14). In this study, a full-length human GNS cDNA with a c-Myc purification tag was cloned into an expression vector, pCIneo, and expressed in Chinese hamster ovary cells. The secreted recombinant human GNS (rhGNS) was concentrated from culture medium and a one-step purification with c-Myc affinity chromatography was performed. The purified rhGNS demonstrated the expected molecular weight of the secreted form of GNS at approximately 110 kDa by SDS-PAGE. Deglycosylation assay with PNGase F showed that rhGNS expressed in CHO cells is highly glycosylated as expected. Further biochemical characterization and *in vitro* identification in MPS IIID fibroblasts will be performed to identify if this recombinant protein can be a feasible enzyme replacement therapy candidate for MPS IIID patients.

Clinical response to eliglustat in treatment-naïve patients with Gaucher disease type 1: Post-hoc comparison to imiglucerase in a real-world setting. *R. Mankoski, J.S. Taylor, J. Angell, M.J. Peterschmitt.* Genzyme, a Sanofi company , Cambridge, MA.

Introduction: Gaucher disease type 1 is a multi-systemic lysosomal storage disorder resulting from acid β-glucosidase deficiency. The standard of care for more than two decades has been enzyme replacement therapy. Eliglustat is a novel oral substrate reduction therapy in development for adults with Gaucher disease type 1.

Objective: To compare long-term treatment response to eliglustat and imiglucerase in treatment-naïve patients with Gaucher disease type 1.

Methods: Four-year data from eliglustat-treated patients in an open-label study (NCT00358150, N=26) and 18-month data from a randomized, double-blind, placebo-controlled study (ENGAGE: NCT00891202, n=20 in eliglustat arm) were compared to 75 matched imiglucerase-treated patients enrolled in the ICGG Gaucher Registry who had received at least 15 U/kg/2 weeks.

Results: At baseline, hematologic parameters were similar in the two groups but eliglustat patients had slightly larger spleens and livers. Time course and degree of improvement were similar for eliglustat- and imiglucerase-treated patients for most parameters. After 4 years, mean spleen volume decreased by 63% and 48%, mean liver volume decreased by 27% and 30%, mean platelet count increased by 95% and 99%, and mean hemoglobin level (g/dL) increased by 2.27 and 0.71 in eliglustat and imiglucerase patients, respectively. Improvements in lumbar spine and total femur Z-scores were consistently higher in the eliglustat group at all time points; however, bone data were limited from the imiglucerase-treated patients. The Z-score increases observed with eliglustat were higher than those observed by Wenstrup et al. (2007, J Bone Min Res) during low- to high-dose treatment with imiglucerase (0.06-0.13 Z-score/year) in patients who had similar mean baseline bone mineral density.

Conclusion: Although not a head-to-head trial, this post hoc analysis suggests that eliglustat, in treatment-naïve patients with Gaucher disease type 1, results in improvements in organ volumes and hematologic parameters that are comparable to those observed with imiglucerase in a real-world setting.

ENCORE: A randomized, controlled, open-label non-inferiority study comparing eliglustat to imiglucerase in Gaucher disease type 1 patients stabilized on enzyme replacement therapy: 24-month results. *T.A. Burrow[1], T.M. Cox[2], G. Drelichman[3], R. Cravo[4], M. Balwani[5], A.M. Martins[6], E. Lukina[7], B. Rosenbloom[8], L. Ross[9], J. Angell[9], A.C. Puga[9].* 1) Cincinnati Children's Hospital Medical Center, Cincinnati , OH; 2) University of Cambridge, Addenbrooke's Hospital, Cambridge, UK; 3) Hospital de Niños Ricardo Gutiérrez, Buenos Aires, Argentina; 4) HEMORIO, Rio de Janeiro, RJ, Brasil; 5) Mount Sinai Hospital, New York, NY, USA; 6) Universidade Federal de São Paulo, São Paulo, SP, Brasil; 7) Hematology Research Center, Moscow, Russia; 8) Cedars-Sinai/Tower Hematology Oncology, Beverly Hills, CA, USA; 9) Genzyme, a Sanofi company, Cambridge, MA, USA.

Introduction: Gaucher disease is an autosomal recessive disorder caused by deficient activity of the lysosomal enzyme acid β-glucosidase (glucocerebrosidase or glucosylceramidase), resulting in progressive substrate accumulation and a spectrum of debilitating visceral, hematologic, and skeletal manifestations. Eliglustat is a novel oral substrate reduction therapy in development for adults with Gaucher disease type 1. This open-label Phase-3 trial (ENCORE, NCT00943111, Genzyme, a Sanofi company) evaluated eliglustat and imiglucerase in patients who had reached pre-specified therapeutic goals after ≥3 years of enzyme replacement therapy. We report efficacy data from the 12-month primary analysis period (PAP) and the first 12 months of the extension period during which all patients received eliglustat. **Methods**: Patients were randomized 2:1 eliglustat: imiglucerase. The primary efficacy endpoint was percent of patients remaining stable on a composite of spleen, liver, hemoglobin, and platelet parameters. As this was a non-inferiority trial, efficacy analyses were performed on the per-protocol population (99 eliglustat, 47 imiglucerase patients). **Results**: Eliglustat was non-inferior to imiglucerase: after 12 months, 85% of eliglustat and 94% of imiglucerase patients maintained all four goals (lower bound of 95% CI of difference [-17.6%] within the pre-specified [-25%] non-inferiority margin). One hundred and forty five (91%) of the 159 patients treated in this study completed 24 months of treatment. Preliminary 12-month extension data demonstrate continued stability in spleen volume, liver volume, platelet count and hemoglobin level in most of the 99/106 patients who continued on eliglustat and most of the 46/53 patients who received imiglucerase in the PAP and then eliglustat in the trial extension. Most adverse events were mild or moderate in severity. In general, the overall number, seriousness and relatedness of adverse events for all eliglustat-treated patients during day 1 to month 24 is similar to the profile for eliglustat-randomized patients in the PAP as well as similar to the safety profile in patients who switched from imiglucerase to eliglustat after 12 months. **Conclusions**: In the Phase 3 ENCORE study, most patients maintained clinical stability while on eliglustat for 12 or 24 months.

Assessment of Pompe Patients at Reference Center of Inborn Errors of Metabolism (CREIM). *P. Feliciano, C.S. Aranda, C.S.C. Mendes, M.A. Curiati, C.M. Gonçalves, M.H. Rand, A.M. Martins.* Centro de Referência em Erros Inatos do Metabolismo, Universidade Federal de São Paulo, São Paulo, SP, Brazil.

Objectives: Pompe disease (PD) is a lysosomal storage disorder caused by deficiency of alpha-1,4-glucosidase which leads to an accumulation of glycogen in lysosomes. The aim of this study is to the evaluate the profile of patients with PD who are treated at the Reference Center of Inborn Errors of the Universidade Federal de São Paulo - Brazil (CREIM). Methods: Medical records of patients with confirmed diagnosis of PD were analyzed. Results: Six patients, one male (16.5%) and five female (83.5%) were analyzed. One patient (16.5%) died at seventeen years due to respiratory complications. Patients were divided into two groups: onset of symptoms in childhood (CG) and initial symptoms in adulthood (AG). There were no patients in this sample with neonatal presentation. The current mean age was 36 years (range 11 - 66yr). The mean age of early onset symptoms was between 9.6 years (CG) and 40.3 years (AG) and the mean age of diagnosis was between 13.2 years (CG) and 45.1 years (AG), indicating a delay in diagnosis of 3.6 yr and 4.8 yr respectively. The mean age of enzyme replacement therapy (ERT) beginning was 12 and 48.3 years. The initial symptoms were weakness, shortness of breath and fatigue. One year after eow ERT, two patients showed improvement of respiratory drive, with significant reduction in CPAP parameters. The other three patients never used respiratory support. Conclusion: Pompe disease is a rare disorder that difficulty in patient diagnosis reflects in delayed treatment. Improvement in knowledge about inborn errors of metabolism, especially of treatable lysosomal storage disease is mandatory to anticipate the diagnosis and start treatment to reduce sequel and improve the quality of life of patients.

2284M

CYP2D6 phenotype-based dosing of eliglustat. *S. Turpault, Z. Meng, S. Wang, L. Von Moltke.* Genzyme, a Sanofi Company , Cambridge, MA.

Introduction: Gaucher disease type 1 (GD1) is a multi-systemic lysosomal storage disorder resulting from acid β-glucosidase deficiency. Eliglustat, an experimental oral substrate reduction therapy for adults with GD1, is metabolized mainly by CYP2D6, a polymorphic cytochrome P450 isozyme. Clinical studies used a dose-titration scheme (ranging from 50 to 150 mg BID) to ensure plasma eliglustat steady-state pre-dose concentrations (C_{trough}) above 5 ng/mL; however, this method has limitations in clinical practice. An alternative dosing regimen of 100 mg BID was evaluated for CYP2D6 intermediate and extensive metabolizers (IM/EM), who comprise approximately 90% of patients.

Methods: A pharmacokinetic/pharmacodynamic (PK/PD) modeling approach using population-PK model predicted plasma exposure parameters of eliglustat and observed efficacy from eliglustat clinical studies was conducted.

Results: In the Phase 3 randomized placebo-controlled study of treatment-naïve GD1 patients (ENGAGE, NCT00891202), most of the CYP2D6 IM/EM patients (17/19, 89.5%) were dosed at 100 mg BID (maximum dose allowed) based on C_{trough}. Modeling confirmed that the percent change in spleen volume (primary endpoint) was similar whether patients were dosed by C_{trough} (-27.8%, observed) or if all IM/EM patients had received a 100 mg BID dose (-31.9%). In the Phase 3 randomized controlled study of GD1 patients switching from enzyme replacement therapy to eliglustat (ENCORE, NCT00943111), 55 of 88 IM/EM patients (62.5%) were dosed at either 50 or 150 mg BID (maximum dose allowed) based on C_{trough}. Modeling predicted that the change in spleen volume was similar whether patients were dosed by C_{trough} (-5.96%, observed) or if all IM/EM patients had instead received a 100 mg BID dose (-6.63%) and that this dosing regimen would not result in any additional treatment failures. For all patients, projected eliglustat exposure at the 100 mg BID dose was within the range observed in the clinical studies (i.e., would not be expected to affect safety).

Conclusion: A simplified dosing regimen for eliglustat based on CYP2D6-genotype-predicted phenotype (100 mg BID for IM/EM patients) would achieve exposure, efficacy, and safety results similar to dosing based on plasma eliglustat concentrations.

Hematopoietic stem cell transplantation in a very young child with Hunter Syndrome: four year follow-up. *A.L. Barth[1], A.C. Esposito[1], C. Bomfim[2], M.L.C. Oliveira[3], F. Scalco[3], A.P. Costa[1], A.B. Reis[1], J.C. Llerena Jr[1], D.D.G. Horovitz[1].* 1) Instituto Fernandes Figueira/Fiocruz, Rio de Janeiro, Brazil; 2) Hospital de Clínicas de Curitiba - UFP, Paraná, Brazil; 3) LABEIM, Departamento de Bioquímica - UFRJ, Rio de Janeiro, Brazil.

Enzyme replacement therapy (ERT) in Hunter Syndrome (MPS II) does not cross the blood brain barrier, limiting results in neurological forms of the disease. Hematopoietic stem cell transplantation (HSCT) may be effective for the non-neuropsychological symptoms only, although better outcome may be expected in young patients. We describe the four-year follow-up of an MPS II child submitted to HSCT with umbilical cord blood cells at 70 days preceded by ERT. He was investigated due to positive family history; undetectable iduronate-sulphatase (IDS) activity and the familial p.R88H mutation were detected in amniotic fluid. At birth slight hyper-reactivity and lumbar gibbus, with corresponding L3-L5 abnormality on X-ray were noted. Abdominal and cerebral ultrasound, echocardiogram, ophthalmology, audiology, pulmonary function, brain & spine MRI were normal. Lysosomal storage in placental cells and pericytes were observed by electronic microscopy. IDS activity in plasma [1,2nmol/4h/ml (ref=122-463)] and leukocytes [4,3nmol/4h/mg/ptn (ref=31-110)] re-confirmed MPS II. He received 6 infusions of Idursulfase from age 10 days without adverse reactions. HSCT with umbilical cord blood from unrelated donor was performed at 70 days of age, without additional ERT. Urinary glycosaminoglycans began to decrease during ERT and were in normal range 3 months post-transplant. Engraftment after 30 days revealed mixed chimerism with 79% donor cells. IDS activity 30 days post-transplant was low in plasma (22nmol/4h/ml; ref=122-463) and normal in leukocytes (49nmol/4h/mg/ptn; ref=31-110); 270 days, 2, 3 and 4 years after transplant the same pattern was observed. At age 4 years growth charts and motor development are normal; he is hyperactive and language is delayed. Very mild lumbar gibbus and signs of dysostosis multiplex in hands and lumbar spine are present. Follow-up studies after HSCT in MPS II are scarce, lacking information on longer term effects. Patients with the severe phenotype do not benefit from transplant when gross developmental delay is evident. We decided to go through with the transplant since no reports for children so young were available, and as the only "curative" option. ERT was used as an attempt to prevent storage during the elapsed time from birth to transplant/engraftment. Whether transplantation prior to the onset of neurological symptoms would prevent a severe outcome has yet to be proven. Longer follow-up and reports of similar cases are recommended.

Inhibition of Hepatic Mitochondrial Metabolism during Systemic Immune Activation. *P.J. McGuire[1], S. Matsumoto[2], K. Saito[2], J. Senac[1], S. Cologna[3], T.N. Tarasenko[1].* 1) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) National Cancer Institute, National Institutes of Health, Bethesda, MD; 3) National Institute of Child and Health Development, National Institutes of Health, Bethesda, MD.

Infection plays a significant role in precipitating life-threatening acute metabolic decompensation in inborn errors of metabolism (IEM). Acute metabolic decompensation is defined as a functional deterioration in metabolic status and may result in a range of hepatic perturbations including hypoglycemia, acidosis and hyperammonemia. We hypothesized that hepatic mitochondrial metabolic adaptations that normally occur during the immune response to infection may not be tolerated in IEM. To simulate systemic immune activation, mice were injected with poly I:C, a dsRNA analogue, for 3 days. During this systemic immune activation, reduced amounts of pyruvate dehydrogenase and components of respiratory chain were detected by immunoblot. In addition, pyruvate dehydrogenase (PDH) was hyperphosphorylated, suggesting inhibition of activity. To address functional perturbations in mitochondrial metabolic pathways, we profiled in vivo hepatic mitochondrial function by 13C-methionine oxidation breath testing and MR spectroscopy using hyperpolarized 13C-pyruvate. Following poly I:C treatment, while methionine oxidation was unaffected, significant increases in 13C-lactate/13C-pyruvate and 13C-alanine/13C-pyruvate were seen, consistent with PDH inhibition. The above changes occurred in the absence of mitochondrial morphological and number changes by electron microscopy. By employing a strategy of immunomodulation targeting macrophages, PDH activity improved. Overall, our findings suggest that systemic immune activation has direct effects on hepatic mitochondrial metabolism and that modulation of the immune system may be a viable target of intervention. These findings may have implications for patients with mitochondrial disease and other IEM with significant mitochondrial dysfunction. In addition, our findings may have broader implications for multiple organ dysfunction syndrome due to systemic immune activation (i.e. the Systemic Inflammatory Response Syndrome or sepsis).

2287T

Genotype and Phenotype of Vietnamese patients with ornithine transcarbamylase (OTC) deficiency. *K.Ngoc. Nguyen[1], D.Chi Vu[1], M.Chi Nguyen[1], H.Viet Dau[1], T.Anh Ta[1], G.H Kim[2], H.W Yoo[2].* 1) Department of Endocrinology, Metabolism, Genetics, National Hospital of Pediatrics, Hanoi, Viet Nam; 2) Medical Genetics Center, Aasn Medica Center, Korea.

Ornithine transcarbamylase (OTC) deficiency, a partially dominant X-linked disorder, is the most common inherited defect of the urea cycle. The disease present variable severity affecting both males and females. Molecular diagnosis of OTC deficiency was the first time in Vietnam. **Objectives:** Analyse the phenotype and genotype of three Vietnamese patients with OTC deficiency. **Methods:** Three patients were diagnosed OTC with the criteria of hyperammonemia, hypocitrullinemia and orotic aciduria. 10 exons and their respective exon- intron boundaries of the OTC gene were sequenced using genomic DNA. **Results:** There were 2 boys with newborn - onset form (the age of onset was 2 days and 8 days of age) and 1 girl with late - onset form (the age of onset was 18 months of age) in our study. One of two cases with newborn - onset form had two older brothers died at 5 and 7 days of age due to unknown comma. The rest were the 1st child. The initial symptoms of two newborn - onset cases were poor feeding, irritability, then comma and apnea. The initial symptoms of the late - onset case was vomiting, convulsion, comma and right hemiplegia. Management of hyperammonemic crisis of two newborn - onset cases included glucose infusion, L arginine, L carnitine, hemofiltration, restricted protein diet therapy (metabolic formula). Management of one late - onset case included glucose infusion, L arginine, L carnitine, restricted protein diet therapy (metabolic formula). One case of newborn - onset and one case of late on - set form survived (1 year old and 6years old). The rest died at 8 days old. Analysis of OTC gene detected 3 different mutations in 3 cases: c.77G>A (p.Arg26Gln), c.298+5G>C (IVS3+5G>C), c.422G>A (p.Arg141Gln) heterozygous. **Conclusion:** Newborn - onset OTC deficiency occur in Vietnamese male patients and late - onset one occur in Vietnamese female patients. The outcome depends on the time of diagnosis.

2288M

Precise targeted gene correction of arginase-1 deficiency using single-stranded oligodeoxynucleotides with TALENs or the CRISPR/Cas9 system. *YY. Sin, M. Morales, CM. McCracken, CD. Funk.* Department of Biomedical and Molecular Sciences, Queen's University, Kingston, Ontario K7L 3N6 Canada.

Arginase-1 (ARG1) deficiency, a rare autosomal recessive disorder leads to hyperargininemia with progressive neurological impairment, growth retardation and infrequent episodes of hyperammonemia. This disorder is caused by mutations found throughout the eight exons and several splice sites of the *ARG1* gene located on chromosome 6q23. Currently, there is no cure and pharmacological treatment is limited. Our study aims to correct *ARG1* mutant alleles through nuclease-induced homologous recombination (HR) in the presence of homologous donor repair templates. Using human cells [HEK293, fibroblasts, induced pluripotent stem cells (iPSCs)], we employed engineered transcriptional activator-like effector nucleases (TALENs) and the Clustered Regularly Interspaced Short Palindromic Repeats (CRISPRs)/Cas9 system, designed *de novo*, to target and modify specific DNA sequences at the *ARG1* gene locus. Here, we show that these genome editing tools efficiently cleave chromosomal DNA in a precise, predictable and robust manner, with mutation frequencies (indels) of up to 50%. Moreover, we designed short single-stranded oligodeoxynucleotides (ssODNs) as donor repair templates, which carry a unique novel restriction enzyme site and two flanking homology arms on both sides of the target region. Through selection-independent targeting, these ssODNs introduce desired DNA sequence edits in exons 2, 3 and 7 in conjunction with the delivery of TALENs or CRISPR/Cas9 and a guide RNA (gRNA). Correctly targeted clones are being isolated via limiting dilution, PCR screening and/or RE digestion. Overall, our results demonstrate the versatility of using both TALEN and CRISPR/Cas9 systems to provide proof-of-concept for gene manipulation in human cells and sequence alterations within a defined locus can be achieved simultaneously by introducing ssODNs alongside. iPSCs have been generated from dermal fibroblasts obtained from individuals with ARG1 deficiency. It is anticipated that HR-mediated direct gene corrections in ARG1 deficiency patient-derived iPSC lines may prove useful for autologous cell-based therapies.

Sodium phenylbutyrate decreases plasma branched-chain amino acids in patients with urea cycle disorders. *L. Burrage[1], M. Jain[1], L. Gandolfo[2], B. Lee[1,3], SC. Nagamani[1], Members of the Urea Cycle Disorders Consortium.* 1) Human & Molec Genetics, Baylor College Medicine, Houston, TX; 2) University of South Florida, Tampa, FL; 3) Howard Hughes Medical Institute, Houston, TX.

Sodium phenylbutyrate (NaPB), a nitrogen-scavenging agent, is used to prevent hyperammonemia in patients with urea cycle disorders (UCDs). Previous reports involving small numbers of patients with UCDs have shown that treatment with NaPB can result in lower plasma levels of the branched-chain amino acids (BCAA) but this observation has not been studied systematically. From a large cohort of UCD patients (n=591) enrolled in Longitudinal Study of Urea Cycle Disorders, a multicenter study of the Urea Cycle Disorders Consortium, we evaluated whether treatment with NaPB leads to a decrease in plasma BCAA levels. In our study population, the median levels of all three BCAA (leucine, isoleucine, and valine) were significantly lower (~ 30 %; $p<0.001$) in patients treated with NaPB across all age groups ($p<0.001$). Generalized linear model analysis showed that NaPB use independently affected the plasma BCAA levels even when other important covariates that could influence BCAA levels were taken into account ($p<0.00001$). In addition, NaPB use was not associated with a decrease in the plasma levels of other essential amino acids which indicates that the decrease in BCAA levels is likely due to a specific effect of the drug on BCAA metabolism. Furthermore, NaPB use increased the risk for BCAA deficiency by 2-8 fold. Our study, in an unselected population of UCD subjects, is the largest to analyze the effects of NaPB on BCAA metabolism and conclusively shows that NaPB use is associated with lower plasma BCAA. Our findings have significant clinical implications. First, they indicate that plasma BCAA levels should be monitored in UCD patients who are treated with NaPB and opens avenues to explore whether BCAA supplementation could lead to better metabolic control. Second, they lend further support to the hypothesis that NaPB could be a potential therapy for patients with maple syrup urine disease (MSUD), a disorder of BCAA catabolism characterized by elevations of BCAA. We have shown that NaPB alters the phosphorylation status of branched-chain keto-acid dehydrogenase thus increasing its enzymatic activity and BCAA catabolism. Currently, a randomized double-blind placebo controlled study is ongoing to investigate whether NaPB could be an effective therapy for patients with MSUD.

MEDNIK syndrome: clinical and biochemical delineation of the copper metabolism phenotype and response to zinc therapy. *D. Martinelli[1,2], M. Ben Tanfous[3], C.A. Drouin[4], C. Dionisi-Vici[2], N. Braverman[3,5], S.G. Kaler[1].* 1) Section on Translational Neuroscience, Molecular Medicine Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD, USA; 2) Division of Metabolism, Bambino Gesù Children's Hospital, IRCCS, Rome, Italy; 3) Genetic Department, Montreal Children's Hospital, QC, Canada; 4) Department of Dermatology, Centre Hospitalier Regional Grand-Portage, Riviere-des-Loups, QC, Canada; 5) McGill University-Montreal Children's Hospital Research Institute, QC, CA.

MEDNIK syndrome (MIM 609313) - an acronym for mental retardation, enteropathy, deafness, neuropathy, ichthyosis, keratodermia - is caused by mutations in the *AP1S1* gene, encoding the sigma 1A subunit of adaptor protein complex-1 (AP-1). AP-1 plays a crucial role in the intracellular trafficking of transmembrane proteins, including the copper-transporting ATPases, ATP7A and ATP7B. On this basis, we recently identified disordered copper metabolism in MEDNIK syndrome, and documented clinical and biochemical signs of Menkes (MIM 309400) and Wilson (MIM 277900) diseases in MEDNIK patients (Martinelli et al. Brain 2013). Severe loss of function mutations in *ATP7A* or *ATP7B* genes cause the complete Menkes and Wilson phenotypes, respectively. We have performed serial clinical and neurological evaluations in three subjects with MEDNIK syndrome under zinc therapy (approved for the treatment of Wilson disease because oral zinc limits copper adsorption at the intestinal level). All patients presented with hypocupremia, increased serum free copper level, increased urinary copper excretion, and liver copper accumulation. The hepatic component of the illness has been shown in one patient to respond to zinc and the other two patients are currently receiving this treatment. Interestingly, plasma and cerebrospinal fluid (CSF) neurochemical levels, reliable biochemical hallmarks of Menkes disease, were normal in the one subject studied to date. This patient's CSF copper levels are pending. Skin abnormalities have persisted in all three patients. The above findings pose new questions about the clinical and biochemical effects of AP-1 dysfunction and how the resultant copper metabolic abnormalities should be managed. Chronic zinc treatment may protect affected patients from hepatic copper overload, but some copper may be required for normal brain growth and maturation, as illustrated in patients with Menkes disease. In addition to identifying rational treatment approaches for a novel disorder of copper metabolism, further clinical and translational research studies of MEDNIK syndrome will provide insight about AP-1 cargo specificity and expand our understanding of how adaptor protein complex subunit diversity contributes to the exquisite control of transmembrane protein trafficking exerted by these molecules.

2291T

Spinocerebellar Ataxias with Hypogonadism: PNPLA6 Mutations Broadens the Phenotypic Spectrum of a New Inherited Neurometabolic Disorder. *C. Lourenco[1], C. Sobreira[1], M. Hirano[2], S. Zuchner[3], W. Marques Jr[1].* 1) Neurogenetics, Univ Sao Paulo, Ribeirao Preto, Sao Paulo, Brazil; 2) Columbia University Medical Center, New York, USA; 3) University of Miami, Miller School of Medicine Miami, USA.

OBJECTIVES: To present the clinical data and molecular/biochemical studies of nineteen Brazilian patients with cerebellar ataxia and hypogonadism. BACKGROUND: The association between cerebellar ataxia and hypogonadism was first described in four sibs by Holmes in the beginning of the XX century, and has since become known as Holmes type ataxia. Since then, several syndromes with hypo/hypergonadotrophic hypogonadism and ataxia have been published, with remarkable clinical heterogeneity among them. DESIGN/ METHODS: All patients were evaluated in a neurogenetics clinics by geneticists, neurologists and endocrinologists. Brain MRI, ophtalmological exam, EMG/NCV, hormone and biochemical tests, muscle biopsy with respiratory enzyme assays and coenzyme Q10 measurement, molecular tests (Friedreich ataxia and SCAs 1, 2, 3, 6 and 7) were performed. Exome sequencing was performed in selected patients with a consistent phenotype. RESULTS: All patients had cerebellar ataxia, but the age of the onset was variable; it was worthy to note that ten patients had early onset ataxia . Consanguinity was noted in three families; 12 patients had hypergonadotropic hypogononadism. Intellectual Disability was seen in five patients with hypergonadotropic hypogonadism. None of the patients had chromosomal anomalies. Optic atrophy and retinochoroidal degeneration were found in five patients; axonal neuropathy was present in five patients. Cerebellar atrophy with pons or prominent vermis involvement was a constant feature. Coenzyme Q10 deficiency and CDG Ia were confirmed diagnosis in five patients. Boucher-Neuhauser syndrome (BNS) was identified in other 4 patients with mutation in the PNPLA6 gene identified. CONCLUSIONS: The association between cerebellar ataxia and hypogonadism comprise heterogenous entities. Screening for CDG and Coq10 deficiency should be done in such patients as a part of the work-up investigation. Identification of the molecular basis of BNS widens our comprehension of this rare group of the disorders, with involvement of glycosphingolipids metabolism in its physiopathology.

2292M

DNA diagnostics of MIDD and MELAS syndromes in Slovakia. *D. Gasperikova[1,2], M. Skopkova[1], I. Masindova[1], L. Valentinova[1], J. Stanik[1,3], L. Varga[4], M. Huckova[1,2], M.I.D.D. Study Group[1], M. Profant[4], I. Klimes[1].* 1) Diabgene Laboratory, Institute of Experimental Endocrinology, Bratislava, Slovak Academy of Sciences, Bratislava, Slovakia; 2) Centre for Molecular Medicine, Slovak Academy of Sciences, Bratislava, Slovakia; 3) First Department of Pediatrics, School of Medicine, Comenius University, Bratislava, Slovakia; 4) First Department of Otorhinolaryngology, School of Medicine, Comenius University, Bratislava, Slovakia.

Background and aims. Diabetes and deafness - the leading clinical features of MIDD (Maternally Inherited Diabetes and Deafness) arise from mutations in mtDNA, most often m.3243A>G. This mutation leads to different clinical symptoms according to heteroplasmy levels in different tissues. Usually, the first presentation of MIDD is a sensorineural hearing loss emerging in adolescence; the diabetes mostly develops between 20th-40th year of life. More severe clinical presentation of the mutation is the MELAS syndrome (Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis and Stroke-like episodes). The aim of our study was to search for m.3243A>G mutation among patients sent for MIDD or MODY testing, who lack mutations in the most common MODY genes (i.e. GCK, HNF1A or HNF4A). Materials and methods. Unrelated probands from 257 families fulfilling at least one of the following criteria, i.e. matrilinear inheritance, diabetes plus hearing impairment, diabetes development after 20th year of life, or progressive hearing loss, were tested for m.3243A>G mutation by the RFLP and/or Real-Time PCR. The heteroplasmy was evaluated for peripheral blood and/or buccal mucosa. DNA testing was also extended to the family members of probands carrying the mutation. Results. The m.3243A>G mutation was found in 18 patients from 8 families (3%). Probands' phenotypes varied from diabetes as the sole symptom to a complex picture of the MELAS syndrome (in one proband). Diabetes or impaired glucose tolerance developed all of the probands (diabetes onset ranged from 21 to 52 years), but only 3 of 10 relatives with the mutation. Five probands (62.5%), and 4 (40%) of the relatives with the mutation had hearing impairement. The heteroplasmy was higher in buccal swab samples compared to the peripheral blood (27.9±18.6% versus 12.7±17.3%). In one case, the heteroplasmy was detected in the buccal DNA only, while the blood DNA samples were repeatedly negative. Conclusion. Among 257 probands with the clinical suspicion on MIDD or MODY, 8 (3%) had the m.3243A>G mutation of the mitochondrial DNA. At the time of testing, only 5 (62.5%) of the probands were diagnosed with typical combination of symptoms, i.e. diabetes and hearing loss. Therefore, DNA testing for MIDD seems to be reasonable also in diabetes patients without hearing impairement, particularly using DNA from the buccal mucosa. Supported by APVV 0187-12, „KCMM" (ITMS 26240220071).

2293T

Screening of Adults for Cholesterol ester storage disease (CESD). *M. Beal, D. Roy, J. Kaplan, M. Taylor.* University of Colorado Denver - Anschutz Medical Campus, Aurora, CO.

Background: Cholesterol ester storage disease (CESD) due to lysosomal acid lipase deficiency represents the adult presentation of the more severe and uniformly fatal Wolman disease. The development of enzyme replacement therapy (now in clinical trials) motivates efforts to identify latent cases that may benefit from treatment. To this end, some have recommended that a combination of low high-density lipoprotein (HDL) and high liver aspartate aminotransferase (AST) may be markers of CESD. **Methods:** We undertook a chart review of medical records from a large academic medical center adult hospital of patients with HDL < 15 (mg/dl) and AST > 39 (IU/L) values collected on the same day between 2006 and 2010. Paper and electronic medical records were abstracted by two medical students and evaluated for clinical history, known diagnoses, imaging results and any biopsy reports. **Results:** 104 patients met the HDL and AST criteria (74 men and 30 women; mean age 49.9 +/- 13.6 years). The mean HDL and AST values for the cohort were 11.4 mg/dl and 377.7 IU/L, respectively. No cases of confirmed CESD were found in this cohort, although no patients had evidence of CESD testing performed. Coronary artery disease and high-cholesterol diagnoses were found in 16.3% and 36.5% of patients, respectively. The most common symptoms reported were: abdominal pain (38.5%), joint pain (16.3%), diarrhea (25.0%), nausea (28.8%), shortness of breath (25.0%), and vomiting (26.0%)Potentially confounding diagnoses, common to the cohort, included Alcoholism (20.1%), 'hepatitis' (30.8%), and HIV/Aids (27.9%). Abdominal ultrasound showed hepatomegaly in 32% of patients imaged (27/84). Twenty-six patients had been referred for liver biopsy and 15 of those were available for review by our hepatopathologist (JK). None of the biopsies showed clear pathological features of CESD and only one had minimal evidence of microvesicular steatosis. As DNA was not available from this chart-review cohort, no assessment of LIPA gene mutation status was performed. **Conclusions:** A Low HDL and high AST screen identified a heterogeneous cohort of patients unlikely to have CESD. Hepatic biopsy in a subset of our cohort did not reveal changes consistent with a high proportion of undiagnosed CESD. The addition of exclusion criteria (alcoholism, HIV/Aids, and hepatitis) might increase the sensitivity of these screening criteria by removing confounding diagnoses.

2294M

Meta-analysis of antibody titers, safety, and treatment outcomes in MPS I patients receiving enzyme replacement therapy (ERT) with laronidase (Aldurazyme) in clinical studies. *S. Fallet, Y. Xue, S. Richards, A. Mahmood, G. Cox.* Genzyme, a Sanofi company, Cambridge, MA.

Objectives: Laronidase (Aldurazyme®) is an enzyme replacement therapy approved for the treatment of patients with mucopolysaccharidosis I (MPS I), a genetic disorder caused by deficiency of α-L-iduronidase and subsequent accumulation of glycosaminglycans (GAG) throughout the body. Most MPS I patients treated with laronidase in clinical trials have developed anti-laronidase antibodies. Theoretically, antibodies might alter the biological effects of laronidase by inhibiting its activity, changing its turnover, limiting its uptake into target tissues, and/or causing an allergic reaction. The objective of this meta-analysis was to determine if relationships exist between anti-laronidase antibodies and clinical outcomes, hypersensitivity reactions, and urinary GAG reduction in MPS I patients receiving laronidase. Methods: Data from 73 patients enrolled in 4 clinical trials of laronidase were used for this meta-analysis. Patients received treatment with the labeled dose of laronidase (0.58 mg/kg/wk) for 26 to 208 weeks. Efficacy parameters included 6-MWT, % predicted FVC, liver volume, range of motion, left ventricular mass, investigator global assessments, and uGAG levels, as appropriate, in individual studies. Safety and immunogenicity parameters included infusion-associated reactions (IARs), anti-laronidase IgG antibodies (seroconversion and time to seroconversion, peak titer, overall exposure over time), enzyme activity inhibition and enzyme cellular uptake inhibition assays, and hypersensitivity testing (i.e. IgE, complement activation, and serum tryptase). Results: Based on the analysis of selected clinical outcome measures, there was no apparent correlation between anti-laronidase IgG antibodies and efficacy outcomes. Likewise, there was no apparent relationship between antibodies and the occurrence of potential allergic reactions or IARs. There was, however, a statistically significant inverse correlation between uGAG reduction and antibody titer (p=0.0001), consistent with individual study results. Conclusions: This meta-analysis describes the most comprehensive, systematic review of immunogenicity data from clinical studies of Aldurazyme (including long-term follow-up), and involves patients with all MPS I phenotypes. Although the presence of antibodies correlated with impaired urinary GAG clearance, no impact on the clinical efficacy or safety of laronidase was observed. This study was funded by the Genzyme/BioMarin Joint Venture.

Best Policy for helping LSD patients and Families: Collaboration between Charity Foundation, MOH, and pharmaceutical companies. *F. Hadipour[1,2], A. Hadipour[2,3], A. Torabi[2,3], Z. Hadipour[1,2], Z.Hadipour.* 1) Medical Genetics, Sarem Cell Research Center & Hospital, Tehran, Tehran, Iran; 2) YASNA Charity Foundation, Tehran, Iran; 3) Golden Daric CO, Tehran, Iran.

The lysosomal storage disorders (LSDs) are due to deficiencies of lysosomal enzymes caused by mutations of genes that encode the enzyme, proteins and related cofactors. Lysosomal enzymes degrade most biomolecules. This process is crucial for cells. LSDs result in accumulation of products in lysosomes. More than 45 LSDs are known, and occur in about 1 in 5,000-7,700 live births. LSDs have recessive inheritance. The presence of "founder" mutation in Middle East with a high degree of consanguinity is expected to lead to high prevalence of LSDs. Treatment varies across the LSDs. The ERT of LSDs is expensive comparing with the minimum wage of Iranian; so most of patients could not afford it. Charities play a vital role in facilitating treatment of rare disease especially LSD. Charities exist to help people, serve in areas where there are little or no resources available, and provide aid by educating, setting up programs, providing necessary medical supplies. YASNA is a non-profit, non-political, and non-governmental charity supported by people. YASNA strive to care for patients with rare disease. Main goal of YASNA include: Diagnosis and treatment, prevention, through improvements in public health, and education. When Registration and subsidizing of ERT for each kind of LSD is done in MOH; ERT would be provided for patients in special centers. Iranian MOH subsidized 90% of the price of ERT for LSD. But remaining 10 % should be paid by patients. According to The minimum wage of Iranian which is 248 $ per month; most of patients could not afforded to pay it, and they discontinued their treatment. During 3.5 years YASNA charity Foundation could covered 50% of price of ERT for 70 MPS type 1 patients; and 70% of it for 45 pompe patients whom are living in territory of IRAN(for Iranian or resident in Iran). YASNA's missions are providing access to medical care, and afforded for them regular counseling and training meeting, Genetic counseling, Genetic testing and sometimes prenatal diagnosis. For example genetic testing is done for 12 / 160 patients of Iranian Cystinosis. For countries with situation like IRAN, high rate of consanguinity marriage leads to high rate of rare diseases; and The minimum wage is less than price of ERT per month. The best solution for helping Patients and families is collaboration between pharmaceutical companies, MOH, and charity foundation. MAHAK foundation & YASNA foundation are 2 good examples of such collaboration in Iran.

2296M

Antisense U1-snRNAs-based correction of g.9273C>T and g.9331G>A *GLA* deep intronic mutations which cause Fabry disease. *L. Ferri[1,2], A. Caciotti[2], G. Covello[3], D. Perrone[4], R. Guerrini[1,2], M.A. Denti[3], A. Morrone[1,2].* 1) Department of Neurosciences, Psychology, Pharmacology and Child Health (NEUROFARBA), University of Florence, Florence, Italy; 2) Paediatric Neurology Unit and Laboratories, Neuroscience Department, Meyer Children's Hospital, Florence, Italy; 3) Centre for Integrative Biology, University of Trento, Trento, Italy; 4) Department of Biology and Evolution., University of Ferrara, Ferrara, Italy.

Mutations in the *GLA* gene cause enzyme deficiency of alpha-galactosidase A (α-GAL A) which leads to the X-linked Fabry disease, a lysosomal storage disorder of the glycosphingolipids metabolism. *GLA* produces two transcripts, the major mRNA which encodes α-GAL A and a minor mRNA whose function is unknown. The minor mRNA isoform arises by an alternative splicing and carries a criptic exon between exons 4 and 5 which contains a premature stop codon. Two *GLA* deep intronic mutations, the g.9273C>T and g.9331G>A, have been described being the cause of a pathological unbalanced expression of these two *GLA* transcripts, leading to α-GAL A deficiency and Fabry disease. Antisense-induced Exon Skipping represents a promising approach to correct such kind of mutations and can be obtained by the use of antisense oligonucleotides (AONs) or antisense modified U1snRNAs (U1asRNA). Hence, our research focuses on the setting up of an Exon Skipping based approach to correct the deep intronic mutations of the *GLA* gene. We designed and produced a set of AONs and of U1asRNAs specific to silence both g.9273C>T and g.9331G>A mutations. We also designed three *GLA* minigenes to express the two studied mutations and the wild-type. We tested our antisense molecules against the minigenes by transfection of COS cells. We evaluated the effect by α-GAL A enzyme assay, by Real-Time PCR and by Western Blot analysis. U1asRNAs that we designed promoted the recovery of the α-GAL A activity up to the wild-type level for both g.9273C>T and g.9331G>A *GLA* mutations. Western blot analysis confirmed an increase in the amount of α-GAL A protein produced as a consequence of the treatment with antisense molecules. The analysis of transcripts showed the antisense-induced exon skipping of the criptic exon with an increment of the major *GLA* mRNA. Our study suggests that a new therapeutic strategy based on antisense molecules can be developed and potentially used in the correction of splicing defects in Fabry disease. *Authors wish to express their gratitude to: Fondazione Meyer ONLUS, Florence, Italy (Young Researcher grant to Lorenzo Ferri); Fondazione Meyer ONLUS and Regione Toscana, Italy (grant POR CRO FSE 2007-2013); Italian Ministry of Health and Regione Toscana (Ricerca Finalizzata-2011-02347694); AMMeC Foundation, Italy..*

Nutrient Intake and Growth Patterns among Adult and Pediatric Subjects with Urea Cycle Disorders (UCDs) Participating in Glycerol Phenylbutyrate (GPB) Clinical Trials. *D. Hook[1], G.A. Diaz[2], B. Lee[3], J. Bartley[1], N. Longo[4], W. Berguist[5], C. Le Mons[6], I. Rudolph-Angelich[7], M. Porter[7], B.F. Scharschmidt[7], M. Mokhtarani[7].* 1) Miller Children's Hospital , Long Beach , CA; 2) Icahn School of Medicine at Mt Sinai, New York, NY; 3) Baylor College of Medicine, Houston, TX; 4) University of Utah, Salt Lake City, UT; 5) Stanford University, Palo Alto, CA; 6) National Urea Cycle Disorders Foundation, Pasadena, CA; 7) Hyperion Therapeutics, Brisbane, CA.

Objective: To analyze protein and caloric intake among adult and pediatric UCD patients as well as growth in pediatric patients participating in the GPB (HPN-100, RAVICTI®) clinical trials. Methods: Forty-four adult patients completed a 28 day, randomized, double-blind, placebo-controlled crossover comparison of 24-hr ammonia exposure on GPB vs. sodium phenylbutyrate (NaPBA). Weekly 3-day diet histories were collected. Prescribed and actual protein and caloric intakes were compared to those for healthy individuals (HI) derived from the National Health and Nutrition Examination Survey and current recommendations for UCD patients (UCD-REC). Forty-nine pediatric patients ages 2-mo to 17-yrs received GPB for 12 months at a dose equivalent to their previously prescribed NaPBA dose. Prescribed protein, calorie, height, weight and BMI were assessed at enrollment (baseline) and throughout the 12 month open-label study. Results: In adult patients, mean protein intake was 53-56% of that for HI, greater than UCD-REC, and accounted for 10% of caloric intake vs. 15% for HI. Total caloric intake was ~70% of that for HI and 20-25% less than UCD-REC. There was a positive correlation between blood urea nitrogen (BUN) and total protein intake (r=0.55; p=0.0003). In pediatric patients, mean prescribed protein and caloric intake were 40% to 64% and 92 to 100% of HI and 54% to 97% and 68% to 87% of UCD-REC, respectively. Mean height, weight and BMI z-scores were within 2 standard deviations of normal population at baseline and did not change during the study. BMI correlated negatively with prescribed protein or calories expressed as g/kg/day or kcal/kg/day, respectively, in both adults (protein; r=-0.641; p = 0.007; calories; r=-0.798 p<0.001) and peds (protein: -0.329; p=0.022; calories: r=-0.362 p=0.024), but positively and weakly when expressed as total daily protein (g/day) or calories (kcal/day) in both populations. After 12 months of GPB dosing, the percentage of patients with normal BMI (5-85% percentile) increased from 46% to 59%, those considered obese (>85% percentile) decreased from 50% to 39% and those considered underweight (<5% percentile) decreased from 4% to 2% compared to baseline. Conclusions: Both pediatric and adult UCD patients ingested less protein and fewer calories than HI and more protein, but fewer calories than UCD-REC. Patients' BMI tended to normalize during this 12 month open label and uncontrolled study.

Limited information is available regarding the optimal timing of blood ammonia measurements in patients with urea cycle disorders (UCDs), target ammonia levels, or the relationship of ammonia or glutamine to hyperammonemic crises (HAC). Methods: More than 1000 blood samples obtained from 100 UCD patients chronically treated with sodium phenylbutyrate (NaPBA) who participated in short and long-term glycerol phenylbutyrate (GPB) trials were analyzed with respect to the relationship between fasting ammonia, glutamine and occurrence of HACs over 12-month treatment with GPB. Results: Nineteen of 100 UCD patients (49 pediatric, 51 adults) treated with GPB for 12 months experienced a total of 27 crises compared to 30 patients reporting 53 crises on NaPBA during the 12 months before enrollment. There was a strong positive relationship between fasting ammonia and 24-hr total ammonia exposure (r = 0.764, p < 0.001) and a weak but significant correlation between baseline ammonia and glutamine levels (r=0.27; p = 0.008) that was primarily driven by patients with high ammonia. Baseline fasting ammonia was significantly lower in patients without vs. with a crisis [mean (SD) of 26 (18) μmol/L vs 42(24) μmol/L (p=0.0013)], whereas glutamine was not [mean (SD) of 782 (246) vs 732(186) μmol/L; (p=0.150)]. Similarly, during 12 months of GPB dosing, ammonia values were significantly lower in patients without vs. with a crisis whereas glutamine values were not. For every 10 or 25 μmol/L increase in total ammonia exposure over 12-months, the relative risk of a HAC increased, by 50% and >200% (p<0.0001) respectively. Among patients ≥ 6 years of age (N=77) in whom fasting ammonia can be reliably measured, the relative risk of a HAC was 20 times higher (p = 0.009) in patients with fasting ammonia ≥ 1.0 ULN vs. < 0.5 ULN. Patients with or without a crisis did not differ in terms of other baseline variables often associated with severity of illness such as age, UCD subtype and gender. Conclusions: As compared with glutamine, fasting ammonia correlates strongly and positively with total daily ammonia exposure as well as the long-term risk and rate of HAC. These findings suggest that tight ammonia control (<0.5 ULN) deserves further study as an approach to improving long-term outcome in UCD patients.

2299T

Gene trap of *NDUFS4* in mouse is a viable model of mitochondrial complex I deficiency. *B. Graham[1], T. Donti[1], Y. Lai[2], M. Ge[1], S. Ather[3], R. Lucero[1,4], R. Paulter[3], J. Noebels[1,4], X. Wehrens[3], W. Craigen[2].* 1) Dept Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept Pediatrics, Baylor College of Medicine, Houston, TX; 3) Dept Molecular Physiology & Biophysics, Baylor College of Medicine, Houston, TX; 4) Dept Neurology, Baylor College of Medicine, Houston, TX.

Mitochondria are essential for many fundamental cellular processes, including energy production, ROS metabolism, Ca2+ homeostasis, and apoptosis. Dysfunctional mitochondria frequently result in multiorgan disease that can include neuronal, cardiac and muscular pathology. Mitochondrial complex I is comprised of approximately 45 subunits and is most often implicated in mitochondrial disease. NADH:ubiquinone oxidoreductase iron-sulfur protein 4 (NDUFS4) is one of the nonenzymatic, nuclear-encoded subunits of complex I that is essential for assembly. Defects in *NDUFS4* cause complex I deficiency and a Leigh-like neurological phenotype in humans that typically result in death within 3-16 months of birth. Heart dysfunction is also a common phenotype in primary mitochondrial disease, typically presenting in the context of multi-systemic disease and can manifest as a cardiomyopathy and/or as cardiac arrhythmias. From the International Gene Trap Consortium, mouse embryonic stem (ES) cells that contain a gene trap insertion in *Ndufs4* were obtained and used to generate transgenic animals. Homozygous mutant mice show reduced levels of NDUFS4 protein in various tissues by Western blot. While *Ndufs4* mutants exhibit partial embryonic lethality, surviving adult mutants are able to survive for at least eighteen months. *Ndufs4* mutant animals exhibit partial complex I deficiency, increased oxidative stress in brain and heart, and defects in cellular and mitochondrial respiration. They also exhibit neuronal dysfunction manifested by constitutively abnormal electroencephalograms (EEGs) associated with intermittent myoclonic seizures, as well as increased sensitivity to kainate-induced seizures. In addition, three-month-old mutant and matched wild type *Ndufs4* mice were analyzed by electrocardiography and transthoracic echocardiography. These mutant mice exhibited cardiac arrhythmias combined with left ventricular dysfunction. Mutant animals also exhibited a 30% increase in heart weight normalized to body weight. In summary, *Ndufs4* mutant mice homozygous for a gene trap insertion represents a viable model of mitochondrial complex I deficiency that exhibits increased oxidative stress with neurological and cardiac dysfunction. Comparing the cardiac phenotype of this constitutive *Ndufs4* mutant model with a previously published cardiomyocyte-specific *Ndufs4* conditional knockout (PMID 23931755) suggests that a non-cell autonomous mechanism may be playing a pathogenic role.

A Molecular Genetic Study of Indian Patients with Glycogen Storage Disorders reveals Six Novel Mutations. *S. Shetty[1], V. Tejaswini[1], M. Bhat[1,2], R.K. Sanjeev[4], S. Jagdeesh[3].* 1) Centre for Human Genetics, Bangalore, India; 2) Indira Gandhi Institute of Child Health, Bangalore, India; 3) Fetal Care Research Foundation, Chennai, India; 4) Base Hospital, Delhi, India.

Glycogen Storage Disorders (GSDs) are a set of autosomal recessive conditions caused by mutations in genes that govern different aspects of the glycogen metabolic pathway. Depending on the enzyme that is deficient, the GSDs are classified into 12 different types. GSDs have been a very complex set of diseases to deal with due to the variation in the presenting clinical features, which tend to overlap between types. There are differences not only in the reports of incidence rates in the different types of GSDs but also in establishing which type might be the most commonly occurring/observed GSD. GSD-I, III and VI seem to be the most common among the GSDs and their overlapping phenotypes leads to their grouping which then requires us to take on a differential diagnosis approach with genetic testing. GSD-1 is further divided into Ia and Ib. GSD-Ia is caused by a deficiency of the microsomal glucose-6-phosphatase (*G6PC*) in the liver, kidney, and intestinal mucosa and is indicated as such by an excessive accumulation of glycogen in these organs. Patients with GSD-Ia often suffer from hepatic adenoma/hepatoma, renal insufficiency, and pulmonary hypertension. Distinguishing Ia from Ib necessitates an assay of G6Pase activity in a liver biopsy. GSD-Ib, caused by mutations in the Glucose-6-phosphate translocase (G6PT or *SLC37A4*) shows similar symptoms to GSD-Ia with a few patients exhibiting neutropenia, inflammatory bowel disease and/or recurrent infections. Deficiency of the Glycogen debranching enzyme causes GSD-III. The variable phenotype encountered is explained by differences in tissue expression of the defective enzyme coded by the *AGL* gene and when deficient in both liver and muscle, it is sub-grouped as GSD-IIIa but when the enzyme deficiency is observed only in the liver it is considered as type IIIb. Our initial studies on a set of forty Indian patients, who could all come under one of the three GSD groups named above, have revealed six novel mutations. Four in patients with GSD-1a, one in a patient with GSD-Ib and one with GSD-III. Genetic testing has been fraught with problems encountered in classifying GSDs, as clinical features are not clearly distinguishable between types and genotype-phenotype correlations remain largely indistinct. Our study also illustrates that the Indian population may harbour a much greater variation in mutations as we did not find any of the common or hitherto reported mutations.

Stable Isotope Breath Tests to Assess Metabolite Flux in Methylmalonic Acidemia (MMA). *E.A. Harrington[1], I. Manoli[1], Y. Ktena[1], S. Smyth[2], J. Hattenbach[2], J. Senac[1], J. Sloan[1], K. Chen[2], C.P. Venditti[1].* 1) GMBB, NHGRI, Bethesda, MD; 2) Clinical Endocrinology Branch, NIDDK.

Isolated methylmalonic acidemia (MMA), caused primarily by a defect in the mitochondrial enzyme methylmalonyl-CoA mutase (MUT), is characterized by metabolic instability, multiorgan pathology, and a poor prognosis for long-term survival. Elective liver (LT), kidney (KT) or combined liver kidney transplantation (LKT) are used to stabilize severely affected patients. Secondary mitochondrial dysfunction, characterized by aberrant ultrastructure and decreased complex IV activity, is observed in patient and murine tissues. Mice that express the *Mut* gene under the control of a muscle-specific creatine kinase promoter ($Mut^{-/-}$;$Tg^{INS\text{-}MCK\text{-}Mut}$) were used to probe metabolism of various ^{13}C-isotopomers. These animals are rescued from neonatal lethality but display severe metabolic perturbations, growth retardation, and a hepatorenal mitochondriopathy. 1-^{13}C-propionate oxidation was used to assess *in vivo* Mut activity, while 1-^{13}C-methionine, glycine, α-ketoisocaproic acid and octanoate oxidation were studied as secondary pathways dependent on mitochondrial function. $Mut^{-/-}$;$Tg^{INS\text{-}MCK\text{-}Mut}$ mice displayed decreased propionate (P=0.003), methionine (P=0.03) and glycine (P=0.008) oxidation. We subsequently administered 1-^{13}C-propionate to 6 controls (age range 35-62y) and 16 patients with isolated MMA (*mut* N=12, *cblA* N=3, *cblB* N=1, age range 9-41y). Resting energy expenditure was measured and serial breath samples were collected following an oral or G-tube bolus of the isotopomer. Decreased 1-^{13}C-propionate oxidation was observed in all MMA patients vs. controls (P<0.0001). The most severe *mut* patients, who carried two stop mutations (N=3), showed almost no metabolism of label, despite isolated KT in one patient. LKT recipients (N=2) showed a complete restoration of oxidation rates to control levels (P=0.004 compared to non-transplanted patients), while only minimal oxidation was evident in a recipient after a auxiliary liver allograft and KT. B12-responsive patients with KT (N=2) showed near normal recovery. ^{13}C breath testing with varied isotopomers represents a non-invasive method to assess whole body *in vivo* MUT activity and resulting secondary metabolic perturbations, and could be used as prognostic or outcome measure to study interventions, such as B12 supplementation, transplantation or gene therapy in MMA patients. These methods could be readily applied to other disease states where branched-chain amino acid oxidation and mitochondrial function are disturbed.

Diagnosis of Lesch-Nyhan syndrome in an 8-year-old male referred by nephrology for elevated serum uric acid. *L. Pugliesi, P. Gupta, L. Ely.* Genetics Division, St. Joseph's Regional Medical Center, Paterson, NJ.

Lesch-Nyhan syndrome (AHC [MIM 300322]) is an x-linked genetic condition characterized by elevated uric acid production, neurological abnormalities, and distinct behavioral changes. We present an 8 year old male initially referred to our clinic by nephrology for elevated serum uric acid levels. Medical history is significant for cognitive delay and diagnosis of cerebral palsy made at eleven months of age. The patient displayed finger picking and head banging at four years of age and first presented with lip and finger biting at seven years of age. He was consequently diagnosed with an anxiety disorder due to the self-injurious behaviors. He utilizes a wheel chair and elbow restraints and is post-surgical bilateral hip osteotomy. Family also reports a history of abnormal sleep patterns. Nephrology evaluation noted intermittent discoloration of urine, urethral discharge, and abnormal kidney ultrasound identifying echogenic kidneys with acoustic shadowing in the cortical and pelvic area. Physical evaluation was significant for dysmorphic features, mutilated lower lip, removed incisors, mild scoliosis, tight heel cords, increased tone, abnormal deep tendon reflexes, hyper-reflexive elbows, and bilateral ankle clonus. Family history reveals recurrent miscarriage in his mother, and a maternal uncle with intellectual disability of unknown etiology. Upon genetics evaluation, Hypoxanthine-Guanine Phosphoribosytransferase enzyme testing and *HPRT1* (AHC [MIM 308000]) sequence analysis were completed both confirming a diagnosis of Lesch-Nyhan Syndrome. We present this case to demonstrate how misdiagnosis of individual symptoms may lead to a delayed diagnosis of an over encompassing genetic syndrome. We also aim to bring awareness to the common findings associated with Lesch-Nyhan syndrome to aid health care providers in identifying early signs and symptoms and thus to achieve a diagnosis in affected individuals.

The UDP Self Study Short Course for Genome Wide Analysis. *T.C. Markello[1,2], C.F. Boerkoel[1,2], W.A. Gahl[2], E. Valkanas[1,2,3], E.D. Flynn[2], W.P. Bone[2], A.E. Links[2], C.J. Markello[2], P.J. Pemberton[2], D.R. Adams[1,2], NIH Intramural Sequencing Center, NIH Genomic core, and UDP Clinicial Team.* 1) Med Gen Branch, NIH/NHGRI, Bethesda, MD; 2) NIH Undiagnosed Diseases Program, Office of the Director Common Fund and NHGRI, NIH, Bethesda, MD; 3) Clinical Director, NHGRI/NIH, Bethesda, MD.

Since 2008 the NIH Undiagnosed Diseases Program has found many types of Mendelian and non-Mendelian genetic and molecular mechanisms for human diseases in patients referred to the program. These include: Homozygous recessive cases of identity by descent with parental consanguinity, compound heterozygous recessive alleles including double point mutation pairs, point mutation/deletion pairs and double deletion null allele pairs, unique de novo dominant new mutations, de novo dominant with transmission to the third generation mutations, moasicism including both fixed ratio and progressive telomere shortening, duplications, and a form of variant discovery we call extreme novel findings. These discoveries all occurred in single nuclear families with one exception and typically with only one or two probands. Many are CLIA certified and some are published, with the remainder in various stages of cell biological validation. To teach the techniques that systematically find these types of variants in single families, we have taken 20 such cases and generated a set of self-study exercises, along with a set of 4 narrated power point presentations, and a total of 150 pages of exercise and reference manuals. These cases include annotated VarSifter (and/or .vcf) files, .bam files, take up approximately 800GB of storage, but to run these files currently requires a Windows based 64bit machine with a minimum of 64GB of RAM. We are currently anonymizing this data, and other ongoing interesting other UDP cases, to allow general distribution. We hope that these cases can be used to instruct future generations of genome wide analysts in the UDP agnostic search strategies gained from our real world examples, and practical experiences.

2304S

Effectiveness of Personalized Genetic Education Modules. *A. Jenks, S. Darabi, J. Eggert.* Clemson University, Clemson, SC., USA.

Effectiveness of Personalized Genetic Education Modules Applied genetic therapies and personalized medicine urge the necessity of genetic education for clinicians. Specifically there is a need for education about how to utilize available genetic technologies for practice and how to translate available genetic information into specialty practice. In 2012 Powell et al. reported that only %15 of clinicians feel knowledgeable enough to utilize genetic medicine in their clinic. If genetic medicine is to converge with personalized medicine, then doctors in specialty practice need to be equipped to better utilize and interpret genetic technologies. The purpose of this study was to determine the effectiveness of specialty department personalized genetic education modules for clinicians in hospital settings using pre and post-test measures. For the project, two researchers provided independent presentations on specialty focused genetics in the clinic of two different departments in a large community hospital in the Southeast region of the United States. Before the presentation, both researchers met with department staff to discuss need, observed the assigned departments and developed the presentation content based on identified needs. Pre and post-tests were designed based on the presentations and given to the staff in each department to determine the effectiveness of the presentation to increase clinicians' understanding of genetics and attitudes toward genetic medicine. Overall the researchers found little increase (%9.61) in genetic knowledge. This research is a baseline study to determine the effectiveness of specialty department based personalized education modules for clinicians. Results from this project indicate that healthcare professionals are already being taught the theory of genetic medicine but that application based modules are necessary for clinicians to be open to the importance of personalized genetic medicine to their specialty practice. Reference Powell, K. P., Cogswell, W. A., Christianson, C. A., Dave, G., Verma, A., Eubanks, S., & Henrich, V. C. (2012). "Hey Doc, here is my DNA sequence, what do you think?". *M. Kriek[1,2], H. Sminia[2], C.E. van der Meer[3], I. Arnold[3], E. Aten[1], M. Koopmans[1], A. van Haeringen[1], M.H. Breuning[1], T. Vrijenhoek[4], J.T. den Dunnen[2,1].* 1) Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 3) Workgroup Promotion of expertise General Practitioners Rijnland, Netherlands; 4) Center for Genome Diagnostics, Department of Medical Genetics,-University Medical Center Utrecht.

When my General Practitioner (GP) fell from his chair when I opened my laptop to check whether the drug prescribed matched with my genome, I realized there was a problem. Although DNA-based medicine is at the doorstep, GPs are not trained in this direction and therefore they lack the knowledge to correctly interpret complex clinical data. To bridge this gap, we developed an unique educational project that prepares physicians for their role in the near future; they were trained to translate genome-wide analysis data to the patient's specific clinical situation. The educational module was set up in close collaboration with members of the target group (e.g. GPs) to help us define the most informative and comprehensive way of communication about this subject. The module consisted of: 1. refreshment of genetics through polling 2. case studies 3. genetic gift card 4. practical (bitter tasting and genetic variants) 5. future perspectives. A total 210 GPs participated in the 195-minute genetic training session and afterwards an evaluation form was completed by each participant. There was a difference in appreciation of the educational module between the ' old and the new' generation GPs; the overall rating was 7.9 (scale from 1-10). The majority of the participants was especially interested in Pharmacogenomics (drugs/genes) and pedigree based clinical decision making. And, of great importance, the training lowered the threshold to contact the clinical geneticist. We will elaborate on the content of educational module prior to disclosing the results of the evaluation by the 210 GPs and, finally, we will summarize the lessons learned.

Teaching Genomic Medicine to Physicians - this is our responsibility as medical geneticists !!! *I. Maya[1], L. Basel-Vanagaite[2,3,4], E. Taub[1], A. Koifman[5,6], DM. Behar[7], R. Tomashov-Matar[1], R. Sukenik-Halevi[8], A. Reches[9], M. Hubshman Weiss[1,3], N. Orenstein[1,3], D. Marom[2,10], M. Shohat[1,2].* 1) Rabin Medical Center, Petah Tikva, Israel; 2) The Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Pediatric Genetics, Schneider Children s Medical Center of Israel, Petah Tikva, Israel; 4) The Raphael Recanati Genetic Institute and Felsenstein Medical Research Center, Rabin Medical Center, Petah Tikva, Israel; 5) Institute of Human Genetics, Soroka University Medical Center, Beersheba, Israel; 6) Ben-Gurion University of the Negev, Beersheba, Israel; 7) Rambam Medical Center, Haifa, Israel; 8) Meir Medical Center, Kfar Saba, Israel; 9) Souraski Medical Center, Tel Aviv, Israel; 10) Pediatrics A, Schneider Children s Medical Center of Israel, Petah Tikva, Israel.

Background: Due to the transition of genetic knowledge from research laboratories into clinical practice the new field of "Genomic Medicine" has emerged. Primary care practitioners are facing this era with inadequate knowledge and skills in medical genetics and many are unaware of the technical, ethical, legal and psychosocial implications of genetic testing. The challenges of translating genomic technologies into health care practice require novel approaches to educate existing and future clinical physicians from all medical fields. Methods: We initiated a "genomic education" program for the purpose of providing physicians from different medical fields and from all phases of their medical carrier an advanced knowledge in genomic medicine . In the last 2 years since we initiated the program we are organizing 4 courses a year, both in Rabin Medical Center and in Tel Aviv University. We emphasized the main take-home messages for physicians, defined as: risk calculation for various genetic diseases, recognition of the mode of inheritance from pedigrees, guidelines for decision-making on which technique to use, interpretation of test results and their clinical implications. Results: To date, 111 physicians have participated in 7 courses of our "genomic education" program, which included lectures, workshops and guided tours in genetic laboratories. The physicians that participated in our program came from 14 different hospitals and 2 HMO in Israel. Two thirds where senior physicians defined as specialists for more than 10 years, and 1/3 were junior physicians (both residents, fellows and young specialists). In the "pre-course" examination the average score was 56%, the median was 55% (range 20%-80%), whereas in the "post-course" examination it was 78%, Median 80% (range 40%-100%). The average improvement in score as a result of the course, both for junior and senior physicians was 20% (range 0%-80%). The physicians who participated in our program reported a very high level of satisfaction from the theoretical and practical knowledge they acquired as well as the concept of a "one-week update course". Conclusion: A one-week "genomic education" program is an effective strategy to update physicians regarding the advances in Genomic Medicine in order to improve their care of patients.

Medical Student Confidence and Knowledge about Hereditary Retinoblastoma. *J. Govindavari, A. Nath, W. Blazey, D. McMahon, T. Chan, D. Tegay, B. Krishnamachari.* NYIT College of Osteopathic Medicine, Old Westbury, NY.

Background: In the pediatric population, hereditary cancer predispositions are associated with ~5-10% of all cancer diagnoses. Early identification and treatment of hereditary cancer syndromes often significantly improves likelihood of survival. The level of physician knowledge regarding pediatric hereditary cancer syndromes is currently unknown. Assessing pediatric hereditary cancer knowledge amongst physicians and physicians in training, including medical students, is crucial. The goal of this study was to assess perceived confidence in knowledge, and actual knowledge, of pediatric hereditary cancer syndromes in medical students, with a focus on retinoblastoma (RB). Methods: Medical students answered questions regarding confidence in knowledge about hereditary cancer and knowledge-based question derived from national clinical guidelines and recently published literature. 239 students completed the survey. Results: When analyzed by year in school, the four years differed in confidence of their knowledge of hereditary cancer (p=.02), with the highest percentage of students feeling confident in year 2 (42.0%). However, there was no statistically significant difference between class years in terms of answering knowledge questions correctly. Students who felt confident in their knowledge of hereditary cancer were more than 2 times more likely to know that the risk for extra-ocular primary neoplasms is increased in individuals with hereditary RB [OR 2.30 (1.08, 4.91)] and were more than 3 times more likely to know "that genetic screening of the RB1 gene should be considered in any child with bilateral RB" [OR 3.42(1.11, 10.54)], after adjusting for age and years in school. Conclusion: Confidence was associated with knowledge, but knowledge was not associated with increased years of schooling. Students felt most confident in their second year, and less so in their third and fourth years. The increased confidence during year 2 may have been due to students preparing to take their initial board exam. More research is needed to understand the cause of the differences in confidence and knowledge between the four years of medical school classes with extension to assessment of knowledge and confidence in medical residents and attending physicians.

Creation of a genetics education program for OB/GYN resident physicians. *C.M. Osborne[1], E. Hardisty[1], C. Vladutiu[2], N.L. Vora[1].* 1) The University of North Carolina at Chapel Hill, Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, Chapel Hill, North Carolina; 2) The University of North Carolina at Chapel Hill, Department of Epidemiology, Chapel Hill, North Carolina.

Background: Educators in genetics have previously acknowledged that practicing physicians have limited knowledge about genetics, genetic testing options and the implications for medical practice. This deficit is expected to increase as the breadth of genetics knowledge continues to increase exponentially. Prior studies have suggested that a greater emphasis on genetics education is needed at all levels of medical education, including OB/GYN resident programs. Methods: Three hours of educational workshops were developed for OB/GYN resident physicians at the University of North Carolina at Chapel Hill. The educational workshops were intended to increase the residents' exposure to, and knowledge of, clinical and reproductive genetics. The seminars were presented over a three week period, with a one-hour lecture being administered each week. Curriculum content included common fetal aneuploidies, structural chromosome rearrangements, pedigree analysis, Bayesian analysis, risk analysis, application of Hardy-Weinberg equilibrium, ethnicity-based carrier screening and hereditary cancer syndromes. Lectures were created with input from reproductive genetic counselors, Maternal-Fetal Medicine specialists and clinical geneticists. A 14-question, multiple choice pre- and post-test were administered to all resident physicians to determine if overall understanding and knowledge of clinical genetics increased over the three week course. Answers were collected and analyzed anonymously. Pre- and post-test scores were compared using the Wilcoxon Mann Whitney test. Results: Thirteen pre-tests and 13 post-tests were submitted for analysis. The median (interquartile range, or IQR) scores were 8 (6-8) for the pre-test and 10 (9-12) for the post-test. The difference between underlying distributions of the scores from the pre-test and scores from the post-test groups were found to be statistically significant ($z = -2.6888$, $p = 0.0126$). Conclusions: Creation of an intensive genetics curriculum for OB/GYN resident physicians appeared to enhance the understanding of clinical and reproductive genetics among participants. As the complexity and utilization of genetic testing continues to increase in the prenatal setting, implementation of genetics education for the OB/GYN resident physicians should be considered.

2309S

Preparing future physicians to practice genomic medicine: Lessons from the first two years of the University of Miami Master of Science in Genomic Medicine program. *W.K. Scott[1,2], S.E. Hahn[1,2], S.C. Sacharow[1,2], M. Tekin[1,2], E. Rampersaud[1,2], B. Johnson[1], G. Ghaffari[1], E.M. Bendik[1,2], J.M. Vance[1,2].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Needs Assessment: One barrier to the implementation of genomic medicine in the clinic is the concern among physicians that they do not have the knowledge needed to use genomic information in patient care. Lowering the barrier requires training at three levels: medical school, residency, and continuing education. While medical schools should be the leaders in this educational effort, curricula are saturated with topics required for subsequent board exams. **Rationale**: To address this barrier in medical school, we have created a 4-year Master of Science program in Genomic Medicine (MSGM) that is completed concurrently with the medical curriculum. Students apply to the program in the first semester of medical school and instruction begins in the second semester. **Course Content**: MSGM topics were selected by faculty with expertise in genomic medicine, genetic counseling, clinical and human genetics, epidemiology, statistics and laboratory science. Topics include ethical, legal, and social issues in genomic medicine; computational methods; bioinformatics; clinical laboratory methods and technology; pharmacogenetics, and research ethics. The first 3 semesters also contain courses in clinical applications of genomic medicine that examine cases from physiological systems studied in the medical curriculum. **Teaching Strategies**: A *flipped classroom* model is used the first 2 years. Didactic materials (lectures, media, interactive modules) are provided online for self-directed learning. Lessons are reinforced by weekly small-group discussions of core topics and examples from medical literature. The final 2 years include a 4-week clinical genetics clerkship and a practicum consisting of clinical experience and research performed with a faculty mentor. **Outcomes**: In total 17 students (5 in the first class, 12 in the second) have enrolled in the MD/MSGM program. All have continued to be successful in the medical curriculum. All reported satisfaction with the current structure and curriculum and believe the knowledge acquired will enhance their future clinical practices regardless of anticipated specialty. A frequent suggestion was to increase coverage of clinical applications and to reduce research-oriented discussions. This suggests students chose the program to acquire knowledge in genomic medicine, and not as a path to research careers. We believe this is a viable approach to prepare future physicians to incorporate genomic medicine into their daily clinical practice.

2310S

Building Integrated, Individualized, Themed Genetics Electives for Resident Trainees at Johns Hopkins. *T. Wang[1, 2], J. Bodurtha[1], P. Sosnay[3], H. Vernon[1], J. Fahrner[1,2], N. Green[4], C. Thomas[1,2], D. Augustyniak[4], B. Shapiro[4], D. Valle[1,2].* 1) Inst Gen Med, Johns Hopkins Univ, Baltimore, MD; 2) Medical Genetics Residency Program, Johns Hopkins University, Baltimore, MD; 3) Department of Internal Medicine, Johns Hopkins University; 4) Kennedy Krieger Institute, Baltimore, MD.

Needs and Objectives: With the rapid advances in clinical genomics and individualized medical care, genetic contributions to all diseases are increasingly recognized. Genetics residents and other healthcare providers at all levels need enhanced genetics education. The existing one-size-fits-all genetics elective provides only partial exposure to the broad range of genetics conditions. More than 40 clinics, centers, and clinical programs exist at Johns Hopkins to care for patients with individual genetics conditions. The educational potentials of these resources are much under-utilized for residency training due to lack of coordination and organization. We aim to organize campus-wide clinical genetics resources at Johns Hopkins to build integrated, individualized, and themed electives in medical genetics for resident trainees in genetics and other specialties. **Setting**: Specialized clinics, centers, and programs caring for genetics patients at Johns Hopkins and Kennedy Krieger Institute (KKI). **Participants**: Second year residents in medical genetics programs at Hopkins (n=5). **Descriptions**: We built four themed electives including Adult Genetics, Biochemical Genetics, Clinical Genomics, and Syndromes & Malformations. Each resident will (1) meet with elective directors to discuss their background, interests, and training goals, (2) select 4-6 clinics of their interest among participating clinics at Johns Hopkins and KKI to build his/her own individualized, themed elective plan, (2) participate in all clinical educational activities during the elective (2-4 weeks), (3) study online teaching materials related to the elective theme, (4) directly interact with elective directors and attending physicians (5) contribute to 1-2 case summaries or presentations, and (6) participate in online evaluations before and after the elective to assess progress toward objectives. **Evaluation**: direct feedback, structured survey, and online evaluations by attending **Lessons Learned**: All participating residents are very enthusiastic about these electives. They particularly like that these electives are tailored to individualized interests and learning objectives, and are more efficiently support them to meet their educational goals. 90-95 percent of the residents consider these electives from “very good” to “excellent” and will recommend to other trainees in genetics. Online teaching resources and evaluation tools are being developed.

2311S

Personal Pharmacogenetic Testing in the Medical School Curriculum: Student Knowledge and Attitudes. *S.C. Sanderson[1], S.A. Scott[1], N. Schrager[1], M. Zweig[1], L. Shi[1], A. Kasarskis[1,2], G.A. Diaz[1].* 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY 10029.

As increasing numbers of personalized medicine programs have begun to pre-emptively genotype pharmacogenetic variants, the utilization of clinical pharmacogenetic testing is escalating. The recent publication of clinical practice guidelines has facilitated this process, but concern over the lack of expertise among clinicians to interpret pharmacogenetic test results is often cited as a barrier to uptake. To assess the effects that direct experience with pharmacogenetic testing have on knowledge and attitudes about pharmacogenetics, medical students at the Icahn School of Medicine at Mount Sinai were offered the option of being anonymously genotyped for actionable variants in CYP2C9, CYP2C19, CYP2D6, and VKORC1 through the CLIA-certified Mount Sinai Genetic Testing Laboratory as part of their medical genetics and genomics training. After an introductory presentation, all students were given the option of receiving personal or example genotype reports, and simultaneously offered the opportunity to participate in a research protocol assessing knowledge and attitudes on pharmacogenetics using a structured survey before and after the educational module. In the first year of the program, 93 out of 140 (66.4%) second year medical students opted for personal pharmacogenetic testing. Among those who answered the pre-course questionnaire (86.0%), decisional conflict scores were low, indicating that this decision was made easily by most students. Almost half (45.7%) believed the information would not be medically useful or change medical decisions, and 42.9% felt that pharmacogenetic testing costs too much. The strongest reasons in favor of testing were general curiosity (91.0%), to understand what a patient may learn or experience (91.4%), and to help get a better understanding of human genetics (91.4%). Importantly, knowledge about pharmacogenetics was significantly higher after compared to before the course (p=0.03), and the proportion of students who stated that physicians have a professional responsibility to help individuals understand pharmacogenetic testing results, even if the physician has not ordered the test, significantly increased from 8.6% before to 14.3% after the course (p= 0.021). These results suggest that given the option to undergo pharmacogenetic testing and receive their personal results as part of their training, the majority of medical students opt to do so, and that this may have a positive impact on their educational experience.

2312S

Dissecting the genetic susceptibility to sporadic molar pregnancies and mechanisms of their formation. *Y. Khawajkie[1], NMP. Nguyen[1], W. Buckett[2], P. Sautier[3], M. Breguet[3], R. Slim[1].* 1) McGill, Montreal, Canada; 2) Obstetrics and Gynecology, McGill University Health Center, Montreal, Quebec, Canada; 3) Service de Gynécologie Oncologique, Hôpital Notre-Dame, Université de Montréal, Montréal, Québec, Canada.

A hydatidiform mole is an abnormal human pregnancy characterized by absence of, or abnormal, embryonic development, excessive trophoblastic proliferation, and hydropic degeneration of placental villi. The common types of moles are sporadic and affect 1 in 600 pregnancies in western countries. Among patients with one mole, up to 20% have a second reproductive loss, which is higher than the incidence of recurrent SAs in the general population (2-5%). This indicates that these patients are genetically susceptible to reproductive loss. Based on the parental contribution to sporadic molar tissues, there are three main genotypic types of moles: diploid androgenetic monospermic, diploid androgenetic dispermic, and triploid dispermic. However, it is not known whether these three genotypic entities have the same genetic predisposition to reproductive loss. In addition, it is not known whether the other forms of reproductive loss in women with one mole are caused by the same or by different mechanisms. To address these questions, we compared the reproductive histories of patients with the three genotypic types of moles with each other and with those of patients with recurrent spontaneous abortions and no moles. We then used flow cytometry, fluorescent microsatellite genotyping, and fluorescent in situ hybridization on a total of 69 pregnancy losses from 50 patients to determine the parental contribution to all their available products of conception. At the meeting, we will present our comprehensive analysis and discuss the genetic susceptibility and mechanisms of pregnancy losses in patients from the three categories of sporadic moles and patients with recurrent spontaneous abortions and no moles.

2313S

Kyoto Model of developing a genetics education program in Japan. *N. Akiyama[1], M. Torishima[1], T. Katayama[2], T. Wada[1], S. Kosugi[1].* 1) Kyoto University Graduate School of Medicine, Kyoto, Kyoto, Japan; 2) Osaka Prefectural Hirakata High School.

[Introduction] Genetic technology has been advancing rapidly and genetic tests are becoming increasingly common in Japan. The curriculum of primary, junior high, and high schools in Japan includes little information regarding human genetics. In order to improve genomic literacy in Japan for this dawning genomic era, we have started developing a genetics educational program for ordinary people, schoolchildren in particular. [Methods and Results] (1) Exhibition of human genetics at several events at universities or in society: (a) A two-hour exhibition with more than 60 groups from all faculties in a one-day event at Kyoto University. We exhibited a DNA model (zometool®), illustrated books about genetics, a quiz game in a PowerPoint file, and extraction of DNA from a chicken liver. We discussed genomic topics with participants who ranged from young children to adults. (b) At a two-day Kids Festival event at Kyoto railway station. More than 3000 kids and their families participated in the event, and more than 500 come to our section on human genetics among eight scientific exhibitions from Kyoto University. Families observed human chromosomes with a microscope and studied DNA and chromosomes with genetic counselors. (2) Lectures in a high school biology class: We conducted three 50-minute lectures on human genetics. We discussed several genetic subjects, including genetic tests for HBOC and prenatal diagnosis for Down syndrome by NIPT. The lecturer is a student earning their master’s degree in genetic counselling. Students studied the basic of human genetics and how to draw a family chart. (3) Seminars on human genetics for primary school pupils: We plan to have several seminars for 20 schoolchildren each time during weekends or on summer vacation. Each four-hour seminar will be composed of lectures on the basics of human genetics, an exercise on DNA extraction, drawing of the family tree, and discussion of genetic topics. [Conclusions] Our project is unique in that master’s students or certified genetic counselors are leading the project. The purpose of our project is to familiarize children and parents with human genetics, to enable them to appreciate genetic information so they can better manage their health. It is important that we consider how and what we should teach about human genetics to children and students. We have just started the program, and it will take time to evaluate our project.

2314S

Attitudes and Response to Genetic Risk Information Among Adolescents. *C. Bloss[1], B. Darst[1], B. Daley[2].* 1) Scripps Genomic Medicine, Scripps Translational Science Institute, La Jolla, CA; 2) High Tech High, San Diego, CA.

Genome sequencing with pediatric populations is currently being performed, however there is little data on the impact of genetic risk information on younger individuals. Furthermore, most work in this area is focused on specific clinical populations, and the voices of minors themselves are often overlooked with most studies focused on parents. The current, school-based study assessed attitudes and response to genetic risk information in group of tenth graders before and after an educational seminar on genomics and personalized medicine. Students recruited from a local group of San Diego charter schools attended an educational seminar on genetics and genomics and then received information about a test of genetic risk for complex disease and drug response traits within the context of an analogue study design. Specifically, each participant was randomly assigned to one of four conditions, which varied by the number of diseases or drug response traits that showed a high risk result. Students completed demographic, attitudinal, and behavioral assessments before and after the seminar and exposure to the analogue vignette. 140 students across three biology classrooms were offered participation. Of those, 80 students enrolled and completed both the baseline and follow-up assessments. All participants were in the 10th grade and ranged from 15 to 17 years of age. There were no significant differences in emotional response between students in the four genetic risk conditions. Analyses of follow-up data also showed significantly lower anxiety towards genomic testing than the already low levels reported at baseline before the seminar. Further, after attending the genomics seminar, students' knowledge of genomics increased significantly and a large majority of students said that they would consider undergoing genetic testing if it seemed warranted. Our findings suggest a lack of adverse emotional responses among adolescents exposed to genetic risk information. While analogue methods cannot perfectly replicate reality, previous studies suggest that responses to risk information observed in such studies are similar to those seen in actual clinical situations. Although studies with larger samples are needed, these results also highlight the utility of education programs for minors to increase genomic literacy. Such efforts are critical given that the youngest members of our society are likely to be increasingly exposed to genomic medicine as they develop into adulthood.

Teaching the relationship between genotype and phenotype with public data and Molecule World™ on the iPad. *TM. Smith, SG. Porter.* Digital World Biology LLC, Seattle, WA.

It is impossible to grasp fundamental concepts in biology without understanding the relationship between sequence, structure, and function. Modern data collection technologies are creating enormous data resources that can be used to help students' understand these relationships, but currently are underutilized. This is due to the fact that easy-to-use tools that meet teachers' needs for clear instruction are not yet commonplace. Filling the gap between the embarrassment of data riches and practical classroom use requires three things: user-friendly tools, content that demonstrates specific applications with interesting stories, and packages that combine instruction, assessments, and inquiry-based investigations.

Digital World Biology is addressing this need with its on-line courses and mobile apps. The on-line courses increase students' computer literacy while using standard tools like Cn3D, Blast, ORF finder, and multiple databases, in directed and exploratory ways, and help students better understand biology as well gain a better appreciation for the value of the data and the field of bioinformatics. In response to nearly two hundred interviews with K-12 and college teachers and students, we created Molecule World and the Molecule World DNA Binding Lab™ iPad apps to display 3D-data from multiple structure databases (MMDB, PDB, and PubChem) using a novel rendering engine that allows us to uniquely highlight chemical properties and sequence orientation. The ability to display and highlight sequences within molecular complexes enables exploration into the relationships between sequence, structure, and function in new ways. Preliminary data collected in professional development workshops, and many demonstrations, supports the hypothesis the being able to view and simultaneously interact with data improves teaching capabilities and student engagement. This work has been supported by NSF grant IIP 1315426.

Teaching the genome generation, a laboratory intensive high school genomics and ethics course. *C. Wray[1], M. McKernan[1], D. Waring[2].* 1) Genomic Education, The Jackson Laboratory, Bar Harbor, ME; 2) Personal Genetics Education Project, Harvard Medical School, Boston MA.

To increase genetic and genomic literacy and train the next generation of scientists, we have developed, tested and assessed an intensive Genomic Biology course, entitled Infinite Variations, Personalized Medicine and Genomics. The course is multi-faceted and includes bench molecular biology experiments, bioinformatics exercises and focused bio-ethics discussions. The goals of the course are four-fold. First the course introduces the complexity of human genetic and genomic variation and stresses the importance of individual variants. Rather than discussing mutant and wild-type alleles, the course highlights the fact that every genome is rife with single nucleotide polymorphisms (SNP), insertion-deletions (indels), and structural or copy number variants (CNV). Second, at the hands-on skill level, the course instructs students in the use of molecular assays used to detect genetic variation. Four experimental modules and a panel of de-identified human genomic DNA samples are used to demonstrate and assay for SNPs, indels, and CNVs; simple PCR-restriction digest assays are taught and compared to higher throughput molecular beacon PCR techniques and traditional sequencing. The third goal of the course is to introduce students to Bioinformatics and the use of public databases to learn about genetic diseases and genetic variation in humans. The fourth, final and vital goal of the course is challenge students with relevant ethical dilemmas that anchor genomic biology within real-world situations. Students are engaged in discussions covering genetic privacy, genetic pre-determinism, prenatal genetic testing, and biomedical research ethics. Over the most recent three year period a pre-course and post-course assessment strategy has been used to measure learning outcomes. In all three years the student participants have shown significant gains in genomic and genetic literacy and knowledge of bioethics; on average, % correct answers on the post-course assessment increase by 24%. The course is currently being re-designed as a teacher professional development exercise in order to increase dissemination across New England high schools.

Learning a language through Genome Education: Spanish School Experience. *S. C. Zapico[1], S. Martinez de Castro[2].* 1) Anthropology, Smithsonian, NMNH, MRC 112, Washington, DC; 2) Consejo de Residentes Españoles en Washington, CRE, Washington, DC.

Nowadays, genetic research, and the application of these studies to everyday life, is more attractive to the public, especially as it can be used to find cures for diseases. Also as scientists, it is important to increase the interest for science in new generations to ensure future advancements of the field. The Spanish School of Washington DC promotes the study and practice of the Spanish language for children born in the United States, but with parents of Spanish origin. This education takes place through extracurricular classes and cultural activities, conducted in Spanish, outside of their English-speaking schools. One such activity was a visit to "Genome: unlocking life's code," an exhibit at the National Museum of Natural History. Children were divided into three groups of 12, each group ranging in ages from 7 to 15 years old. The explanation in Spanish started with the basic concepts of DNA, which included how DNA is processed to form proteins, the history of DNA, and the sequencing of the whole genome. Once the students understood these concepts, the next step was to teach the significance of recent advances in sequencing in keeping the balance of the ecosystem. After that, the rest of the lesson was focused on human genetics; from how migrations are marked in our mitochondrial DNA, to how the advances in genetics let us diagnose diseases and look for new drugs and treatments. Although some of the concepts were difficult to explain to some of the younger students, the approach was to take examples from real life, connecting our genotype with our phenotype. To illustrate the concept of DNA, at the end of the lesson the students were given the opportunity to work as scientists. We performed an experiment that consisted in extracting DNA from strawberries and bananas through a protocol that used common household items. Both parents and students were involved in this activity, and at the end many of the students were successful in the extraction of DNA. The students and parents reacted positively to the lesson and especially the experiment: they kept the protocol and many expressed their desire to try it again at home. In summary this activity achieved our two primary objectives: to promote science in new generations, and make young students familiar with science concepts in Spanish, increasing their knowledge of this language.

Accelerating public awareness of personal genetics. *D. Waring[1], M. Gelbart[2].* 1) Depart of Genetics, Harvard Medical School, Personal Genetics Education Project Boston, MA; 2) Marnie Gelbart Harvard Medical School Department of Genetics Personal Genetics Education Project Boston, MA.

The Personal Genetics Education Project (pgEd.org) is using a unique and expanding platform of strategies to address the growing gap between what researchers are learning at the frontiers of genetics and what the public understands. Here, we focus on our most recent accomplishments in the domains of policy, entertainment, gaming, and education. First, in 2014, pgEd conducted a Congressional briefing to draw policymakers' attention to scientific advances in personal genetics and the importance of raising public awareness. Second, pgEd is expanding its emphasis on advancing awareness through television and film through partnerships with Hollywood, Health & Society and the Science & Entertainment Exchange. Third, pgEd is continuing to develop the on-line game, Map-Ed (map-ed.org) for spreading awareness. Our 2014 expansion of Map-Ed's topics include the microbiome and genetic discrimination. To date, Map-Ed has 5,400 players on all 7 continents. Fourth, pgEd is building our up-to-date and freely available on-line curriculum that addresses the benefits and implications of personal genetics. Finally, pgEd's efforts training teachers to engage young people on the interdisciplinary topic of personal genetics are extending beyond the biology classroom and into health, social studies, and literature. pgEd is continuing to set new goals, including engaging faith-based communities, and is seeking partners and collaborators to expand our vision and reach.

Celebrity disclosures and information seeking: The case of Angelina Jolie. *R. Juthe[1], A. Zaharchuk[2], C. Wang[3].* 1) Office of Communications and Education, National Cancer Institute, Rockville, MD; 2) iDoxSolutions, Inc., Bethesda, MD; 3) Department of Community Health Sciences, Boston University School of Public Health, Boston, MA.

Background: On May 14, 2013, actress Angelina Jolie disclosed that she had a deleterious *BRCA1* mutation and underwent a preventive bilateral mastectomy to reduce her inherited cancer risk. Her disclosure generated media frenzy and much discussion about her potential "effect." We sought to document the impact of her disclosure on information-seeking behavior, specifically regarding online cancer genetics and risk reduction resources available from the National Cancer Institute (NCI). **Methods:** Using Adobe Analytics, daily page views for 11 online resources, including resources written for the public and health professionals, were tracked over a 9-week period from April 23, 2013 through June 25, 2013. Online usage data were also obtained for 4 resources over a 2-year period (2012-2013). Source of referral by which viewers located a specific resource was also examined. **Results:** Jolie's disclosure led to a dramatic and immediate increase in traffic to NCI's online resources. The *Preventive Mastectomy* fact sheet written for the public saw the largest increase with 69,225 page views on May 14, representing a 795-fold increase compared with the previous Tuesday. The Cancer Genetics Services Directory for the public saw a 31-fold increase in page views from May 7 to May 14. A fivefold increase in page views was observed for the health professional Physician Data Query (PDQ)® *Genetics of Breast and Ovarian Cancer* summary in the same timeframe. Health professional PDQ® summaries on the genetics of other inherited cancers, including skin cancer and colorectal cancer, received increases of up to 65% from May 7 to May 14. Two-year data demonstrated the magnitude and longevity of Jolie's effect. A substantial increase from 0% to 49% was seen in referrals from news outlets to NCI's breast cancer resources from May 7 to May 14. **Conclusions:** Celebrity disclosures, such as Jolie's disclosure of her *BRCA1* mutation status and her risk management decision, can dramatically influence online information-seeking behaviors. Efforts to capitalize on these disclosures to ensure easy access to accurate information are warranted.

Public Perspectives on Genetic Ancestry Testing. *C.D. Royal[1,2], C.M. Wolpert[1,2], A. Hoffmeyer[3], J.D. Powell[1,2], K. Haynie[1,4], R. Agans[3].* 1) Department of African & African American Studies, Duke University, Durham, NC; 2) Institute for Genome Sciences & Policy, Duke University, Durham, NC; 3) Carolina Survey Research Laboratory, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Political Science, Duke University, Durham, NC.

Little is known about the general public's familiarity with and views of genetic ancestry testing (GAT). Preliminary data in the United States (n= 761) suggest that 68% (±4%) of the adults surveyed had heard of using genetic testing to find out about one's ancestry, and furthermore, 62% (±6%) said they would be interested in knowing their genetic ancestry. When examining minority and non-minority status differences, both non-Whites (68%; ±7%) and Whites (67%; ±5%) were equally familiar with GAT, but non-Whites were more interested in knowing their genetic ancestry (66% vs 60%, respectively) (r = .136, p=.059). In addition, non-Whites were more likely to consider having GAT (41.2%; ± 2%) in comparison to Whites (23%; ±2%). Overall, 73% (±1%) of the respondents believe that their genetic ancestry is related to their health and 86% (±1%) would tell their doctor about their GAT results. At present, there are no White/non-White differences here. The general public seems to be familiar with GAT and interested in knowing their genetic ancestry; however, when minority and non-minority status are considered, respondents who self-identified as non-White reported greater interest in both knowing their genetic ancestry and having GAT. Further research is ongoing and is expected to inform efforts to better engage the general public in order to explore their views on GAT and their perceptions of the relationship between genetic ancestry and health.

REU Site: Research Experiences for Underrepresented Minority Undergraduates in Basic Science and Genetic Research at Louisiana State University Health Sciences Center (LSUHSC). *K. Foley, A. Umrigar, A. Musto, H. Farris, F. Tsien.* LSUHSC, New Orleans , LA.

The Louisiana State University Health Sciences Center (LSUHSC) in New Orleans provides research training for a period of ten weeks for up to ten Louisiana underrepresented minority (URM) undergraduates interested in exploring graduate school and biological research careers, particularly in genetics. In the New Orleans area, Blacks account for 60.1% of the population, Hispanics 5.0%, and Native Americans 0.3%, compared to12.6%, 16.3%, and 0.9%, respectively in the US. The field of genetics is constantly evolving and it is therefore imperative for students who are pursuing biological science careers to be proficient in hypothesis-driven scientific problem solving, current methodology, data analysis, and communication skills. The objectives of the proposed REU program in basic biology research include: 1) Scientific problem solving 2) Learning state-of-the-art laboratory techniques 3) Developing scientific communication skills including teaching at a genetics workshop to high school students 4) Acquiring resume and CV writing and career education resources 5) Participate in a number of seminars and interactive workshops. Students present posters at an end of the summer symposium which are judged by local scientists. Additional seminars regarding graduate school professional development are presented by currently enrolled genetics graduate students and invited faculty. Students complete anonymous pre- and post-internship surveys designed to measure their self-assessed research interest, demographics, and achievement. The students will be followed up for a period of at least 3 years following the completion of the program to gauge the degree to which their experiences have had a lasting influence on their respective career paths. Students will also use an on-line REU assessment tool. We will stay in close contact with the students via a yearly electronic survey. Following the REU program, interns also have the opportunity to teach genetic concepts to New Orleans area schools during the academic year, an important skill that will enhance their future careers as scientists.

2322S

Gene hunting with IMG-ACT: Integrating genomics research into the undergraduate biology curriculum. *K. Moitra.* Dept of Biology, Trinity Washington University, Washington DC, DC.

Genome annotation is the process of linking biological information to gene sequences. It involves annotating predicted genes and connecting these genes to protein functions. The integration of genomics research into the undergraduate biology curriculum provides students with the opportunity to become familiar with state-of-the-art bioinformatics tools and answer original research questions. Our purpose with this research project was to upscale the research experience so that large numbers of students could have access to research. One way to achieve this is through integration of research with the classroom experience. Students in an introductory genetics class annotated predicted ABC (ATP Binding Cassette) genes of Methanothermobacter thermautotrophicus using the Integrated Microbial Genomics-Annotation Collaboration Toolkit (IMG-ACT) developed by the Joint Genome Institute. This research project is linked to the much larger scientific question: What can the sequence of an organism's genome tell us about its overall biology? A variety of pre-course and post-course tests and surveys were conducted to assess if the project engaged students and generated interest in scientific research. Preliminary results suggest that it did. This session will discuss: initiation and overview of the project, integration of research into the biology curriculum, up-scaling research projects for involvement of larger numbers of students, student learning outcomes and data collected from student surveys/assessments, including how future career choices were impacted by this research project. The session will also highlight building and scaffolding research skills in a research-intensive genetics course and the integration of research into the curriculum.

Development of a molecular test and human pedigree analysis on Alpha-1 Antitrypsin Deficiency. *A. Olson, D. Caporale.* Biology, University of Wisconsin-Stevens Point, Stevens Point, WI.

Alpha-1 Antitrypsin Deficiency (Alpha-1) is a monogenic recessive disorder affecting roughly 1 in 4,000, making it 1 of 3 of the most common genetic diseases to cause death among adult Caucasians in the United States. The deficiency is caused by a mutation of the SERPINA1 gene, located on chromosome 14, which codes for the serpin peptidase inhibitor alpha-1 antitrypsin. Inheriting two mutated variants can result in Emphysema, COPD, and/or liver disease between ages 40-60. In one case study, an individual was recently diagnosed with this disorder and was found to be homozygous for the affecting variant "Z", rendering each parent a carrier. This raised several concerns for other family members, who then wished to seek genetic testing. Current genetic tests include restriction digestion of amplicons, which can be less reliable or repeatable due to partial digestion issues. The objective of my undergraduate research was to design a novel genetic test for the SERPINA1 "Z" single-nucleotide polymorphism (SNP) based on DNA sequence comparisons - that is reliable, repeatable, noninvasive and relatively easy to perform - to facilitate the detection and diagnosis of Alpha-1 patients. Since the "Z" variant is a result of a transition missense mutation, whereas a guanine (found in the wild type form denoted as "M") is replaced by an adenine, our methods included designing a forward and reverse primer pair that would successfully amplify this SNP region and generate DNA sequences representing an individual's genotype that is easily interpreted. Eighteen members of the Alpha-1 affected family were used as controls to verify the reliability of this molecular test. Amplified products were cycle-sequenced by the fluorescent Sanger method and electrophoresed using an automated capillary system. After protocol optimization, homozygous wild types (MM), heterozygous carriers (MZ), and homozygous mutants (ZZ) became easily discernable among the respective electropherograms. Heterozygote electropherograms displayed equal representations (concentrations) of adenine and guanine at the polymorphic site. In addition, a genogram was constructed that successfully illustrated the congruence of their genotypes with their respective phenotypes of this disorder. We conclude that our molecular method for identifying M/Z genotypes associated with Alpha-1 Antitrypsin Deficiency is a reliable test that can be easily adapted for research or diagnostic purposes.

Using a PyMOL activity to reinforce the connection between genotype and phenotype in an undergraduate genetics laboratory. *A. Ribes-Zamora, T.K.T. Nguyen, A.D. Simmons.* Biology Department, University of St Thomas, Houston, TX.

With the purpose of developing activities that would help clarify and reinforce genetic concepts that undergraduates find challenging, we designed a 3-hour teaching module using the PyMOL software, which can be downloaded for free for educational purposes, plus other genomic browsers. We believe this teaching module reinforces the concept of mutation and the connection between genotype and phenotype. Pre-lab handouts with background information on a specific protein or protein family are provided to the students the week before the day of the activity. Students are also given a homework assignment that allows them to begin exploring some of the tools of the PyMOL software. On the day of the lab session, teams of four students are given different handouts that prompt students to find the location of the gene in the human genome, see how many introns and exons it has, and investigate the structure and function of a specific protein. They are also given a few disease-associated amino acid changes that lead to a particular disease and asked to predict how the change can ultimately alter overall protein shape or function. Teams are given two hours to complete the activity and then give a 10-minute presentation on their findings and show their models. After the activity we were interested in measuring if there was a better understanding of mutation among students that were enrolled in the laboratory and the lecture concurrently, as compared to students who were only enrolled in lecture. Students were asked to complete an anonymous post-quiz. In all three lab sections, the average post-quiz grade was slightly higher than the average post-quiz grade for students that did not take the lab. Also, there were 6 questions in which there was a higher percentage of students that took lab and lecture concurrently that obtained the correct answer as compared to students that only were enrolled in the lecture. While this data is encouraging, the differences we observe are not statistically significant. We believe this is the case because we have small class sizes and we would probably have to pool data from various sections to achieve significance.

2325S

Orchid DNA-Barcoding: a guided research project for undergraduate genetics students. *A.D. Simmons[1], C. Ribadeneyra[1], K. Foss[1], E.J. Baenziger[2], A. Ribes-Zamora[1].* 1) Biology Department, University of St Thomas, Houston, TX; 2) Department of Modern and Classical Languages, University of St Thomas, Houston, TX.

Recent studies have found that undergraduate STEM courses in which students are taught using problem-based approaches exhibit greater learning gains than do students in traditional courses. Studies done by the National Academies and The American Association for Advancement of Science indicate that undergraduate education can be enhanced significantly when students are involved in authentic research. DNA barcoding is a method by which organisms of various species can be characterized by obtaining a specific short genomic sequence. In Fall 2013, our genetics laboratory course was modified so that students were taught lab skills in the context of conducting a research project using the DNA barcoding technique. Our hypothesis was that structuring the lab course around an actual research project would be a more effective way to teach the scientific method and increase the student's future interest in the scientific field, while also producing potentially publishable data. We had three sections of lab, each with 9-15 students. Lab teams were composed of 3-4 students, and each team collected leaf samples from 3 different species for a total of 33 different species. Throughout 6 of the 11 lab sessions students worked on the project, beginning with an introduction to DNA barcoding and its applications, then moving on to basic lab techniques, performing the data analysis using DNA Subway and ending with presentations of the phylogenetic trees students produced. At the beginning of the semester, students were given a survey that asked them how confident they were in various aspects of experimental design and presentation after taking the prerequisite course, which employed a standard lab approach. At the end of the semester, the students were asked to fill out the same survey, this time ranking how they felt after completing our research-oriented lab. All surveys were anonymous. After taking this lab, over 95% of students felt confident or very confident at applying the scientific method, compared to only 27% before the lab. While approximately 60% of students were confident or very confident in their abilities to organize and present scientific data before the lab, an additional 35% of students shared this confidence after completing the lab.

Sex and Gender Differences in Health: Educational and Collaborative Outreach to Genetics Researchers, Clinicians, and Students. *M.R. Tennant[1], M.E. Edwards[2], H.F. Norton[2], N. Schaefer[2].* 1) Health Science Center Libraries/Genetics Institute, University of Florida, Gainesville, FL; 2) Health Science Center Libraries, University of Florida, Gainesville, FL.

Purpose: Historically, medical and scientific thinking has been based largely on male anatomy, disease presentation, and response to therapy. This focus presents ethical and scientific challenges. We embarked on an outreach project to promote equitable research sensitive to sex and gender differences in the basic and clinical sciences, including genetic research. Given the NIH policy to reduce gender bias in research, this project provides timely information to clinicians, researchers and students at our institution. Through National Library of Medicine/NIH Office of Research in Women's Health funding, a team of librarians partnered with researchers and clinicians to promote awareness of the need for research in sex and gender differences in health, facilitate collaboration among such practitioners and students, and make research in this area more accessible. Setting/Methods: A large land grant institution with contiguous main and health center campuses. "Collaborating with Strangers" (CoLAB) workshops were held to facilitate collaboration among participants interested in this discipline. Affiliations represented the gamut of health, life, and social sciences, as well as clinical and research realms. Instructional sessions related to the science of sex and gender differences in health were performed for a number of cohorts, including graduate and undergraduate students in genetics and genomics. In order to make sex and gender differences research results more accessible within and external to the institution, an open access publication fee fund was created. Researcher records in the campus finding tool (VIVO) were augmented with keywords, and publications arising from the university's sex and gender differences researchers were included in the Institutional Repository (IR). In the second year of funding the team collaborated in the university's outreach to high school students and teachers, catching students early in the pipeline when they contemplate careers in science and medicine. Results/Conclusions: In its first year the team hosted two CoLabs with 37 attendees; a third session has been held in Year 2. Evaluations suggest that participants connected with other researchers and gained potential collaborators. Instructional sessions for genetics students yielded cohorts ready to enter medical and graduate school with a greater understanding of sex and gender differences research, and how those differences relate to genetics, health and disease.

Studying Ourselves: Using SNP Genotyping to Engage Undergraduates in Genetics and Research. *E.E. Murray[1], M.D. Hineman[2], A. Hinshaw[2], M. Harrison[3].* 1) Integrated Sci & Technol, Marshall Univ, Huntington, WV; 2) Chemistry, Marshall University, Huntington, WV; 3) Biological Sciences, Marshall University, WV.

The human genome project has made it possible for students to interrogate their own DNA with PCR and to answer questions about human diversity for many non-health related biological characteristics including taste, athletic ability, stress management and hair and eye color. Over the last four years, we developed SNP genotyping assays for polymorphisms as research class projects in an undergraduate human genetics class. Successful projects were a springboard for senior capstone projects using larger biology or forensic science classes as sample populations while providing those classes with a human genetics laboratory. This permitted student researchers to take on the role of co-PI for the SNPs they chose to investigate. Students isolated their own DNA using Epicentre MasterAmp or BuccalAmp kits. PCR was performed using Promega 2X mastermix. Lonza Flash gels were used to rapidly test PCR amplification and in some cases, RFLP polymorphisms. Lonza PAGEr Gold precast gels were used to resolve some RFLP polymorphisms. In some human genetics class SNP projects, published primers and/or PCR cycles were available (PTC tasting, ACTN3 and athletic ability, COMT and test anxiety, HVR 1 and 2 and ethnic origin) while in other projects, students used NCBI database and dbSNP to locate the relevant SNP(s) and design primers (Red hair, cilantro tasting, blue eyes) and either RFLP assays, qPCR genotyping or direct DNA sequencing. Detailed protocols for all assays will be provided. Results: New assays were developed in four annual human genetics classes. Three students from the human genetics classes continued this research in larger student populations as senior capstone projects. Capstone students were required to write an IRB submission and obtain informed consent from research participants. DNA samples were tracked with a number rather than a student name to maintain confidentiality, and samples were discarded after the conclusion of the project. Students in the Cell Biology Class that served as capstone subjects for Cilantro tasting project were surveyed using a Likert scale (with 1 being strongly disagreed and 5 being strongly agreed). Students ranked learning about PCR and SNPs highest as 4.47 and learning about bioinformatics lowest at 3.94. 81% of students surveyed stated that more experiments like this would be valuable in Cell Biology laboratory. Capstone students were uniformly satisfied with the projects.

Statewide Education Regarding Personalized Genomic Medicine, the Iowa Experience. *C.A. Campbell[1], C. Nishimura[1], M.A. Mansilla[1], T. Bair[1], S. Maddhi[1], A.E. Kwitek[1], K.L. Knudtson[1], O. Shchelochkov[1], S. Gunstream[2], R.J. Smith[1].* 1) Iowa Institute of Human Genetics, University of Iowa, Iowa City, IA; 2) Integrated DNA Technologies , Iowa City, IA.

As Personalized Genomic Medicine (PGM) is incorporated into medical practice, we are challenged with educating the health care team and public about genomic medicine, as well as developing a work force to support the growing genomic needs of the population. The Iowa Institute of Human Genetics (IIHG) provides an interface for, and support of, state-wide activities related to human genetics with a mission to educate Iowans and others about human genetics. To accomplish this mission we've introduced multiple educational activities. Programs for *students* include; Careers in Human Genetics Day, and Personalized Genomic Medicine: Careers in Bioinformatics & Big Data. Following these events, 97% and 83%, of attendees report an increased interest in careers in PGM, respectively. Attendees report; "I have many more options than I thought"; "It helped me realize what kind of environment I'd like to work in"; "I didn't realize the magnitude of teamwork"; "I wish I could've attended earlier because it could've steered me in the right direction sooner". A genetic counseling internship provides students with clinical experience and is the only undergraduate genetic counseling internship in the country. The IIHG also offers a "Topics in Human Genetics" summer course, and outreach to Iowa colleges and high schools. Opportunities for *researchers and clinicians* include; Next Generation Sequencing and Bioinformatics User Groups Monthly Conferences; Bioinformatics Short Course; and Exome Analysis for Rare Disease program. For the *general public*, we have hosted seminars for the general public on genetics in art, cinema, medicine, and ethics. Our plain language patient brochures and website provide educational materials for patients, students, researchers and health care providers.

Formal collection of feedback on all activities is used to gauge the interests and needs of our target populations for future program development. The average satisfaction score is 4.59 out of 5 for all of the offerings. Following our events, students have applied for bench and computational human genetics laboratories jobs, and graduate school. This demonstrates our education programs are effective in motivating students to pursue careers in PGM. We are committed to educating and engaging the entire community by creating a public awareness of personalized genomic medicine as an investment in our future.

Molecular Genetic Studies in Indian Patients with Ectodermal Dysplasia. *s. kushmakar.* pediatrics, All India Institute of Medical Science, New Delhi, India.

Introduction: Ectodermal Dysplasia (ED) is a group of about 170 heritable disorders that affect the ectoderm, the outer layer of tissue. Each of the roughly 170 ED syndromes represents a different combination of abnormalities. Inheritance pattern are variable include autosomal dominant, autosomal recessive, X linked dominant and X linked recessive disorders. Here we report our experience with X-linked hypohidrotic or anhidrotic ectodermal dysplasia. The EDA gene which causes this disease is present on Xq12 - q13 and comprises of 12 exons. Eight of which encode the transmembrane protein ectodysplasin-A and 4 exon are non coding. More than 179 mutations have been reported from different groups, including missense, splicing, small deletions and insertions. Objectives: Our objectives were to identify the spectrum of mutations in Ectodermal Dysplasia patients and to plan a strategy for molecular diagnosis so that optimal management, genetic counselling, and prenatal diagnosis can be offered. Material and methods: Thirty (25male and 5 Female) patients with clinical features suggestive of ED were included in the study. In two families mothers also had mild features suggestive of ED. Four of the families were consanguineous.DNA was extracted from 30 patients and their parents. PCR amplification was carried out using 8 pairs of primers and sequencing was done . All the patients who were found negative for EDA gene sequence variation were subjected to screening of EDAR gene. Results: 14 patients out of 30 were reported with sequence variant and out of 14 ,8 were reported and 6 patients were found to be a reported mutations, c.2 T>A (exon 1) ,c.463 C>T (exon 3) , c.466 C>T (exon 3) ,c.1045 G>A (exon 9) and c.820 T>A (exon8) were found in one patient each. Five novel mutations, c.502+1 G>T, c.924+2 T>G (exon 9) c.371A>G (exon 1) c.292_304del17 (exon-1) and c.906 C>A were identified in six patient each. Two patients were found to have a splice site mutation.. Protein prediction softwares, polyphen 2/SIFT predicted that one of the novel changes has a pathogenic effect. In EDAR gene 10 patients were found positive for different sequence variation involving exon 4,8,12 and IVS11. Conclusion: We detected variation of EDA and EDAR genes with variable phenotype of Ectodermal Dysplasia. This study should be useful for genetic counseling and prenatal diagnosis for the families enrolled in study and in expanding the database on EDA and EDAR gene.

Patient Perspectives on the Use of Electronic Health Records for Research: The MI-GENES Study. *R.A. Haddad[1], H. Jouni[1], I.N. Isseh[1], J.B. McCormick[2], C.G. Chute[3], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Department of Internal Medicine, Mayo Clinic, Rochester, MN; 2) Division of Biomedical Ethics, Departments of Internal Medicine and Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN.

Background: The use of electronic health records (EHRs) is increasing due to federal mandates. The myocardial infarction genes (MI-GENES) study, an eMERGE genomic medicine implementation pilot, is exploring the integration of genomic results into the EHR. The views of participants in genomic studies on the use of EHRs for research are not known. **Methods:** The MI-GENES study randomized adults aged 40-65 years, at intermediate risk for coronary heart disease (CHD) and not on statins, to receive either the 10-y risk of CHD based on conventional risk factors versus the 10-y risk based on a genetic risk score and conventional risk factors. We assessed participants' perspectives regarding the use of EHRs for clinical care and research using the health information national trends survey (HINTS). This survey was completed by all study participants at the initial study visit. **Results:** The survey was completed by 212 study participants recruited from the community (mean age 58.8±5.1 y, 47% male). The majority (n= 208, 98.1%) were in support of investigators having the ability to access and review EHRs for research; 99% of participants (n=210) felt that physicians should be able to share medical information in EHRs and 204 (96.2%) felt confident in the mechanisms in place to maintain confidentiality of their EHRs. Most participants (n=191, 90.1%) felt it is important to be able to access information in their own EHRs; 201 (95.2%) had internet access but only 119 (56.1%) used the internet to communicate with their medical providers. A significant proportion (n=154, 72.6%) was aware about the availability of direct-to-consumer genetic testing. **Conclusion:** Among participants in a genomic medicine implementation study, the majority supported the use of EHRs for research and felt confident in the mechanisms in place to maintain confidentiality of their EHRs.

A systematic review of individuals' perspectives on broad consent and data sharing in the United States. *N.A. Garrison[1,2], M. McPheeters[3,4], N.A. Sathe[3], R.R. Walden[5], E.W. Clayton[1,2].* 1) Center for Biomedical Ethics and Society, Vanderbilt University, Nashville, TN; 2) Department of Pediatrics, Vanderbilt University, Nashville, TN; 3) Vanderbilt Evidence-Based Practice Center, Institute for Medicine and Public Health, Vanderbilt University, Nashville, TN; 4) Department of Health Policy, Vanderbilt University, Nashville, TN; 5) Eskind Biomedical Library, Vanderbilt University Medical Center, Nashville, TN.

Objective: The purpose of this systematic literature review was to synthesize and evaluate evidence related to individuals' willingness to provide broad consent for biobank research and data sharing. Study Design: We searched bibliographic databases (MEDLINE® via the PubMed interface, Web of Science, National Reference Center for Bioethics Literature databases (EthxWeb, GenETHX), and Dissertation Abstracts International) for original research conducted in the United States and published since 1990. Two reviewers independently screened studies against predetermined inclusion criteria using DistillerSR™, an online systematic review tool. Next, the two reviewers independently assessed the quality of studies using a tool designed for the review. Data were extracted using a predefined instrument. Any disagreements that arose between reviewers were resolved through discussion. Results: The final sample consisted of 46 articles. Most studies involved surveys (n=26), followed by focus groups (n=8), mixed methods (n=9), analyses of consent forms (n=2), and interviews (n=1). Overall, women were more often included in these studies than men. The quality of studies ranged from good (n=18), to fair (n=26), and poor (n=2). This presentation highlights our major findings. First, individuals were more willing to provide broad consent if the samples are de-identified. Respondents' preference for broad consent over other types of consent (such as tiered or study-specific) became stronger when they learned more about the logistics and costs associated with maintaining large biobanks and when the privacy concerns were adequately addressed. Second, most respondents would allow data derived from their samples to be shared with many researchers. Preferences about data sharing, however, varied across demographics; individuals from under-represented minority backgrounds tended to be less willing to have their data shared. Furthermore, respondents were less willing to provide broad consent if pharmaceutical companies had access to the data, regardless if it is de-identified or not. The participants who were less willing to consent to data sharing cited privacy and confidentiality concerns. Conclusions: Further research is needed to explore factors that affect willingness to participate in research by demographics and biobank model in order to address remaining barriers, seek a wider diversity of opinions, and enhance public support of this research.

2332M

Attitudes and concerns related to placing genomic information in the electronic medical record: a survey of biobank participants. *A. Fiksdal[1], J. Olson[2], K. Maschke[3], JB. McCormick[1].* 1) Biomedical Ethics Program, Mayo Clinic, Rochester, MN; 2) Health Sciences Research, Mayo Clinic, Rochester, MN; 3) The Hastings Center, Garrison, NY.

Introduction: Biobanks are repositories of biological specimens and health information that provide researchers with the resources to carry out large-scale genomic research studies that would not be otherwise possible. As genomic testing becomes increasingly incorporated into clinical settings, biobanks now have the potential to serve a greater role in supporting clinical genomics in the context of personalized medicine, with some researchers envisioning placing genetic information directly into the electronic medical record (EMR). Although the integration of genomic information into EMRs and everyday medical practice holds the potential to improve care, ethical implications of such practices must be addressed as the process unfolds. Methods: Mayo Clinic recently conducted a study that involved testing samples of participants in the Mayo Clinic Biobank for known pharmacogenetic variants and automatically placing the results in the electronic medical record. We sent a follow-up survey to individuals who had either consented, refused, or did not respond to an invitation to take part in that parent study. Our survey was designed to assess the factors influencing decisions to participate in the parent study and evaluate potential concerns related to placing genomic information in the EMR. Results: Our sample consisted of 643 total respondents, including 285 individuals who consented, 178 who refused, and 180 who did not respond the invitation to take part in the parent study. Concerns related to placing genetic information into the medical record varied by group. Those consented to take part in the parent study were less likely to report such concerns than those in the refused group (25% vs. 58%). Respondents in the refused group were also less likely to report feeling comfortable with sharing their genetic information with outside researchers than those who had consented (50.1% vs. 73.3%). A majority of all respondents in all groups (86.9%) reported being concerned if their genetic information was made available to insurance companies. Conclusion: Although most respondents reported feeling comfortable with placing genetic information into the medical record, concerns related to who has access to that information remain for a notable minority of individuals. Researchers utilizing biobanks should be mindful of those concerns as they establish data-sharing agreements and develop informed consent procedures.

2333T

Research Use of STored samples (RUST)-Community Perspectives from a Developing Country. *S. Ramalingam.* Molecular Medicine, PSGInstitute of Medical Sciences and Research, Coimbatore, Tamilnadu, India.

Introduction: Human biological samples including blood, tissue and other body fluids are very important for biomedical research. Rapid development in the newer technologies increases the scope of bio banking in developing countries. In countries like India with a large number of diseases there are large volumes of left over samples and tissues which are being used for biomedical research. However there are lot of ethical and legal implications in the reuse of these samples for research. Bio banks are often sought for International collaborative research to generate newer findings that are generalizable across populations in the world. Lacks of clear guidelines compounded with lack of awareness of biomedical research especially with stored samples are important problems in countries such as India. Paucity of data on this in a populated country such as India with a huge potential for bio banking makes this study an important one. Aims: To study the perspectives and attitudes of the community towards the use of stored sample for biomedical research. Methodology: A cross sectional survey from patients and general population at a tertiary care hospital in South India and the field practice area of community medicine was carried out. Data was analyzed using the SPSS 19 software. Results: There were 225 respondents with 52.4% females and 47.6% males. 62% of the population did not want to store their samples for research. 88% opined that they will consent if their treating doctor informs them about the use of samples for research and explains about the scope of research. There was a significant association between age and consenting for research. the younger the age, more likely that they are consenting for use of their leftover samples. ($p<0.05$) but this difference was not observed between the sexes.Though they agreed for use in general research, many did not agree for genetic research. They also wanted to know the results of the study for which their samples are being used and most of them (61%) felt that the left over samples of their children will not be used for research. Conclusions: Community should be made aware about the scope of using the left over samples for research -both biomedical and genetic research. A uniform policy on research using stored sample should be drawn based on the literacy and education status and also keeping in mind the cultural context.

Genes for Good: An Online Community Study of Genes, the Environment, Health and Disease. *J.R. Forster[1], W. Li[1], M. Zawistowski[1], J. Wu[2], K. Brieger[3], S.I. Vrieze[1], G.R. Abecasis[1].* 1) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, School of Public Health, Ann Arbor, MI; 2) School of Information, University of Michigan, Ann Arbor, MI; 3) Medical School, University of Michigan, Ann Arbor, MI.

Genetic studies with traditional recruitment strategies using in-person assessments, tissue sampling, and medical evaluations are precise, but also very expensive and exclusive. Not everyone can join these traditional studies both due to limitations on available time and geography, among others. Genes for Good is a research study conducted at the University of Michigan and designed to break down these research participation barriers. We have developed a database driven dynamic survey and passive monitoring platform for large scale genetic association studies that uses the internet and social media to recruit participants and provide online surveys that can be completed by participants when convenient for them. The software is currently available as a Facebook App, allowing us to engage thousands of participants quickly and cost-effectively through a popular and widely-used social media platform.

Participants that complete a minimum number of surveys about their health and behavior are eligible for DNA analysis. We send participants spit kits to collect saliva in a simple and non-invasive manner. Extracted DNA is genotyped with a reference set of GWAS and coding variants. To motivate participants to contribute and promote literacy about genetic information, we have developed web-based software applications that provide participants information about their genetic ancestry and their survey results. Users can download their survey results in full and receive their own raw genetic data. At the time of abstract submission we are about to launch, pending an NIH certificate of confidentiality, and expect to present data on participation rates, attrition, measurement accuracy, and cost efficiency of the research design. Participants will be snowball sampled, in a process that will be started by the investigators using twitter and posts on their Facebook wall. Our software platform will then rely on existing Facebook social networking to encourage active participants to invite their Facebook friends to participate and to advertise the study by posting to their Facebook wall. We ultimately want to open our platform up to any researcher with a relevant scientific question. They will be able to use this research tool, including the genetic and phenotypic data we have collected, to answer a wide range of questions about the links between genetic information and health.

Practical Solutions for Protecting Individual Genomic Privacy. *J. Fellay[1, 2], J.L. Raisaro[3], Z. Huang[3], M. Humbert[3], E. Ayday[3], P.J. McLaren[1, 2, 4], A. Telenti[4], J.P. Hubaux[3].* 1) School of Life Sciences, Ecole Polytechnique Fédérale de Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) School of Computer and Communications Sciences, Ecole Polytechnique Fédérale de Lausanne, Switzerland; 4) Institute of Microbiology, University Hospital and University of Lausanne, Lausanne, Switzerland.

The increasing availability of genomic data has major implications for personal privacy. The issues raised by genomic privacy reside at the crossroads of medicine, computer science, legislation and public policy. We here describe the design and development of new privacy enhancing technologies that aim to find the optimal balance between usability and privacy of genomic data in clinical care and in biomedical research. First, we propose a privacy-preserving algorithm for genetic risk testing in clinical care that uses homomorphic encryption and proxy re-encryption. After genomic data (e.g. sets of variants from whole genome sequencing) are generated by a certified institution, they are encrypted and stored at a centralized “storage and processing unit” (SPU). Our architecture, while preserving data privacy, enables a medical unit to retrieve the encrypted information from the SPU and to use it for individualized care. We deployed this solution in a pilot pharmacogenomics study of 180 patients participating in the Swiss HIV Cohort Study. Retrieval and processing of encrypted genotypes, for a test using 50 markers (SNPs), take less than 1 second on commodity hardware. An interim analysis showed this to be acceptable by clinicians as both usability and privacy of genomic data are preserved. Second, we developed a system to protect the privacy of mapped short reads (e.g. bam files). Millions of sequencing reads from individual genomes are stored at a SPU in encrypted form. Our scheme allows a medical unit to privately retrieve a subset of the reads without revealing the nature of the request to the SPU. In addition, the SPU can mask particular parts of the retrieved reads if they are not in the requested range or not consented by the patient (e.g., regions revealing sensitive diseases). Finally, we provide a method, based on graphical models and belief propagation, to estimate the erosion of genomic privacy of an individual when genomic data of some of his/her relatives are publicly available. We showed how a target genome can be reconstructed by relying on Mendel’s laws and linkage disequilibrium. As a result of this inference attack, we proposed different possible definitions of genomic privacy metrics.

Data Sharing in Human Pluripotent Stem Cell Research: Developing a Principled, proportional process. *R. Isasi, B. Knoppers.* Centre of Genomics and Policy, McGill University, Montreal, Quebec, Canada.

Biobanks serve as the primary resource for access to authenticated, quality-controlled and ethically sourced human pluripotent stem cell (hPSC) lines. Their scientific value is predicated on the quality of the data associated with their curated cell lines. Collections of hPSC lines including well-annotated genomic, epigenomic, and donors’- research participants’ phenotypic and demographic data are essential, given that genetic and epigenetic variations contained in the lines could have an impact on the value of their associated data. Comprehensive data curation facilitates disease modelling, drug development, and further contributes to the understanding of genetic variation and its role in normal cell behaviour. Moreover, next generation sequencing technologies - from microarrays to whole genome analysis - provide data on a wide range of healthy and sick participants with the potential to contribute to the clinical translation of cell based-therapies and personalized medicine. Several scientific and social developments are prompting reconsideration of the ways in which the scientific and ethical imperative of data sharing and security are not only conceptualized but also implemented. Data sharing is envisaged as a tripartite responsibility of data producers, users, and funders. These factors, together with reports of the ease of re-identification in the scientific literature and popular press, contribute to changing public attitudes regarding the meaning of individual privacy and attendant expectations about the In the context of hPSC research specifically, on behalf of the International Stem Cell (Funders) Forum this presentation will propose guidance for research consortia, stem cell banks, and registries, in the drafting of data sharing agreements that are proportional to the nature of cell line derivation (e.g. hESC vs. iPSCs). We offer policy recommendations for determining thresholds for the release of individual and summary data (e.g. genomic, epigenomic, phenotypic, and demographic) as well as identity profiles (e.g. STR, SNP, etc.) associated with an hPSC line to bona fide researchers.

Utilizing Online Consent and Data Collection in Studying Genetic Changes Related to Autism. *B. Smith-Packard, S. Martin, W.A. Faucett, Simons Variations in Individuals Project.* Genomic Medicine Institute, Geisinger Medical Ctr, Danville, PA.

The Simons Variations in Individuals Project (Simons VIP) was designed to characterize the natural history of individuals with copy number variants (CNVs) related to autism (e.g., del 16p11.2) by collecting detailed phenotypic information through phone and in-person evaluations of probands and family controls. In September 2010, a website (www.simonsvipconnect.org) was developed to serve as a patient registry, to provide families with community support and resources, and to function as a novel method of online study recruitment and engagement. In “Phase 1” of the study, the website was primarily used for recruitment and community engagement. Members of the online community who indicated interest in research submitted their genetics lab report to be evaluated by the Simons VIP study team for eligibility. Medical and family history information was collected by phone, and comprehensive, in-person evaluations at one of five collaborating medical centers throughout the United States.

Given the success of online subject recruitment and retention, “Phase 2” of the study was launched in February 2014 to provide an online method of data collection by utilizing remote assessments (primarily online and by phone and mail as needed) to collect phenotypic information. In transitioning to Phase 2, the community support and resource features of the website were retained while a direct portal to online research participation was designed and incorporated. Through this online portal, subjects can learn about the study, opt-in (or out) of research participation, complete online consent and assent, and complete online research surveys, allowing longitudinal contribution of phenotypic data from anywhere around the world. Since the launch of Phase 2 in February 2014, there have been 66 families consented and enrolled in Phase 2 (206 individuals total; 55 families re-enrolled from Phase 1, 11 new families). Online research surveys have been assigned to 121 individuals, of whom 99 (82%) have completed the assigned surveys. Of those completed, 81 (82%) finished in less than a week, with about one quarter (26%) of these individuals finishing surveys in less than 2 days. Our experience has shown that families are able to successfully enroll in an online research study and complete online consent/assent for research. We have found that once online research surveys are assigned, the majority of subjects will complete the surveys in a timely manner.

Whole genome sequencing of children: Consent, parental choice, and the hunt for secondary variants. *N. Monfared[1], C. Shuman[2], J.A. Anderson[9], R. Hayeems[1], M. Szego[6,7,8], R. Zlotnik Shaul[5,6,9], M.S. Meyn[1,2,3,4,5], S. Bowdin[1,4,5].* 1) The Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 4) Division of Clinical and Metabolic Genetics, Dept of Paediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Paediatrics, University of Toronto, Toronto, ON, Canada; 6) Joint Centre for Bioethics, University of Toronto, Toronto, ON, Canada; 7) McLaughlin Centre, University of Toronto, Toronto, ON, Canada; 8) Centre for Clinical Ethics; Providence Healthcare, St. Joseph's Health Centre and St. Michael's Hospital; Toronto, ON, Canada; 9) Department of Bioethics, The Hospital for Sick Children, Toronto, ON, Canada.

Background: Traditionally, consent processes preceding single or multigene genetic tests have focused on preparing individuals for test outcomes related to clinical presentation and/or family history. WES and WGS can also reveal medically important variants unrelated to the primary diagnosis (secondary variants) thereby challenging existing genetic counseling models. As part of The Hospital for Sick Children's Genome Clinic, a research project designed to model routine use of WGS in paediatric genomic medicine, we are studying the process of informed consent for WGS of children and the choices parents make regarding return of secondary variants (SVs) and carrier variants. Methods: We offer WGS to children undergoing clinical molecular testing for a suspected genetic disorder. Prospective participants (child and parent trios) are counseled regarding the nature of WGS and the opportunity to learn about the child's pharmacogenomics as well as childhood and adult-onset medically actionable variants (MAVs) and carrier status variants in over 2800 disease genes listed in NIH's Clinical Genomic Database. Parents are also offered the option to undergo targeted testing for adult onset MAVs and carrier status variants identified in their child. Results: Of the 321 families approached to date, 54% agreed to participate; 42% declined. The initial consenting session averages 45-60 minutes with parents and children participating in the decision making process. The mean lag between the first counseling appointment and enrollment is 9 days with most families requiring more than one appointment in this interval.There was no consensus among families regarding return of SVs. 58% of those enrolled chose to learn about all secondary adult-onset MAVs and 63% chose to learn about carrier variants, while 17% elected not to learn of any SVs. The most common concerns raised by families declining to learn about SVs included the psychological burden of identifying SVs in the child and themselves, potential impact on other family members, and/or fear of life insurance discrimination. Among parents who decided to learn of their child's adult-onset MAVs and carrier variants, 68% chose to learn their own status for the same risk variants. Conclusion: Our findings highlight the need for genetic counseling models, decision aids and resources to evolve in order to support the complex decision making processes necessary for clinical use of WES/WGS.

Pediatric whole genome sequencing: the benefit-risk calculus of parents and health care providers. *R.Z. Hayeems[1,2], J.A. Anderson[3], M.J. Szego[4], M.S. Meyn[5,6,7], C. Shuman[5,6,7], N. Monfared[6,7], S. Bowdin[6,7], R. Zlotnk Shaul[3].* 1) Child Health Evaluative Sciences, Hospital for Sick Children, Toronto, Canada; 2) The Institute for Health Policy Management and Evaluation, University of Toronto, Toronto, Canada; 3) Department of Bioethics, The Hospital for Sick Children, Toronto, Canada; 4) Centre for Clinical Ethics, St. Joseph's Health Centre, The Centre for Applied Genomics, The Hospital for Sick Children; Department of Family and Community Medicine, University of Toronto. Toronto, Canada; 5) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 6) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 7) The Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, Canada.

Objectives Implementing pediatric whole genome sequencing (WGS) requires attending to parents' and health care providers' (HCPs) experiences with its use. The Hospital for Sick Children's Genome Clinic analyzes genomic data for both primary and secondary variants and uses a choice-based model for managing return of secondary variants (SVs) to parents of index children. In this context, we elicited parental responses to the consent process, their reasons for pursuing or declining receipt of SVs, and HCPs' perceptions of WGS. **Methods** Parents of children enrolled in the Genome Clinic were invited to participate in semi-structured interviews following completion of an informed consent discussion and pre-test counseling. HCPs who referred patients to the Genome Clinic and those peripheral to it, were also invited to participate in interviews. Transcripts were analyzed thematically, using techniques consistent with interpretive description. **Results** 58% of the parents of 174 enrolled children elected to receive adult onset medically actionable variants (MAVs) identified in their children, while 42% did not (26% declined, 16% undecided). For all 25 parents interviewed, pursuing WGS was motivated by their child's diagnostic quest and by their belief in new genomic technologies. All were satisfied with the detailed consent process; 18 opted to receive all SVs (including adult onset MAVs), 3 opted to receive only carrier results, and 4 opted to receive only childhood onset MAVs. Those who opted to receive all SVs were more enthusiastic about the potential for SVs to prevent future health risks for their child and were less worried about an over-protected childhood, psychological burden, and insurance discrimination than those who opted to receive only some SVs. Views of 6 initial HCPs interviewed are both optimistic and guarded. Upon receipt of SVs from a laboratory, HCPs feel obligated to return results to families. They orient to the best interests standard from a broad, family-based perspective. **Conclusion** Our findings suggest that parents' preferences regarding receipt of SVs range widely and are motivated by marked differences in definition and balance of best interests-oriented values. HCPs have mixed views about WGS that are informed by clinical and ethical imperatives. Given the primacy placed on achieving a diagnosis by all participants, value-based tensions related to SVs, that are experienced by parents and HCPs warrant further deliberation.

2340M

Attitude toward genetic research on children and informed assent. *Z. Yamagata[1], I. Ishiyama[2], K. Muto[3], J. Minari[4], G. Yoshizawa[4], K. Kato[4].* 1) Dept Health Sciences, School of Medicine, Univ Yamanashi, Yamanashi, Japan; 2) Teikyo-Gakuen Junior College, Yamanashi, Japan; 3) Dept Public Policy, Inst Medical Science, Univ Tokyo, Tokyo, Japan; 4) Dept Biomedical Ethics and Public Policy, Graduate School of Medicine, Osaka Univ, Osaka, Japan.

[Aim] The aim of this study is to determine the attitudes of the general Japanese public toward genetic research on children and to clarify factors related to such attitudes based on nationwide surveys conducted in 2014. [Methods] From the general Japanese population, 2,400 people (age = 20-69) were selected using a stratified two-phase sampling method. In a mail survey administered in February 2014, the participants were surveyed regarding the following topics: (1) their attitudes toward genetic testing, the genetic testing of children, and obtaining blood donations from children for research; (2) their perspective regarding informed consent; (3) their level of scientific literacy regarding genomics; and (4) their demographic information and socioeconomic status. [Results] The response rate was 56.4%(1,354/2,400). We calculated genomic literacy scores by considering the participants' (1) knowledge of genomic terminology, (2) contextual understanding of genomic terminology, and (3) awareness of the benefits and risks of genomic studies. Conducting genetic testing on children for disease susceptibilities was favored by 58.4% of participants. Regarding obtaining blood donations from children, 53.2% approved, 11.3% disapproved, and 34.8% were undecided. A higher proportion of participants with high genomic literacy levels approved of obtaining blood donations from children. The multiple logistic analysis odds ratio regarding genomic literacy was 1.28 (95% confidence interval = 1.05-1.50). Regarding whether seeking consent from children is appropriate, 47.0% of people answered that seeking consent from a child is acceptable if the child understands the details of the research and 42.9% answered that seeking consent from a child is acceptable if the child can judge the pros and cons of participating in the research. These responses were associated with genomic literacy. [Discussion] Many birth cohort studies have been conducted worldwide. The results of this study suggest that people's genomic literacy is essentially related to people's perspective on genomic research on children.

EuroGentest Guidelines for Diagnostic Next Generation Sequencing. *P. Bauer[1], G. Matthijs[2], M. Alders[3], A. Corveleyn[2], S. Eck[4], I. Feenstra[5], V. Race[2], H. Scheffer[5], E. Sistermans[6], E. Souche[2], M. Sturm[1], M. Weiss[6], H. Yntema[5], Participants of the EuroGentest Workshop on Diagnostic NGS Guidelines.* 1) Institute of Medical Genetics and Applied Genomics, Univ Tuebingen, Tuebingen, Germany; 2) Center for Human Genetics, Leuven, Belgium; 3) Department of Clinical Genetics, Academic Medical Centre (AMC), Amsterdam, Netherlands; 4) Center for Human Genetics and Laboratory Diagnostics, Dr. Klein, Dr. Rost, Martinsried, Germany; 5) Department of Human Genetics, Radboud University Medical Center (RUMC), Nijmegen, Netherlands; 6) VU University Medical Center, Amsterdam, Netherlands.

The use of Next generation sequencing (NGS) for clinical diagnostics is increasingly recognized. While the exploitation for research purposes has made tremendous advancements in human genetics, the diagnostic use brings challenges at different levels including data production and storage, and interpretation of results. Although several diagnostic NGS guidelines have been issued by the American, Australian, Dutch and British genetic professional societies, a couple of relevant topics have not yet been addressed and therefore, a EuroGentest expert group has been working on compiling, integrating and completing these guidelines. Among other statements, the guideline delivers three major definitions: "diagnostic utility", "quality scoring for NGS tests", and "reportable range". We believe that defining the 'diagnostic utility' of the NGS test is the laboratory's first duty when preparing to offer diagnostic NGS. Our scoring system for the different NGS assays depends on quality and comprehensiveness. With this system, referring physicians, patients, and stakeholders in the health system will be enabled to compare different tests offered at the market. This scoring system is new, as it does not feature in any other guideline. As far as 'reportable range' is concerned, we propose the use of 3 specific percentages depending on the reference (technical target, coverage of transcript in a gene panel, coverage with reference to the genome) which will again allow to compare individual results within runs, between tests and between laboratories. The guidelines propose a generic template for reporting NGS results as well. While dealing with informed consent, unclassified variants and unsolicited findings, again from the laboratory standpoint, is already addressed in aforementioned published guidelines, the distinction of diagnostic and research is a very relevant topic when it comes to the "duty to recontact". The latter is elaborated with a practical solution.

2342M

Attitudes toward direct-to-consumer genetic testing and its regulation in Japan. *K. Muto[1], A. Nagai[1], A. Kamisato[1], B. Zhao[1], H. Hong[1], Z. Yamagata[2].* 1) Dept Pub Policy, Inst Med Sci, Univ Tokyo, Tokyo, Japan; 2) Dept Hlth Sci, Sch Med, Univ Yamanashi, Chuo, Japan.

[Background] Direct-to-consumer genetic testing (DTCGT) in the US and China has been suspended due to alerts by the authorities in these countries. However, DTCGT can still be purchased in Japan. The Ministry of Health, Labour and Welfare (MHLW) in Japan has ignored these international alerts for a long time. The Ministry of Trade and Industry (METI) have conducted market research three times since 2007, to create a new market and to educate consumers in this field. The METI considered the regulations governing DTCGT and attached importance to quality control, scientific evidence, and informed consent. There is at present no ban on genetic discrimination or legal protection of personal genomic information in Japan. Several surveys have been conducted to clarify questions regarding public or consumer attitudes to DTCGT; however, there is still little data available in East Asia. [Purpose] The aim of this study is to clarify public attitudes towards DTCGT and the unique regulations in Japan. Method: We conducted a web-based questionnaire survey to investigate general perceptions in 2014. In total, 7,350 Japanese citizens completed the questionnaire (RR = 30.5%). We analyzed this data and compared it with past datasets. [Results] Of the respondents, 21.8% knew about DTCGT, and just 1% had purchased it before. Regarding actionable diseases, 50% of the respondents reported that they would like to receive their results via their physicians. Only 10% wanted to receive the results by post or on a website. We asked respondents to report their willingness to undergo 4 types of genetic testing based on scientific evidence. About 50% reported that they would like to undergo genetic testing on drug susceptibility genes or genetic susceptibility to actionable diseases with certain scientific evidence. However, 25-26.4% responded that they would undergo such testing even if there was no scientific evidence. More than 70% of the respondents reported that they needed ban on DNA theft and usage without permission. The perceived need for regulation on genetic discrimination in employment and in insurance was 59.7% and 52.8% respectively. [Discussion] A limitation of our study was that the percentage of respondents who reported "I can't decide" was relatively high. Compared with past studies in Korea and Taiwan, Japanese respondents showed less interest in DTCGT. Before promoting DTCGT in Japan, legislation for protection of personal genomic information is needed.

2343T

Development of the Clinical NGS Industry in a Shifting Policy Climate. *M.A. Curnutte[1], K.L. Frumovitz[1], J.M. Bollinger[2], A.L. McGuire[1], D.J. Kufman[2].* 1) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX; 2) Genetics and Public Policy Center at Johns Hopkins University, Washington, DC.

There is active debate about appropriate regulation of the rapidly evolving clinical next generation sequencing (NGS) industry. Interviews with industry leaders (n=19) and a web-based search of NGS companies (n=94) suggest the industry is developing services along the NGS pipeline partly in response to this regulatory uncertainty. Currently, few companies offer the full range of technology, software, and services needed to perform clinical testing. Rather, the industry tends to sell laboratories Research Use Only (RUO) products that do not stand alone as a clinical test. Clinical laboratories with expertise in laboratory standards, reimbursement, and clinical reporting then assemble these components into medical NGS assays that are classified as laboratory-developed tests (LDTs), subject to little NGS-specific regulation. Manufacturers of components of the LDTs have few clear standards to meet. This is occurring against a backdrop of evolving policy, technology, and insurance coverage. A better understanding of how the NGS business is developing in response to the current policy environment should inform regulatory efforts.

The protection of genetic privacy in the European Union and the proposed data protection reforms. *A.C. de Paor.* Centre Disability Law & Policy, Natl Univ Ireland, Galway, Galway, Galway, Ireland.

With developments in genetic science and technology, genetic information is becoming more widely accessible. However, the increasing availability of genetic information raises many ethical and legal issues that may threaten advancing science, in the absence of sufficient regulation. One such issue is the violation of genetic privacy. Genetic information is sensitive personal information that can reveal intimate details about an individual and an individual's family. In light of the sensitive nature of genetic information, the potential abuse is clear, as is the desire to protect such information from access and disclosure. Therefore, there are compelling reasons to maintain the privacy and confidentiality of genetic information. In the European Union (EU), the Data Protection Directive (introduced in 1995) provides a framework that protects the privacy of personal information. However, there is currently no substantive provision for genetic data and no specific reference to this category of information, indicating a gap in the privacy protection for genetic data in the EU. Recent developments indicate an intention to include genetic data within the scope of EU data protection laws, with the proposal of a new Regulation. With this new Regulation, the European Commission aims to develop an updated data protection framework. It is committed to reform data protection legislation, in line with the realities of today's society, and changing norms. The draft Regulation identifies 'genetic data' as a category of personal data designated for special protection. 'Genetic data' is defined broadly to include 'all data, of whatever type, concerning the characteristics of an individual that are inherited or acquired during early prenatal development', thereby presumably incorporating all genetic data including family medical history. Although this draft Regulation has encountered delay and a lack of consensus, it will enhance the protection of personal information (including genetic information) in the EU, when it is introduced. As regards protection of genetic privacy in third party contexts, this draft Regulation is welcomed as expressly recognising genetic information as a category that deserves protection. This paper analyses the issue of genetic privacy in the EU. It examines the current data protection framework, as well as the proposed reform of the EU data protection framework and the impact that these reforms will have on the protection of genetic data.

2345T

Towards an ethics "safe harbor" for global genomic research. *E.S. Dove[1], M.H. Zawati[1], E. Lévesque[1], J. Simard[2], B.M. Knoppers[1].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Molecular Medicine, Laval University, Quebec City, Quebec, Canada.

Genomic researchers are becoming increasingly globally connected and collaborative. Though global data-driven research holds great promise for disease discoveries, the underlying research ethics review system in much of the world challenges improvements in human health and paradoxically may not improve respect for persons who participate in research. Case reports illustrate that the current system is costly, fragmented, inefficient, inadequate, and inconsistent. There is an urgent need for criteria to determine whether there is "substantial equivalency" between the principles and procedures, ethics review and governance to be able to share data across jurisdictions. Building on the international privacy "safe harbor" model that was developed following the adoption of the European Data Protection Directive in 1995, we propose a federated "Safe Harbor Framework for International Ethics Review Equivalency" that could facilitate the harmonization of ethics review of specific types of data-driven international genomic and/or disease research projects, while respecting globally transposable research ethics norms and principles. The Safe Harbor Framework would consist in part of a newly constituted organization (provisionally called the International Federation for Ethics Review, or IFER), formed by a voluntary agreement among countries, granting agencies, philanthropies, institutions, and healthcare, patient advocacy, and research organizations. IFER would be both a central ethics review body and also a forum for review and follow-up of policies concerning ethics norms for international research projects. It would be built on five principle elements: 1) registration, 2) compliance review, 3) recognition, 4) monitoring and enforcement, and 5) public participation. A Safe Harbor Framework would create many benefits for researchers, countries, and the general public. Research participants would enjoy uniform adequate protection, while researchers would enjoy ensured ethics review expertise, proportionate ethics review, and a reduction in cost, time, administrative hassle, and redundant regulatory hurdles. Most importantly, society would enjoy the maximization of the potential benefits of genomic and disease research.

2346M

Analysis of ethical and social issues of large scale genome cohort/biobanking projects in Japan. *J. Minari[1], Y. Hanabusa[1], S. Toda[2], F. Nagami[2], K. Kato[1,3].* 1) Graduate School of Medicine, Osaka University, Suita, Osaka, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 3) Institute for Integrated Cell-Material Sciences, Kyoto University, Kyoto, Japan.

In the last decade or so, many large scale genome cohort/biobanking projects have been developed all over the world. Their aim is to establish infrastructures for disease and heath research. Many of the projects collect a large number of blood samples and associated life style information from healthy people, while some projects target patients with a variety of diseases.

In Japan, several large scale projects have been established starting from early or middle 2000s. One well-known example is the Biobank Japan project which has a collection of DNA and blood serum samples of 200,000 patients. Other projects started relatively recently. The Tohoku Medical Megabank has been set up in the Tohoku area which has been hit by the big earthquake in March 2011. It has begun collecting samples in 2013 with the aim of establishing two cohorts of 150,000 people. It has also completed whole genome sequencing of 1000 individuals in the fall 2013.

For the ethical, legal and social issues that have to be addressed, projects in Japan tended to work on them relatively independently. Many project have been initiated, but each project struggles to establish their own policy without sufficiently learning from existing projects. In order to maximize the resources and efforts used for the projects and to overcome the shortcomings aforementioned, it has become imperative to exchange experiences beyond individual projects. To this end, we have conducted a cross project comparison of ethical and social issues as well as governance mechanisms of several large scale projects in Japan.

Our analysis has shown several features of the current Japanese projects. One is that many of them are considering data sharing as a necessary activity, while sharing materials is still controversial especially with foreign researchers. Another interesting feature is that healthy participants for cohort studies are often recruited in conjunction with the system of health monitoring in the local community, which is feasible based on the existing trust between participants or community and researchers. Our findings are valuable for creating a common framework of research governance in the global community.

2347T

De-implementation of newborn bloodspot screening: ethical and policy issues. *S.G. Nicholls.* Epidemiology and Community Medicine, University of Ottawa, Ottawa, Ontario, Canada.

Background: Newborn bloodspot screening (NBS) is one of the oldest and largest population-based screening programs in the world and involves testing blood taken via a heel prick for a number of serious and life limiting conditions. Today, NBS is applied across most continents and was recently recognized by the Centers for Disease Control (CDC) as one of ten great public health achievements of the last decade. While there has been increasing debate about criteria for expanded screening, far less attention has been paid to the exclusion or removal of conditions within existing panels. This is highly relevant given recent experiences of screening for Krabbe disease in New York: in five years of testing only a handful of cases have been identified at a cost of millions of dollars. In addition, some parents have received results where it remains uncertain if, how, or when symptoms might appear and what could be done. Other conditions, such as Duchenne Muscular Dystrophy (DMD) have been withdrawn from programs on the basis of problems with the supply of products needed to undertake the test. In part, due to limited number of programs worldwide, there has been a lack of quality control materials. Recent discussion in the field of implementation science has called for greater exploration of issues pertaining to the de-implementation of technologies and specifically "[research] to understand better the other, cognitive or political factors that facilitate or hinder de-implementation" (Prasad and Ioannidis, 2014). Objective: To explore the ethical and policy issues relating to the de-implementation of newborn bloodspot screening programs or program elements. Results: Using case studies a number of ethical and policy issues are identified. Key questions to be answered include: who are the relevant stakeholders in decisions to de-implement screening programs or program elements? What role should these different stakeholders play? What are the relevant priorities of factors such cost-effectiveness or justice? How are harms and benefits to be evaluated? Conclusions: To date there has been little consideration to the de-implementation of newborn screening programs or program elements. Experiences with other population screening programs suggest that de-implementation decisions may be controversial. Due consideration needs to be given to the appropriate roles and weight applied to ethical issues that frame the discussion of empirical evidence.

Concerns of researchers and physicians regarding the chromosomally integrated HHV-6. *V. Noël[1], R. Drouin[2], L. Flamand[3], C. Bouffard[1].* 1) Université de Sherbrooke, Sherbrooke, Canada; 2) CHR du Grand-Portage, Rivière-du-Loup, Canada; 3) Université Laval, Québec, Canada.

INTRODUCTION: The human herpesvirus 6 (HHV-6) has the unique capacity, among HHVs, to integrate to the telomeres of the chromosomes (ciHHV-6) of nucleated cells after infection. ciHHV-6 can therefore be found in gametes and be transmitted both from one generation to the next, and through organ and tissue donation. This worrisome situation affects more than 70 million people around the world and may be associated with more than 50 illnesses (pneumonitis, encephalitis, infertility, cancers, etc.), of which some are fatal. Despite its consequences on the health of individuals and populations, this phenomenon has attracted little interest in scientific and public health milieus. To highlight the importance of the problem, several researchers and physicians publish warnings in purely scientific journals. Thus, our objectives are to understand the positions of these researchers and the solutions they propose, in order to identify their clinical and socio-ethical concerns regarding the effects of ciHHV-6. METHODOLOGY: 1) Comprehensive narrative synthesis of the literature: a) research by key words in databases; b) thematic inductive analysis; c) interpretative synthesis. RESULTS: Of the 90 articles analysed, 62 contained opinions, recommendations or lines of question bearing on: a) population health, b) grafts and transplants, c) diagnostic tests, d) clinical and therapeutic care and e) pathogenicity. Certain authors also raise the idea of a screening test, as a solution for the negative effects of ciHHV-6 on population health. Finally, the problems identified by researchers and the solutions they propose incite us to revisit the notion of reproductive autonomy, as well as the principle of beneficence. We will conduct interviews based on our results with researchers and physicians who are members of the HHV-6 Foundation. CONCLUSION: This research demonstrates the importance of possessing knowledge making it possible to reflect on: a) the medical and socio-ethical consequences of ciHHV6, b) the relevance of offering a screening test and c) patient care. It could contribute to the establishment of measures that would act early on the consequences of ciHHV6, to support the work of researchers and physicians, to improve and harmonize practices for the wellbeing of affected individuals and populations.

Regulating Gamete Donation in the US: Ethical, Legal and Social Challenges. *M. Sabatello[1, 2].* 1) Psychiatry, Columbia University, New York, NY., USA; 2) Center for Global Affairs, NYU, New York, NY, USA.

The practice of gamete donation has received growing attention in the past two decades. As an increasing number of individuals and couples resort to this practice, and the children born as a result (donor-conceived-children) are reaching maturity, many are grappling with the question how to address the dilemmas that arise. Do recipient-parents have a duty to tell their donor-conceived child about his/ her genetic origins? Should the identity of the donor be disclosed or remain anonymous? Does the child have a right to know her conception story and to receive information, including identifying, medical, and genetic information, about the donor? And if a donor-conceived-child has a right to know, who has the duty to tell her about it? Focusing on the US context, this paper explores these questions having in mind the larger question of what do we as a society owe children born as a result of assisted reproduction, especially gamete donation. It underscores the ethical, legal and social dilemmas that arise, comparing and contrasting with international developments in this arena. It highlights the medical justifications for regulating this field, explores the emerging so-called right of the child to know his/ her genetic origins ("the right to know"), and considers the challenges such a right evokes to existing principles of medical ethics in the US as well as other broader societal implications of such a right.

Illuminating the changing landscape from newborn screening to newborn sequencing: Ethical, psychological, and societal implications for research and policy-making in the genomics era. *L. Bush[1], K. Rothenberg[2].* 1) Pediatric Clinical Genetics, Columbia University Medical Center, New York, NY; 2) Genomics and Society, National Human Genome Research Institute, Bethesda, MD.

As the genomics and bioethical communities engage in newly-funded research investigating the application of whole exome/genome sequencing both on healthy newborns (NBSeq) within the context of a population-based newborn screening (NBS) initiative as well as with ill newborns as a diagnostic test, it is critical that the complexity of emerging issues are illuminated to enhance understanding and exploration of the challenges ahead -- the ethical, legal, psychosocial, and policy implications on our multi-cultural society. Historically, both NBS and genetic testing of children have been fraught with controversy - such as informed consent autonomy issues, psychological impact of false positives, wide variability in access, what constitutes the best interest of the child - and concerns raised will accelerate in parallel with the mounting information generated by genomic sequencing. Foresight and thoughtful planning are especially needed in the research domain when infants are involved. Ethical deliberation with diverse voices is essential to set policy, particularly since the potential benefits of genomic findings on a newborn co-exist with a multitude of potential risks. By expanding identification of conditions exponentially through the implementation of new comprehensive genomic technologies, NBS as a social justice leveler may be jeopardized with NBSeq as some states lack resources to provide necessary follow-up, especially as many variants of uncertain significance are discovered. While tolerance to uncertainty varies, the potential for heightened anxiety must be seriously considered. Moreover, the ability to protect the interests of vulnerable newborns by traditionally mandating NBS for some conditions may be eroded with NBSeq due to informed consent and return of results blurring boundaries among a public health screening measure, research, and clinical test paradigms. From an ethical and societal perspective, this is really tough terrain. To facilitate reflection and ethical inquiry among ASHG attendees and enrich the policy process, contextual nuances surrounding this changing genomic landscape are illuminated.

2351T

Whole genome sequencing in newborn screening? A Statement on the continued importance of targeted approaches in newborn screening programmes. *B.M. Knoppers[1], H.C. Howard[2], M. Cornel[3], E. Wright Clayton[4], K. Senecal[1], P. Borry[5].* 1) Centre of Genomics and Policy, Human Gen Dept, McGill University, Montreal, Qc, Canada; 2) Centre for Research Ethics & Bioethics, Uppsala University, Uppsala, Sweden; 3) Department of Clinical Genetics and EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, The Netherlands; 4) Center for Biomedical Ethics and Society, Vanderbilt University, Nashville, USA; 5) Department of Public Health and Primary Care, University of Leuven, Leuven, Belgium.

Background: Whole genome sequencing (WGS) is a powerful technology that which sequences the entire genome of a person. It can be used at any stage of life, including at birth. The rapid development of WGS has led some to predict that the use of this technology will change the current practice of medicine and public health by enabling more accurate, sophisticated and cost-effective genetic testing. Some believe that the earliest applications of WGS will be restricted to settings in which genetic testing is already a routine part of clinical or public health practice, such as state newborn screening (NBS) programs. That being said, a critique of this view could point to the fact that the routine nature of NBS and thus its often implied consent, as well as its public health context, and the particular vulnerability of the population tested, could, in fact, make it an unsuited context into which to first welcome a WGS-based approach. Objectives: The aim of this project was to develop consensus recommendations on the possible introduction of WGS into NBS program. Method: To formulate the Recommendations, we: 1) reviewed the normative texts guiding newborn screening programs and relevant literature addressing the issues raised by WGS in NBS to identify both existing and emerging guidance; 2) developed a background paper and draft recommendations; 3) validated the recommendations through a series of consultations with: members of the Professional and Public Policy Committee of the European Society of Human Genetics; Human Genome Organisation Committee on Ethics, Law and Society; and P3G International Paediatric Platform. Results: Along with the members of the above mentioned Committees, we formulated recommendations with regards to the potential use of WGS in newborn screening programs. Conclusion: The responsible use of WGS within a public health programme should not be dictated by the mere availability technologies, but rather on the basis of its public health potential and the best interests of the target population(s).

Abundant pleiotropy complicates the return of genetic results and incidental findings. *J.M. Kocarnik[1, 2], C.M. Connolly[2], S.M. Fullerton[2, 3].* 1) Epidemiology, University of Washington, Seattle, WA; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Bioethics and Humanities, University of Washington, Seattle, WA.

Introduction: Current guidelines regarding the return of incidental findings generated in the course of whole genome sequencing recommend only returning information that meets stringent thresholds of clinical validity and utility. The American College of Medical Genetics and Genomics (ACMG), for example, recommends that variants in 56 genes associated with 24 phenotypes are sufficiently important that they should be sought out and reported when any clinical sequencing is performed (Green et al. 2013). However, these and other guidelines do not account for the issue of pleiotropy, where a single gene is associated with multiple phenotypes that may differ in their appropriateness for return. In such pleiotropic genes, one genotype-phenotype relationship may be clinically actionable, while another might be of unproven validity. Since the genetic information is the same, returning information on the former also returns information on the latter. We previously reported that 77% of the genes in the ACMG recommendations have pleiotropic relationships (Kocarnik et al. 2014). To further characterize the potential extent of this issue, we evaluated how many genes are associated with additional phenotypes across the entire Online Mendelian Inheritance in Man catalog, a publicly accessible database of human genes and genetic disorders (OMIM.org). Methods: We recorded how many and what kind of MIM phenotypes were noted as associated with each gene listed in OMIM. Initially, only phenotypes with an assigned MIM number were counted. Results: As of 5/14/2014, 879 of the 4555 genes in the catalog (19%) listed associations with multiple unique MIM phenotypes (range 2-14). Some of these genes, such as PTEN and PIK3CA, were associated with more than ten phenotypes. When not restricted to phenotypes that had been assigned MIM numbers, 1075 (24%) of these genes listed multiple phenotypic relationships (range 2-16). Conclusion: A substantial fraction of the genes in the OMIM catalog are associated with multiple phenotypes, which could be conveyed inadvertently when returning genetic results. Pleiotropy appears to be a pervasive issue that has not been addressed in current incidental findings guidelines, which provide no guidance for how to deal with these extraneous yet easily-discoverable relationships. Future recommendations will need to consider the potential impact of such pleiotropic relationships when determining how best to return individual genetic results.

Unknown knowns? Challenging concepts for patient regarding whole-exome sequencing. *J.M. O'Daniel[1], D. Skinner[2,3], A.K.M. Foreman[1], C. Rini[4], M. Roche[5], G. Henderson[5].* 1) Genetics, University of North Carolina, Chapel Hill, NC; 2) Frank Porter Graham Child Development Institute, University of North Carolina; 3) Anthropology, University of North Carolina; 4) Gillings School of Public Health, University of North Carolina; 5) Social Medicine, University of North Carolina.

As the technical and diagnostic merits for whole-exome sequencing are assessed, parallel research is underway to elucidate and meet the challenges it may present for clinicians and patients. NCGENES is a NIH-CSER study aiming to investigate these challenges in a cohort of ~500 genetics patients. One of the project goals is to explore patient perspectives and educational needs to inform results return of both diagnostic and incidental findings. To aid this study, six focus groups were held in November and December 2013 with a total of 40 participants from the UNC genetics clinics: 31 adult patients (23 hereditary cancer / 8 general genetic) and 9 parents of minor or intellectually disabled patients. The group discussions utilized a vignette to explore several areas related to incidental findings resulting from whole-exome sequencing: terminology, desire for information, types/categories of information, patient consent/choice, and process for return of results. A number of important findings emerged. First, participants viewed incidental findings to be of possibly equal or even greater, importance than the diagnostic results. As such, a more neutral term for them was desired, such as "additional." In general, participants stated that any information that may be significant to current or future treatment should be a "routine part of the test," however; they also agreed that patients should have a right to refuse any incidental findings. Parents of minor/intellectually disabled patients had more ambivalence than adult patients in desire for incidental findings if they did not pertain to the immediate health of the child. This may be attributed to their more variable diagnoses and testing experiences. Many participants desired clinician involvement to help determine the health importance of results and what information to request; others voiced the need to learn all available information so as to become their own health advocates. Throughout all focus groups, the concept of running a medical test and yet not interpreting all the data was a significant challenge. This failure to differentiate genomic data from test results has important implications for counseling patients, and possibly whether they ask for incidental findings.

Changing Preferences About Secondary Results From Exome Sequencing: Separating Preference Setting from Informed Consent. *J. Crouch[1], S.M. Jamal[2], A.G. Shankar[2], J. Yu[2], M.J. Bamshad[2,3], H.K. Tabor[1,2].* 1) Seattle Children's Research Institute, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

Debate continues over whether, how and when people should be allowed to select preferences for return of secondary results (SR) identified through clinical exome and whole genome sequencing. One unresolved issue is whether soliciting SR preferences at the time of informed consent for sequencing is an effective approach for patient decision-making. This debate is complicated by a lack of empirical data on the SR preference setting process. We recruited 145 people whose exomes had been sequenced previously to select preferences for SR return using My46, a web-based results management tool. Participants selected "yes," "no" or "I am undecided" as their preference for each of 11 SR categories: carrier status, medication response, ancestry, and disease risk (heart & lungs, brain & nervous system, blood, senses, cancer, muscle & bones, metabolism & hormones, and digestive system). Participants could change these preferences at any time. Seven percent (n=10) changed at least one of their SR preferences, either during their first preference setting session (n=6) or 10-34 days after their initial session and after participating in a study interview (n=4). Most of them (n=7) selected additional SR categories for reasons including curiosity, family history, conducting further personal "research," discussions with family members, improved understanding about which results were available, and changing priorities after recovering from a recent major surgery related to a primary diagnosis. However, 3 participants decided not to learn about certain SR information or to receive only a few results before deciding whether to receive more. Preferences for SR about blood conditions were most commonly changed (n=4), followed by ancestry (3) and cancer (2). Among 51 participants interviewed, 8 (16%) anticipated changing preferences in the future. These findings suggest that for some individuals, SR preference setting is a dynamic and iterative process influenced by discussions with others, taking time to reflect on personal interpretations of benefits and risks of specific SR categories, and responding to changing personal contexts such as health status. While more empirical data across different clinical and research contexts are needed, SR return policies should consider disassociating informed consent and preference setting in order to accommodate an informed and deliberative process, and to allow individuals to prioritize SRs and modify preferences over time.

2355T

Next generation DNA sequencing and incidental findings: consultand's opinion about the impact of being informed. *J. Forbes[1], C. Riolfi[1], M. Vianna[2], R. Pavanello[1], S. Igreja[1], T. Genesini[2], M. Zatz[1].* 1) Human Genome Res Ctr, University Sao Paulo (USP) , São Paulo, São Paulo, Brazil; 2) Institute of Lacanian Psychoanalysis - IPLA, Sao Paulo, Brazil.

Incidental findings, will be each time more common after the implantation of Next generation DNA sequencing, which is already a reality in our center (Human Genome and stem-cell research center- HUG-CELL center) in São Paulo University, Brazil. This technical advance has brought ethical and psychological concerns to geneticists and psychoanalysts, the professionals who are either responsible for genetic counseling or for providing support to those with psychic suffering caused by a diagnosis of a genetic disorder. These concerns relate to the potential advantages and disadvantages of communicating an incidental finding, that is, mutations not related to the specific patient' disorder and/or of an uncertain prognosis. The concern with what to do with this kind of finding is relatively new. For instance, in December 2013, the document "Antecipate and communicate - Ethical Management of Incidental and Secondary Findings in the Clinical, Research, and Direct-to-Consumer Contexts" was produced. This document advises to researchers on when and how to tell people about such findings. However, these recommendations do not include the patient's willingness to know or not the potential risk to develop a disease in the future. From a psychoanalytic point of view, we question whether the knowledge about someone's body should be given to a third party. Is it reasonable for the society to delegate to researchers the ethical responsibility to impose on the individuals seeking a specific diagnosis the knowledge about additional unrelated genetic risks? In order to address this question we are currently studying people's opinion about the potential effects of being informed about incidental findings as a result of next generation DNA sequencing. The results of this survey, which is undergoing at the HUG-CELL center will be presented.

Compare and Contrast: A cross-national study across UK, USA and Greek Experts toward Return of Incidental Findings from Clinical Sequencing. *E.G. Gourna, N. Armstrong, S.E. Wallace.* Heath Sciences, University of Leicester, Leicester, United Kingdom.

Guidance for the return of incidental findings (IFs) from clinical sequencing is being drafted at national and international levels. However, no studies have as yet been published comparing attitudes of experts across different countries to determine where similarities and differences of opinion and practice lie. We investigated attitudes toward returning IFs from clinical sequencing across UK, USA and Greek experts. Thirty in-depth interviews were conducted with experts including clinical geneticists, lab-based geneticists and experts with legal background. The majority of experts expressed numerous concerns and these were consistent regardless of their country. Major differences were only observed between experts according to their professional background. Clinical geneticists were mainly driven to return only medically actionable findings while the other experts also favored returning IFs that had personal utility for patients. Clinical geneticists were more inclined to order targeted tests instead of Next-Generation Sequencing (NGS) to avoid finding IFs, while lab-geneticists considered NGS as a good source of useful information for the patient's health. All experts saw the need for extensive pre-test counseling where patients could be helped to make informed choices to receive Ifs, but post-test decisions were seen as more complicated and genetic counseling was considered crucial. No consensus was reached regarding the dissemination of information to family members. In all three countries, the final decision to disclose or not to disclose, usually lied with the clinical geneticist, who was also responsible for communicating the findings and was occasionally supported by a multidisciplinary team. Our study showed more similarities than differences across countries. Professional background seemed to play a more important role, while even experts with the same professional background relied on their previous experiences to inform their attitudes. Our experts could only agree that medically actionable results should be communicated to patients. As well, they acknowledged how time and labor intensive the decision process is, and asked for clear guidance to support them. However, the type of guidance seen as most appropriate differed according to the infrastructure and resources of their health system. We conclude that while over-arching principles can be created at the international level, guidance for specific practice needs to be country-specific.

2357T

Participant satisfaction with a preference-setting tool for the return of individual research results in pediatric genomic research. *I. Holm[1,2,3], B. Iles[4], S. Ziniel[2,5,6], P. Bacon[7], S. Savage[1], K. Christensen[8], E. Weitzman[2,5,9], R. Green[8,10], N. Huntington[2,11].* 1) Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School; 3) Manton Center for Orphan Disease Research, Boston Children's Hospital; 4) McLean Hospital; 5) Division of Adolescent/Young Adult Medicine, Boston Children's Hospital; 6) Center for Patient Safety and Quality Research, Program for Patient Safety and Quality, Boston Children's Hospital; 7) Johns Hopkins University School of Medicine; 8) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School; 9) Children's Hospital Informatics Program at the Harvard-MIT Division of Health Sciences and Technology, Boston Children's Hospital; 10) Partners Personalized Medicine; 11) Division of Developmental Medicine, Boston Children's Hospital.

Although return of individual research results (IRR) to participants in genomic biobank research may be desirable, the feasibility of IRR return and how to incorporate participant preferences are unclear. There is skepticism that participants truly understand the implications of their choice of IRR to receive suggesting that incorporating preferences may be unrealistic. The role of preferences is particularly complex in pediatrics where a parent receives IRR on their child. We developed an online preference-setting tool for the return of IRR based on the preventability and severity of a condition, dimensions that resonated with parents in interviews. The tool also allows parents to opt-out of receiving results from 4 categories: mental illness, developmental disorders, childhood-onset degenerative conditions, and adult-onset conditions not treatable during childhood. We tested this tool in an online survey emailed to parents of patients <18 years of age at Boston Children's Hospital. Parents were randomized to the hypothetical scenario that their child was enrolled in 1 of 4 biobanks with different policies for return of IRR on their child: 1) receive no IRR (None); 2) receive all IRR (All); 3) given a choice to receive all or no IRR (Binary); and 4) use the preference setting tool to choose categories of IRR to receive (Granular). Parents were given a hypothetical research result report for their child. In this analysis we report on participant satisfaction with the process, biobank, and hypothetical results received. There were 11,391 emails delivered with a response rate of 24%. The granular group was the most satisfied with the process, biobank, and hypothetical results received while the None group was least satisfied with each ($p<0.001$). The None group was least likely to agree that the biobank they were randomized to was beneficial ($p<0.001$) and most likely to agree it was a "bad thing" ($p<0.001$). The Binary and All groups rated satisfaction nearly as high as the Granular group. No significant difference was found between the groups regarding agreement/disagreement with the statement that the biobank was harmful. Recognizing that the results returned were hypothetical, our data suggest that return of IRR may increase satisfaction for biobank participation. Our results also suggest that compared to limited or no choice on results to receive, providing participants with the ability to designate their preferences leads to the greatest satisfaction.

Patients' Perceptions of Whole Genome Sequencing Results and Plans to Use Non-Actionable Findings. *L. Jamal[1,2], J.O. Robinson[1], P. Lupo[1], J. Blumenthal-Barby[1], L.Z. Feuerman[1], J.L. Vassy[3], K.D. Christensen[4], M.J. Slashinski[1], J. Wycliff[1], R.C. Green[4], A.L. McGuire[1] for the MedSeq Project.* 1) Baylor College of Medicine, Houston, TX, United States; 2) Johns Hopkins Berman Institute of Bioethics, Baltimore, MD, United States; 3) Section of General Internal Medicine, VA Boston Healthcare System, Boston, MA, United States; 4) Department of Medicine, Brigham and Women's Hospital, Boston, MA, United States.

Background: There is much debate over best practices for returning results from clinical whole-genome sequencing (WGS). An emerging trend is to categorize WGS results into 'bins' based on their clinical utility. How patients interpret and intend to use WGS results is not well understood. Methods: The MedSeq Project is a randomized clinical trial exploring the use of WGS in cardiology and primary care settings. At baseline (before WGS), 106 patient-participants were surveyed and a subset of 28 completed in-person, semi-structured interviews. Transcripts of recorded interviews were consensus coded and analyzed thematically. Target enrollment of 200 patient-participants is expected by summer 2014. Results: Consistent with previous studies, the majority of patient-participants (87%) wanted all their WGS results. However, qualitative data show that the majority of interviewed patient-participants (n=24) had difficulty distinguishing among result types. When asked, they struggled to provide clear examples of results associated with preventable or treatable conditions as distinct from results with less clinical utility. These difficulties did not reflect poor study understanding or genetic literacy. Many patient-participants (n=17) wanted results associated with non-preventable or treatable conditions to inform their professional or financial plans, supportive care, and quality of life. Conclusion: Patients may not easily distinguish among the types of results described in WGS informed consent documents. They value WGS results for both medical and non-medical reasons. These data challenge the conceptual framework underlying many emerging models of WGS results disclosure, which define the clinical utility of results and base disclosure practices on these definitions.

What do younger breast cancer patients want to learn about individual results from genome sequencing? *K.A. Kaphingst[1], J. Ivanovich[1], B. Biesecker[2], J. Seo[1], L. Dressler[3], P. Goodfellow[4], R. Dresser[5], M. Goodman[1], M. Ray[1], S. Bell[1], K. Walton[1].* 1) Division of Public Health Sciences, Washington University School of Medicine, St. Louis, MO; 2) Social and Behavioral Research Branch, National Human Genome Research Institute, Bethesda, MD; 3) Mission Health, Fullerton Cancer Center, Asheville, NC; 4) College of Medicine, The Ohio State University, Columbus, OH; 5) Washington University School of Law, St. Louis, MO.

Background: Many communication challenges arise with return of individual results from genome sequencing. While the type of genome sequencing results that should be returned has been hotly debated, few findings are available to inform what patients would like to know about a result. These data are needed to develop communication strategies for the return of results, particularly among populations targeted for early application of genome sequencing such as patients diagnosed with breast cancer at a young age. Methods: We conducted 60 semi-structured individual interviews with women diagnosed with breast cancer at age 40 or younger to investigate what they would like to learn about individual genome sequencing results. We stratified recruitment by family history of breast cancer and BRCA1/2 mutation status to examine differences by these factors. Interviews examined interest in return of individual results for six types of gene variants (e.g., affects risk for a preventable disease, affects treatment response, uncertain clinical significance) as well as what content participants would like to learn about each type of result. Two coders independently coded all interview transcripts; analysis was based on consensus codes. Qualitative thematic analysis was conducted using NVivo. Results: Across different types of genome sequencing results, participants were most interested in learning about the health implications of the variant: "long term, what to expect...I would want to learn as much as I could so I could know how to deal with it." Other common content topics of interest included effect of the variant on disease risk for relatives, prevalence of the variant among different populations, and cause of the variant (e.g., hereditary, environment). We observed some differences in themes across strata. For example, the theme of wanting to learn everything possible about a variant was more common among women who have a known BRCA1/2 mutation. Some participants also highlighted the importance of clear communication in returning results: "I think I'd want to know everything that was in the scientific literature around that, but in layman's terms..." Conclusions: Participants most wanted to learn about the health implications of individual genome sequencing results, but were also interested in specific information about variants. These findings can inform the development of strategies to communicate with patients about genome sequencing results.

2360M

Returning incidental findings to family members of deceased research participants: Perspectives from a cancer biobank. *B.A. Koenig[1], C. Radecki Breitkopf[2], S.M. Wolf[3], M.E. Robinson[4], K.G. Rabe[2], N.M. Lindor[5], G.M. Petersen[2].* 1) Social & Behavioral Sci/Inst Hlth & Aging, Univ California, San Francisco, San Francisco, CA; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Consortium on Law and Values in Health, Environment, and the Life Sciences, University of Minnesota, Minneapolis, MN; 4) Biomedical Ethics Program, Mayo Clinic, Rochester, MN; 5) Department of Health Sciences Research, Mayo Clinic, Scottsdale, AZ.

Intense debate surrounds the return of incidental findings to participants in genomics research. Should researchers offer results to family members after the participant's death? Prior law and policy protect individual privacy, choice, and control, preserving each person's right not to learn the results of genetic tests. Given that actionable information, such as cancer risk, may be revealed by mutations shared among blood relatives, it is critical to develop evidence-based policy governing the management of results discovered after a participant's death. There are no rigorous empirical data documenting preferences of research participants. We report the results of the first survey to inform this debate, using a comprehensive tool based on 51 in-depth interviews with participants and family members. Surveys were mailed to 6,137 participants from a registry of pancreatic cancer patients, their family members, and healthy controls, asking preferences about return of findings. 2 repeat mailings to non-responders were sent at 30-day intervals. We addressed protecting "the right not to know" vs. offering results; weighing the wishes of individuals vs. family benefit; and participants' vs. researchers' roles and obligations. 3,645 surveys were returned (464 affected/probands, 399 spouses, 1,040 unaffected blood relatives, 1,727 controls and 15 individuals whose status could not be determined; 59% response rate). 13% endorsed protecting the "right not to know," with the majority choosing to "offer genetic research results to all participants, even at the risk of upsetting those who may not want to be offered results." 57% endorsed "whether blood relatives would benefit" as a justification for offering results vs. 43% who gave priority to "the wishes of the individual participant." 77% thought researchers bore responsibility to offer findings to participants. Participants supported offering results in spite of privacy protections, suggesting that the incidental findings debate must broaden to include consideration of return to family.

2361T

How Research Participants Value Result Confirmation in *CLIA* Compliant Laboratories. *M.Y. Laurino[1,2], A. Truitt[1], L. Tenney[2], D. Fisher[2], G.P. Jarvik[3], P. Newcomb[2,5], D. Veenstra[4], S.M. Fullerton[1,6].* 1) Institute for Public Health Genetics, University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Division of Medical Genetics, University of Washington, Seattle, WA; 4) Pharmaceutical Outcomes Research and Policy Program, University of Washington, Seattle, WA; 5) Department of Epidemiology, University of Washington, Seattle, WA; 6) Department of Bioethics and Humanities, University of Washington, Seattle, WA.

The Clinical Laboratory Improvement Amendments of 1988 *(CLIA)* requires that clinical laboratories meet quality standards to ensure that patients receive accurate, reliable, and timely results. Given that clinical utility is one of the main justifications supporting return of results from genetic and genomic research, there is disagreement about the necessity of validation in a *CLIA* compliant laboratory prior to returning research results. Under the *CLIA* research exception, results of tests performed in non-*CLIA* compliant laboratories may be returned with the caveat that such results are used for informational purposes only and not for clinical care. At present, limited data exist regarding the extent to which research participants act to confirm results of tests performed in non-*CLIA* compliant laboratories. To address this gap, this study examined whether participants at the Fred Hutchinson Cancer Research Center Colon Cancer Family Registry site pursued the recommendation to confirm their research results in a *CLIA* compliant laboratory by using a mixed-methods approach. Of registry participants who received Lynch syndrome (LS) related findings, 29/35 (83%) participated in a 2-month and 12-month post-test disclosure survey. In addition, 8/29 (28%) also participated in an in-depth follow-up interview. Of the 29 participants, 14 had disease-causing mutations, 14 tested negative for the familial mutation, and 1 had a variant of uncertain significance. Six of 29 (21%) participants validated results in a *CLIA* compliant laboratory, and the research and clinical results were concordant in all cases. Five additional participants shared their intent to confirm their research results but had not done so within 12 months post-test disclosure. The majority of those who validated their research findings, 4/6 (67%) had disease-causing mutations. For the 8 participants who participated in in-depth interviews, reasons for pursing or not clinical validation were: acting on the recommendation of the research team and informing future clinical care vs. lacking insurance coverage and perceiving limited personal benefits. The study results provide important empirical data on how research participants value result confirmation in *CLIA* compliant laboratories, and suggests the need to better communicate its advantages.

Microarray-based comparative genomic hybridization (aCGH) is commonly used to assist in diagnosing patients presenting with a phenotype compatible with a microdeletional syndrome or with intellectual disability with or without malformation. Since aCGH is interrogating the whole genome of an individual for micro rearrangement, there is a risk to be confronted to incidental findings (IF), defined as a finding that has potential health importance for the propositus or his family and is not related to the indication of the test. In order to anticipate the ethical issues due to the IF with the generalization of new genome wide analysis technologies, we sent a questionnaire to the French clinicians and cytogeneticists about their experience with IF in aCGH within a 7 years period. We collected data from all the French University Hospitals. All the aCGH were prescribed for developmental delay, intellectual disabilities and/or malformations, the majority of IF was found in children. None were diagnosed antenatally. 39 IF were included, 24 corresponding to autosomal dominant disease with incomplete penetrance (including 11 cancer predispositions), 3 to autosomal dominant disease with complete penetrance, and 12 to X-linked disease. None heterozygotes for frequent autosomal recessive disease were reported. Therapeutic/preventive measures or genetic counselling could be argued for all cases except 3 (Charcot-Marie-Tooth type 1A, SCA11 and choroideremia). Only 1/39 was intentionally not returned to the patients, because the disease was incurable with no access to any preventive care. The choice of returning or not the results was discussed collegially in 22/39 cases. Clinicians reported difficulties to return the results in 33% of the cases. In 9/39 cases, they reported their difficulties in predicting the phenotypic expression of the disease in the future. In 6/39 cases, it was due to psychological difficulties with the family to cope with these unexpected results, and in 3/39 to the difficulty of the family in understanding the results since the question of IF had to been anticipated. Indeed, only 51% of the clinicians used consents mentioning the risk of IF. With the emergence of new technologies such as Next Generation Sequencing (NGS) in the diagnosis yield, these national experiences will be crucial to progress in the ethical reflexion in this area. In particular, it shows the importance of informing the family of the possibility of IF.

2363T

Returning Participants Results from Genome Research in National Health and Nutrition Examination Surveys. *J. McLean, S. Lukacs.* Division of Health and Nutrition Examination Surveys, National Center for Health Statistics, Centers for Disease Control and Preventio, Hyattsville, MD.

Historic DNA banks are struggling to balance consents dating back decades that specify no return of results and advances in genomic research that have increased the potential for recognizing incidental findings. The National Center for Health Statistics (NCHS) National Health and Nutrition Examination Surveys (NHANES) Genetic Program has been working to resolve the retrospective and prospective issue of returning results to survey participants. NHANES is a multistage nationally representative probability sample of the multi-ethnic, civilian, non-institutionalized U.S. population conducted for over fifty years. The NHANES DNA Specimen bank opened to internal and external researchers in 1999. In 2011, the potential issue of incidental findings in genomic research and the implication of returning incidental findings to participants prompted NCHS to host a panel of experts for a one day meeting on returning results to survey participants. From that meeting NCHS initially decided to report findings to participants and use the binning method to determine which results to return. However, the NCHS Board of Scientific Counselors recommended that NHANES obtain wider scientific input. While deliberating this issue, NHANES temporarily closed the DNA bank to new proposals in 2012. NCHS commissioned the National Academy of Science Committee on National Statistics to convene a two day workshop. “Guidelines for Returning Individual Results from Genome Research Using Population-Based Banked Specimens” was held in February 2014. The workshop included participants from the Federal government, universities, and the private sector from a variety of specialty areas including research scientists, bioethicists, lawyers, epidemiologists, and clinical geneticists The preliminary outcome of the meeting 1) retrospectively, guidance was not to return results due to consent language and lack of CLIA certification for lab processing of the DNA specimens and 2) prospectively, consents should allow for returning results and to develop a method to return results. Receiving input and guidance from a panel of experts was a valuable approach to understanding and reconciling the evolving issue of returning results for genomic research particularly for historic DNA banks.

Parental decision-making for children enrolled in exome sequencing research and attitudes toward receiving variants of uncertain significance. *J. Sapp[1], M. Crenshaw[1], D.A. Dong[2], L.G. Biesecker[1], B.B. Biesecker[1].* 1) National Human Genome Res Inst, Bethesda, MD; 2) Genzyme, Boston, MA.

Genome sequencing is increasingly being employed to identify the cause of rare diseases. Yet policies and practices regarding the interrogation, annotation, validation, and return of genomic research data to participants are currently evolving and under debate. Many participants in genomic research are children whose parents consent and make decisions regarding the return of results on their behalf. In an NIH study to find the genetic causes of rare conditions we explored participants' preferences regarding the return of both primary and secondary findings. We conducted semi-structured interviews with 22 parents of 13 pediatric probands with rare disorders. Parents were asked to reflect on the notion of being offered choices in learning their child's variant results and about their attitudes toward receiving variants of uncertain clinical significance (VUCS). All parents appreciated the opportunity to make individual choices about receiving categorized variant results for their child, and seven participants stated that they would not have participated in genomic research if they had not had the opportunity to learn their child's sequence results. Parents had mixed attitudes toward the possibility of receiving their child's VUCS. Most parents with positive attitudes about receiving these variants discussed their hope that this information could prove useful in their child's future and planned to retain and occasionally revisit these results over time. Nine parents held negative or neutral attitudes toward VUCS because of the ambiguity inherent in these findings and perceived them to be of less utility. Parents' own personal experiences with uncertainty informed their attitudes toward learning their child's VUCS; some parents referenced a learned comfort with uncertainty as part of coping with their child's illness while others perceived receipt of these results as an undesired additional burden and worried about where they would find expertise to meaningfully interpret findings of this nature. Our findings suggest that investigators employing genome sequencing where both primary and secondary variant results are offered to parents of pediatric research participants can expect enhanced participant engagement, informed consent, and decision-making. Further understanding of how these attributes affect longitudinal outcomes of receiving results may inform discussion of best practices regarding the return of genomic data to research participants.

"Bring it on!" Preference setting for secondary results from exome sequencing using My46. *H. Tabor[1,2], J. Crouch[1], S.M. Jamal[2], A.G. Shankar[2], J-H. Yu[2], M.J. Bamshad[2,3].* 1) Treuman Katz Ctr Pediatric Bioethics, Seattle Children's Hospital, Seattle, WA; 2) Dept of Pediatrics, University of Washington, Seattle, WA; 3) Dept of Genome Sciences, University of Washington, Seattle, WA.

Exome sequencing is widely used in clinical and research settings, yet it is unclear whether and how individuals should be allowed to set their preferences about what secondary results (SR) they want to receive. It is also unknown how different patient populations will respond to the opportunity to receive a variety of SR, which SR they will choose, and why or why not. We recruited 145 people whose exomes (58 adults) or child's exomes (87 parents) were previously sequenced to select SR preferences using My46, a web-based results management tool. Participants selected "yes," "no" or "I am undecided" for each of 11 SR categories (SRC): carrier status, medication response, ancestry, and disease risk (e.g., blood, cancer, etc). The majority (79%) selected "yes" for all SRC (83% of parents, 75% of adults). A subset (n=51) were interviewed about SRC selection, including 12 who refused ≥1 SRC. Most interviewees (92%) described optimism and excitement; 31% volunteered that they were not worried or anxious. A subset (n= 11) simultaneously expressed ambiguity and nervousness about possible "bad" results but said that optimism about benefits outweighed concerns. Participants used both family history and their or their child's condition or future health prioritize their SR preferences. The average number of SRC refused was 1.8 for parents and 3.5 for adults. The SRC most frequently refused by parents was ancestry (n=7) and by adults was brain and nervous system (n=10). Two parents refused SRC to defer SR until adulthood (carrier status) or avoid worry in childhood (cancer). These findings suggest that most people are comfortable receiving all or most SR, at least when organized categorically, but a subset want to be able to refuse, defer or prioritize specific SR for reasons that may vary across populations and conditions. This conclusion is tempered by the fact that a limited number of SR examples were offered for each SRC, raising the question as to whether offering more examples with a broader range of impacts would facilitate better informed and/or more selective decision-making. Either way, it is clear that a one-size-fits all opt-out SR policy in which all SR are packaged together will poorly accommodate many people.

Returning findings within longitudinal cohort studies: the 1958 Birth Cohort as an exemplar. *S. Wallace[1], N.M. Walker[2], J. Elliott[3].* 1) Health Sciences, University of Leicester, Leicester, United Kingdom; 2) Juvenile Diabetes Research Foundation/Wellcome Trust Diabetes and Inflammation Laboratory Department of Medical Genetics Cambridge Institute for Medical Research University of Cambridge Cambridge, UK; 3) Centre for Longitudinal Studies Institute of Education London, UK.

Population-based, prospective longitudinal cohort studies are considering the issues surrounding returning findings to individuals as a result of genomic and other medical research studies. While guidance is being developed for clinical settings, the process is less clear for those conducting longitudinal research. Research was conducted on behalf of The UK Cohort and Longitudinal Study Enhancement Resource programme (CLOSER) to examine consent requirements, process considerations and specific examples of potential findings in the context of the 1958 British Birth cohort in order to inform future decision making regarding policy. Beyond deciding which results to return, there are questions of whether re-consent is needed and the possible impact on the study, whether there is a need to introduce third parties such as genetic services to assist in the feedback process and how that will be managed, and what resources are needed to support and manage the feedback process. Recommendations are made for actions a cohort study should consider taking when making vital decisions regarding returning findings. Any decisions need to be context-specific, arrived at transparently, communicated clearly, and in the best interests of both the participants and the study.

2367T

Participant preferences regarding the return of mental health related research results from a pediatric biobank and associations with social-demographic factors, comfort and concerns with novel health information. *E. Weitzman[1,2,3], S. Ziniel[1,2,4], S. Savage[2], K. Christensen[1], N. Huntington[1,3], P. Bacon[5], C. Cacioppo[6], R. Green[7,8], I. Holm[1,6,9].* 1) Department of Pediatrics, Harvard Medical School, Boston, MA; 2) Division of Adolescent/Young Adult Medicine, Boston Children's Hospital; 3) Children's Hospital Informatics Program at the Harvard-MIT Division of Health Sciences and Technology, Boston Children's Hospital; 4) Center for Patient Safety and Quality Research, Program for Patient Safety and Quality, Boston Children's Hospital; 5) Johns Hopkins University School of Medicine; 6) Division of Genetics and Genomics Boston Children's Hospital; 7) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School; 8) Partners HealthCare Center for Personalized Genetic Medicine; 9) Manton Center for Orphan Disease Research, Boston Children's Hospital.

Preferences for return of individual research results (IRR) from a pediatric biobank may depend on features of a disease category, which can hold social, historical and medical meanings. Mental illness (MI) is one such category encompassing common problems that may complicate other conditions and carry stigma. To investigate these issues we developed a preference-setting tool for IRR based on the preventability and severity of a condition, allowing exclusion of 4 disease categories including MI. We consented and enrolled parents of Boston Children's Hospital patients <18 years of age to an online study, randomizing them to 1 of 4 hypothetical biobank designs: 1) receive no IRR (None); 2) receive all IRR (All); 3) may choose all or no IRR (Binary); and 4) use the preference setting tool for return of IRR (Granular). Following an educational video, granular arm participants completed a survey about preferences, social and demographic factors and perceptions about new health information. We report on preferences concerning MI IRR. Of 11,394 invited parents 2,718 (24%) participated in the survey, including 1,026 randomized into the granular arm (mean age 44, 91% female, 86% white). Of these 12.8% opted-out of MI IRR. No differences were found among participants who did and did not opt-out of mental health results in sex, race, ethnicity, education, history of participating in medical research or employment in the healthcare setting. Participants who set preferences for return of severe IRR and preventable IRR were less likely to opt out of MI results than individuals who excluded these results (adjusted ORs and 95% CIs for MI IRR as a function of severe and preventable IRR: 0.42, 0.32, 0.57, p<.001; and, 0.73, 0.57, 0.93, p=.01). Participants who reported a family history of developmental delay were less likely to opt out of MI IRR (8.3%) than were participants who did not (15.3%) (adjusted OR 0.62, 95% CI 0.4, 0.96, p<.05). Participants who reported a family history of MI were less likely to opt out of MI IRR (10.6%) than participants who did not (15.2%) (p<.05) but results were not significant in multivariate models. Most participants set preferences to return MI IRR concerning their child. Doing so was associated with preferences for IRR about severe and preventable conditions. Few other factors distinguished this group. Findings suggest high willingness to be informed of a common and complex problem.

Uptake and motivations to learn incidental genome sequencing results among cancer patients. *E. Glogowski[*1], Y. Bombard[*1, 2], K. Schrader[*1], J.G. Hamilton[3], M. Salerno[1], M. Corines[1], S. Patil[4], M.J. Massie[3], V. Joseph[1], Z. Stadler[1], S. Lipkin[5], K. Offit[1], M. Robson[1], *equal contributions.*
1) Clinical Genetics Service, Department of Medicine, Memorial Sloan Kettering Cancer Service, New York, NY; 2) University of Toronto, Li Ka Shing Knowledge Institute of St. Michael's Hospital, Toronto, ON, Canada; 3) Department of Psychiatry and Behavioral Sciences, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Weill Cornell Medical College, New York, NY.

Background: There are increasing efforts to disclose incidental results of whole genome or exome sequencing (WG/ES) to patients and research participants; however, limited data exist as to individuals' interest and motivations to learn their incidental data in the cancer setting. Our aims were to: (1) assess the uptake and (2) explore motivations to learn incidental WG/ES disease risk information. **Methods:** We are offering the return of incidental results to patients whose genomes/exomes are sequenced as part of other cancer predisposition discovery research, in an effort to assess the safety and utility of returning incidental results. Our protocol includes: pretest counseling and results return in person, a follow-up call to confirm result category selections prior to CLIA-validation, an in-depth interview, and distress and behavioral measures. We descriptively analyzed survey data and used content analysis of counseling notes. **Results:** Of 31 eligible patients invited thus far, 8 have enrolled in the study, resulting in a 29% uptake rate (average age: 55, 8 college-educated, 4 married and 3 employed). Thirteen (42%) were lost to follow-up and 10 (32%) declined via reply postcard, follow-up call or in person. Motivations to participate included: curiosity (6/8); interest in incidental disease risks for themselves (8/8) and/or relatives (6/8); and a desire to improve health (7/8) and help research (7/8). Reasons for declining study participation included: worry about the results (5/10), difficulty traveling into the city/clinic (6/10), concern about getting or keeping insurance (4/10) and/or a job (1/10); and lack of desire to learn genomic results (4/10) and/or disease risks (4/10). Additional reasons for declining the study offered were: a recent cancer recurrence, time constraints, and a preference for targeted clinical testing. **Conclusion:** A majority of individuals ascertained through cancer discovery research decline to learn their incidental genomic findings due to a lack of desire, worry about learning their results, or perceived barriers to participation. Disinterest in incidental findings among cancer patients appears to arise from a preference for targeted, cancer-specific information. These preliminary results provide insights into cancer patients' interest levels, motivations and perceived barriers, which may inform study designs aimed at returning incidental WG/ES results in the oncology setting.

Penetrance of Actionable Incidental Genomic Findings in Exomes from the Framingham Heart Study. *N.B. Gold[1], A.G. Bick[2], H.M. McLaughlin[3,4], P. Kraft[5], H.L. Rehm[3,4], J.G. Seidman[2], C.E. Seidman[2,6], R.C. Green[1,4].*
1) Division of Genetics, Department of Medicine, Brigham and Women's, Harvard Medical School, Boston, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 4) Partners HealthCare Personalized Medicine, Boston, MA; 5) Program in Genetic Epidemiology and Statistical Genetics, Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Division of Cardiology, Department of Medicine, Brigham and Women's Hospital and the Howard Hughes Medical Institute, Harvard Medical School, Boston, MA.

Background: The American College of Medical Genetics and Genomics (ACMG) has recommended that pathogenic variants (PVs) in 56 genes, corresponding to 24 diseases, should be returned as incidental findings following clinical sequencing. Penetrance of these variants is largely understood based upon familial disease. We hypothesized that PVs in these genes would, as a group, be associated with suggestive clinical features (SCFs) of the corresponding diseases in a population unselected for family history. Methods: We classified 2068 variants in 56 genes from 462 Framingham Heart Study (FHS) subjects as pathogenic, likely pathogenic (LPVs), uncertain significance, or benign. Longitudinal clinical history (mean follow-up 20.4 years) and the most recent echocardiograms, electrocardiograms and lipid measurements were reviewed. Results: The fraction of subjects with PVs or LPVs who exhibited SCFs was compared to the expected fraction based on those without PVs or LPVs. PVs and LPVs were observed in 1.5% and 0.6%, respectively, of individuals. SCFs were observed in 5 subjects with PVs (71%), while only 0.9 (13%) were expected (p = 1.9 x 10-4). SCFs were only seen for cardiomyopathy, dyslipidemia and BRCA2-associated breast and prostate cancer. No individuals with LPVs had SCFs. Conclusions: These data indicate that in a population unselected for family history, subjects harboring PVs for at least a subset of the ACMG gene list are at high risk for the development of disease. Furthermore, the identification of 5 unaffected FHS subjects harboring PVs or LPVs raises issues around the debate of whether to return this actionable information to subjects unaware of their risk.

Attitudes of Genetics Professionals Toward Return of Incidental Results from Exome and Whole Genome Sequencing. *J. Yu[1], T.M. Harrell[1], S.M. Jamal[1], H.K. Tabor[2], M.J. Bamshad[1,3].* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Treuman Katz Center for Pediatric Bioethics, Seattle Children's Research Institute, Seattle, WA.

Professional recommendations for return of results from exome and whole genome sequencing (ES/WGS) have been controversial. The lack of clear guidance about whether, and if so, how to return ES/WGS incidental results limits the extent to which individuals and families may benefit from ES/WGS. Genetics professionals' perspectives, particularly of those at the forefront of using ES/WGS in clinics, are largely unknown. Data on stakeholder perspectives could help clarify how to weigh expert positions and recommendations. We conducted an online survey of 9857 genetic professionals to learn their attitudes on return of incidental results from ES/WGS and recent American College of Medical Genetic and Genomics Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing. Of 847 respondents, 760 completed the survey. The overwhelming majority of respondents think that incidental ES/WGS results should be offered to adult patients (85%), healthy adults (75%), and parents of a child with a medical condition (74%). The majority think that incidental results about adult onset conditions (62%) and carrier status (62%) should be offered to parents of a child with a medical condition who has undergone ES/WGS. About half think that offered results should not be limited to those deemed clinically actionable. The vast majority (81%) think that patient / family preferences should guide return. Clinician and researcher attitudes differed significantly on a number of questions. Multivariate analysis showed that researchers were nearly twice as likely as clinicians to be open to offering non-actionable results (p=0.008) and 85% more likely to agree with returning adult onset results to parents of children who have undergone sequencing (p=0.027). Genetic professionals' perspectives on return of ES/WGS results differ substantially from current recommendations and vary between professions. This underscores the need to establish clear purpose for recommendations on return of incidental ES/WGS results as professional societies grapple with developing and updating recommendations. Further, professional differences in attitudes suggest the need for greater discussion about return in clinical versus research settings.

2371T

Participant Experiences Receiving Incidental Findings Through Genome Sequencing. *K.L. Lewis[1], P. Connors[2], M.F. Wright[1], T. Hyams[1], L.G. Biesecker[1], B.B. Biesecker[2].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Social and Behavioral Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

As an increasing number of people have genomic sequencing, there is still debate about whether and how to return individual results. Several studies have examined patients' hypothetical preferences for the return of results; however, little is known about participants' actual experiences. We report on a qualitative interview study of research participants' perspectives on the medical and psychological impacts of receiving results. Participants were recruited from the ClinSeq® study, which enrolls mostly health participants and offers genome sequencing results to individual participants. Subjects are offered a choice about receiving results unless they are of urgent medical significance, and given results in person by a physician and a genetic counselor in most cases. Twenty-nine participants (67% of those eligible) agreed to participate and were interviewed. Participants received results for a wide range of conditions, the majority of which were medically actionable and pertained to cancer, cardiomyopathy or arrhythmia susceptibility. The interviews were recorded, transcribed, and coded. Half of the interviews were reviewed by an independent, second coder; 80% consensus was achieved and discrepant codes were reconciled. Most participants reported sharing their result with at least one physician, but had no changes to their medical care. Participants stated that they valued the result regardless of its medical utility because it encouraged them to do their own research on the condition, prompted them to be vigilant in watching for symptoms or seeking out screening, helped them feel prepared for what might lie ahead, and satisfied their curiosity. Roughly half of the participants received a result that was unexpected, but only three felt distressed. These findings provide insight into participants' perspectives of the value of their results and whether they are likely to share their results. The data provide early evidence regarding the clinical and emotional reactions of participants to results and suggest that, among early adopters, adults are resilient even when results are unexpected and have serious health implications.

2372M

Does prior comfort with new health information influence parents' preferences for receiving genetic research results about their children? *N. Huntington[1,2], S. Savage[3], S. Ziniel[4,5], P. Bacon[6], E. Weitzman[2,4,7], K. Christensen[8], R. Green[8,9], I. Holm[2,3,10].* 1) Division of Developmental Medicine, Boston Children's Hospital; 2) Department of Pediatrics, Harvard Medical School; 3) Division of Genetics and Genomics, Boston Children's Hospital; 4) Division of Adolescent and Young Adult Medicine, Boston Children's Hospital; 5) Center for Patient Safety and Quality Research, Boston Children's Hospital; 6) Johns Hopkins University School of Medicine; 7) Children's Hospital Informatics Program, Boston Children's Hospital; 8) Division of Genetics, Department of Medicine, Brigham and Women's Hospital; 9) Partners Personalized Medicine; 10) Manton Center for Orphan Disease Research, Boston Children's Hospital.

Background: In genomic biobank research, questions remain about how to maximize benefit and minimize harm when returning individual research results (IRRs) to parents about their children. Result- and parent-specific factors can influence a parent's reaction to receiving IRRs. We examined the impact of comfort with health information on parents' preferences for receiving IRRs about their children. **Methods**: An online survey was completed by 2,718 parents of recent Boston Children's Hospital patients (response rate 24%). Respondents were randomized to one of three survey groups: 1)"No choice"-half receive All IRRs, half receive None); 2)"Binary choice"-parent chooses to receive All or None; 3)"Granular choice"-parent sets preferences for IRRs based on preventability and severity of conditions, plus options to opt-out of specific condition categories (mental health, developmental disorders, degenerative conditions, adult-onset conditions). Parents then viewed a hypothetical IRR report reflecting their survey condition/preferences and rated their satisfaction with the report (scale 1-10). Before setting preferences, parents were asked 9 questions about their comfort with getting new health information about their child. A cluster analysis on the responses identified three types of Health Information Comfort (HIC): 1)Positive (HIC-P: sees benefits of knowing with little harm); 2)Ambivalent (HIC-A: sees both benefits and harms); and 3)Negative (HIC-N: sees harms with little benefit). **Results**: IRRs received were categorized as All, None or Some (Granular group only). HIC was related to results preferences for the Binary ($p<0.001$) and Granular ($p<0.001$) groups: HIC-P were most likely to want IRRs, HIC-N least likely and HIC-A were in-between. In the Binary group, most HIC-A chose All results, in a proportion similar HIC-P. In the Granular group, HIC-A preferences shifted towards Some results, with proportions similar to HIC-N. As expected, there was no relationship between HIC and results received in the No Choice condition. HIC was related to satisfaction with results in the Binary ($p=0.02$), Granular ($p<0.001$) and No Choice ($p=0.008$) conditions: HIC-P>HIC-A>HIC-N. For all HIC types, satisfaction was highest in the Granular group and lowest in No Choice. **Conclusion**: Finding the right alignment between comfort with knowing health information and preferences for which IRRs to receive may serve to maximize the benefits of returning IRRs to biobank participants.

2373T

Navigating Contested Ideas about DNA Ancestry Testing in American Indian and Freedman Populations in Oklahoma. *J.W. Blanchard[1], G. Tallbull[1], C.M. Wolpert[2], M. Foster[1], C.D. Royal[2, 3].* 1) Department of Anthroplogy, University of Oklahoma, Norman, OK., Select a Country; 2) Institute for Genome Sciences & Policy Duke University Medical Center Durham, NC; 3) Department of African and African American Studies Duke University.

Commercial genetic and genomic ancestry testing has been available for sale on the markets for over ten years. Today there are nearly 200 DNA ancestry products, packages, and services being offered by about 40 different companies. Direct-to-consumer DNA Ancestry tests incite critical skepticism among various publics and scholars alike, especially with regard to the potential for such tests to perpetuate racial essentialism, to challenge personal identities and community histories, and to promote unrealistic ideas about the usefulness of test results. The long-term implications of these relatively new and increasingly accessible genomics technologies are largely unknown for indigenous and other historically exploited communities that have long been suspicious of the goals and local value of genetic exploration. This presentation explores the processes whereby researchers in an ongoing, long-term study engage Oklahoma tribal and Freedmen populations about the risks and benefits of community participation in genomic research and in genetic ancestry testing. These communities, in particular, have especially timely ideas about the use of genetic testing for ancestry purposes. At the center of ongoing enrollment disputes between some Oklahoma tribes and Freedmen individuals are historically contested ideas about "blood," "ancestry," and "citizenship". This suggests that the availability and use of ancestry testing for members of these communities has potentially significant implications for both those seeking to authenticate specific ancestral identities to secure tribal membership, as well as for tribal nations whose sovereign rights to determine membership may be challenged by the introduction of such testing.

2374M

Direct-to-Consumer Ancestry Testing: Psychological and Behavioral Impacts. *D.L. Boeldt[1,2], A.G. Lucy[5], L. Ariniello[1,2], O. Libiger[1,2,4], V. Bansal[1,2,4], E.J. Topol[1,2,3,4], L. Kessler[5], N.J. Schork[1,2,4], C.S. Bloss[1,2].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Scripps Health, La Jolla, CA; 3) Scripps Clinic Medical Group, La Jolla, CA; 4) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 5) Arcadia University, Glenside, PA.

Introduction: There is a growing population of consumers who are purchasing direct-to-consumer (DTC) genetic ancestry tests. Ancestry.com, a DTC ancestry testing company, recently reported that more than 400,000 individuals have purchased their AncestryDNA test. Despite consumer interest, however, few studies have examined the impact of ancestry testing at an individual level. The current study aimed to evaluate attitudes towards ancestry testing and characteristics associated with response to testing in a large cohort. **Methods:** The Scripps Genomic Health Initiative (SGHI) is a longitudinal cohort study originally designed to assess response to DTC genomic testing for complex disease risk. SGHI participants who completed a baseline health assessment were also provided with personal genetic ancestry testing performed by a team of scientists at the Scripps Translational Science Institute. Individuals who viewed their ancestry results were invited to complete an additional optional survey (http://www.stsiweb.org//sghi/) to assess response to the information provided. Participants also self-reported race/ethnicity prior to receiving their ancestry results. **Results:** 3,465 individuals were provided with personal genetic ancestry testing, 1,317 logged into the website to view their results, and a subset of 322 (24% response) completed the ancestry response survey. Although 46% of respondents reported that their ancestry results were surprising or unexpected, <1% reported being distressed by the results. In addition, 39% reported a change or possible change in their perception of their cultural roots, 24% a change in the likelihood that they would travel to certain parts of the world, and 21% that the results reshaped their personal identity. A majority (81%) of participants stated that they planned to share the test results with their family members, and 12% reported the intention to share results with a healthcare provider. **Conclusion:** Data from this selected sample of ancestry test recipients suggests that although genetic ancestry testing does not induce stress, it does impact a notable proportion of individuals with respect to cultural perceptions, personal identity, and propensity to share genetic information with family and healthcare providers. Our findings suggest that ancestry information may be particularly useful in promoting sharing and thus peer-peer education in genomics.

2375T

Motivations for Participation in Genomic Research in Hispanics vs. Non-Hispanics. *M.L. Cuccaro[1, 2], C.P. Manrique[1], M.A. Quintero[1], R. Martinez[1,2], J.L. McCauley[1,2].* 1) Dr. John P. Hussman Institute for Human Genomics , University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Racial and ethnic minorities are underrepresented in genomic research. This underrepresentation has the potential to exacerbate existing health disparities. Increasing the engagement of minorities in genomic research is one strategy to reduce health disparities and to identify population specific genetic risk for different diseases. As part of ascertainment for a study of genetic risk for multiple sclerosis (MS), we surveyed individuals who had either agreed or refused to participate about their reasons for this decision. Our dataset (N=101) was predominantly female (80%) and mainly white (96%). The most frequent age ranges were 46-55 (27%) and 56-65 (20%). Hispanics constituted (80%) of the sample. Among the 101 individuals surveyed 95% had agreed to participate in the MS genetics study. Individuals were asked to identify, from 11 possible choices, the reasons which most influenced their decision. The most frequently cited reasons for participating in the MS genetics study were helping to find a cure (56%), having the disease (46%), and helping future generations (37%). We tested whether these three reasons differed by ethnic group using Pearson chi-square. Hispanics and non-Hispanics did not differ in their rates of endorsement of participating in genomic research to help find a cure (HI 56%, NHI 56%, $p=0.97$) or helping future generations (HI 34%, NHI 50%, $p=0.26$). However, the groups differed significantly on endorsement of having the disease as a reason to participate in the study. Specifically, 52% of the Hispanics endorsed having MS as a reason to participate vs. 19% of non-Hispanics ($p=0.015$). We also tested whether these reasons differed by age group and found no differences. However, among the youngest individuals (18-35 years) 74% endorsed finding a cure as a reason for participating vs. 39% of the oldest group (>56 years). Our findings offer a preliminary perspective about the motivations for participating in genomic research among Hispanics and non-Hispanics. The results suggest that motivations to participate in genomic research may differ by ethnic group and that the impact of having a particular disease (e.g., MS), may be more likely to motivate involvement in Hispanics. Larger samples across different diseases can shed light on group motivations to participate in genomic studies. Such findings can help tailor recruitment strategies and engagement to aid in closing the gap in health disparities in genomic research.

Reasons for declining preconception carrier testing using genome sequencing: Implications for research and practice. *M. Gilmore[1], C. Young[2], M. Leo[2], J. Davis[2], T. Kauffman[2], E. Esterberg[2], F. Lynch[2], B. Wilfond[3], K.A.B. Goddard[2].* 1) Department of Medical Genetics, Kaiser Permanente Northwest, Portland, OR; 2) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 3) Truman Katz Center for Pediatric Bioethics, Seattle Children's Hospital, Seattle, WA.

Genome sequencing is an emerging technology for use in clinical practice, and its utility is not well understood for applications such as preconception carrier testing. An important facet of understanding the implementation of this new technology is to investigate reasons why potential participants decline expanded carrier testing using genome sequencing. We are investigating preconception expanded carrier testing in generally healthy couples. Potential participants are identified because their provider ordered at least one preconception carrier test, typically cystic fibrosis screening. They are contacted by phone to see if they are interested in the study. If they decline participation, they are invited to complete a survey on their reasons for declining as well as demographic information. We collect similar information for those who consent to join the study. We are comparing participants and decliners on factors such as race, education level, income and characteristics related to knowledge of genetics, such as knowing a family with a child with a genetic condition, to determine whether there may be any participation bias. In addition to the survey, we have implemented qualitative approaches including journaling by study staff and focus groups to enhance our understanding of reasons why potential participants decline the use of expanded preconception carrier testing using genome sequencing. Of the women who declined participation at any time after initial contact (N=45), seventy-two percent have completed the decliner survey. The most common reasons cited were a lack of time (fifty-five percent), not interested in participating (twenty-four percent), didn't want to know about their risk (twenty-one percent), and worried about discrimination (nine percent). Synthesis of qualitative data support the reasons captured in the survey. The high response rate for the decliner survey may suggest a high level of interest in preconception expanded carrier testing for this population. Concerns about discrimination are less common than we anticipated as a reason to decline to participate. Further analysis of decliner survey results will enhance our understanding of genomic sequencing technology implementation in the clinical setting.

Personal Genomics Online in Australia: A mixed methods study of Australian consumers' knowledge, attitudes and experiences of direct-to-consumer personal genome testing. *J. Savard[1], J. Mooney-Somers[1], A. Newson[1], I. Kerridge[1,2].* 1) Centre for Values, Ethics and the Law in Medicine (VELiM), School of Public Health, The University of Sydney, New South Wales, Australia; 2) Hematology Department, Royal North Shore Hospital, New South Wales, Australia.

Health, including both one's current and future health, is increasingly being understood in genetic terms, with personal genomic information marketed as a means by which individuals can "know" and "control" their health and reduce their likelihood of illness. Unfortunately, there is often a discrepancy between the expectations that consumers have of what personal genome tests may provide and what explanatory power they actually have. In part, this is because we still lack scientific and epidemiological knowledge needed to usefully interpret the information these tests divulge. In this paper we present findings from the Australian Genetics Online Study - a mixed methods exploration of the beliefs, knowledge, expectations and experience of Australian consumers regarding direct-to-consumer personal genome testing (DTC-PGT). The first phase of the study, which involved an online public survey, explored lay knowledge, expectations and experiences of DTC-PGT. The results of this study suggest that Australian consumers have an interest in genetic testing - both for health and ancestry purposes, and many value this information as much as they value other sources of personal information - but appear disinclined to pursue it. The second phase of the study, semi-structured interviews with potential and current consumers of a personal genome testing service, revealed a wide range of motivations for pursuing testing along with varying degrees of understanding with respect to what the test could (and did) tell the consumer about themselves, their future health and/or their ancestry. The final phase of the project, an autoethnography, documented the researcher's (Jacqueline Savard's) journey through the process of becoming a consumer of DTC-PGT. The results of the Genetics Online Project provide the first quantitative and qualitative account of DTC-PGT in Australia. These findings will be discussed in light of ongoing debates about the impact that publicly accessible genetic testing is having on the design and delivery of health care, information about health care and about the impact of genetics on the social construction of health, illness and identity.

A novel scale to assess perceptions of uncertainty in genome sequencing information. *B. Biesecker[1], W. Klein[2], K. Lewis[3], L. Biesecker[3], P. Han[4].* 1) Soc Behavioral Res Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland 20892; 2) Division of Cancer Control and Population Sciences, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892; 3) 3Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland 20892; 4) Maine Medical Center Research Institute, Center for Outcomes Research and Evaluation, 81 Research Dr Scarborough, ME 04074.

The scope of uncertainty in genomic sequence information is vast. Yet our understanding of how adults perceive medical uncertainty is poorly understood. Such perceptions are likely to play a key role in deciding to undergo genomic sequencing and in understanding and acting on the findings. Guided by a taxonomy of medical uncertainty developed by Han and colleagues, we aim to further understanding of perceptions of uncertainties. The NHGRI ClinSeq® cohort study represents a strategic opportunity to assess predictors of decisions to learn and use genomic sequencing information. We present analytic data on baseline perceptions of uncertainty originating from a novel scale. Methods: The Perception of Uncertainties of Genome Sequence Results (PUGSR) scale assesses perceptions of uncertainty specific to genomic sequencing. Development of items was informed by focus group findings. Ten items assessed three sub-domains of uncertainty: medical, affective and trustiworthiness. Results: Five hundred seventeen ClinSeq® participants completed the scale prior to making a decision about whether to learn their sequence results. There was a normal distribution in responses with an overall mean uncertainty score of 3.5/5 (SD 0.58) with high internal consistency (α=0.835). Results of exploratory factor analysis revealed three factors; medical (four items), affective (four items) and trustworthiness (two items) uncertainty about sequence information. Perceptions of medical uncertainty were highest and contributed most to the variance (2.85). These data can be used to guide informed consent for genome sequencing, to clarify the role of uncertainties in decision-making, and to anticipate uncertainties of greatest concern to recipients of genome sequencing information.

The influence of false positive results from newborn screening for cystic fibrosis on cascade testing and family planning. *Y. Bombard[1], F.A. Miller[2], R.Z. Hayeems[2,3], C.J. Barg[2], S.J. Patton[2], P. Durie[4,5], J.C. Carroll[6], P. Chakraborty[7,8], B.K. Potter[9], K. Tam[10], L. Taylor[11], E. Kerr[12], C. Davies[7], J. Milburn[7], F. Ratjen[4,5,11], A. Guttmann[2,4,5,13].* 1) Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, ON, Canada; 2) Institute of Health Policy, Management and Evaluation, University of Toronto, ON, Canada; 3) Child Health Evaluative Sciences, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 4) Division of Paediatric Medicine, Department of Paediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Pediatrics, Faculty of Medicine, University of Toronto, ON, Canada; 6) Department of Family and Community Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 7) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 8) Department of Pediatrics, Faculty of Medicine, University of Ottawa, ON, Canada; 9) Department of Epidemiology and Community Medicine, Faculty of Medicine, University of Ottawa, ON, Canada; 10) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 11) Division of Respiratory Medicine, Department of Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 12) Department of Psychology, The Hospital for Sick Children, Toronto, ON, Canada; 13) The Institute for Clinical Evaluative Sciences, Toronto, ON, Canada.

Objectives: The majority of infants with false positive (FP) newborn screening (NBS) results for cystic fibrosis (CF) are eventually identified as carriers of one CF mutation. Carrier detection can enable reproductive planning, provided results are appropriately shared. We examined carrier communication, carrier testing and family planning following NBS detection of carrier infants. **Methods**: We surveyed mothers of infants confirmed to be FP after confirmatory testing (Time-1) and one year later (Time-2) to ascertain self-reported communication, intended and actual carrier testing, and subsequent reproductive choices. Mothers were invited for an interview. We report cross-sectional analyses for Time-1, and longitudinal analyses for carrier testing uptake by Time-2. **Results**: We received completed surveys from 134 of 245 mothers (55%) at Time-1 and 96 of 214 (45%) at Time-2, and interviewed 66 mothers. 77 of 127 mothers (61%) reported one mutation in their infants (i.e., carrier-mothers); 30 (24%) reported no mutations and 20 (16%) were unsure (presumed non-carriers). Carrier testing uptake was 55% (n=23/42) among carrier-mothers. 13 intended to have carrier testing at time-1 and of those 6 were tested by time-2. 91% of carrier-mothers told relatives they may be carriers (n=70/77), as did 48% (n=24/50) of non-carrier mothers. Results were expected to influence family planning for 35% of carrier-mothers (n=26/74) and 24% of non-carrier mothers (n=11/46). Interviewees valued carrier information whether or not they intended to share it with relevant relatives. **Conclusion**: While mothers describe reproductive value in carrier results, survey data are equivocal given moderate intended and actual CT uptake and limited influence on family planning.

Personalized medicine in the context of prenatal diagnosis and medically assisted procreation. *G. Lapointe[1], R. Drouin[2], C. Bouffard[1].* 1) Université de Sherbrooke, Sherbrooke, Québec, Canada; 2) CHR du Grand-Portage, Rivière-du-Loup, Québec, Canada.

Personalized medicine (PM) is based on the analysis of an individual's cumulated genomic, behavioral and environmental data. It aims to evaluate, on a personalized basis, a person's risk of suffering from illnesses and to determine the most efficient and safe preventative and therapeutic approaches. The 4P medical approach (predictive, preventative, personalized and participative) adds a participative dimension in which citizens are more responsible for and in control of their own health. Prenatal diagnosis (PND) and medically assisted procreation (MAP) are also affected by the new role of individuals in questions of health. Yet, as the consequences of decisions made in the context of PM are not the same for the fetus and embryos as they are for adults and children, this situation raises particular clinical and socio-ethical concerns. However, while a vast literature exists on PM, it does not appear to take into account PND and MAP. Yet the information that genomic tests reveal about a fetus and embryo raise major clinical and socio-ethical issues that deserve to have their place in the PM movement. Based on the PM literature, our objectives were the following: 1) create a repertoire of the major PM issues, 2) determine whether PND and MAP have been discussed in terms of PM, 3) identify the clinical and socio-ethical issues that emerge. METHOD: Scoping review of academic and grey literature (perspectives, legal documents, government reports, etc.): 1) publication research by key words in databases (Pubmed, EBSCO, etc.), 2) comprehensive and comparative thematic analysis. RESULTS: Of the 98 articles analyzed, 5 major themes emerged: the level of responsibility, equity, aptitude to understand information, genetic counseling and the importance of the opinion of citizens. Yet, few article discuss PND and MAP in terms of PM (10/98). When the subjects are broached, it is in the context of non-invasive prenatal testing (4/10) and the instances involve concerns such as social control of reproduction, eugenics and the risk of coercion. No study mentioned participation and the opinions of citizens. CONCLUSION: From a clinical as well as a socio-cultural level, the participative dimension of PM implicates a societal responsibilization that will be problematic in the context of PND and MAP. It is imperative to develop knowledge based on convincing data concerning the positions of stakeholders.

ACE, ACTN3 and ADRB3 polymorphisms in elite soccer players according to the team position. *L. Ruzic, V. Vucetic.* Faculty of Kinesiology, University of Zagreb, ZAGREB, Croatia.

The aim of the this paper was to investigate the relationships between three polymorphisms in ACTN3, ACE and ADRB3 genes and playing positions in elite soccer players of the Croatian national selection and the national championship winner. We examined 44 top-level Croatian soccer players (4 goalkeeper, 13 defense -fullback, 15 middle field and 12 forward attackers). Depending on the polymorphisms on the above mentioned genes the subjects obtained the indices between 0 and 6; 0 being "no strength type" and 5 being the highest "strength/explosivness type" . We looked into the relationship between the aerobic and anaerobic components of the position at which the player plays and the obtained indices. As the sample comprised only 4 goalkeeper their genetic strength indices were as follows: 2 goalkeepers type 6, 1 goalkeeper type 5 and 1 goalkeeper type 4 which strongly indicated the genetic tendency of the goalkeepers towards the explosive/strength activities. Among other players we should emphasize that only 1 player (2%) in middle field was type 2 while 28% of the others were type 3, 40% type 4 and 30% type 5 which lead us to believe that even though the soccer is highly demanding aerobic game it still requires a big amount of explosive strength and speed so the endurance type genotypes are not largely present among top level soccer. The Spearman rank correlation showed a significant but weak correlation between the playing position and the strength genetic index ($p<0.05$) meaning that fullback and attack positions had higher indices, being more explosive whilst the midfielders showed lower indices, e.g. tendency toward endurance. An interaction of three polymorphisms (ACE and ACTN-3 and ADRB3) might be related to the position at which the soccer player plays but it probably does not have a high usefulness selection of the younger soccer players as the positions are attributed later in career. Larger scale studies and more genes analyzed would give better insight in the significance of the genetic predispositions for soccer players. Pimenta, E.M., Coelho, D.B., Veneroso, C.E., Barros Coelho, E.J., Cruz, I.R., et al. Effect of ACTN3 geneon strength and endurance in soccer players.(2013). J. Strength. Cond. Res. 27, 3286-3292. Massidda, M., Corrias, L., Ibba, G., Scorcu M., Vona, G., Calò, C.M. Genetic markers and explosive leg-muscle strength in elite Italian soccer players. (2012). Influence of the social environment on the development of breast cancer through epigenetic modifications: A comprehensive scoping review. *O. Martin[1], R. Drouin[1,2], C. Bouffard[1].* 1) Division of Genetics, Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Québec, Canada; 2) CHR du Grand-Portage, Department of Obstetrics-Gynecology, Rivière-du-loup, Québec, Canada.

For 20 years now, several research groups have attempted to establish a link between stressful events and susceptibility to developing breast cancer, but results have been contradictory. While some show evidence supporting the direct link between acute and chronic stress at a young age, traumatic events and breast cancer development, others suggest that stressful events cannot be considered risk factors.Nonetheless, it has been established that epigenetic modifications may play a predominant role from the onset of breast cancer and throughout its development. We can't dismiss the idea that social environments that submit an individual to an acute and chronic stress might modify methylation patterns, thereby increasing susceptibility to certain chronic illnesses including cancer. The results presented here stem from a comprehensive and comparative analysis of academic literature bearing on the potential of the social environment, mainly acute and chronic stress, to induce epigenetic modifications linked to breast cancer among individuals with or without a known mutation in terms of a breast cancer susceptibility gene. Methodology: Comprehensive scoping review of academic literature: 1) research by keywords in: databases (Pubmed, EBSCO, etc.), reference lists of key papers, hand searching of journals not indexed on databases. Rigorousness criteria: English and French articles, from 1980-2014, epigenetics, breast cancer; 2) comparative thematic analysis. Results: Despite several publications on epigenetic modifications and the environment as factors of susceptibility of breast cancer development, the social environment remains a largely unconsidered subject. While it is ever more accepted that acute and chronic stress might be a susceptibility factor, no study has yet been able to draw a real correlation between epigenetic modifications induced by stress and the development of breast cancer. Important knowledge gaps currently exist regarding the links between social environments, stress, epigenetic modifications and breast cancer. Among other things, the effect of these relationships in a heterozygous patient for a BRCA1 or BRCA2 gene remains unknown. Conclusion: There is still a great deal to be done to obtain sufficient data to establish that social environments and human behaviour may induce epigenetic modifications that may increase the risk of developing breast cancer. However, the latest discoveries in the field tend to lean towards this possibility.

2383T

Genetic Ancestry Testing and Identity: Exploring the Relationship. *C.M. Wolpert[1], J.D. Powell[1], K. Haynie[3], R. Kittles[4], C.D. Royal[1,2].* 1) IGSP, Duke University Medical Center, Durham, NC; 2) AAAS, Duke University, Durham, NC; 3) Dept. of Political Science, Duke University, Durham, NC; 4) University of Illinois Chicago, Illinois.

Genetic ancestry testing (GAT) uses individuals' DNA to estimate their genealogical and geographic ancestry. Scholars have hypothesized that GAT provides information that may cause individuals to reshape their identities. Yet, there are limited empirical data to support this view. Furthermore, there is very little discussion in the research literature about the types of identity that are likely to be affected by GAT. In this study we sought to investigate whether and how GAT test takers (N = 455), the majority of whom self-identified as non-white, spontaneously referenced identity in relation to GAT. Three time points were investigated: Time 1 (pre-test), Time 2 (post-test - immediately after receiving test results), and Time 3 (8-10 year follow-up). Test takers completed self-report instruments at all three time points and a semi-structured interview at Time 3; both quantitative and qualitative data were analyzed. At Time 1, 48% (n = 218) of the 455 GAT test takers spontaneously referenced identity. Further analysis of these data revealed that different dimensions and types of identity were referenced: identity exploration, including ethnic identity exploration; personal identity; essential identity; and group identity (in decreasing order of frequency). At Times 2 and 3, individuals started referencing identity commitment. At Time 3, test takers had high levels of ethnic identity commitment as measured with the Multigroup Ethnic Identity Measure-Revised (MEIM-R) and ethnic identity achievement as measured with the Ethnic Identity Scale (EIS), both of which are associated with well-being. Hence, in this data set, identity was a salient issue for about half the participants, with identity exploration being most frequently discussed prior to testing. Subsequent to GAT, some test takers referenced identity commitment. Thus, it appears that before testing potential test takers use GAT as a tool for exploring their identity and after GAT some individuals commit to a new or existing identity.

2384S

Psychosocial factors associated with the uptake of contralateral prophylactic mastectomy among *BRCA1/2* noncarriers with newly-diagnosed breast cancer. *J.G. Hamilton[1], M. Salerno[2], K. Amoroso[2], M. Sheehan[2], M. Harlan Fleischut[2], E. Glogowski[2], B. Siegel[2], A.G. Arnold[2], E.E. Salo-Mullen[2], J. Hay[1], K. Offit[2], M.E. Robson[2]*. 1) Behavioral Sciences Service, Department of Psychiatry & Behavioral Sciences, Memorial Sloan Kettering Cancer Center, New York, NY; 2) Clinical Genetics Service, Department of Medicine, Memorial Sloan Kettering Cancer Center, New York, NY.

Women who are newly diagnosed with breast cancer can consider whether to have a contralateral prophylactic mastectomy (PM) to reduce their future risk of cancer in their unaffected breast. Pre-surgical *BRCA1/2* genetic testing may provide valuable risk information to guide this choice, given that *BRCA1/2* mutation carriers have a 27-37% ten-year risk of developing a new cancer in their unaffected breast. Despite *BRCA1/2* mutation noncarriers' much lower risk of contralateral breast cancer (which can be as low as 3-10%), some still choose to undergo a PM; the factors that motivate *BRCA1/2* noncarriers to select PM are not well understood and warrant investigation. Thus, as part of a larger study of the impact of pre-surgical *BRCA1/2* testing, we examined the frequency of uptake of contralateral PM among newly-diagnosed breast cancer patients who were identified as *BRCA1/2* mutation noncarriers. In addition, we examined the association between various sociodemographic and psychosocial factors and *BRCA1/2* noncarriers' subsequent decision to undergo PM. Self-report questionnaire data from 75 *BRCA1/2* noncarriers (mean age=44.1 years, range=29-59) were analyzed. A sizeable minority of the *BRCA1/2* noncarriers (29.3%) elected to undergo a PM after learning their mutation status (as compared to 88% of the 8 *BRCA1/2* carriers in the sample). Both bivariate and multivariable analyses indicated that perceiving that one's physician had recommended PM (OR=7.79, p=0.02), perceiving greater risk for breast cancer (OR=1.86, p=0.04), and perceiving greater pros of PM (OR=1.34, p=0.006) were all significantly associated with noncarriers' decision to undergo PM. However, factors including age, Ashkenazi Jewish ethnicity, breast cancer-related distress, perceived cons of PM, and decisional conflict regarding PM were not significantly related to the decision to undergo PM (all ps>0.05). Results demonstrate that although noncarriers' decision-making regarding PM was unrelated to sociodemographic and emotional factors, their cognitive perceptions of contralateral disease risk, surgical benefits, and physician recommendations were particularly important. Future studies should examine the content of patient-physician communication regarding PM and hereditary risk in greater detail, and explore how these conversations shape and interact with women's past experiences, emotions, and beliefs to influence their cancer risk management decision-making.

2385S

The Effect of Disclosing Coronary Heart Disease Genetic Risk on Shared-Decision Making. *T.M. Kruisselbrink[1,2], H. Jouni[1], R.A. Haddad[1], I.N. Isseh[1], V.M. Montori[3], I.J. Kullo[1]*. 1) Division of Cardiovascular Diseases, Department of Medicine, Mayo Clinic, Rochester, MN; 2) Center for Individualized Medicine, Mayo Clinic, Rochester, MN; 3) Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Mayo Clinic, Rochester, MN.

Background: Whether disclosure of genetic risk influences shared-decision making for reducing coronary heart disease (CHD) risk is not known. We investigated the effect of disclosing genetic risk for CHD on shared decision making during a patient-physician encounter. **Methods:** The Myocardial Infarction Genes (MI-GENES) study randomized participants 40-65 y old, at intermediate CHD risk, and not on statins, to receive the 10-y risk of CHD based either on conventional risk factors alone (CRF) or CRF plus a 27 SNP genetic risk score (GRS) (CRF*GRS). CHD risk was disclosed by a genetic counselor during a 30 min scripted session. Each participant then met with a physician to engage in shared-decision making regarding the need for statin therapy. This encounter was facilitated by the Statin Choice decision aid (Weymiller et al, Arch Intern Med, 2007) modified to display both conventional and genetic CHD risk, with and without statin therapy. Afterwards, study participants were asked to complete a validated 11-question shared decision-making questionnaire (SDM-Q). Responses to each question were transformed to agree (1) and disagree (0) yielding a shared decision making score ranging between 0-11. **Results:** To date, 122 participants have completed the second study visit (mean age 59.1±5y, 48.3% male). CHD risk (risk =8.4±3.4%) estimated from CRF was communicated to 62 study participants (59±5.3y, 50% male) and 60 participants (59.1±4.7y, 53.3% male) received CHD risk estimated from CRF*GRS (risk = 9.2±7.4%). There was no difference in shared-decision making perception in the two groups (10.7 ±1 vs. 10.4±1.9, P=0.34). Specifically, there was no difference in participants' perception of adequate consultation time between the two groups: CRF vs. CRF*GRS [62 (50.8%) vs. 59 (48.3%), P=0.23, respectively]. Incorporating the GRS in the decision-making process did not affect participant's perception of sufficient discussion of different treatment options including use of statins vs. other medications or lifestyle modifications, selection of the treatment, advantages of each treatment, and feeling of inclusion in the treatment decision (P=NS for all). **Conclusion:** We demonstrate that disclosure of genetic risk for CHD does not affect participants' perception regarding shared-decision making. Participants in both study groups perceived that they had sufficient consultation time to discuss their CHD risk, different treatment options, and selection of treatment.

Adopting Genomes - Motivations of Adopted Persons when seeking Personal Genomic Services. *N.M. Baptista[1, 2], D.A. Carere[3], J.R. Duggan[1], T.A. Moreno[4], J.L. Mountain[5], S.A. Broadley[2], J.S. Roberts[6], R.C. Green[1], the PGen Study Group.* 1) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 2) School of Medicine, Gold Coast Campus, Griffith University, QLD 4222, Australia; 3) Department of Epidemiology, Harvard School of Public Health, 677 Huntington Avenue, Boston, MA 02115; 4) Pathway Genomics Corporation, 4045 Sorrento Valley Blvd., San Diego, CA 92121; 5) 23andMe, Inc. 1390 Shorebird Way, Mountain View, CA 94043; 6) Department of Health Behavior and Health Education, University of Michigan School of Public Health, 1415 Washington Heights, Ann Arbor, MI 48109.

Background: The use of personal genomic testing (PGT) by adopted individuals is largely unstudied. Using data from the Impact of Personal Genomics (PGen) Study, a longitudinal study of new PGT customers of 23andMe and Pathway Genomics, we conducted an exploratory analysis to characterize adoptees in the PGen population, and examined their motivations for seeking testing and their satisfaction with PGT results. **Methods:** PGen Study participants were surveyed before receiving results (baseline), and 2 weeks and 6 months after receipt of results. Of the 1,464 baseline survey respondents eligible for follow up, 1,042 completed the 6 month survey. At baseline, participants rated the importance, on a 3-point scale ("very important," "somewhat important," "not at all important"), of 12 possible motivations for seeking PGT. At 6 months, satisfaction with PGT results was measured by endorsement of 6 statements on a 5-point scale from "strongly disagree" to "strongly agree." Associations between adoption status and each motivation or satisfaction statement were analyzed using chi-square tests and logistic regression, adjusting for age, gender, race, education, company, and prior PGT. In all analyses, responses were dichotomized to "very important" and "somewhat/not at all important" for motivations, and to "strongly/somewhat agree" and "neither agree nor disagree/strongly/somewhat disagree" for satisfaction statements. **Results:** Of 1,042 6 month survey respondents, 57 (5%) were adoptees. In comparison to non-adoptees, adoptees were younger (42±13 years vs. 47±16 years, p=.01), and less highly educated (63% vs. 81% college degree or higher, p<.01). No significant difference was found between adoptees and non-adoptees' gender, race, income, or prior PGT. Adoptees were more strongly motivated to seek PGT because of their limited family health history (86% vs. 32% considered it "very important", p<.0001), and to learn their personal risk of specific diseases (OR=2.2, 95%CI 1.1-4.4, p=.03). Adoptees were no more satisfied than non-adoptees with the health information they gained, but were more likely to believe that seeking PGT was a wise decision (OR= 4.7, 95%CI 1.1-19.9, p=.03). **Conclusions:** Adoptees were younger, less highly educated, and more motivated than non-adoptees to seek genetic testing because of limited family health history and an interest in their disease risk. Belief that PGT was a wise decision may reflect a knowledge gap that adoptees wanted to fill.

2387S

Expert knowledge shapes decision-making for couples receiving uncertain prenatal chromosomal microarray testing results. *M.A. Rubel, K. Kellom, F.K. Barg, B.A. Bernhardt.* University of Pennsylvania, Philadelphia, PA.

Chromosomal microarrays (CMA) are increasingly utilized in prenatal settings to detect copy-number variants (CNVs) of probable or clinical significance not detectable by conventional cytogenetics. Up to 20% of microarray testing results in some kind of positive finding, including both pathogenic and uncertain results, which can complicate decision-making about pregnancy. When faced with ambiguous results, patients and their partners often turn to various forms of "expert knowledge" to mitigate uncertainty, including clinicians, internet resources, medical literature, and personal support networks. This study aims to investigate how couples utilize expert knowledge in the face of uncertain test results to navigate the decision-making process to terminate or continue a pregnancy. This qualitative study documents experiences of couples receiving uncertain prenatal CMA results from diagnosis centers in the US via phone interviews. Men and women separately discuss their experiences with CMA testing, understanding of and emotional response to the results, factors affecting decision making, and needs throughout the testing process. Interview transcripts were coded using NVivo10. Of the 18 male partner/female patient transcripts analyzed to date, most participants receiving uncertain results sought information from multiple sources. Female patients show a propensity to emphasize the impact of information in making their decision, cite various information sources, and seek expert advice from networks of family and friends. After receiving results from clinicians, women are predominantly information-seekers, with many reporting independently locating relevant clinical literature through internet searches. While most women found internet sources of expert knowledge helpful, some noted a fine-line between feeling informed by versus anxious from expert knowledge. In cases where uncertain results were not bolstered by additional understanding, expert knowledge could become "toxic knowledge," meaning that the information produced greater anxiety and emotional hardship. Male partners refer to the results and decisions as uncertain with greater frequency and tend to primarily rely on clinicians and their female partner to find and disseminate results, often seeing their role to be the primary emotional support. This study highlights both partner's varying utilization of expert knowledge as critical factors in the decision-making in a pregnancy with uncertain outcomes.

2388S

A genomic decision aid linked to the electronic health record to disclose coronary heart disease risk and enable shared decision-making. *K. Shameer[1], H. Jouni[1], R. Chaudhry[2], A.K. Dalenberg[1], V.M. Montori[3], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Department of Medicine, Mayo Clinic, Rochester, MN; 2) Division of Primary Care Internal Medicine, Department of Medicine, Mayo Clinic, Rochester, MN; 3) Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Mayo Clinic, Rochester, MN.

Background: The myocardial infarction genes (MI-GENES) study is a randomized controlled trial of disclosing genetic risk of coronary heart disease (CHD) leveraging the electronic health record (EHR). We created a genomic decision aid integrated within the EHR to disclose CHD risk to study participants and enable shared decision-making regarding statin therapy to reduce risk. **Methods:** The Generic Disease Management System (GDMS), a web-based clinical decision support system used at the point of care and integrated within the EHR, was configured to estimate the 10-y CHD risk based on conventional risk factors extracted from the EHR. A link within GDMS provides access to the Statin Choice decision aid which has been proven effective for CHD risk communication (Weymiller et al, Arch Intern Med, 2007). This tool aids with initiation of statin therapy depicting not only the 10-y risk for CHD but also the potential benefit of using statins and the related costs/side effects. A feature was added to the tool enabling the genetic counselor, physician, and patient to visualize the change in 10-y CHD risk after incorporating the genetic risk score (GRS) based on 27 genetic susceptibility loci. CHD risk was disclosed by a genetic counselor in a 30 min scripted session using a pictogram that displays how many among 100 patients with the same risk profile will suffer a myocardial infarction in the ensuing 10 years. Afterwards, the participant meets with a physician for shared decision-making regarding the need for statin therapy. The tool is also equipped with a report generating function and a 'frequently asked questions' page for additional information about GRS. **Results:** The tool is being used for disclosure of genetic risk of CHD in the MI-GENES study. So far, we have randomized 212 participants (47% males, mean age 58.8±5.1y) to receive the 10-y probability of CHD estimated by conventional risk factors vs that estimated from conventional risk factors plus a GRS. Patients are surveyed for satisfaction with genetic counseling and physician encounters, understanding of genetic risk, and shared decision-making. **Conclusion:** In summary, we have developed and successfully implemented a genomic decision aid integrated within the EHR to disclose CHD risk and enable shared decision-making in the clinical setting. The results of the study will facilitate development of best practices for incorporating probabilistic genetic risk for common diseases in the EHR.

The predictive power of breast cancer family history in the clinic. *H.C. Cox, E. Rosenthal, R. Wenstrup, B.B. Roa, K.R. Bowles.* Myriad Genetic Laboratories, Inc., Salt Lake City, WA.

Background: Women with an estimated >20% lifetime risk of breast cancer are candidates for more aggressive clinical management, including screening at younger ages, at more frequent intervals, and with more sensitive technologies, i.e. breast MRI. Family history is a key component of most models for estimating breast cancer risk, but family history analysis may be insufficient to identify at-risk individuals carrying moderately penetrant pathogenic mutations due to limited sibship sizes in contemporary families. We utilized pedigree simulation to estimate the probability that a female proband, who is a carrier of a pathogenic mutation conveying a moderate increase is breast cancer risk, will be identified as having at least a 20% lifetime breast cancer risk as determined by the Claus model. Methods: The SIMLA and SLINK pedigree programs were used to simulate 200 three-generation pedigrees each for 2, 3, 4, or 5-member sibships. The proband was assumed to be a 40-year old female carrying one copy of an autosomal dominant pathogenic mutation conveying a ~25% risk of breast cancer to age 80. Simulated pedigrees were one-sided and limited to either the maternal or paternal side segregating the disease allele. Phenotypes were simulated according to age-dependent liability classes modeled from the Surveillance, Epidemiology, and Ends Results (SEER) breast cancer incidence data. Resulting pedigrees were assessed by the Claus model to determine the proband's eligibility for modified medical management. Results and Discussion: Analysis of simulated pedigrees indicate that <9% of female probands, carrying a pathogenic mutation conveying a ~25% risk of breast cancer, would receive modified clinical risk management based only on Claus model risk assessment. Thus, genetic testing may be critical for identifying individuals carrying pathogenic mutations in moderate penetrance breast cancer susceptibility genes who would benefit from increased surveillance, as outlined in current professional society guidelines. Although population screening for moderately penetrant gene mutations may not yet be economically feasible, clinicians may wish to consider broader pan-cancer testing using a panel composed of both high and moderate penetrance genes when screening the patient for other cancer risks, such as colon, endometrial, and ovarian cancers.

Colorectal cancer screening for people with a family history: should recommendations vary by age? *I. Lansdorp-Vogelaar[1], S.K. Naber[1], K.M. Kuntz[2], N.B. Henrikson[3], M.S. Williams[4,5], N. Calonge[6], K.A.B. Goddard[7], D.T. Zallen[8], E.P. Whitlock[7], T.G. Ganiats[9], C.M. Rutter[3], E.M. Webber[7], A.C.J.W. Janssens[10], M. van Ballegooijen[1], A.G. Zauber[11].* 1) Department of Public Health, Erasmus Medical Center Rotterdam, Rotterdam, Netherlands; 2) Department of Health Policy & Management, University of Minnesota, Minneapolis, MN, United States; 3) Group Health Research Institute, Seattle, WA, United States; 4) Intermountain Healthcare, Salt Lake City, UT, United States; 5) Genomic Medicine Institute, Geisinger Health System, Danville, PA, United States; 6) The Colorado Trust, Denver, CO, United States; 7) Center for Health Research, Kaiser Permanente Northwest, Portland, OR, United States; 8) Department of Science and Technology in Society, VirginiaTech, Blacksburg, VA, United States; 9) Department of Family and Preventive Medicine, University of California, San Diego, CA, United States; 10) Department of Epidemiology, Emory University, Atlanta, GA, United States; 11) Memorial Sloan-Kettering Cancer Center, New York, NY, United States.

Objective. People with first degree relatives (FDRs) diagnosed with colorectal cancer (CRC) are at an increased risk for developing CRC. It is therefore recommended to screen them more frequently than the general population. Although the relative risk for colorectal cancer decreases with the age of the person at risk, none of the screening recommendations take this age into account. The aim of this study is to determine the potential benefits of age-specific screening guidelines for people with a family history of CRC. **Methods.** For the age groups 30-44, 45-49, 50-54, 55-59, 60-64, 65-69 and 70+, we based the relative risk of having 1, 2, 3 and 4 or more FDRs diagnosed with CRC as compared to the general population on a literature review. These relative risks were incorporated into the MISCAN model to estimate costs and effects of colonoscopy screening strategies varying in age range and interval for people with 1, 2, 3, or ≥4 FDRs diagnosed with CRC. For each age and level of FDR, we determined the most cost-effective screening schedule with an incremental cost-effectiveness ratio (ICER) comparable to that of screening in the general population. Because past screening could influence the cost-effectiveness of future screening, we assessed the influence of screening history on the optimal screening interval in a sensitivity analysis. **Results.** While effectiveness of colonoscopy screening increased with the number of FDRs people have, total costs of care decreased. Colonoscopy screening was even cost-saving in people with a family history. Consequently, screening should start earlier at age 40 (35 for those with ≥4 FDRs) in people with a family history. The optimal screening interval ranged from 5 years for people with 1 FDR, to 1-3 years for people having 4 FDRs or more. Despite the decreasing relative risk with age, the optimal screening interval was similar for all age groups. **Conclusions.** Although the relative risk of people with FDRs diagnosed with CRC decreases with age, optimal screening intervals do not vary with age but do vary with number of affected FDRs. People with a family history should be offered screening from age 40 (35 if ≥4 FDRs) with an interval of 5 years in case of 1 FDR, 3 years in case of 2-3 FDRs and 2 years in case of ≥4 FDRs.

Improving pedigree capture: Development and validation of an interview-optimized iPad app to eliminate the need for paper. *J.M. Miller[1], M.J Italia[1], E.T Dechene[2], A. Wilkens[2], C.E Gaynor[1], N.B Spinner[3,4], I.D Krantz[5], P.S White[6,7].* 1) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 5) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA; 6) Department of Pediatrics, Cincinnati Children's Hospital, Cincinnati, OH; 7) Department of Biomedical Informatics, University of Cincinnati, Cincinnati, OH.

Large gene panel, exome and whole genome sequencing-based clinical tests produce data at a scale that is time intensive and difficult to interpret. Trio and inheritance analyses are increasingly utilized as a means for reducing the volume of variants that must be reviewed. In addition to the sequence data, these analysis methods greatly benefit from well-documented pedigree and family history data. Electronic capture of pedigree and family member data provides a way to use this data for subsequent analysis, review, and use. However, while a number of electronic solutions have been developed, these systems typically do not perform well in a busy clinical setting. Consequently, these systems have not generally supplanted the use of paper-based manual abstraction, especially for pedigree representation, resulting in decreased efficiency and increased risk of transcription error. We hypothesized that a multi-touch iPad application could compete with paper on clinical usability, producing both suitable clinical documentation and structured data useful for inheritance analysis in the laboratory. As part of the NHGRI's Clinical Sequencing and Exploratory Research (CSER) Program, we developed Proband, an iPad app for capturing pedigrees, available in the Apple App Store. The app enables the user to create complex family pedigrees by implementing nomenclature outlined by the Pedigree Standardization Work Group (PSWG). The primary method of user input is a series of intuitive touch gestures. To streamline data entry, the app relies on the user's context to make the appropriate functionality available at the right time. Proband runs on a local data store and generates pedigree results as PDF or XML. We performed formal usability testing with ten genetic counselors. Each counselor was asked to recreate a pedigree after viewing a training video. The counselors then completed the System Usability Scale (SUS), a standard ten-question survey used to measure user satisfaction. The mean score was 90, well above the average SUS score of approximately 70. Qualitative responses indicated a functional convenience equivalent to, and for some tasks, exceeding that of paper. Initial user feedback at our hospital as well as other institutions has been very positive. In one instance, a counselor in a busy clinic completely replaced paper with Proband, creating over 100 pedigrees to date. We continue to evaluate and improve Proband for use in clinical diagnostic environments.

Non-specific psychological distress in women undergoing noninvasive prenatal testing because of advanced maternal age. *N. Suzumori[1], K. Kumagai[1], S. Goto[1], T. Ebara[2], Y. Yamada[2], M. Kamijima[2], M. Sugiura-Ogasawara[1].* 1) Division of Clinical and Molecular Genetics, Department of Obstetrics and Gynecology, Nagoya City University, Nagoya, Japan; 2) Department of Occupational and Environmental Health, Nagoya City University, Nagoya, Japan.

Objective The objective of our study was to describe our clinical experience in providing noninvasive prenatal testing (NIPT) for fetal aneuploidy to pregnant women, highlighting the degree of non-specific psychological distress. Methods Data were collected from Japanese women who were offered and underwent NIPT after genetic counseling and control pregnant women who did not undergo NIPT as part of the Japan Environment and Children's Study (JECS) Control A planning. The degree of mental distress was assessed using the Kessler 6 (K6) screening scale with a score ≥10 indicating depression or anxiety disorder. Results Among the 505 women who underwent NIPT because of advanced maternal age, 9.1 %, had a K6 score ≥10. Compared with matched Controls (n=1,010) adjusted for maternal age and gestational age, the NIPT group showed a trend toward higher K6 scores (OR 1.44, 95% CI 0.97-2.13, P = 0.07). Higher K6 scores were associated with women whose husbands were the primary decision makers during NIPT counseling (P = 0.06). Conclusions Women electing NIPT tend to have higher scores of depression/anxiety, and those with higher depression scores tended to defer the decision to their husbands.

DIAGNOSTIC CHALLENGES AND BEHAVIOR PROBLEMS IN RWANDAN PATIENTS WITH DISORDERS OF SEX DEVELOPMENT: ETHICAL ISSUES IN AFRICAN CONTEXT. *L. Mutesa[1], J. Hitayezu[1], A. Uwineza[1,2], S. Murorunkwere[1], J. Ndinkabandi[1], A. Ndatinya[3], F. Rutagarama[3], O.R. Karangwa[3], A. Gasana[4], J.H. Caberg[2].* 1) Medical Genetics, National University of Rwanda, KIGALI, Kigali, Rwanda; 2) Center for Human Genetics, University of Liege, Belgium; 3) Department of Pediatrics, Rwanda Military Hospital, Rwanda; 4) Department of Urology, Rwanda Military Hospital, Rwanda.

Background Disorders of sex development (DSD) comprise a variety of congenital diseases with anomalies of the sex chromosome, the gonads, the reproductive ducts and genitalia. The most common DSDs result from disruption of androgen levels and activity that affect later embryonal development, such as congenital adrenal hyperplasia and androgen insensitivity syndrome (AIS). DSDs are always challenging and very difficult to manage. Socio-economic and cultural aspects have a great impact on decision making regarding the management of these conditions. The situation is more complicated in resource-poor settings like in Africa, where access to education and medical care is limited in both quantity and quality of infrastructure, diagnostic tools and medical professionals. In addition, traditional values and beliefs are also very strong in various cultures and sexual issues are taboo subjects. Methods The present study is a 5-year prospective descriptive cohort of patients with suspicion of DSDs referred to our genetic clinic between January 2009 and January 2014 for genetic investigations and counseling. All patients underwent abdominal ultrasound or MRI and hormonal analysis before genetic testing including karyotype and molecular tests. Results In total, 49 patients aged between 1 and 39 years were clinicaly and geneticaly diagnosed with DSDs associated with behavior problems in most of cases. The majority were diagnosed either with sexual ambiguity and hypospadias, or micropenis, or primary amenorrhea, or poor development of secondary sexual characteristics, or primary infertility. In most of female cases, the ultrasound and MRI revealed absence of uterus and ovaries. The FSH, LH or testosterone hormons revealed major abnormal values in more than 60% of patients. The AIS and Rokitansky syndrome were observed in the majority of these patients. The choice of gender identity after karyotyping raised several psychological and ethical issues in the majority of adults patients. The outcome of surgery was successful for the social integration of some of these patients. Conclusion The present study showed that patients with DSDs have major behavior problems in African context. They suffer from extreme anxiety and very high psychological behavior disorders related to their gender identity. Our data suggest that gender assignment has to be avoided before expert and multidisciplinary evaluation especially in young patients.

Making sense of diagnostic uncertainty after newborn screening for cystic fibrosis. *C.J. Barg[1], R.Z. Hayeems[1,2], F.A. Miller[1], Y. Bombard[1,3], P. Durie[4,5], J.C. Carroll[6], P. Chakraborty[7,8], B.K. Potter[9], K. Tam[10], L. Taylor[11], E. Kerr[12], C. Davies[7], J. Milburn[7], K. Keenan[4], A. Price[13], F. Ratjen[4,5,11], A. Guttmann[1,4,5,14].* 1) Institute of Health Policy, Management & Evaluation, University of Toronto, Toronto, ON, Canada; 2) Child Health Evaluative Sciences, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 3) Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, ON, Canada; 4) Division of Paediatric Medicine, Department of Paediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Pediatrics, Faculty of Medicine, University of Toronto, ON, Canada; 6) Department of Family & Community Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 7) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 8) Department of Pediatrics, Faculty of Medicine, University of Ottawa, Ottawa, ON, Canada; 9) Department of Epidemiology and Community Medicine, Faculty of Medicine, University of Ottawa, ON, Canada; 10) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 11) Division of Respiratory Medicine, Department of Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 12) Department of Psychology, The Hospital for Sick Children, Toronto, ON, Canada; 13) Department of Pediatrics, London Health Sciences Centre, London, ON, Canada; 14) The Institute for Clinical Evaluative Sciences, Toronto, ON, Canada.

Objectives: Diagnostic uncertainty related to cystic fibrosis (CF) has long been challenging to understand and manage. Newborn screening (NBS) for CF extends these challenges to the early days of life. We explored the parental experience of diagnostic uncertainty arising from NBS. **Methods**: Drawing from a mixed methods prospective cohort study of screen positive and screen negative control infants, we report on qualitative interviews with parents of children who received inconclusive results for CF after NBS and follow-up testing. Through the tertiary care centre that manages the majority of screen positive care in Ontario, we recruited parents of children identified since the inception of CF NBS in Ontario (2008). We used qualitative description to analyze transcript data. **Results**: We conducted 19 interviews with 14 parents of infants with uncertain diagnoses, ranging from 3 months - 4 years in age. Five parents completed interviews at two time-points, separated by one year. We learned that parents gain support through research involvement, but struggle to understand the meaning of an uncertain diagnosis in the face of an apparently healthy newborn, worry about their infant's health-related vulnerability, and fear labeling and over-medicalization from continued medical surveillance. Time appears to mitigate concerns. **Conclusion**: The experience of diagnostic uncertainty is deeply challenging for some families, particularly in the early newborn period. These results should inform decisions by NBS programs and clinical teams about protocols for testing, clinical follow-up, and support for families of those who screen positive, but warrant triangulation with survey data and longitudinal follow-up.

Reconciling the downsides of screening: Mothers' experiences with false positive CF NBS results. *F.A. Miller[1], R.Z. Hayeems[1,2], Y. Bombard[1,3], S.J. Patton[1], C.J. Barg[1], P. Durie[4,5], J.C. Carroll[6], P. Chakraborty[7,8], B.K. Potter[9], K. Tam[10], L. Taylor[11], E. Kerr[12], C. Davies[7], J. Milburn[7], F. Ratjen[4,5,11], A. Guttmann[1,4,5,13].* 1) Institute of Health Policy, Management & Evolution, University of Toronto, Toronto, ON, Canada; 2) Child Health Evaluative Sciences, The Hospital for Sick Children Research Institute, Toronto, ON, Canada; 3) Li Ka Shing Knowledge Institute of St. Michael's Hospital, Toronto, ON, Canada; 4) Division of Paediatric Medicine, Department of Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 5) Department of Paediatrics, Faculty of Medicine, University of Toronto, Toronto, ON, Canada; 6) Department of Family and Community Medicine, Mount Sinai Hospital, University of Toronto, ON, Canada; 7) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 8) Department of Pediatrics, Faculty of Medicine, University of Ottawa, Ottawa, ON, Canada; 9) Department of Epidemiology and Community Medicine, Faculty of Medicine, University of Ottawa, Ottawa, ON, Canada; 10) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 11) Division of Respiratory Medicine, Department of Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 12) Department of Psychology, The Hospital for Sick Children, Toronto, ON, Canada; 13) Institute for Clinical Evaluative Sciences, Toronto, ON, Canada.

Objectives: One of the downsides of population screening is the generation of false positive screening results. In newborn screening (NBS) for cystic fibrosis (CF), however, many of these results identify carriers of one mutation, which is often seen as a benefit. We sought to understand how mothers interpret this false positive experience. **Methods**: As part of a longitudinal mixed-methods cohort study of NBS for CF, we surveyed mothers of infants with false positive results within 3 months of birth and one year later. Participants who agreed were also interviewed. We present descriptive and qualitative thematic analyses. **Results**: We received completed surveys from 134 of 245 mothers (55%) at time-1 (T1) and 96 of 214 (45%) at time-2 (T2). We report on 31 T1 interviews. Quantitatively, majorities agreed to feeling informed (T1:95%, T2:86%) and relieved (T1:90%; T2:83%) about their baby's result; and minorities agreed that learning about a false positive (T1:32%; T2:40%) or carrier result (T1:4%; T2:3%) was a disadvantage of NBS. Qualitatively, mothers identified their NBS experience as highly burdensome. Tolerance for this burden was expressed in 4 ways - by downplaying the burden in retrospect, appreciating the system of care, identifying benefit for self (reproductive and otherwise), and identifying benefit for others. **Conclusion**: These findings suggest significant tolerance for the downsides of NBS. They also identify ways in which burdens are made tolerable. Notably, reproductive benefit is only one way; systems of care that help to mitigate burdens, and an ethic of care for others, are also important.

2396S

Numeracy, Genetic Knowledge, and Perceived Risk for Coronary Heart Disease in the MI-GENES Study. *H. Jouni[1], I.N. Isseh[1], R.A. Haddad[1], K.D. Christensen[2], R.R. Sharp[3], R.C. Green[2], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Department of Medicine, Mayo Clinic, Rochester, MN; 2) Division of Genetics, Department of Medicine, Brigham & Women's Hospital & Harvard Medical School, Boston, MA; 3) Biomedical Ethics Program, Mayo Clinic, Rochester, MN.

Background: Genetic knowledge, numeracy, and risk perception likely influence how patients interpret and respond to genetic test results. We assessed these characteristics in participants of the Myocardial Infarction Genes (MI-GENES) study that is exploring integration of genomic results into the electronic health records. **Methods:** Participants were residents of Olmsted County, aged 40-65 y, at intermediate risk for coronary heart disease (CHD), and not on statins. They were randomized to receive the 10-y risk of CHD based either on conventional risk factors alone or conventional risk factors plus a 27 SNP genetic risk score. We assessed numeracy, genetic knowledge, and self-perceived risk for CHD at baseline before disclosing CHD risk. Numeracy and genetic knowledge were assessed using previously validated surveys. We adapted the Health Information National Trends Survey (HINTS) to assess CHD risk perception. **Results:** The mean age of 212 participants was 58.8±5y, 47% were male, all were non-Hispanic white, 21% had completed high school and 62% had graduated from college or graduate school. At baseline, participants scored highly on numeracy; 42.9% answered all of the 8 questions correctly and 31.1% answered 7 questions correctly. For genetic knowledge, 22% answered ≥14 of 16 questions correctly while most participants (62%) answered between 9-13 questions correctly. The mean perceived 10-y risk was significantly higher than the estimated 10-y risk for CHD (25.6%±20.3% vs 8.5%±4.1%, respectively, P<0.01). Although patients overestimated their risk for CHD, the majority (80%) described their risk as the same or lower than that of healthy peers. Participants with family history of CHD were more likely to perceive increased genetic susceptibility to CHD than participants without such history (63% vs. 26%, respectively, P<0.01). Higher numeracy was associated with lower self-perceived risk for CHD (ρ -0.2, P=0.004). Genetic knowledge scores were not associated with perceived risk regardless of family history (P=NS). **Conclusion:** Early adopters of genetic testing for CHD in this study were facile with numbers and knowledgeable about genetics, but greatly overestimated their risk for CHD. Interestingly, numeracy but not genetic knowledge, was inversely correlated with perceived CHD risk. Our results indicate that education and counseling protocols for genetic testing should also address numeracy misperceptions about disease risk.

Genomic Sequencing in the Infant Population: Exploring Parental Motivations, Expectations and Utilization of Sequencing Results in the *Tell Me More* Study. *F. Facio[1], B. Solomon[1], S. Haga[2], E. Klein[1], K. Huddleston[1], A. Khromykh[1], S. Hull[3], B. Berkman[3], E. Sutton[4], K. Hurley[5], J. Evans[6], J. Vockley[1], J. Niederhuber[1].* 1) Inova Translational Medicine Institute, Falls Church, VA; 2) Institute for Genome Sciences & Policy, Duke University, Durham, NC; 3) Bioethics Core, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Center for Bioethics and Social Sciences in Medicine, University of Michigan, Ann Arbor, MI; 5) Teachers College, Columbia University, New York, NY; 6) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC.

Advances in genome sequencing (GS) technologies have increased their use in research and clinical practice. However, many barriers exist to translating GS to routine clinical care, including a lack of data documenting motivations, expectations, and behavioral outcomes as well as parental perspectives and behaviors. We describe findings from a large, prospective trio-based whole GS study within a multi-hospital health system (~20,000 annual deliveries, half of which are at the main study hospital). Approximately 10% of these deliveries enroll in the longitudinal GS study, largely limited by full trio availability. We have enrolled ~1500 trios to date (we accrue ~80-100 trios/month). Reasons for participation include potential benefits related to finding medically relevant information, altruism, lack of cost, enthusiasm regarding science and genomics, and the fact that the study is conducted directly through the same health care system. Reasons for study decline include unwillingness to undergo phlebotomy (especially fathers due to the need for an additional blood draw), privacy concerns and questions related to government access to genetic/genomic and other health information, concerns about potential effects on insurance coverage, and stigma associated with research, especially related to genetics/genomics. Focus groups of study participants have shown an overwhelming desire to know both specific and general genetic/genomic information. As an initial step, we have started returning CLIA-validated pharmacogenetic results within the focus groups to determine the impact of return of these results. To explore the sociobehavorial aspects of GS further, we have also designed the *Tell Me More* study, which aims to investigate parental motivations for enrolling or not enrolling their infants, expectations about GS results and the use and impact of such information. This nested study is recruiting a total of 40 participants - 20 parents who opted to pursue GS for their newborn (intervention group) and 20 who declined (control group), and uses phenomenological methods to explore parental experiences and decision-making processes. Parents in both groups complete interviews post informed consent and parents in the intervention group complete interviews post disclosure of results. Ultimately, this study will generate results that can be used as building blocks for larger projects and inform best practices in clinical applications of GS in the infant population.

Supporting the International Rare Diseases Research Consortium: achievements and challenges. *P. Lasko[1,2], B. Cagniard[3], S. Höhn[3], L. Lau[3], S. Peixoto[3], S. Aymé[3], IRDiRC Consortium.* 1) International Rare Diseases Research Consortium, Montreal, Quebec, Canada; 2) Institute of Genetics, Canadian Institutes of Health Research, McGill University, Montreal, Canada; 3) SUPPORT-IRDiRC, INSERM US 14, Paris, France.

The International Rare Diseases Research Consortium (IRDiRC) brings together members that have agreed to common goals and principles and to work in a coordinated and collaborative manner within a multinational consortium to advance research in this critical area. Its over 35 members are public and private research funding organizations and companies that have each dedicated over 10 million US$ to research into rare diseases. Present members are from Europe, North America, Asia and Australia. IRDiRC's two main objectives are to deliver 200 new therapies for rare diseases and the means to diagnose most rare diseases by the year 2020. To accomplish this, IRDiRC engages in a range of initiatives. The first one is to support financially strategic research projects. The funding agencies remain independent in their calls for proposal but discuss jointly their strategy and agree on main areas to be supported. The second instrument is to identify and highlight strategic infrastructures which could be used by the researchers to speed up their projects. The third is to identify and promote standards to be used to make data interoperable and as easy to access and share as possible. Many working groups have been put in place to advice the consortium in these and other areas, and their suggestions are reviewed by three scientific committees who directly advise the executive board. A label 'Recommended by IRDiRC' has recently been created to identify preferred tools, protocols, and guidelines that directly contribute to IRDiRC goals. Consortium achievements are posted in a timely manner on its website (www.irdirc.org), enabling all the activities of its many committees and working groups to be as transparent as possible. As part of its dissemination and communication plan, IRDiRC publishes feature articles on strategic research projects and infrastructures and offers on its website a space for its members to communicate. It organized an International conference in Dublin in 2013 which was the real public launch of this initiative. The next IRDiRC conference will be focused on fostering international collaboration with Asia and will be held in Shenzhen (China) on 7-9 November 2014 thanks largely to support from BGI.

2399S

Assessment of factors that should be addressed in prenatal counseling for non-invasive prenatal test. *L. Wang[1], Y. Gu[1], Q. Meng[1], X. Tang[1], H. Wang[1], S. Yang[1], H. Mao[1], F. Liu[1], J. Zhang[1], H. Wu[1], Q. Shi[1], N. Zhong[2].* 1) Department of Prenatal Diagnosis, Lianyungang Maternal and Child Health Hospital, Lianyungang, China; 2) Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Objectives: To investigate the potential factors affecting the women's attitude toward using a non-invasive prenatal test (NIPT) as well as knowledge of prenatal diagnosis in pregnant women, and the clinical efficiency of identifying fetal chromosomal aneuploidies in pregnant women using an NIPT. Method: A survey of the potential factors (age, education, and residential area) affecting pregnant women's choice of prenatal diagnosis and their understanding of prenatal diagnosis that was conducted in our hospital. Moreover, 917 women with high-risk pregnancies were invited to participate in an NIPT trial. Complete karyotyping of the amniotic fluid was performed to validate each abnormal case identified in NIPT. Results: Women older than 35, rather than 18 to 35 years, were statistically significantly inclined to choose NIPT as their prenatal diagnosis procedure ($P < 0.05$). The percentages of women knowing of the purpose, advantage, limitation and costs of NIPT were less than that of amniocentesis. Moreover, an average of 24.46% women understood the indications for NITP. The NIPT trial with validation by full karyotyping of the amniotic fluid identified 3.60% high-risk pregnancies with fetal aneuploidies, including 2.73% trisomy 21 (Tri21), 0.33% trisomy 18 (Tri18), 0.44%Turner syndrome (45, X), and 0.11% Klinefelter's syndrome (47, XXY). In addition, in the NIPT tiral, one woman with maternal mosaicism (45, X and 46, XX) and one case of false-positive Tri18 caused by confined placental mosaicism (CPM) were also identified after karyotype validation. Conclusions: Pregnant women's age was the primary factor affecting women's choice for NIPT, and more education on NIPT is necessary for promoting clinical application of NIPT. Meanwhile, discordant positive results found with NIPT can be caused by confined placental mosaicism and maternal mosaicism, which underlines the need to confirm all positive NIPT results via conventional invasive testing and karyotyping at NIPT's current stage of development.

Genetic Counselling for Psychiatric Disorders: Exploring the Psychiatric Health Professionals' Perspective in the United Kingdom. *S.E. Jenkins[1,2], M. Arribas-Ayllon[2].* 1) Wessex Clinical Genetics Service, Southampton, Hampshire, United Kingdom; 2) Institute of Medical Genetics, Cardiff University, Cardiff, Wales, United Kingdom.

Background Historically genetic counselling is not offered for psychiatric disorders in the United Kingdom through regional clinical genetics departments provided by the NHS. The purpose of genetic counselling through these specialist centres is to provide patients and their families with information about the nature and consequences of a disorder, in addition to the probability of developing symptoms of the disorder and passing it on to future generations. The options available to the patient and their families in management and treatment are discussed, and in some cases genetic testing can then be explored. Recent genomic advances identifying a greater genetic contribution to mental illness is anticipated to increase the demand for psychiatric genetic counselling and is expected to cause significant changes in the management and treatment of these disorders. **Methodology** The study employed both quantitative and qualitative methods of research to explore the attitudes and experiences of psychiatric health professionals with respect to identifying a potential for genetic counselling services within clinical psychiatry in the UK. **Results** Data analysis revealed the following emerging themes: -Demand for genetic counselling; -Responsibility for genetic counselling provision; and -Barriers for the service. Evaluation of the data led to the conclusions that although demand for psychiatric genetic counselling has not been voiced in the UK at present, psychiatric health professionals believe that such a service would be a useful and desirable. Genomic advances which identify susceptibility loci for psychiatric disorders may have significant implications for genetic counselling in clinical psychiatry if these discoveries lead to genetic testing. Psychiatric health professionals describe clinical genetics as a skilled profession capable of combining complex risk communication with much needed psychosocial support. However, the possibility of such a service is confronted with a range of barriers and challenges including, but not limited to, the complexities of uncertainty in psychiatric diagnoses, patient engagement and ethical concerns regarding limited capacity and increased suicidality.

Autism Spectrum Disorder in Taiwan: Parents' report. *J. Ye[1], T.Y Huang[2], S.X Zhao[1], L. Xu[1], E. Jung[3], Y.Y Wu[4], D. Tsai[5], D. Talwar[1], L.S. Chen[1].* 1) Department of Health and Kinesiology, Texas AM University, College Station, TX; 2) Department of Special Education, National HsinChu University of Education, HsinChu, Taiwan; 3) Department of Educational Psychology, Texas AM University, College Station, TX, USA; 4) Department of Psychiatry, Chang Gung Memorial Hospital- Linkou Medical Center, Chang Gung University College of Medicine, Tao-Yuan, Taiwan; 5) Department of Social Medicine, National Taiwan University College of Medicine, Taipei, Taiwan.

Background: In the United States, one in 50 school-age children are affected by Autism Spectrum Disorder (ASD). As a global challenge, limited research has been conducted on ASD outside the U.S. This study reports preliminary findings and characteristics of children with ASD at pre-schools and elementary schools in Taiwan. Methods: A total of 443 parents of children with ASD, recruited from pre-schools and elementary schools of Hsinchu city and county, Taoyuan and Miaoli counties, completed the paper-and-pencil survey. Results: The average maternal and paternal ages at the time of ASD child's birth were 29.47 years (SD=4.6) and 33.28 years (SD= 5.33), respectively. The majority of the affected children were predominantly boys (6.94:1). The age of confirmatory diagnosis for ASD was 4 years (SD=2.2). About one-fifth (18.5%) of the parents were unaware about the classification of ASD that affected their child. Most of the parents (73.5%) reported that they received either very low or low support from the society for their children. Conclusions: Our study indicated the average age when children were diagnosed with ASD was beyond the recommended age of two. Some parents were ignorant about the type of ASD associated with their child's ASD and most parents reported low support from the society. Relevant agencies in Taiwan should address this urgent issue to facilitate better care and support for the affected family.

Carrier screening of recessive disorders in vitro fertilization couples and gamete donors and recipients by targeted next generation sequencing. *A. Abulí[1], B. Rodríguez-Santiago[2], M. Garcia-Aragonés[2], M. Boada[3], B. Coroleu[3], E. Clua[3], M. Parriego[3], A. Veiga[3], M. Del Campo[1], P. Barri[3], L. Pérez-Jurado[4], L. Armengol[2], X. Estivill[1].* 1) Genomics and Personalized Medicine Unit, Dexeus Woman's Health, Quirón-Dexeus University Hospital, Barcelona, Spain; 2) Research and Development Department, qGenomics, Barcelona, Spaing; 3) Reproduction Medicine Service, Obstetrics, Gynecology and Reproduction Department, Quirón-Dexeus University Hospital, Barcelona, Spain; 4) Genetics Group, Pompeu Fabra University, Barcelona, Spain.

Screening tests for carriers of recessive disorders interrogating specific mutations in selected genes using SNP-genotyping approaches have been developed. By contrast, next generation sequencing (NGS) technologies enable deep gene sequencing in a cost-efficient manner. We developed an NGS-based approach targeting 215 genes causing prevalent and severe recessive diseases for testing in vitro fertilization (IVF) couples and donors/recipients in donation programs. We measured overall sensitivity and specificity of different known genetic mutations present in a blinded training set. Bioinformatics analysis is keystone in the process, as it combines several algorithms optimized for the identification and annotation of different types of mutations (point mutations, indels, copy-number and rearrangements). Our experience with NGS gene panels showed extremely high sensitivities (>99%) for all kinds of mutations. For carrier test validation, we obtained DNA from 57 unrelated individuals: 39 patients and 18 previously genotyped controls. The validation set was composed of 49 different known mutations (67 in the patients), including 29 SNVs, 13 indels and 25 CNVs causing different diseases: cystic fibrosis, phenylketonuria, spinal muscular atrophy, hypothyroidism, thalassemia, factor V deficiency and Duchenne muscular dystrophy. All but one (48/49) different mutations were correctly scored in the blinded study and only one deletion-type mutation remained undetected. This information allowed us to finely tune the algorithm to reach maximum sensitivity. All single nucleotide changes were validated and no known recessive mutations were called in the control samples. To date, we evaluated the spectrum of mutations found in 113 patients referred for carrier testing by IVF clinics. We have identified 62 carriers (54%) and a total of 56 different mutations. We detected multiple carriers for common mutations in the European population but we also identified rare mutations and novel deleterious variants that are predicted to be pathogenic (nonsense, frameshift mutations and mutations at splice site positions), as well as collected evidences for discrepancies between disease prevalence and population frequency of apparently pathogenic mutations. A significant proportion of the identified mutations, specially the novel mutations, would have not been detected by traditional methods. NGS has higher detection rates resulting in lower residual risks.

2403S

Inherited cancer predisposition in children: challenging issues faced by a genetic clinic in a pediatric oncology hospital. *F.T. de Lima[1,2], V.F.A. Meloni[3], C.R.P.D. Macedo[2], N.S. da Silva[2], A.M. Cappellano[2], R.V Gouveia[2], E.M.M. Caran[2].* 1) Gynecology and Obstetrics Department, UNIFESP-EPM, São Paulo , São Paulo, Brazil; 2) Pediatric Oncology Department - GRAACC (Support Group for Children and Adolescents with Cancer), UNIFESP-EPM, São Paulo, São Paulo, Brazil; 3) Genetics and Morphology Department, UNIFESP-EPM, São Paulo, São Paulo, Brazil.

INTRODUCTION: Genetic predisposition in childhood cancer is variable, and the access of children with neoplasms to genetic services skilled in hereditary cancer and dysmorphology is limited, even in well-developed countries. OBJECTIVES: We described the structure, the patients' clinical characterization and challenges faced by a new genetic clinic, in a public pediatric oncology hospital in Brazil. METHODS: We reviewed the initial proposal for the clinic's structure, the protocols and charts of all patients seen from August 2012 to December 2013, as well as the patient's database. RESULTS: The initial structure was centered in patients' care, with standard initial clinical evaluation protocol, and follow-up protocols for specific conditions, e.g., neurofibromatosis (NF) and tuberous sclerosis (TS). Appointments occur once a week. The main reason for referral was a diagnosis with known genetic implications, followed by association of cancer and malformation. Other reasons included cancer family history and concerns about recurrence in another child. Almost half of the 172 patients (152 families) seen had NF (46/26,7%) or retinoblastoma (41/23,8%); 37 (21,5%) patients had other diagnosis. The exact diagnosis was not obtained in 48 patients (27,9%), classified as suspected malformation syndromes associated to cancer (25), or suspected familial/hereditary cancer (23). Most were seen just once (113/65,7%). Issues faced included an appreciable number of patients needing evaluation, lack of knowledge about the goals of genetic counseling and about family history. To overcome some, a folder with orientations was created for easy referral. The need for a stronger and closer interaction with the clinical staff was also observed, and periodic grand rounds were proposed. Due to the hospital structure, focused on childhood cancer care, the identified at-risk family members were referred to external health care. In Brazil, there were no public provision of genetic testing, and since patients cannot afford their costs, DNA and tumor samples were stocked on a biobank, with all legal and ethical policies being observed, hoping for a change in this situation. CONCLUSIONS: A genetic cancer clinic in a pediatric oncology hospital, focused on care, research and education, helps the identification of a specific tumor predisposition or a congenital malformation syndrome in children with cancer, adding value on patient's management and counseling of at-risk relatives.

2404S

Implementing a universal public health policy for the care of rare diseases in Brazil. *D.DG. Horovitz[1], M.J.B Aguiar[2], V.E.F. Ferraz[3], M.F. Galera[4].* 1) Centro de Genetica Medica, Instituto Fernandes Figueira / Fiocruz, Rio de Janeiro, RJ., Brazil; 2) Faculdade de Medicina da Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 3) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil; 4) Departamento de Pediatria - Faculdade de Medicina da Universidade Federal de Mato Grosso, MT, Brazil.

Brazil is an 8 million km^2 developing country, with 190 million population and 3 million births/yr. Since 1988 the Unified Health System (SUS) became universal and accessible to all. Better access to health care and partial control of poverty-related diseases led to progressive increase in burden of birth defects, shifting from fifth to second leading cause of infant mortality, highlighting the need for specific health policy strategies. Scattered governmental actions related to birth defects/genetic diseases comprise birth defects notification, newborn screening, rubella immunization, folic acid flour fortification and few treatment programs for rare diseases. Despite close relationship between clinical genetics and management of birth defects/genetic diseases, less than 30% of the total demand is currently met, due to difficult access to specialized services, insufficient laboratory support and lack of funding. Most genetic services are not fully integrated to the SUS, and non-recognition of medical genetics in the health system impeded their growth. A national policy for clinical genetics was published in 2009 but never implemented. In 2012, after significant pressure from users, a working group to elaborate a national policy for rare diseases in the SUS, composed of specialists, users and technicians from the Ministry of Health was instituted. After public consultation in 2013, the policy was published early 2014 and its implementation is underway. It was designed to cover rare diseases as lines of care, classified as genetic (congenital anomalies and later onset diseases, intellectual disability, inborn errors of metabolism) and non-genetic (inflammatory, infectious, autoimmune and other) rare diseases. The policy will be centered in clinical services, for which minimal requirements must be met (access to laboratory investigation, developmental services, genetic counseling); it will also regulate treatments for rare diseases. An official policy for rare diseases means recognition of the importance of medical genetics in the care and prevention of birth defects, reimbursement for consultations and exams, rational use of resources and enhanced coverage. The organization of a functional integrated network will not only use the already existing services as the backbone, but also stimulate the creation of new clinics throughout the country. Rare disease prevention, education, and epidemiological data collection are recommended as complementary measures.

2405S

Effect of Co-Payment on Behavioral Response to Consumer Genetic Testing. *J. Outlaw[1], L. Ariniello[2], W. Liu[1], D. Boeldt[1], N. Wineinger[1], N.J. Schork[1], E.J. Topol[1], C.S. Bloss[1].* 1) Rady School of Management, UCSD, San Diego, CA; 2) Scripps Translational Science Institute, La Jolla, CA.

Existing research in consumer behavior suggests that a person's perception and usage of a product post purchase might depend on how the product was marketed, including the price paid. As improvements in technology make genetic testing cheaper and more accessible to increasing numbers of consumers, it is important to consider the effect marketing practices may have on the adoption of and response to testing. In particular, it is unclear how the price paid for a genetic test may influence the consumer's subsequent behavior. In the current study, we examined the effect of price paid for a direct-to-consumer (DTC) genetic test on consumer post purchase behavior. Participants were enrolled in the Scripps Genomic Health Initiative (SGHI), a longitudinal cohort study originally designed to determine the impact of DTC genomic testing on consumers. Co-payment amounts for the test varied from $150 to $470, representing a price increase over time to encourage early enrollment. A small proportion of participants received fully subsidized testing from their employer. Of the subjects recruited for the study, 2,037 completed behavioral and psychological assessments before and approximately 5.6 months after genomic testing. Results indicated that with respect to clinical screening test completion, consumers that paid for the genetic test were significantly more likely to both obtain follow-up health screenings ($p<0.05$) and to share results with their physician ($p<0.05$), compared to those whose test was fully subsidized. Prior to receipt of their genetic test results, neither group differed in their propensity to visit a physician. In addition, neither group showed any significant changes in diet, exercise, or anxiety after receiving genetic risk results. The out-of-pocket price paid for DTC genetic tests may influence how results are interpreted and acted upon by consumers. Cognitive dissonance theory may help explain the increase in screening propensity for paying consumers. Such individuals may obtain follow-up screenings as a way of confirming the value of the test and validation of their initial decision to expend personal resources to obtain it. Understanding of co-payment effect on behavioral response to genetic testing may help shape public policy in this rapidly evolving area of health care.

2406S

Costs and burden of pediatric hospital admissions with a single gene or chromosomal diagnosis, United States, 2009. *R. Fisk Green[1], S. Grosse[2], R.S. Olney[2].* 1) Carter Consulting, National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA; 2) National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, GA.

To update and better understand the impact of single gene and chromosomal disorders on pediatric hospitalizations and inpatient costs, we analyzed a sample of pediatric inpatient hospital admissions with an ICD-9 code indicative of a single gene or chromosomal disorder diagnosis using 2009 national data from the Kids' Inpatient Database, Healthcare Cost and Utilization Project, Agency for Healthcare Research and Quality. About 3% of admissions included a single gene or chromosomal disorder diagnosis, with an estimated annual cost >$5 billion (about 12% of estimated total pediatric inpatient hospital costs). Diagnoses observed most often and with highest estimated total admission costs included sickle cell disease, cystic fibrosis, muscular dystrophy, hemophilia and other bleeding disorders, metabolic newborn screening disorders, hereditary immunodeficiencies, velocardiofacial (VCF)/DiGeorge syndrome, neurologic disorders, skeletal dysplasias, and trisomy 21. Admissions with severe combined immunodeficiency (SCID) or VCF/DiGeorge syndrome diagnoses had the highest estimated mean cost per admission, while estimated mean costs per day were highest for admissions with diagnoses of Fragile X syndrome, MEN syndrome, hemophilia and other bleeding disorders, Apert syndrome, or VCF syndrome. For those admissions with a single gene or chromosomal code, the estimated mean length of stay was more than twice as long as those without these codes. Among admissions with a single gene or chromosomal code, those with combined immune deficiency/SCID or galactose disorders had the longest estimated mean lengths of stay. About 20% of admissions in which the child died during hospitalization included a single gene or chromosomal code, with the highest estimated number of deaths for organic acid disorders. The highest estimated number of admissions for most single gene or chromosomal codes occurred among infants <1 year of age, and the estimated number of admissions decreased with age. However, the estimated number of admissions was higher in late adolescence, compared with younger ages, for admissions with some single gene or chromosomal diagnoses, including sickle cell disease, cystic fibrosis, neurofibromatosis, von Willebrand disease, Ehlers Danlos syndrome, and hereditary peripheral neuropathy/Charcot Marie Tooth. Our results confirm that single gene and chromosomal disorders, while individually rare, substantially contribute to hospital inpatient costs and utilization.

Utilizing telemedicine to support informed decision making and expand access to cancer genetic services in community clinics. *A.R. Bradbury[1,2], L. Patrick-Miller[3], D. Harris[1], E. Stevens[1], B. Egleston[4], L. Fleisher[5], R. Mueller[1], A. Brandt[1], J. Stopfer[1], P. Higgins[1], S. Domchek[1].* 1) Medicine, Division of Hematology-Oncology, University of Pennsylvania, Philadelphia, PA; 2) Medical Ethics and Health Policy, University of Pennsylvania, PA; 3) Medicine, Division of Hematology-Oncology, University of Chicago, Chicago, IL; 4) Biostatistics, Fox Chase Cancer Center, Philadelphia, PA; 5) Children's Hospital of Philadelphia, Philadelphia, PA.

Background: Given high demand and a limited workforce, many patients do not have access to genetic providers. Telemedicine (TM) has been used to expand services to low access populations and could increase the use of pre-test counseling, informed decision-making and the appropriate use of genetic services. Methods: Patients at 3 community sites received pre-test (V1) and post-test (V2) counseling for cancer susceptibility with a genetic counselor (GC) at an expertise center through secure 2-way audio and visual communication. Surveys assessed knowledge, satisfaction, psychosocial responses and experiences. We used paired T-tests for changes between time points and linear regressions. Results: Of 100 patients approached, 83% consented to telegenetic services. 57 have completed V1 and 70% proceeded with testing. 31 patients have received results, including 3 carriers (BRCA2, MSH2, PMS2). 4% of sessions were aborted due to technology failure, 30% had disconnections but were completed by TM. Although 34% of patients reported technical difficulties, 94% were satisfied with their telegenetics visit. Knowledge (BL 20.9, SD 2.8; postV1 22.0, SD 3.0; $p<0.01$) and satisfaction with genetic services (SGS) significantly increased (postV1 39.5, SD 3.9; postV2 42.2, SD3.6; $p<0.01$), general anxiety (BL 7.4, SD 4.1; postV1 6.6, SD4.1; $p=0.02$; postV2 5.7, SD 3.5, $p=0.06$) and depression (BL 3.9, SD 3.9; postV1 3.5, SD 3.4; $p=0.05$; postV2 2.9, SD 3.5, $p=0.07$) significantly decreased, event anxiety did not change significantly (Table 1). Patients reported many advantages to telegenetics (e.g. less travel burden, informative) and few disadvantages (e.g. audio and technical challenges, less personal). Conclusions: Ensuring informed decision making across diverse clinical populations is increasingly important given the range of testing options (targeted v. multiplex) with variable utility and risk for uncertainty. Telemedicine delivery of cancer genetic services is feasible, increases knowledge, identifies mutation carriers and family history related cancer risk, and is associated with high satisfaction, suggesting an innovative model for delivery in community practices without institutional access to genetic providers.

2408S

Cree Leukoencephalopathy and Cree Encephalitis Carrier Screening Program: Evaluation of Knowledge and Satisfaction of High School Students. *J. Le Clerc-Blain[1], V. Gosselin[2], A. Bearskin[3], J.E. Torrie[2], G.A. Mitchell[1,4,5], B.J. Wilson[6], A. Richter[1,4,5], A.M. Laberge[1,4,5].* 1) CHU Sainte-Justine, Montreal, Quebec, Canada; 2) Cree Board of Health and Social Services, Chisasibi, Quebec, Canada; 3) Eeyou Awaash Foundation, Chisasibi, Quebec, Canada; 4) Medical Genetics Division, CHU Sainte-Justine, Montreal, Quebec, Canada; 5) Department of Pediatrics, University of Montreal, Montreal, Quebec, Canada; 6) Department of Epidemiology and Community Medicine, University of Ottawa, Ottawa, Ontario, Canada.

BACKGROUND: A population-based carrier screening program (CSP) started in 2006 for Cree encephalitis (CE) and Cree leukoencephalopathy (CLE), two neurodegenerative autosomal recessive conditions with high carrier rates in the James Bay Cree communities (Northern Quebec, Canada). Developed by local health authorities in collaboration with the Eeyou Awaash Foundation (community family support group), the CE-CLE CSP offers education/counseling sessions and carrier screening, targeting high school students (≥ 14 years), and women of reproductive age and their partners, mostly in prenatal settings. OBJECTIVE: To describe high school students' knowledge and satisfaction with the CE-CLE CSP. METHODOLOGY: Surveys were handed out before (survey A) and after (survey B) the CSP education sessions to grade 9-11 students in six high schools (n=267). Students who had already been tested were excluded (n=43). Data was collected on demographics, knowledge of CE-CLE (clinical features, myths, inheritance, carrier risk) and satisfaction with the program. We report results from our analysis of both surveys. Chi-square tests were used to compare results between surveys. RESULTS: Of 224 eligible students, 90 (40%) answered survey A, and of these 42 answered survey B. Ages ranged from 14-20 years. Seventeen (19%) were either pregnant or already had had at least one child. Eleven (12%) reported a positive family history for CE or CLE. When comparing groups who answered both surveys, improvement in knowledge following the education session was significant for 11/14 questions ($p<0.05$). Of the 42 respondents, 34 (81%) thought they had enough or more than enough information to help them decide about carrier testing, and 30 (71%) thought it is a good or very good idea to offer carrier testing in high school. Immediately following the education session, 59/224 (26%) of eligible students had CE-CLE carrier testing. FURTHER STUDIES: We will increase participant numbers by administering surveys A and B in three more high schools, and assess screening outcomes (e.g. impact of carrier status on reproductive decisions, use of cascade screening), knowledge retention and satisfaction prospectively in a follow-up survey (survey C), one year after participation in initial surveys. CONCLUSION: Education sessions seem to have a positive impact on high school students' knowledge of the CE-CLE CSP. High uptake and positive image of carrier screening confirms its acceptability in high schools.

2409S

Determinants of the value of genetic testing in clinical decision-making. *B. Lerner[1], N. Marshall[2,5], S. Oishi[2], A. Lanto[2], A.B. Hamilton[2,4], E. Yano[2,5], M.T. Scheuner[2,3,5].* 1) Veterans Hospital Administration, Boston, MA; 2) VA Greater Los Angeles Healthcare System, Sepulveda, CA; 3) VA Greater Los Angeles Healthcare System, Los Angeles, CA; 4) David Geffen School of Medicine, University of California, Los Angeles, CA,; 5) UCLA Fielding School of Public Health, Los Angeles, CA.

Objective: The value of genetic testing in clinical decision-making depends on factors within the environmental, organizational, provider, patient and encounter domains. We sought to identify determinants within those domains that are associated with favorable value ratings for the use of genetic tests for six clinical indications. Methods: We administered a key-informant Web-based survey to clinical chiefs of neurology, medical oncology, gastroenterology, cardiology and primary care at Veterans Health Administration facilities. The value of genetic tests was rated on a 5-point scale, then dichotomized into “not at all, minimally and moderately valuable” and “very to extremely valuable.” Bivariate and logistic regression analyses identified associations between determinants and the value ratings for each indication. Results: The response rate was 63%; (n=353). Genetic testing was rated as very-extremely valuable for the indications: inform clinical management (58.6%;), inform disease prevention (56.4%), assist with reproductive options (50.1%), assist with life planning (43.9%), confirm a suspected diagnosis, (39.9%), and confirm an established diagnosis (32.3%.) The most frequently identified determinants associated with favorable value vs. unfavorable ratings regardless of indication were a culture that fosters genetic testing (ranging from OR 4.8, CI 2.3-9.9, p<0.001 to OR 2.3, CI 1.2-4.6, p<0.01) and the availability of genetic testing guidelines (ranging from OR 2.8, CI 1.3-5.9, p<0.001 to OR 1.9, CI 0.99-3.8, p<0.1). Other significant associations include: evidence demonstrating utility of genetic tests (OR 3.4, CI 1.7-6.9, p<0.001); provider specialty using primary care as the reference (ranging from OR 0.3, CI 0.2-0.8, p<0.01 to ability to OR 2.8, CI 1.1-7.2, p<0.5), obtain genetic consults (OR 2.4, CI 1.4-4.2, p<0.001); experience ordering genetic tests (OR 2.6, CI 1.3-5.2, p<0.01); and patient demand for testing (ranging from OR 1.8, CI 1.0-3.2, p<0.05 and OR 1.6, CI 0.94-2.9, p<0.1). Conclusion: We identified several determinants associated with the value of genetic tests in patient care. These findings can guide the design of multi-level implementation efforts within healthcare organizations adopting genetic testing services. Such programs should focus on strengthening a culture that facilitates testing, promoting guidelines for genetic testing, educating providers and patients about genetic testing, and ensuring access to genetic consults.

Lean - production management rules applied to a genomics core facility. *J. Altmüller[1,2], C. Becker[1], P. Nürnberg[1].* 1) Cologne Center for Genomics, Cologne, Germany; 2) Institute for Human Genetics, University of Cologne, Germany.

Lean management is a production management systems approach, originally coming from the automobile company Toyota. It was reviewed to have an enormous value creation per employee, superior to anything known before. Starting 25 years ago, this success model was investigated in the western world, standardized, adopted, and expanded in many fields of production. The Next Generation Sequencing platform with its large variety of applications, fast changing protocols, and comparably small projects intensified the need for professional workflow and capacity planning and quality control implementation. Adopting lean principles, our core facility steadily improves service orientation, data quality and cost effectiveness. With this presentation we will show how lean management tools can help both research and diagnostic labs to maximize flexibility, minimize waste, and reduce mistakes.

Newborn screening for cystic fibrosis: role of primary care providers in caring for screen positive children. *J.C. Carroll[1], R.Z. Hayeems[2,3], F.A. Miller[2], C.J. Barg[2], Y. Bombard[2,4], P. Durie[5,6], P. Chakraborty[7,8], B.K. Potter[9], J.P. Bytautas[10], K. Tam[11], L. Taylor[12], E. Kerr[13], C. Davies[7], J. Milburn[7], F. Ratjen[5,6,12], A. Guttmann[2,5,6,14].* 1) Family & Community Med, Mount Sinai Hospital University of Toronto, Toronto, ON, Canada; 2) Institute of Health Policy Management and Evaluation, University of Toronto, Toronto, Canada; 3) Child Health Evaluative Sciences, The Hospital for Sick Children Research Institute, Toronto, Canada; 4) Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Canada; 5) Division of Paediatric Medicine, Department of Paediatrics, The Hospital for Sick Children, Toronto, Canada; 6) Department of Pediatrics, Faculty of Medicine, University of Toronto, Canada; 7) Newborn Screening Ontario, Children's Hospital of Eastern Ontario, Ottawa, Canada; 8) Department of Pediatrics, Faculty of Medicine, University of Ottawa, Ottawa, Canada; 9) Department of Epidemiology and Community Medicine, Faculty of Medicine, University of Ottawa, Canada; 10) Division of Health Care and Outcomes Research, Toronto Western Research Institute, Toronto, Canada; 11) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 12) Division of Respiratory Medicine, Department of Pediatrics, The Hospital for Sick Children, Toronto, Canada; 13) Department of Psychology, The Hospital for Sick Children, Toronto, Canada; 14) The Institute for Clinical Evaluative Sciences, Toronto, Canada.

Context: Expanded newborn screening (NBS) has increased positive screening results, prompting attention to the role of primary care providers (PCP) in providing care to children who screen positive for genetic disorders. Objective: To explore PCPs’ role in caring for children who receive a positive cystic fibrosis (CF) newborn screen and are confirmed to have CF, an uncertain CF diagnosis or are CF carriers. Participants: PCPs in Ontario, Canada, identified by Newborn Screening Ontario as having a positive CF NBS result in their practice in the previous 6 months. Intervention: Mailed questionnaire inquiring about their role in caring for children with CF, uncertain CF diagnosis and CF carriers, confidence in care, and management of CF family planning issues. Outcome measures: The primary outcome measure was the role PCPs identified in providing well-baby care for children with CF, uncertain CF diagnosis and CF carriers. Results: 329/653 PCPs (50%) completed surveys. Survey respondents were: 65% family physicians/nurse practitioners, 21% pediatricians, 14% midwives. Most PCPs (81%) agreed they have an important role to play in NBS. For infants confirmed to have CF, for routine well-baby care: 22% PCPs would provide total care, 69% share with a specialist, 9% refer to a specialist completely; for infants with uncertain CF diagnosis: 49% would provide total care, 46% share with a specialist, 5% refer to a specialist completely and for CF carriers: 89% would provide total care, 9% share with a specialist, 2% refer to a specialist completely. Most PCPs were extremely/very confident (54%) or moderately confident (35%) in providing reassurance about the health of CF carriers. Only 24% knew how to order CF carrier testing for parents, 66% knew how to refer for prenatal diagnosis. Conclusion: The majority of PCPs are willing to treat infants with a range of CF NBS results in some capacity. It is concerning that 11% indicated that carriers should have specialist care involvement and only 54% were very confident reassuring about carrier status. This raises issues about the possible medicalization of carrier status, prompting the need for specific education for PCPs about genetic disorders and the meaning of genetic test results.

An assessment of clinician and researcher needs for support in the era of genomic medicine. *C.A. Brownstein[1,2,5], S.K. Savage[1], S.I. Ziniel[2,3,4], I.A. Holm[1,2,5], J. Stoler[1,2], D.M. Margulies[1,2,6,7].* 1) Genetics-Research Connection, Boston Children's Hospital, Boston, MA; 2) Department of Pediatrics, Harvard Medical School; 3) Division of Adolescent/Young Adult Medicine, Boston Children's Hospital; 4) enter for Patient Safety and Quality Research, Program for Patient Safety and Quality, Boston Children's Hospital; 5) Manton Center for Orphan Disease Research, Boston Children's Hospital; 6) Division of Developmental Medicine, Boston Children's Hospital; 7) Center for Biomedical Informatics, Harvard Medical School.

Introduction: To assess and characterize the need for a centralized service to support the utilization of genomic testing at Boston Children's Hospital (BCH), we conducted a web-based survey of clinicians and researchers regarding their past, current, and anticipated future use of next generation sequencing and their anticipated needs for support. Results: We received 283 survey responses from 36 departments and divisions (5.5% response rate). A large proportion of clinician respondents anticipate that they will use exome/genome sequencing (44.8%) and/or candidate gene panels (50% clinician) within the next year. About an equal percentage of researcher respondents anticipate the need for exome/genome sequencing (48.0%), while a smaller percentage anticipates the use of candidate gene panels (31.8%). Estimated volume data show an increase in the use of these tests in the future compared to past estimates. However, few respondents (13.6%) said that they felt "Completely Ready" or "Pretty Much Ready" to incorporate NGS into their clinical practice or research. Respondents indicated varying degrees of need for a diverse list of support services, with interpretation and clinical correlation assistance ranked as the most needed services. Conclusion: The results of this study highlight the current and growing need for various types of education, support, and assistance (e.g., data and result interpretation) and make a convincing argument for hospitals and medical centers to invest in the development of institutional genomic services. Some of the key challenges to the success of such genomic service models will involve the need for more precise, powerful, and efficient interpretation tools; expanded data sources; and expert resource networks to inform the interpretation process, not to mention issues of cost, billing, and reimbursement around these components. Data from this study will guide BCH's establishment of a new institutional service, Interpretive Genomic Services (IGS), which will support clinicians and researchers in their use of NGS testing and data. BCH will leverage existing institutional expertise in genetics and genomics, genetic counseling, bioinformatics, and many subspecialties to create a true multi-disciplinary service.

2413S

Physician Response to EMR-Based Genetic and Non-Genetic Risk Results for Actionable Complex Disease and Pharmacogenomics in a Randomized Controlled Trial of Genomic Counseling. *K. Sweet[1], J.F. Garcia-Espana[2], A.C. Sturm[1], T. Schmidlen[2], K. Manickam[1], J. McElroy[1], A.E. Toland[1], J.Scott Roberts[3], M. Christman[2].* 1) Division of Human Genetics, Ohio State University, Columbus, OH; 2) Coriell Institute for Medical Research, Camden, NJ; 3) School of Public Health, University of Michigan, Ann Arbor, MI.

Background: The correct interpretation of genomic variant and family history information for actionable complex disease and pharmacogenomics (PGx) may motivate physicians and patients to take preventive and clinical actions. The impact of genomic counseling performed by genetic counselors on this process has yet to be established. The OSU-Coriell Personalized Medicine Collaborative (CPMC®) is a physician-blind randomized controlled trial of in-person genomic counseling (GC) for patients with chronic disease in a hospital setting. **Method:** 208 patients (mean age: 58 years; 45% female; 56% with a bachelor degree or higher) were enrolled by 8 Cardiovascular Medicine (CM), 12 Internal Medicine (IM), and 11 Family Medicine (FM) physicians over a two year period; 5 were recruited by Media/Research Match. Participants received 8 actionable complex disease reports (e.g., type 2 diabetes; macular degeneration; coronary artery disease) and one PGx result (*CYP2C19*: clopidogrel) via the CPMC® web portal. Patients seen for GC received a summary letter post-visit. All CM/IM physicians received a pre-study educational module on genetics, genomics, PGx, study processes, the availability of test reports and GC summary letters in the EMR; FM physicians had no educational intervention. The primary outcome analyzed was clinical relevant actions taken (yes; no) by the physician team. The EMR was searched for key terms: genetic, genomic, variant, risk, family history, genetic study, CPMC. Relevant actions taken (e.g. ophthalmology referral) were recorded. A secondary outcome was the difference in physician actions by educational intervention (CM/IM; FM). **Results:** Analyses were conducted based on the intention-to-treat principle. One quarter of patients had actions taken by a physician. A multivariable logistic regression model estimated the independent effect of genomic counseling on physician action, adjusted for gender, education and significant covariates. Patients in the GC arm were more likely to have actions taken as compared to the no-GC arm (OR: 2.17; 95% CI: 1.44-3.27; p=0.0002). There was a trend for a positive association between higher level of patient education and actions taken (OR=1.67; 95% CI: 0.97-2.85; p=0.063). No significant difference in physician actions by educational intervention group was found (CM/IM, 26%; FM, 19%; p=0.32). **Conclusion:** Genomic counseling of patients was associated with increased preventive and clinical actions taken by physicians.

A rapid evidence review for the inclusion of genetic data in clinical care for a common, complex disease. *J. Malinowski[1], E.W. Clayton[2], D.C. Crawford[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN.

Personalized medicine (PM), defined as differentiated clinical care based, in part, on the genetic background of an individual, has been implemented for cancer treatments and to guide pharmaceutical interventions for various clinical traits. Despite a recent history of direct-to-consumer (DTC) companies offering risk prediction for dozens of diseases and traits based on the genotyping of hundreds of thousands of single nucleotide polymorphisms (SNPs), the clinical validity and utility of these SNPs for common, complex diseases have not been adequately investigated. We performed a rapid evidence review in an academic setting to identify analytic evidence that the inclusion of genetics in routine clinical care improves health outcomes for complex disorders. We identified a common, complex disease (hypothyroidism) and a related quantitative trait (serum thyroid hormone (TSH) levels) with several known genetic associations, including *FOXE1* rs7850285, *PTPN22* rs24766012, *SH2B3* rs3184504, *VAV3* rs4915077, and *HLA* region rs2517532. These variants were previously used by a DTC company to report risk of developing hypothyroidism. We developed key questions to identify analytic validity, clinical validity, clinical utility, and the ethical, legal, or social issues (ELSI) pertaining to the use of these genetic data in the clinical setting. Using medical subject headings (MeSH) terminology, we performed a PubMed search for articles, completed abstract and full text reviews, and analysis of the results. All data collection and review were maintained in REDCap databases. Six hundred and thirty abstracts were evaluated, from which 346 articles were full text reviewed (54.9%). Fifteen (4.3%) of the full text reviewed articles included odds ratios or effect sizes and p-values for the genetic association. None (0) of the articles provided evidence of clinical validity or utility for the genetic associations. This rapid review was completed in seven months over two academic semesters with two individuals. Our study supports others that have found a general lack of published data to indicate genetic research findings have demonstrable clinical utility. Despite these negative results, our rapid review methodology serves as an example of deploying an evidence review in an academic setting to systematically identify the essential data required to accurately assess the utility of including genetic data to improve health outcomes for common, complex diseases.

Genetic Test Recipient as a Source of Data: A Novel Approach to Obtaining Genotypic and Phenotypic Data for Input into Genomic Databases. *B.E. Kirkpatrick[1], E. Riggs[1], M. Giovanni[1], R. Green[2], A. Janze[3], P. Krautscheid[4], J. Krier[2], C.L. Martin[1], D. Metterville[5], D. Miller[6], M. Murray[1], H. Rehm[5,7], D. Riethmaier[8], W. Rubinstein[9], B. Smith-Packard[1], C. Tan[10], K. Wain[11], W.A. Faucett[1] on behalf of the Clinical Genome (ClinGen) Resource.* 1) Geisinger Health System, Danville, PA; 2) Division of Genetics and Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) GeneDx, Gaithersburg, MD; 4) ARUP Laboratories, Salt Lake City, UT; 5) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Cambridge, MA; 6) Department of Laboratory Medicine and the Division of Genetics, Boston Children's Hospital, Boston, MA; 7) Department of Pathology, Harvard Medical School, Boston, MA; 8) InVitae, San Francisco, CA; 9) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD; 10) Department of Human Genetics, University of Chicago, Chicago, IL; 11) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Large datasets of genomic variants and observed phenotypic consequences have been identified as important resources of information that will help clinicians and researchers understand the extensive variability in the human genome and its impact on disease. The Clinical Genome (ClinGen) Resource, together with the National Center for Biotechnology Information (NCBI), is developing ClinVar, an open-access database of genomic variants, associated phenotypic information, and clinical classifications with supporting evidence. Genomic databases including ClinVar are incomplete, and various avenues are being investigated to increase the amount of information available. As genotypic information in isolation has limited value, the availability of phenotypic information is crucial to variant interpretation. Previous efforts have focused on obtaining linked genotypic and phenotypic information from laboratories, researchers, and clinicians. These approaches often yield limited information due to lack of time, resources, and/or incentive. In contrast, patients themselves are valuable sources of information regarding their own medical histories, and they may be highly motivated to share this information for the benefit of advancing scientific understanding. By developing an online patient registry portal, ClinGen seeks to enhance the detailed genotypic information available from laboratories with detailed phenotypic information provided by patients. Registry participants will complete an online consent process explaining the project and implications of genomic data sharing. Each participant will be asked to complete a general, review-of-systems-type online health questionnaire; follow-up questionnaires will obtain detailed information on health issues identified on the original survey. Participants also will be asked to share a copy of their genetic test results, which will be curated by the registry coordinator. This approach will allow for the accurate representation of genotype information. Strategies for allowing the linkage of data from different sources on the same individual into ClinVar are in development. As far as the researchers are aware, this is the first attempt to obtain information directly from genetic test recipients for the purposes of building genomic databases.

A comparison of anthropometric status, blood pressure and oxygen saturation in athletic and non-athletic females. *H. Kaur, B. Badaruddoza.* Human Genetics, Guru Nanak Dev University, Amritsar, India.

Obesity and overweight for all age groups are major concern in both economically developing and developed countries. Physical and mental health is directly related to obesity and hypertension. This study aimed to compare anthropometric status, blood pressure and oxygen saturation between athletic and non-athletic females. The athletic and non-athletic female subjects aged 18-25 years were selected from Guru Nanak Dev University, Amritsar, India. The anthropometric, physiometric and socio-economic variables along with oxygen saturation was recorded for all the study samples. The data was analyzed on SPSS v. 18.0 using correlation, ANOVA, univariate and multivariate regression analysis.In this study weight gain, BMI, SBP and DBP were found higher in athletic female group as compared to non-athletic group. Whereas, waist circumference, hip circumference, waist-hip ratio and skinfolds were higher in non-athletic female group. The percentage of saturated oxygen content has been found maximum in non-athletic group.

The NINDS Repository: A Public Collection of Biomaterials for Disease Modeling, Gene and Biomarkers Discovery in Neurological Research. *C. Tarn[1], G. Balaburski[1], S. Heil[1], K. Reeves[1], J. Santana[1], J. Gilroy[1], M. Self[1], K. Gwinn[2], M. Sutherland[2], R. Corriveau[2], C. Pérez[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD, USA.

Neurological diseases are a major public health care concern but the pathological mechanisms in neurodegenerative disorders remain largely not understood. The major challenges in disease mitigation reside on lack of reliable genetic and molecular biomarkers for caustic, diagnosis, and progression monitoring; and limited reproducible cellular models for reearch. The National Institute of Neurological Disorders and Stroke (NINDS) Repository, funded by NINDS, was established with the mission of providing high quality biospecimens as a strategy to facilitate and accelerate research in neurological diseases. The NINDS Repository collects biosamples and de-identified clinical data from diverse patients diagnosed with various neurological disorders as well as neurologically normal controls. In addition, the NINDS Repository features collections of patients-derived fibroblasts and induced pluripotent stem cells (iPSC) with well-defined mutations as essential research tools for understanding the pathological mechanisms and establishes cellular models for neurological diseases. Recently, the NINDS Repository has broadened its collections to include whole blood RNA, plasma, serum, cerebrospinal fluid, and urine, to facilitate biomarker research utilizing longitudinal samples from both affected and neurologically healthy individuals. Since its establishment, biomaterials from more than 44,000 individuals with cerebrovascular diseases, Parkinsonism, motor neuron diseases, epilepsy, Tourette syndrome, Dystonia, Huntington's disease and neurologically-normal controls have been banked in the NINDS Repository. The NINDS Repository has established validated standard operating procedures and rigorous quality control assessments that span the life cycle of all biospecimens collected to provide premium samples. The NINDS Repository aims to ensure and implement standardization for collecting and processing across all samples. In addition, the NINDS Repository utilizes secure and integrated laboratory information management systems to monitor inventory, processing, storage, and distribution of biospecimens, and facilitates sample-data association by cross-referring with other databases. By developing such a centralized collection of human biospecimens and their associated de-identified clinical data, the NINDS Repository thus provides a vital resource for research designed to discover and validate genetic and proteomic biomarkers of neurological disorders.

Patients and caregivers as sources of innovative ideas and solutions: A multiple case study approach. *V. Francisco[1,2], R. Oliveira[3], P. Oliveira[3], L. Zejnilović[3], S.A. Oliveira[1,2].* 1) Instituto Medicina Molecular, Portugal, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, 2780-156 Oeiras, Portugal; 3) Católica-Lisbon School of Business and Economics, 1649-023 Lisboa, Portugal.

Recent academic literature shows that patients and caregivers are a significant source of innovative solutions related to their medical condition. To date, little is known about the process by which these innovations emerge, how they diffuse, and how they impact the lives of patients and caregivers. In this work we follow a multiple-case study approach to map a set of patient innovations and adoptions of patient innovation cases, and systematically explore how and how far patients and caregivers innovate in the health care field. In addition, we propose some explanations for why patients and caregivers stop at a certain stage of progression of the innovation process. We conducted 15 extensive semi-structured interviews with patients and caregivers of the following group of diseases: spinal cord injuries, Angelman syndrome, epidermolysis bullosa, cerebral palsy, and hemiparesis. These individuals shared with us their experiences with their disease and their efforts, or the lack of them, to overcome specific problems related to their health condition. This includes 4 “holistic” case studies and 26 “embedded” case studies. With the information from these cases, we analyze patient innovation paths and present them in the fall-offs conceptual framework. Through a cross-case analysis, we find that duration of the experience with the disease, complexity and pressure of a certain situation, belonging to a group or a community, and perceived value of a solution are among the most important reasons that impact how far patients and caregivers take their innovations. As a result of our multiple-case analysis we present a set of propositions from which future research in the field is warranted.

2419S

Diffusion as a validation process: Learning from patient innovators. *S.A. Oliveira[1,2], T. Fidelis[3], L. Zejnilovic[3,4,5], P. Oliveira[3].* 1) Instituto Medicina Molecular, Faculdade de Medicina, Universidade de Lisboa, 1649-028 Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, 2780-156 Oeiras, Portugal; 3) Católica-Lisbon School of Business and Economics, 1649-023 Lisboa, Portugal; 4) Carnegie Mellon University, Pittsburgh, PA 15213, USA; 5) Instituto Superior Técnico, 1049-001 Lisboa, Portugal.

There is growing evidence that patients and their family members innovate in therapies and medical devices. These patient innovators are increasingly recognized as an important source of innovation. However, little is known about the paths they take to validate their solutions before involving health regulators. We attempt to understand these patterns of informal validation and how their comparison with current validation methods of medical innovations can improve such processes. To address this, we study cases of patient innovators who attempted to share their innovations with other patients. More specifically, we structure the observed processes of patient innovation diffusion as a process model for an iterative observational trial process in which incremental validation of the innovation is performed by diffusing it to other patients. We argue that learning from patient innovators’ practices is important for discussing viable frameworks and structures for improving these processes, and discuss related implications to innovation research, management and policy.

2420S

Multiplex panel testing improves the yield of mutation detection in cancer genetics clinics. *J.O. Culver, C.N. Ricker, K. Lowstuter, D.Y. Sturgeon, C.R. Chanock, W.J. Gauderman, K. McDonnell, G.E. Idos, S.B. Gruber.* USC Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA.

Multiplex hereditary cancer panel testing for individualized cancer risk assessment is commercially available, but the diagnostic yield and clinical utility of panels are not yet known. We conducted a retrospective IRB-approved chart review of 317 cancer genetics clinic patients tested with a multiplex cancer gene panel. We analyzed the yield of panels versus the traditional approach of testing for specific hereditary syndromes. Panels were performed by Myriad (n=242), Ambry (n=64), Fulgent (n=9), University of Washington (n=1), and City of Hope (n=1). Our cohort included 142 patients from the USC Norris Comprehensive Cancer Center and 175 patients from the Los Angeles County + USC Medical Center. The mean age was 48.8 years (SD=12.5) and 85.5% were female; 80.1% had a history of cancer (n=254); race/ethnicity reported was 48.9% Hispanic, 34.4% Caucasian, 4.4% Black, 10.0% Asian, and 2.2% other. Among 317 panel test results, 17.0% contained at least one deleterious mutation (n=54) and 47.3% contained at least one variant of uncertain significance (VUS) (n=150). Of 242 Myriad myRisk panel results, 16.9% had at least one deleterious mutation (n=41) and 48.4% had at least one VUS (n=117). Of the 64 Ambry panel results (CancerNext, OvaNext, BreastNext, ColoNext and others), 12.5% had at least one deleterious mutation (n=8) and 42.2% had at least one VUS (n=27). Among 129 patients with breast cancer, 6.2% carried a mutation in *BRCA1* or *BRCA2* (n=8) and 9.3% carried a mutation in *BARD1, CDH1, CHEK2, MUTYH, PALB2, RAD51D*, or *TP53* (n=12). Among 69 patients with colorectal cancer, 14.5% had a mutation in *APC, MLH1, MSH2, MUTYH*, or *PMS2* (n=10) and 2.9% had a mutation in *RAD50* or *RAD51C* (n=2). Thus, multiplex panel testing increased mutation detection over a traditional approach in 9.3% of breast cancer patients and 2.9% of colon cancer patients. Similar analyses for other cancer sites found the supplemental yield of panels was 7.4% for ovarian cancer (2/27), 11.7% for endometrial cancer (2/17) and 22.2% for gastric cancer (2/9). In the overall cohort of 317 patients, 7.6% (n=24) had a mutation identified on a panel that would not have been tested in a traditional approach. In most cases, identifying these mutations led to enhanced surveillance recommendations for the patient and family members. We conclude that multiplex panel testing increases the yield of mutation detection and adds to the capability of providing individualized cancer risk assessment.

Cost-effective NGS based BRCA - TP53 screening panel for hereditary breast cancer in India. *M. Sen[1,2], P. Agrawal[1,2], N.S.N. Swetha[1], V. Vittal[1], V. Pathak[1], G. Deshpande[1], D. Vishwanath[1,2], S. Sankaran[1], R. Hariharan[1], P. Ramamoorthy[1], K. Subramanian[1], V. Gupta[1,2].* 1) Strand Centers for Genomics and Personalized Medicine, Strand Life Sciences Pvt. Limited, Bangalore, India; 2) Strand at Mazumdar-Shaw Center for Translational Research, Bangalore, India.

Introduction: Hereditary BRCA1/2 mutations in breast cancer show high correlation with Triple Negative Breast Cancers (TNBC). In India, the incidence rate for TNBCs is approximately 25-30%, significantly higher than the rest of the world. This creates a need for a in-parallel, high throughput, cost-effective screening method for hereditary breast cancer mutations in India. Several studies in Indian cohorts also implicate mutations in TP53 gene (Li-Fraumeni syndrome) associated with multiple hereditary soft-tissue tumors including breast cancer. Cost effective hereditary mutation screening assays can have tremendous utility in the identification and management of women at high risk of hereditary breast cancer. We have designed and standardized a NGS based test for screening BRCA1/2 and TP53 genes. This assay is about one tenth the price of Sanger based sequencing, the current 'gold standard' for diagnostics in detecting hereditary breast cancer. Materials and Methods: We designed a comprehensive BRCA-TP53 NGS panel covering all HGMD/ClinVar mutations with the potential to identify any novel coding mutations. We demonstrate the use of 120mer IDT Lock down probes to perform in-solution capture of genomic DNA libraries using Agilent Sure Select kits. We have used 15 known samples (Hapmap, cell lines and pre-validated clinical samples) and evaluated the performance characteristics of the panel. Results: Our enrichment based assay panel covers 100%of the targets with greater than 20 reads (0 low coverage regions), with an average coverage of 260X per target per sample. The protocol is faster, automation friendly and potentially scalable to 96 parallel sequencing. The overall sensitivity, specificity and reproducibility characteristics of the panel were greater than 95%.Compared to commercially available research use only panels, our laboratory developed assay found additional mutations in the clinical validation samples Our results demonstrate higher design coverage and superior analytical performance of the Strand developed BRCA-TP53 NGS assay compared to known commercial NGS based panels for research use. Our results reflect that the assay performs uniformly even across high GC bias or low complexity regions, in these genes. Results will be presented from both technical and clinical validation of this panel vis-a-vis other commercial panels with these genes.

2422T

A Two-Step Clustering Methodology for Grouping Clinical Genetic Testing Panels. *G. Hooker, J. Staples, T. Murphy, M. Cottrell, M. Schenfield, G. Gross, B. Blackshear, J. Schneider.* Bioinformatics, NextGxDx, Franklin, TN.

Introduction: As the genetic testing landscape expands in both the complexity and quantity of clinically available testing products, the task of finding, comparing, and selecting appropriate genetic tests becomes increasingly burdensome. The genetic testing landscape can be divided into two categories: single-gene tests and panels. While tests, which interrogate a single genetic target are relatively simple to group, panels, which interrogate multiple genetic targets, prove considerably more difficult. We set out to develop an organizational schema that allows for the side-by-side comparison of similar panel testing products. Methods: Leveraging our data resource of all currently available genetic tests from more than 200 CLIA-certified US testing laboratories, we tested the efficacy of four unsupervised machine learning algorithms in clustering multi-target genetic tests (panels) based solely on their diagnostic targets (genes). Using hyper-parameter optimization and domain expertise, we identified a high performance algorithm, DBSCAN, and generated a novel set of genetic test clusters. Next, we manually curated the algorithmically-generated clusters to provide greater clinical relevance. Results: Our dataset initially contained 1875 panels manually grouped into 709 clusters (Avg. 2.7 tests/cluster, SD=2.5). Algorithmic sorting decreased the number to 358, while subsequent expert curation, taking into account intended use of the test, increased the number to 478, (Avg. 4.1 tests/cluster, SD=5.85). To assess clustering efficacy, we calculated the mean intra-cluster vertex connectivity, observing a 33% increase in relatedness within clusters following the two-step process (Manual: 1.45, Two-Step: 2.14). Conclusion: Our two-step clustering process effectively groups similar clinically available panels. As the genetic testing market expands, completely manual curation of genetic testing products becomes increasingly impractical and error-prone. Semi-automated methods of organizing data, such as the one presented here, increase accessibility of the wide range of available testing products, thus improving clinical workflows and, potentially, diagnostic outcomes.

2423S

Recurrent hydrocephalus by POMT2 mutation unraveled by exome sequencing of DNA from preserved Umbilicus. *K. Kosaki[1], T. Takenouchi[2], A. Wataanbe[3], H. Miyake[4], T. Abe[4], C. Torii[1], K. Nakabayashi[5], K. Hata[5], R. Kosaki[6].* 1) Center for Medical Genetics, Keio University, Tokyo, Japan; 2) Department of Pediatrics, Keio University, Tokyo, Japan; 3) Division of Clinical Genetics, Nippon Medical School Hospital, Tokyo, Japan; 4) Department of OBGYN, Nippon Medical School Hospital, Tokyo, Japan; 5) Department of Maternal-Fetal Biol, National Center for Child Health and Development, Tokyo, Japan; 6) Division of Medical Genetis, National Center for Child Health and Development, Tokyo, Japan.

The etiologies of congenital hydrocephalus include infections, vascular abnormalities, mechanical obstruction and chromosomal abnormalities. In the majority of patients, reaching the exact genetic diagnosis of congenital hydrocephalus is often challenging, mainly because of the limitations in the non-specific nature of ultrasonography findings. Here we report a 36-year-old father and a 37-year-old G4P1 mother who were referred to us for genetic counseling for recurrent congenital hydrocephalus. The mother's first pregnancy with a female fetus was complicated by meningocele first detected at 15 weeks of gestation. This pregnancy resulted in the spontaneous abortion. The second pregnancy with a female fetus complicated by hydrocephalus detected at 21 weeks of gestation, resulting in the termination of the pregnancy. The third pregnancy lead to a birth of normal male. In the fourth pregnancy, an ultrasonography examination performed at 21 weeks of gestation revealed severe congenital hydrocephalus, leading to termination of the pregnancy. Since none of the three affected fetuses had undergone a molecular diagnosis of their condition, upon the termination of the fourth pregnancy, the parents agreed to preserve a part of the umbilicus for future diagnostic procedures. The recurrent severe congenital hydrocephalus in both male and female fetuses conceived by healthy parents strongly suggested a autosomal recessive Mendelian disorder, and the parents were counseled as such. The parents were referred to us for further genetic evaluation. DNA samples were extracted from the preserved umbilicus obtained during the fourth pregnancy according to the standard protocol. The parents' DNA samples were extracted from their peripheral blood. Exome sequencing identified de novo compound heterozygous mutations in exon11 and exon19 of POMT2 (NM_013382), i.e., c.1248C>G p.His416Gln and c.1912C>T p.Arg638*, respectively. The present observation illustrates the utility of exome sequencing using preserved umbilicus in undiagnosed fetal structural abnormalities. The correct molecular diagnosis enabled us to provide the parents with the recurrence risk of 25% together with the possibility of prenatal genetic diagnosis for a future pregnancy. In light of the rapid advances in molecular diagnostic technology, the preservation of umbilical cord should be considered in fetal cases with undiagnosed structural defects, particularly when a Mendelian disorder is highly suspected.

2424M

Targeted Single-Molecule Oligonucleotide-Selective Sequencing for Genetic Diagnostics. *S. Bruce, P. Salmenperä, M. Gentile, S. Myllykangas.* Blueprint Genetics, Helsinki, Finland.

Diagnostic applications of next-generation sequencing have been impeded by complex experimental workflows associated with target DNA enrichment methods and errors and biases caused by PCR during sample preparation. Here we demonstrate single-molecule Oligonucleotide-Selective Sequencing (OS-Seq) for simplified and clinical-grade targeted sequencing. OS-Seq consolidates capture and sequencing of DNA in situ flow cell of a next-generation sequencing system. We developed a programmable and automated OS-Seq technique using the MiSeq sequencing system and implemented a PCR-free sample preparation method for single-molecule OS-sequencing. In addition, we introduced batch indexing, which utilizes several index sequences per sample and improves the uniformity of the sequencing yields between pooled samples. We developed two OS-Seq assays targeting coding exons, exon-intron boundaries and known pathogenic variants in introns of 136 and 49 genes (495,567 and 159,198 bases, respectively) implicated in cardiovascular diseases. The median sequencing depths were 420 and 733 and 99.35% and 99.8% of the bases on target regions were covered >15x. We validated SNPs, INDELs and CNVs using whole genome sequenced reference samples. High-quality genotypes for NA12878 were obtained from the Genome-in-a-bottle consortium and INDELs were confirmed with Sanger sequencing. Sensitivity to detect SNPs was >99% and 100%, respectively, and specificity was >99.99% for both assays. Sensitivity and specificity to detect short INDELs was 100% and sensitivity to detect CNVs of >1kb was >99%. We showed that single-molecule OS-Seq omits sequence duplicates, reduces sequencing errors by two-fold and improves uniformity of the coverage by 30%. Our results demonstrate the usability of OS-Seq for clinical sequencing applications.

Implementing next generation sequencing in clinical practice of children's hospital. *Y. Enomoto, I. Ohashi, Y. Kuroda, C. Hatano, T. Yokoi, K. Ida, T. Naruto, K. Kurosawa.* Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Genetic disorders and birth defects account for a high percentage of the admissions in children's hospitals. Congenital malformations and chromosomal abnormalities are the most common causes of infant mortality. However, highly heterogeneous causes of the disorders in the cases of children's hospital provide low yield of molecular diagnostic procedures. Next generation sequencing (NGS) has a basically broad impact on many facets of biological and clinical research. To date the NGS is not routinely used in genetic diagnosis. Advent of NGS in the clinical laboratory setting requires the adoption of many processes and procedures. We developed diagnostic flows of molecular diagnosis using NGS to identify mutations in several malformation syndrome and related disorders in Kanagawa Children's Medical Center. This panel approach was successfully established in the cases with unknown sequence alterations. Depending on the clinical diagnosis, we identified causative mutations in the patients. NGS-based panel analysis is reliable and cost-effective approaches in clinical setting of heterogeneous diseases. However, the panel analysis is so limited in the case of application for the extremely high heterogeneous disorders, such as autism and unknown multiple anomalies. We present clinical utility of exon sequencing of Mendelian disorders (TruSight One) in the clinical context in our children's hospital. These results indicated the clinical exome sequencing is useful for pediatric practice, and bioinformatic process will become essential for the clinical practice.

2426S

Active organic solvent-free paraffin removal is the key to efficient extraction of NGS-quality DNA from FFPE tissues. *H. Khoja, E. Rudd, J. Han, A. Purdy, S. Kakumanu, A. Palmer, G. Durin, J. Laugharn.* Covaris Inc,, Woburn MA.

Formalin Fixation and Paraffin Embedding (FFPE) of tissues, a mainstay of clinical histological analysis for the past century, is rapidly being adopted for targeted and whole genome sequencing. The extreme formaldehyde fixation and tissue dehydration of FFPE preserved tissue presents not only a technical challenge to reproducible DNA and RNA extraction and molecular analysis, but also a workflow challenge in a clinical setting. In this poster we present truXTRAC™, a novel and highly reproducible method of extraction and purification of DNA and RNA from FFPE tissue utilizing Covaris Adaptive Focused Acoustics™ (AFA). Our novel method utilizes highly controlled acoustic energy for effective removal of paraffin from FFPE cores, sections, and slides enabling efficient and rapid tissue rehydration, tissue digestion, crosslink reversal, and nucleic acid release. This critical step is carried out without the use of dangerous organic solvents or messy mineral oils. We will present quantitative fluorescent microscopy data illustrating the efficiency of active paraffin removal from tissues utilizing this novel approach. We will also illustrate the significant effect of efficient active paraffin removal on downstream applications and analyses of DNA and RNA from FFPE tissues. Our results, utilizing replicates of different tissue types indicate high dsDNA yields, and improved DNA and RNA quality as indicated by commercial qPCR based kits designed to assess DNA quality. To quantitate the quality of the extracted DNA, as a function of sequence coverage across the entire genome, we compared whole genome sequencing data from FFPE samples to sequencing data obtained from matched frozen tissue DNA. Our data clearly indicate significant improvement of sequence coverage and uniformity in FFPE samples processed using Covaris AFA. Our data also indicate that the high quality controllable DNA extraction allows for preparation of large insert (1-6kb) libraries which has previously been considered very difficult to achieve with FFPE stabilized tissues. The simplified single-tube method and rapid workflow allows for the parallel processing of 8 to 96 FFPE samples in a batch format easily adaptable to the throughput requirement of medium to high volume clinical labs. We present data showing highly reproducible extraction and purification results regardless of the throughput of FFPE samples being processed.

2427M

CONNECT1: Next-Generation Sequencing Chip for Dominant Connective Tissue Disorders. *J. Milunsky, A. Nikiforov, K. Wu, X.Y. Zhang, C.T. Baldwin.* Center for Human Genetics, Inc., Cambridge, MA.

Hereditary disorders of connective tissue are fairly common in the general population with Ehlers-Danlos syndrome (EDS), Marfan syndrome, Stickler syndrome, and Loeys-Dietz syndrome being the most well recognized. Significant clinical overlap exists between these disorders making individual sequential Sanger sequencing less cost-effective than simultaneous testing via a next-generation sequencing platform. Aneurysms involving the aorta and other vasculature are typically dominantly inherited and genetic testing is offered for several of the more common genes involved. We have developed and validated a next-generation (Ion Torrent) panel that analyzes 23 dominant genes that cause EDS (types I, II, IV), Marfan syndrome, Loeys-Dietz syndrome (types I-IV), Stickler syndrome (types I-III), and hereditary aneurysms (7 genes). The Ion AmpliSeq software was used to design a custom primer pool to amplify exonic and 25 bases of flanking intronic regions from 23 genes (1274 amplicons). Two Ion Torrent 318 chips were utilized for 15 blinded samples (4 with known mutations in different genes). The average depth across the 23 gene target regions (>40 reads) was 474. All positive samples were accurately identified. Reproducibility was assessed to be 99.2% for 257 SNP's (2 duplicate samples on each chip). 117 amplicons were Sanger sequenced to improve overall coverage to greater than 99% of the targeted regions. Separate MLPA assays were performed for deletion/duplication analyses of those genes reported to have these pathogenic variants. CONNECT1 is the optimal cost-effective first line test for those with suspected dominant undiagnosed hereditary connective tissue disorders or those with a dominant family history of aneurysms.

2428T

Xeroderma Pigmentosum (XP): Single nucleotide variants (SNV) that probably affect function in two Indian families identified using next generation sequencing (NGS) of 8 XP genes. *K. Reddy[1], M. Reddy[2].* 1) Institute of Bioinformatics, Whitefield, Bangalore 560066, India; 2) Ophthalmology, St Johns Medical College, Koramangala, Bangalore 560034, India.

Two Indian families with Xeroderma pigmentosum (XP) were tested using next generation sequencing (NGS) of 8 autosomal recessive XP genes; XPA, XPC, ERCC1, ERCC2, ERCC3, ERCC4, ERCC5 and DDB2. Family 1: had a novel substitution variation in the ERCC5 gene, c.1A>G and a loss of the start site. Each parent had one copy of the gene with this variant and the two affected sons carried variants on both copies of ERCC5. The siblings presented with XP with no apparent neurological abnormality (IQ85 and IQ70 is probably due to impaired vision). In Nature there is also a read through fusion transcript BIVM-ERCC5 [Homo sapiens], an important paralog of ERCC5. The expression of the conjoined genes may be another mechanism for gene regulation in eukaryotes and should be considered in correlating the phenotype with the genotype. Gene sequence and protein profile of ERCC5 and BIVM-ERCC5 may be necessary to assess the functional impact of SNVs in ERCC5 gene Family 2: had a c.1677C>G variation in XPC gene that has been reported in literature and creates a premature stop codon. One copy of the gene in the father, one copy in the mother and both copies in the proband carried this variant. These are the first Indian SNVs described in XP families and they are different from the frequent mutations from other parts of the world. Hence, variants that affect gene function in XP families from all parts of India will be assessed and haplotyped to identify a founder mutation. A focus on the mutations in areas of high consanguinity could potentially simplify the test. Also, understanding the distribution of SNVs in XP gene would aid in counseling families about consanguineous marriage and provide prenatal diagnosis option for carriers. Early eye sight corrections in patients would enhance performance in school. In the long run we hope to decrease the incidence of XP.

2429S

Steroid resistant nephrotic syndrome (SRNS): NGS panel testing to direct therapy and intervention. *L.J. Yarram-Smith[1], A. Bierzynska[2], D. Smith[1], M. Saleem[2,3], M. Williams[1].* 1) Bristol Genetics Laboratory, North Bristol NHS Trust, Southmead Hospital, Bristol.Bristol Genetics Laboratory, Bristol, United Kingdom; 2) Academic Renal Unit, Dorothy Hodgkin Building, Whitson Street, Bristol, BS1 3NY; 3) University of Bristol, Children's Renal Unit, Bristol Royal Hospital for Children, Bristol, BS2 3BJ, UK.

Steroid Resistant Nephrotic syndrome (SRNS) is a disorder of the glomerular filtration barrier. It is characterised by massive proteinuria, hypoalbuminaemia and oedema, and is managed by non-specific heavy immunosuppression. An invasive biopsy is often required and the majority of patients progress to end stage renal failure. SRNS is associated with over thirty genes expressed at the glomerular filtration barrier. Rapid genetic diagnosis is important for therapy and intervention as genetic SRNS is non-responsive to immunosuppression, and has a lower rate of post transplant recurrence. A genetic result enables appropriate family counselling including choice of transplant donor and has the potential to avoid invasive renal biopsy.

Bristol Genetics Laboratory has received >120 worldwide diagnostic referrals (80% paediatric and 20% adult) for NGS clinical panel testing of 37 SRNS genes (Haloplex; MiSeq; open-source pipeline, including CNV analysis using CONTRA). The panel was validated using 24 patients and 440 variants identified in the University of Bristol Academic Renal Unit RADAR study (Nimblegen/exome). Likely pathogenic variants have been identified in 30% of cases, most commonly occurring in NPHS1, NPHS2, WT1, COL4A3 and COL4A4 with a different mutation spectrum in adult and paediatric patients. A further 30% of cases have candidate variants. Variant stratification is challenging with a global service due to the presence of rare variants in under-sequenced populations, this is assisted by detailed phenotyping and new genotype/phenotype correlations are emerging. A pathogenic LMX1B mutation, c.737G>A, was associated with nail-patella-like renal disease, and a patient with a c.287C>T variant presented with thrombocytopaenia and SRNS associated with MYH9-related disease. WT1 variants causing nephrotic syndrome occur in exons 8 and 9, are usually de-novo and associated with early onset disease. A novel exon 9 WT1 variant, c.1169G>A, was identified in both an affected adult and their affected father. Variants in COL4A3, COL4A4 and COL4A5 can cause Alport syndrome and also thin basement membrane nephropathy. Two unrelated patients have variants in more than one collagen gene. Prenatal diagnosis was performed for a Pierson syndrome family with two pathogenic LAMB2 variants, c.[4198_4199delCT];[928T>C]. We present our results illustrated by cases highlighting the clinical benefit of panel testing.

2430M

Validation of a Robust PCR-only Assay for Quantifying Fragile X CGG Repeats. *K.W. Choy[1], C.S.W. Lin[1], K.M. Wong[1], F.M. Lo[2], Y.K.Y. Kwok[1], J.K. Moore[3], S. Wu[3], S.T.S. Lam[2], M. Schermer[3], T.Y. Leung[1].* 1) Department of Obstetrics and Gynaecology, The Chinese University of Hong Kong, Hong Kong; 2) Clinical Genetic Service, Department of Health, Hong Kong; 3) PerkinElmer Health Sciences, Inc., 940 Winter Street, Waltham MA 02451, USA.

Sizing of FMR1 trinucleotide repeats requires the use of capillary sequencer instruments, or by a labor Southern blot. To validate a simple, robust PCR assay for quantification of CGG repeats. We validated a new PCR-only method for quantifying Fragile X CGG repeat that utilizes a low-cost capillary electrophoresis instrument and the FragilEase™ reagent kit. Analytical performance was first demonstrated on 12 Coriell reference samples comprising normal through full mutations. Subsequently, a set of 112 archived clinical DNA samples, enriched for premutation and full mutations was analyzed. All samples were amplified successfully. Quantification of repeat numbers was interpreted by the use of standards with known repeats. The repeat numbers from the new assay were concordant with those obtained with the reference method. The intra-assay (CV < 2.5%) and inter-assay imprecision was within 1 CGG repeat. Our result demonstrated this new method is fast, robust that facilitates Fragile X testing in a clinical laboratory.

2431T

Bridging the gap between sequencing gene panels and whole exomes for clinical diagnosis. *S. Abbs[1], H. Martin[1], K. Brugger[1], F. Rodger[2], R. Littleboy[2], I. Delon[1], G. Sagoo[3], S.G. Mehta[1], S-M. Park[1], R. Armstrong[1], G. Woods[1,2], S. Holden[1], M. Kroese[3], R. Sandford[1,2], E. Maher[1,2].* 1) Medical Genetics Service, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; 2) Dept of Medical Genetics, University of Cambridge, Cambridge, UK; 3) PHG Foundation, Cambridge, UK.

Clinical diagnostic next generation sequencing requires cost effective, efficient and robust methodology. Targeted gene panels are readily available, but significant resources are required to design, optimise and validate each panel, thus restricting the number of panels, number of diseases that can be tested for, and number of patients who can benefit from these tests in an individual laboratory. Whole exome sequencing (WES) overcomes this hurdle, but is considered impractical or too expensive in many health care settings. We have therefore investigated a single test which sequences 4813 clinically relevant genes and offers the best attributes of both panel and WES approaches. We first undertook a technical validation of the Illumina TruSight One sequencing panel by testing 195 samples with mutations in 74 different genes, previously identified by Sanger sequencing. All 188 single nucleotide variants, 20 deletions and 15 insertions were identified correctly. This was followed by sequencing all 4813 genes in 300 patients chronologically referred for diagnostic sequencing of either a large single gene, or a number of genes associated with a genetically heterogeneous condition. Sequencing results were filtered so the analysis focused only on genes determined by Clinical Geneticists to be relevant to the clinical presentation. Among the first 110 newly referred patients, 82 were analyzed for one of 36 different gene panels, ranging from 2-28 genes. 28 patients were analyzed for just single genes. Analysis of results from the remaining 290 samples is ongoing. To date, clear pathogenic mutations were detected in 57% (16/28) of patients analyzed for single genes, and in 28% (23/82) analyzed for gene panels. This allows confirmation of diagnoses for 35% of patients. Mutations were detected in 32 different genes; 8 patients (7.3%) had mutations in 7 genes for which genetic testing is currently not available in UK.

A single sequencing test covering a wider range of genes than currently available by panel or Sanger sequencing has been rapidly validated and introduced into diagnostic service. Sequencing of this clinical exome offers versatility and simplicity, with comparable mutation detection rates to full exome sequencing but at significantly less cost. This test will enable more patients with a wide range of rare genetic diseases to receive rapid molecular confirmation of their diagnosis.

Implementing an Augmented Clinical Exome and Reference Improvements to Enhance Diagnostic Yield and Discovery. *R. Chen, M. Pratt, D. Church, S. Luo, G. Bartha, J. Harris, S. Garcia, J. Tirsch, M. Clark, C. Haudenschild, N. Leng, J. West.* Personalis, Inc., Menlo Park, Ca.

Clinical exome sequencing is increasingly used for solving diagnostic odyssey cases in children with suspected genetic syndromes and also cancer. The complex process of going from DNA sample to clinical report involves multiple, technologically, scientifically, and medically complex steps; despite early success, significant improvements can be made to increase the overall diagnostic yield of exome sequencing tests. We have developed an augmented exome approach that boosts accuracy and coverage in over 7000 genes that are medically relevant to Mendelian disease, cancer, and pharmacogenomics as referenced by multiple databases and literature sources. The performance of this augmented exome was assessed using three methods: coverage over all exonic bases in our ACE exome assay compared to other standard exomes, comparison against the NIST standard genome, and examination of the structure and coverage of the 7000 medical genes in the latest reference assembly (GRCh38). Of the over 7000 targeted medical genes, our augmented clinical exome completely covers 50% more genes than standard exomes at comparable coverage. Further we demonstrate increased sensitivity and specificity as evaluated against the NIST standard. In evaluating against the reference, over 650 of these medical genes are on 'Fix' patches released as part of incremental reference improvements by the NCBI, suggesting that the structure of these genes were not well described in GRCh37 and need to be addressed as part of clinical informatics pipeline. Over 150 of the patched genes are on existing panels, which may need to be re-assessed in light of new assembly information. An augmented exome sequencing and informatics approach enables clinical grade performance over a large percentage of medically important genes. We report on specific examples of pathogenic variants that would have been missed by standard exomes in clinical cases processed through our testing laboratory.

Contextualization and recommendation: How doctors and patients discuss whole-genome sequencing results. *J.L. Vassy[1,2], K. Davis[3], J. Oliver Robinson[4], J. Blumenthal-Barby[4], K.D. Christensen[4], R.C. Green[1,5], A.L. McGuire[4], P.A. Ubel[3] for the MedSeq Project.* 1) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) VA Boston Healthcare System, Boston, MA; 3) Fuqua School of Business and Sanford School of Public Policy, Duke University, Durham, NC; 4) Baylor College of Medicine, Houston, TX; 5) Partners HealthCare Center for Personalized Genetic Medicine, Boston, MA.

Background: There are concerns that non-geneticist physicians are not prepared for the role genomics will play in clinical medicine. It is unknown how they will talk to their patients about whole-genome sequencing (WGS) and its complex results. **Methods**: We have enrolled primary care physicians and cardiologists to participate with their patients in the MedSeq Project: a randomized trial of WGS in clinical care. Physicians undergo brief CME in genomics prior to patient enrollment. Each patient's WGS data are interpreted and reported on a Genome Report, including results for monogenic disease variants, carrier status, complex polygenic traits, and pharmacogenomics. The Genome Report is delivered to the patient's physician, and the two meet for a disclosure visit to discuss its findings. Disclosure discussions are recorded, transcribed, and coded with thematic content analysis to identify emergent themes. **Results**: 16 of 100 planned WGS disclosure visits have occurred to date: 11 in generally healthy primary care patients and 5 in cardiomyopathy patients. We identify 5 major themes. 1) Contextualization: Physicians use additional clinical information, such as age, family history, lack of symptoms, or other test results, to interpret the significance of WGS findings for each patient. 2) Prioritization: Among the many results listed on each patient's Genome Report, physicians tend to emphasize explicitly the 1 or 2 most clinically relevant WGS findings for each patient, identifying "the single biggest thing to come out of this." 3) Limitations of WGS: Some physicians discuss the technological limitations of sequencing and the unknown penetrance of certain variants in cautioning patients against over-interpreting certain WGS results. Some discuss their own inability to interpret certain WGS findings. 4) Misinformation: We have identified a few instances of inaccuracies in physicians' interpretations of WGS results, such as underestimating a patient's risk of having a child with cystic fibrosis. 5) Recommendation: Physicians ultimately synthesize WGS results and all other clinical information to make recommendations for each patient, including genetic testing for family members, additional diagnostic testing, and referrals to subspecialists. **Conclusions:** Physicians and their patients discuss WGS results similarly to other tests in clinical medicine. Concerns about their unpreparedness may be overstated, but efforts to reduce misinformation are warranted.

Towards highly sensitive diagnostic exome sequencing without the need for confirmations by Sanger sequencing. *K.L.I. van Gassen, M.G. Elferink, P.H.A. van Zon, I.J. Nijman, B. van der Zwaag, J.K. Ploos van Amstel.* Department of Medical Genetics, University Medical Centre Utrecht, Utrecht, Netherlands.

Current best practice genetic diagnostics by massive parallel sequencing includes confirmations of all reported findings by Sanger sequencing. Such confirmations eliminate false positive variant calls and exclude potential sample swaps, but often need the design of new PCR primers. Designing and ordering new PCR primers for confirmations create a laboratory bottleneck, adds substantial capital costs and leads to an increase in test turnaround-time. The proposed workflow utilizes the power of an independent biological replicate without the need for extra target enrichments or sequencing resources and is applicable to most enrichment techniques that support multiplexing. This replicate eliminates the need for Sanger confirmation of most variant calls. Additionally, this workflow should theoretically decrease false positive and false negative variant call rates. Here, we present the details of this workflow. We report on false positive and false negative variant call rates using this approach.

2435S

Biological assays to predict the functional impact of missense mutations: the case of the tumor suppressor gene BRCA1. *G.A. Millot[1,2], P. Thouvenot[1], B. Ben Yamin[1], L. Fourrière[1], C. Houdayer[3,4], D. Stoppa-Lyonnet[3,4], D.E. Goldgar[5], A. Nicolas[1].* 1) UMR3244, institut curie, Paris, Paris, France; 2) Sorbonne Universités, UPMC Univ Paris 06, 4, Paris, France; 3) Service de Génétique Oncologique & INSERM U830, Institut Curie, Paris, France; 4) Université Paris Descartes, Paris, France; 5) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, Utah.

Missense mutations generally come from single nucleotide polymorphisms (SNPs) present in the coding regions of genomes. These mutations trigger the weakest sequence modification in a protein, since a single amino acid is replaced by another one. The resulting effect of this amino acid substitution can range from "no effect" to "complete alteration" of protein function. For this reason, it is difficult to predict the functional consequences of missense mutations. Moreover, the ever-growing amount of exome data will dramatically increase the number of detected missense mutations, and likewise increase the challenge of interpreting their functional impacts. Our work is focused on the tumor suppressor gene BRCA1, whose germline inactivation leads to hereditary breast and ovarian cancers. To date, 668 different germline missense mutations have been identified in BRCA1. However, only a small fraction has been characterized as pathogenic (37) or neutral (103) using classical genetic methods. The 528 additional missense mutations remain unclassified, due to the lack of familial/populational information and the inability to predict their functional impacts. To address this issue, we designed and validated four experimental assays. Using 40 missense mutations, 25 previously classified as pathogenic and 15 previously classified as neutral, by genetic methods, we showed that these assays are efficient in predicting the pathogenicity of BRCA1 missense mutations. We also propose a method to improve the computation of sensitivity and specificity, two parameters critical for functional assays. Altogether, these results contribute to the high-throughput classification of missense mutations, a major challenge for the next decade.

2436M

Complete *APTX* deletion in a patient with ataxia with oculomotor apraxia type 1. *R. van Minkelen[1], M. Guitart[2], C. Escofet[2], G. Yoon[3], P. Elfferich[1], G.M. Bolman[1], R. van der Helm[1], R. van de Graaf[1], A.M.W. van den Ouweland[1].* 1) Department of Clinical Genetics, Erasmus Medical Centre, Rotterdam, Netherlands; 2) Genetic Laboratory, UDIAT-Centre Diagnòstic, Neuropediatrics Unity, Corporació Sanitària Universitària Parc Taulí, Sabadell, Spain; 3) Division of Clinical and Metabolic Genetics, Department of Pediatrics, The Hospital for Sick Children and University of Toronto, Canada.

Background Ataxia with oculomotor apraxia type 1 is an autosomal-recessive neurodegenerative disorder characterized by a childhood onset of slowly progressive cerebellar ataxia, followed by oculomotor apraxia and a severe primary motor peripheral axonal motor neuropathy. Ataxia with oculomotor apraxia type 1 is caused by homozygote or compound heterozygote mutations in *APTX* (chromosome 9p13.3). Case presentation Our patient has a clinical presentation that is typical for ataxia with oculomotor apraxia type 1 with no particularly severe phenotype. Multiplex Ligation-dependent Probe Amplification analysis resulted in the identification of a homozygous deletion of all coding *APTX* exons (3 to 9). SNP array analysis using the Illumina Infinium CytoSNP-850K microarray indicated that the deletion was about 61kb. Based on the SNP array results, the breakpoints were found using direct sequence analysis: c.-5+1225_*44991del67512, p.?. Both parents were heterozygous for the deletion. Homozygous complete *APTX* deletions have been described in literature for two other patients. We obtained a sample from one of these two patients and characterized the deletion (156kb) as c.-23729_*115366del155489, p.?. The more severe phenotype reported for this patient is not observed in our patient. It remains unclear whether the larger size of the deletion (156kb vs 61kb) plans a role in the phenotype; no extra genes are deleted besides the non-coding *APTX* exons 1A and 2. Conclusion Here we described an ataxia with oculomotor apraxia type 1 patient who has a homozygous deletion of the complete coding region of *APTX* instead of homozygosity or compound heterozygosity for *APTX* mutations. We were unable to confirm a more severe phenotype for ataxia with oculomotor apraxia type 1 patients with a complete deletion of *APTX*, however, more research is needed to study the exact breakpoints/sizes of these kind of *APTX* deletions.

2437T

Next generation sequencing of the *HEXA* and *HEXB* genes in African Americans with positive enzymatic carrier screening result for Tay-Sachs disease. *J. Zhang, J. Liao, S. Guha, W. Zheng, L. Edelmann, R. Kornreich, C. Yu.* Mount Sinai Genetic Testing Laboratory, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Tay-Sachs disease (TSD) is an autosomal recessive lysosomal disorder caused by mutations of the *HEXA* gene which results in the deficiency of hexosaminidase A enzyme and devastating neurodegenerative disease. TSD carriers are more prevalent among Ashkenazi Jewish (AJ) individuals with a frequency of ~1:27, and some other genetically isolated populations such as French Canadians in Quebec, Cajuns from Louisiana and the Old Order Amish. The carrier frequency in the general population is ~1:300. Carrier screening for TSD usually includes both an enzymatic assay and a *HEXA* common mutation panel as recommended by American Congress of Obstetricians and Gynecologists (ACOG). It has been noted that the enzyme positive rate in African American (AA) patients is unusually high compared with the carrier frequency in the general population. A retrospective study was performed to analyze the inconclusive rate based on self-reported ethnicity. We found that the inconclusive rate in African Americans (n=173) is 25% compared to 3.6% in AJ (n=1530), 4.5% in Asian (n=313), 4.6% in Caucasian (n=747), and 6.0% in Hispanic (n=341). In addition, 12 AA individuals (1:15) had enzyme results within the carrier range; however, none were positive by targeted mutation analysis. Next-Generation Sequencing of the *HEXA* and *HEXB* genes was performed in nine AA individuals with positive enzyme results either in the inconclusive or carrier range. No pathogenic mutations in *HEXA* or *HEXB* gene were identified; however, two *HEXA* missense SNPs common in AA, c.1195A>G (rs1800430) and c.1306G>A (rs1800431), were present in either the heterozygous or homozygous state in all nine individuals. We hypothesize that these two SNPs are partial pseudodeficiency alleles, which have reduced cleavage activity against the artificial N-acetylgalactosamine substrates used in the in vitro assay, but do not impact the HEXA enzymatic activity in vivo. We are currently testing a larger cohort of AA with normal HEXA activity to demonstrate that these two alleles are associated with the high positive TSD enzyme results in this population.

2438S

Enhanced detection of large indels in diagnostic exome sequencing. *D. Shinde, L. Shahmirzadi, D. El-Khechen, Z. Powis, C. Mroske, D. Salvador, H. Lu, K. Farwell Gonzalez, S. Tang.* Ambry Genetics, Aliso Viejo, CA.

Diagnostic exome sequencing (DES) has been remarkably successful as both a diagnostic and novel gene discovery tool. It represents one of the most comprehensive tests available and requires a robust bioinformatics pipeline for base calling, sequence alignment, variant calling, annotation, filtering, and prioritization. While single nucleotide substitutions are generally efficiently identified in well-covered exonic regions in DES, accurate mapping of indels, especially those larger than 20 nt, is challenging due to complicated gapped alignment and paired-end sequence inference. There are very limited data on the detection limit of indels of different pipelines based on the current exome sequencing platforms. Of 153 positive/likely positive cases in the first 500 unselected DES cases referred to Ambry Genetics, 4 (2.6%) were associated with large indels (> 40 nt) up to 115 nucleotides in size. These large indels were identified by Ambry Variant Analysis (AVA) pipeline and confirmed by Sanger sequencing. In the first family, a maternally inherited heterozygous UBE3A deletion of 89 nt was detected in a pediatric patient with a differential diagnosis of Angelman syndrome (AS). It is presumed that the asymptomatic mother's deletion occurred on her paternally inherited allele, which was inactivated due to imprinting. In a second pediatric patient with suspected arthrogryposis, AVA detected a de novo heterozygous 115 nt deletion in the MYH3 gene. In a pediatric patient with recurrent infections, immunodeficiency and significantly decreased expression of CD127, compound heterozygosity of a splice site mutation and a 58 nt deletion in the RFXANK gene was observed. Lastly, a homozygous 41 nt indel in the PDE6B gene caused by a 47 nt deletion coupled with 6 nt insertion was detected in a 14 year old patient with retinitis pigmentosa consistent with the gene finding. In conclusion, although detection of large indels is inherently difficult for DES, indels larger than 40nt account for 2.6% of the positive cases in our cohort and indels up to 100 nt can be identified by AVA. Our data highlight the importance of an optimized bioinformatics pipeline for the detection of large indels to improve clinical sensitivity and diagnostic yield.

2439M

Efficient diagnostic routing using whole exome sequencing. *M. Weiss, D. van Beek, R. Straver, I. Bakker, H. Meijers-Heijboer, E. Sistermans, Q. Waisfisz.* Clinical Genetics, Genome Diagnostics, VU University Medical Center, Amsterdam, Netherlands.

Whole exome sequencing (WES) can provide a molecular diagnosis in families with an unexplained phenotype. When using this technique in a diagnostic setting it is important to follow a well documented diagnostic routing. Here we present an effective routing and the results of the first 31 families. All candidate families for a diagnostic WES procedure are discussed and selected in a monthly meeting with clinicians, clinical laboratory geneticists and a molecular geneticist. Selection criteria are based on the assumed likelihood of revealing the molecular diagnosis and include clinical phenotype, likely mode(s) of inheritance, available family members, and diagnostic relevance. During this meeting the diagnostic routing is defined which can include: exclusion of other genes in differential diagnosis, exclusion of deletions and duplications (array), revealing the regions of homozygosity (SNP array), and determination of the primary filtering strategy according to the expected inheritance model. Filtering of variants is performed with Cartagenia using four different validated filtering trees: trio analysis de novo, trio analysis recessive/X-linked, multiple affected dominant/mosaic/imprinted, and multiple affected recessive/X-linked. The diagnostic WES procedure was performed for 31 families with different clinical phenotypes. In two families the causative mutation was identified before exome sequencing was initiated. Both cases were from consanguineous families and in each family the candidate gene was identified in a common region of homozygosity. In the remaining 29 families (including 14 trio's, 10 multiple affected, and 5 single cases) WES was performed using different filtering strategies. In 17 families a (probably) pathogenic variant and in 2 families a possible pathogenic variant was detected. Analysis of families with multiple affected family members showed the highest diagnostic yield (73%, 8/11), compared to trio analysis with one patient (43%, 6/14). In two cases the actual mode of inheritance proved to be different from what was originally thought most likely. In 12 families no clinical relevant variant was identified. We have implemented an efficient strategy for using WES in clinical diagnostics. The diagnostic yield is high: 19/31 (61%) families received a probably molecular diagnosis. The diagnostic WES procedure includes a close and structured communication between physicians and the laboratory.

Performance of in silico sequence conservation tools in predicting the pathogenicity of missense variants in HBOC and Lynch syndrome-associated genes. *I.D. Kerr, K. Moyes, B. Evans, B.C. Burdett, A. van Kan, H. McElroy, P.J. Vail, D.B. Sumampong, N.J. Monteferrante, K.L. Hardman, R.J. Wenstrup, J.M. Eggington.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Non-synonymous missense changes that result in amino acid substitutions in the protein product represent the majority of variants of uncertain clinical significance (VUSs) identified by genetic testing. To analyze whether commonly used in silico tools can accurately characterize the possible disease association of missense mutations, we compared the accuracy of six commonly used algorithms (Align-GVGD, SIFT, PolyPhen-2, MAPP-MMR, SIFT, Grantham Analysis and Condel) using a dataset of 1,118 BRCA1, BRCA2, MLH1, and MSH2 variants previously classified as clinically deleterious or benign by our laboratory's variant classification program. For all algorithms, except Align-GVGD, the false-positive (FP) rate compared to the reference classification was substantially higher than the traditionally accepted threshold for clinical confidence, with a range from 30.6% - 58.5% for BRCA1, 27.1% - 40.1% for BRCA2, 17.9% - 67.9% for MLH1 and 17.1% - 56.1% for MSH2. Although the FP rates using Align-GVGD for all four genes were lower, including values of 2.2% for BRCA1 and 7.9% for BRCA2, the sample size was too small to provide robust analysis due to exclusion of 750 variants that were used to train the algorithm. The high FP rates for Condel, which classifies variants based on a weighted average of scores from five in silico tools, suggests that the use of multiple models is not significantly more accurate than any of the individual models in isolation. The results of this study suggest that none of the commonly used in silico tools achieve the traditionally accepted minimum threshold of specificity for the clinical use of predictive tools.

2441S

Detection of Pathogenic Mutations in Moderate Penetrance Breast Cancer Genes Significantly Increases the Number of Patients Identified as Candidates for Increased Screening. *E. Rosenthal, H. McCoy, K. Moyes, B. Evans, R. Wenstrup.* Myriad Genetic Laboratories, Salt Lake City, UT.

Hypothesis/Purpose: We sought to establish the clinical utility of multigene hereditary cancer panels for the identification of patients who may benefit from interventions to reduce cancer risk, focusing on 3 genes in which pathogenic mutations are estimated to carry a >20% lifetime risk for breast cancer: CHEK2, PALB2 and ATM. This level of risk meets professional society recommendations for initiating breast screening at younger ages and the use of MRI in addition to mammography. We determined the proportion of women identified as candidates for modified screening through genetic testing who would not have been identified with family history. Methods: We used the Claus tables to evaluate the reported family histories of women in whom pathogenic mutations were found in CHEK2, PALB2 and ATM through clinical testing with a 25-gene hereditary cancer panel. We determined the proportion of these women who would have been identified as having a >20% lifetime breast cancer risk based on family history. Results: Among 9201 patients tested between 09/04/2013 and 04/17/2014, 174 female patients were identified with a single mutation in either: CHEK2 (n=71), PALB2 (n=39) and ATM (n=64). Three patients carried mutations in 2 of the genes. Excluding 5 women who also carried a mutation in BRCA1 or BRCA2, only 15 (8.7%) of the remaining 172 women reached the >20% threshold for lifetime breast cancer risk using the Claus tables. By comparison, among this same group of 9201 tested individuals, 275 had a pathogenic mutation in BRCA1 or BRCA2. Therefore, inclusion of the 3 moderate penetrance genes improved the sensitivity of the testing, as defined by the identification of a genetic finding associated with an established breast cancer screening recommendation, by 62.5%. Conclusions: Clinical testing including the moderate penetrance genes CHEK2, PALB2 and ATM significantly increases the likelihood of identifying women who can benefit from modified medical management strategies that would not have been applied based on family history alone.

Update on evaluation of ACMG Recommended Incidental Findings in Clinical Whole Exome Sequencing. *P. Vitazka, J. Neidrich, J. Scuffins, B. Friedman, J. Tahiliani, H. Hanson Pierce, D. Copenheaver, N. Smaoui, J. Juusola, G. Richard, S. Bale, E. Haverfield.* GeneDx, Gaithersburg, MD.

In March, 2013 The American College of Medical Genetics and Genomics (ACMG) issued recommendations to include reporting of incidental findings (IF) on all individuals who receive clinical whole exome sequencing (WES) or whole genome sequencing (WGS). These recommendations advised actively reviewing 56 genes primarily associated with an increased risk for cancer or cardiac disease for the presence of known pathogenic (KP) or expected pathogenic (EP) mutations, since early intervention is likely to reduce or prevent accrued morbidity or early mortality. The ACMG estimated that ~1% of patients undergoing WES will have reportable incidental findings. At GeneDx, IF analysis has been offered since July 1, 2013. Since then, 2148 unrelated probands underwent WES, 433 (20.2%) of whom opted out of receiving IF. The recommended 56 genes were assessed for KP and EP mutations present at ≤1% frequency in the 1000 Genomes database or our internal GeneDx annotation database, excluding previously identified polymorphisms and large copy number mutations. All variants were evaluated for evidence of pathogenicity in the literature (HGMD database), and consistency with the ACMG reportable mutation spectrum for the gene. Of the 975 completed tests, we have reported 86 IF in 81 (8.3%) cases. Of the 86 pathogenic variants, 61 (70.9%) were in cardiac-related genes, 9 (10.5%) were in cancer-related genes, and 16 (18.6%) mutations were identified in genes associated with either hypercholesterolemia or malignant hyperthermia. IF were most commonly reported in MYBPC3 (19 mutations), SCN5A (10), KCNQ1 (8), and KCNH2 (7). No reportable variant was found in 34 (61%) of the 56 genes recommended by ACMG. Although previous pilot studies indicated that probands undergoing WES may have a high number of reportable ACMG IF (16-24%), these frequencies have not been replicated in our current study. Based on a much larger dataset, we have now found that the frequency of reportable ACMG IF is ~7-9% of cases undergoing WES, which is ~7-9x higher than the initial estimate provided by ACMG. This number is likely more accurate estimate of IF but may increase slightly in the future as more variants are evaluated for pathogenicity and the literature continues to expand.

2443T

Targeted gene panel sequencing using multi-parallel single-plex PCR amplification for the detection of somatic mutations. *K. Yap, K. Kiyotani, K. Tamura, M. Montoya, Y. Nakamura.* Department of Medicine, Section of Hematology/Oncology. The University of Chicago, Chicago, IL, USA.

The use of whole exome sequencing has been instrumental in the discovery of novel variants and somatic mutations that may be involved in the development of human diseases. Generally, non-synonymous variants which give rise to protein coding changes or protein loss are more likely to be the culprit, indicating the positive utility of exome sequencing. However, the broad target regions of whole exome sequencing usually dictates the sacrifice of overall sequencing read coverage, reducing the ability to detect low frequency variants, which is especially relevant for somatic mutation detection in cancer. In this study, we selected 10 bladder cancer samples that were previously whole exome sequenced, for deeper sequencing using a targeted gene panel of 60 cancer genes (1070 amplicons) developed on the Wafergen Smartchip TE system. Using a multi parallel single plex PCR-based approach, the design avoids the undetectable fall-outs and primer inefficiencies that typically occur in a multiplex primer pool PCR reaction. Additionally the chip-based design improves the throughput of the number of multi-parallel PCR reactions that is possible in a plate-based design. We found that all the variants (33 somatic mutations) that were called on exome sequencing can be confirmed by this targeted gene panel. Furthermore, 10 somatic mutations were additionally detected by the targeted gene panel due to the significantly improved overall read coverage. Conversely, there were a number of false positive variants that arose in this targeted gene sequencing approach due to the PCR-based amplification steps. This issue can be overcome by conservative filtering criteria and disregarding variants that were supported by sequencing reads with strong strand biases. Overall, targeted gene panel sequencing will significantly reduce sequencing cost and increase coverage in target gene regions of interest. This will allow for the detection of low frequency somatic mutations in heterogeneous cancer samples, which is instrumental for disease monitoring. However, additional bioinformatics processing will need to be carried out on data sets derived from targeted gene panels to account for the erroneous variants that may arise due to PCR amplifications.

2444S

Clinical and technical evaluation of NGS based testing for hereditary cancer syndromes. *S. Lincoln[1], A. Kurian[2], A. Desmond[3], M. Gabree[3], Y. Kobayashi[1], M. Anderson[1], G. Nilsen[1], S. Yang[1], R. Hart[1], K. Jacobs[1], K. Shannon[3], L. Ellisen[3], J. Ford[2].* 1) InVitae, San Francisco, CA; 2) Stanford University School of Medicine, Stanford, CA; 3) Massachusetts General Hospital, Boston, MA.

Introduction: Next-generation sequencing (NGS) of gene panels and exomes is gaining clinical acceptance, although questions remain about the sensitivity, specificity and clinical implications of these tests. Expanding on our recently published work (Kurian et al, J Clin Oncol, 2014) we considered whether NGS can both replace and supplement traditional *BRCA1/BRCA2* testing in patients indicated for hereditary breast/ovarian cancer testing. **Methods:** Over 900 patients indicated for *BRCA1/BRCA2* testing under clinical management guidelines were recruited and tested with a 220-gene NGS panel. In this analysis we focused on both sequence variants and copy-number variants (CNVs) detected by NGS in 29 moderate to high penetrance cancer risk genes. These patients also had traditional genetic testing results (e.g. from Sanger sequencing and QPCR) available for comparison. **Results:** 261 alterations (196 pathogenic and 65 others) were reported in the traditional data, and all were detected by NGS when the corresponding test was ordered. In this set are 141 insertions, deletions, complex events and CNVs, with particularly technically challenging variants including indels up to 126bp and CNVs as small as one exon. Specificity was also high: all NGS variants for which we sought orthogonal confirmation (n>2000) were confirmed, including 42 pathogenic variants not previously reported. No single calling algorithm achieved this performance but rather a combination did (GATK, Freebayes, PolyMNP, CNVitae and split-read detection). By testing for genes beyond BRCA1/2, diagnostic yield increased over 50%. As expected, clinical actionability of these findings varied, with various changes in care recommended when we were able to recontact patients. Communication of this information proved clinically feasible and was appreciated by the patients. **Conclusions:** NGS can be a viable replacement for traditional genetic testing techniques for hereditary cancers and other syndromes, with the additional benefit of cost-effectively increasing diagnostic yield. Orthogonal confirmation of clinical NGS results remains a strongly recommended practice, although the high concordance of traditional and NGS data suggests that the cost-benefit of confirmation merits careful consideration over time. **Note:** All of the variants in this study and their interpretations will be released to public databases by the time of the meeting.

2445M

Beyond BRCA1 and BRCA2: results from screening 94 genes in 200 patients with familial breast and ovarian cancer using panel sequencing and custom array-CGH. *A. Rump[1], E. Schrock[1], K. Hackmann[1], L. Mackenroth[1], A. Beyer[1], D. Huenich[3], U. Markwardt[3], N. DiDonato[1], B. Klink[1], P. Wimberger[2], K. Kast[2].* 1) 1Institut für Klinische Genetik, Medizinische Fakultät Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany; 2) 2Abteilung für Gynäkologie und Geburtshilfe, Universitätsklinikum Carl Gustav Carus, Technische Universität Dresden, Germany; 3) 3Zentrum für Informationsdienste und Hochleistungsrechnen (ZIH), Technische Universität Dresden, Germany.

Background Breast and ovarian cancer (BC/OC) predisposition has been associated with a number of high- and low-penetrance susceptibility genes. With the advent of NGS-based panel sequencing, testing all these genes became feasible in addition to the analysis of BRCA1, BRCA2, RAD51C and CHEK2. Here we report on the results of custom array-CGH for deletion/duplication analysis and panel-based screening of 94 genes that have been associated with hereditary cancer predisposition. **Method** Selection criteria for the 200 patients included in this study were defined by the German Consortium for Breast and Ovarian Cancer. High risk patients with previously excluded mutations in BRCA1 and BRCA2 were also included. Target enrichment was performed with the Illumina TruSight cancer panel, which includes 94 genes associated with both common (e.g., breast, colorectal) and rare cancers. All 94 genes were additionally analyzed with a customized, high resolution array CGH. **Results** In 28 % of the patients, BRCA1 and BRCA2 variations have been found. These were either clearly pathogenic protein truncating mutations or rare, unclassified missense variations with high probability of effect. In 30 % of the patients we found nonsense-mutations or unclassified missense variants in low penetrance susceptibility genes, especially NBN, CDH1, ATM and PALB2. TP53 mutations were revealed in 2 % of our cases. Interestingly, one of these TP53 mutations was found as a 10 % mosaic in blood cells from a patient with no familial history of cancer but late onset of both BC and OC. The frequency of the TP53 mutation in these tumors is currently being investigated. In one patient with a familial history of both BC and colon cancer a pathogenic mutation in MLH1 could be identified, along with a frame-shift mutation in BRCA1. Complementary custom array-CGH in all 200 patients identified deletions in ATM, BRCA1, CHEK2 or RAD51C in 3 % of the cohort. Despite comprehensive testing, 37 % of the patients did not reveal any convincing mutation, neither on nucleotide level nor on genomic level. **Conclusion** The extension of mutation screening beyond BRCA1 and BRCA2 reveals disease-causing mutations in high-penetrance genes, like TP53, as well as mutations in low-penetrance susceptibility genes, especially CDH1, ATM and NBN. However, the enormous number of unclassified sequence variants and the detection of mutations in “non-breast-cancer” genes pose a huge challenge for genetic counselling.

2446T

Reporting Candidate Genes: Identifying a Potential Genotype-Phenotype Correlation via Whole Exome Sequencing. *J. Neidich, P. Vitazka, J. Tahiliani, K. Retterer, J. Juusola, S. Suchy, D. McKnight, R. Bai, N. Smaoui, G. Richard, S. Bale, E. Haverfield.* GeneDx, Inc., Gaithersburg, MD.

Whole Exome Sequencing (WES) has become an effective diagnostic tool for the identification of the molecular basis of human genetic disorders. WES allows the investigation of a patient's clinical phenotype through the evaluation of specific variants found by the simultaneous analysis of approximately 20,000 genes in the human genome. The process begins with assessing the over 6000 genes already associated with human diseases. Resources including the Human Gene Mutation Database (HGMD), population frequency databases, gene-specific databases, and in silico pathogenicity prediction tools can be used to evaluate variants. New potential genetic etiologies not yet linked with human genetic diseases (candidate genes) may also be interrogated. The clinical utility and research potential of reporting out variants in candidate genes has yet to be established. During the initial 28 months of our WES program, approximately 7% (157/2242) of the reported variants have been in candidate genes. All reported candidate genes had animal models or pathway, expression, or functional studies tying the phenotype to the gene. Findings reported in candidate genes were retrospectively reviewed to determine whether any new information linking these genes to a genetic disorder became available after the initial report. These candidate genes were crosschecked against HGMD to assess how many of these genes had been newly added to the database since the report date. Of these, 3% (13/431 newly added genes) have since been added to HGMD as genetic causes of human disease. The associated disorders include neuropathies, intellectual disability, kidney, cardiac, and metabolic disorders, and congenital anomalies, including well-described syndromes such as Noonan, Prader-Willi, and Joubert syndromes. This result suggests there is value to reporting findings in candidate genes. Reevaluation of candidate genes on a periodic basis may be helpful in clarifying the cause of a phenotype with unknown genetic etiology. With this additional information, patient counseling should emphasize that genetic information is improving over time as a component of the benefits and limitations of WES. Ongoing review of already reported results is important to maximize the benefits of the existing technology and to ensure appropriate genomic diagnosis is provided.

Diagnostic sequencing in integrated clinical and research laboratory setting for 100 families at the Dorrance Center for Rare Childhood Disorders. *S. Szelinger[1,2,3], K.M. Ramsey[1,2], A.L. Siniard[1,2], I. Schrauwen[1,4], J.J. Corneveaux[1,2], A.A. Kurdoglu[1,2], J. Krate[1,5], B.E. Hjelm[1,2], I. Malenica[1,2], R. Richholt[1,2], M. de Both[1,2], S. Rangasamy[1,2], M.J. Huentelman[1,2], V. Narayanan[1,2], D.W. Craig[1,2].* 1) Neurogenomics Division, Translational Genomics Research Institute, Phoenix AZ, USA; 2) Dorrance Center for Rare Childhood Disorders, Translational Genomics Research Institute, Phoenix AZ, USA; 3) Molecular and Cellular Biology Interdisciplinary Graduate Program, School of Life Sciences, Arizona State University, Tempe AZ, USA; 4) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 5) University of Arizona College of Medicine-Phoenix, Phoenix, AZ, USA.

Integration of a clinical diagnostic center and a genomic research lab provides a unique opportunity to improve the life of children with rare, undiagnosed genetic disorders. To date, we enrolled 225 families and sequenced the whole-exome, whole-genome of 150. Study design included sequencing whole-exome of family trios, constant re-analysis of genomic data with updated annotation and prioritization methods, application of mRNAseq from whole blood for challenging cases and for validation of candidate causal variants, and the establishment of patient specific fibroblast cell lines for functional studies. We report a concise summary of the first 100 families enrolled. Enrollment criteria included a previously undiagnosed condition, ambiguous genetic origin, and negative, or inconclusive genetic tests. Most patients exhibited some form of neurological phenotype and were characterized as one of following condition: Neurodegeneration, Epilepsy, Movement disorder, Mitochondrial disorder, Aicardi Syndrome, Aicardi Goutieres Syndrome, Autonomic Dysfunction, Demyelinating disease, Cerebral Palsy, Leukodystrophy, GI dysmotility, Hearing loss, and Neuromuscular dysfunction. We applied Illumina TruSeq Exome Enrichment capture method, HiSeq2000 platform with a 2×100bp paired-end sequencing set up as standard. In summary, we sequenced 60 family trios, 15 parent-proband duo, 9 singletons, and 16 families with multiple affected and/or siblings. In 16 families, whole genome sequence of the proband and/or the parents were also obtained. In 28 families Illumina TruSeq RNA sequencing was additionally performed, and from 11 families, we obtained fibroblast tissue for cell culture. After filtration and prioritization, we categorized variants by their likelihood as: 1. Presumed Causal 2. Likely Causal/Major Contributor, 3. Candidate, 4. Unknown. In approximately 35% of cases a presumed causal or likely causal variant was found, and in about 9% of cases, we identified a candidate variant. Post diagnosis, we helped facilitate enrollment a number of diagnosed families in NIH funded clinical trials, or connected them with experts in the field, or provided alternative treatment options. We developed mouse models, and large-scale drug screens with previously approved FDA drug compounds for selected causal genes. Continuous outreach to the families and close integration of diagnostic and research approach was able to provide conclusion to the diagnostic odyssey for many families.

2448M

An intronic deleted mutation in the COL3A1 gene affecting exon skipping causing vascular Ehlres-Danlos syndrome. *A. Watanabe[1, 2], B.T. Naing[1, 3], K. Akutsu[4], T. Shimada[1, 2], T. Okada[1].* 1) Dept Biochem & Molec Biol, Nippon Med Sch, Tokyo, Japan; 2) Div Clinical Genetics, Nippon Med Sch Hosp, Tokyo, JAPAN; 3) Dept Molec Med & Anatomy, Nippon Med Sch, Tokyo, Japan; 4) Div Intensive and Cardiac Care Unit, Nippon Med Sch Hosp, Tokyo, Japan.

Vascular type of Ehlers-Danlos syndrome (vEDS), also known as EDS type IV (MIM#130050), is a life-threatening autosomal dominant inherited connective tissue disorder mainly caused by mutations in type III collagen, *COL3A1* gene. The main types of mutations in vEDS are a single amino acid substitutions for glycine in the GLY-X-Y repeat of the triple helical region or invariant splice sites. Recently, premature translation termination mutations are reported affecting nonsense-mediated mRNA decay of mutated allele. Here, we described a 26 y/o female with clinical features and family history of vEDS and characterized the functional consequences of an intronic *COL3A1* deleted mutation. The coding regions and flanking intronic bases of the *COL3A1* gene were screened by high resolution melting curve analysis method using genomic DNA. The patient is a heterozygote for a four bp deletion at 5' splice site of intron 8 with in genomic DNA (c.636+5+4del GTAA/IV8) that do not affect the consensus GT or AG splice sites and changed from G to C transversion at Position +5 of the splice donor site in the intron. A minigene splicing assay demonstrated that this deletion is sufficient to cause a skipping of exon 8. G at Position +5 of the splice donor site is supportive of an importance for splicing of *COL3A1*. Intronic mutations may be responsible for vEDS in some families with otherwise negative mutation screening of *COL3A1*.

2449T

The Relationship between Blood Index and Thalassemia Disease. *N. Ghazavi, M. Behnam, F. Hosseini, A. Hejazifar, A.R. Salehi Chaleshtori, M. Salehi, N. Mansouri.* Medical Genetic Center of Genome, Isfahan, Iran.

Background and Aims: Thalassemia is a severe hemoglobin disease, recognizing by CBC and hemoglobin electrophoresis primarily. It is possible that CBC and hemoglobin electrophoresis were performed for the index case who recognized as α-Thalassemia but finally experimental studies clearly demonstrated that it was different type of thalassemia. In the present study, we report a case of β-thalassemia mutations which is called -101 C>T relative to the transcription start site of β-globin gene, and is a β+-Thalassemia case, but it has been observed with different indices. Methods: The patient was admitted based on hematologic indices as α-Thalassemia, and diagnostic tests for α-Thalassemia, including GAP PCR, ARMS-PCR for α-Thalassemia were performed and all examinations were normal. For increased confidence, sequencing for patient's β-globins' gene was performed. We also observe more cases with the same index. Results: Our findings, present the incidence of mentioned mutation in β-globin gene in β+ patient, in contrast to the hematologic indices for β-Thalassemia heterozygote. Moreover, this case has no resemblance to other β+-Thalassemia cases and it can be mistaken as α-Thalassemia. (For example: The - 88 C> A mutation relative to the transcription start site, which several of our indices present beta-Thalassemia). Conclusion: As mentioned above, our outcomes are extremely similar to the results of CBC and hemoglobin electrophoresis of α-Thalassemia, but the patient was β-Thalassemia. Such conditions as cited above are hazardous and end to affected neonates if the other partner is β-Thalassemia patient. In this condition, Sequencing of β-globins for one of the couples could be helpful.

2450S

Investigation of Genomic Deletions and Duplications by Custom MLPA in a Cohort of 338 Patients with Obesity, Developmental Delay, Hyperphagia, and Additional Features. *C.S. D'Angelo[1], C.V. Monica[1], I.E.C. Claudia[1], A.K. Chong[2], R.B. Debora[2], M.L. Charles[3], P.K. Celia[1].* 1) Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, Sao Paulo, Brazil; 2) Department of Pediatrics, Children Institute, School of Medicine, University of Sao Paulo; 3) Department of Medical Genetics, School of Medicine, University of Sao Paulo.

Obesity is highly heritable and a significant health problem for people with intellectual disability (ID). The recent implementation of whole-genome chromosomal microarray analysis (CMA) has resulted in the discovery of novel and rare CNVs implicated as risk factors for obesity, often also present with ID. However, the strong phenotypic overlap between syndromic forms of obesity poses challenges to accurate diagnosis, and many different individual cytogenetic and molecular approaches may be required. Multiplex dependent-probe amplification (MLPA) enables the simultaneous analysis of multiple targeted loci in a single test, and serves as an important investigation tool in situations where specific microdeletion and/or microduplication syndromes are suspected. Our aim was to design a synthetic probe set to screen for deletions and duplications at previously described loci associated with obesity in a cohort of 338 patients with syndromic obesity of unknown etiology who have had a normal methylation test for PWS or in whom no 1p36 deletion could be found. Eighteen alterations were detected using the synthetic MLPA probe set. Ten of the detected alterations were delineated by chromosomal microarray, while the remaining alterations were fine-mapped by additional MLPA probes incorporated into commercial kits. We identified nine known CNVs representing clinically well defined microdeletion syndromes with obesity as a clinical feature: in 2q37 (4 cases), 9q34 (1 case) and 17p11.2 (4 cases). We also identified three deletions and a reciprocal duplication in the DiGeorge syndrome locus at 22q11.2. Additionally, we have identified two recurrent small deletions within the 22q11.2 'distal' locus associated with a variable clinical phenotype and obesity in some individuals. Three individuals were found to have a recurrent CNV of one susceptibility loci at 1q21.1 'distal', 16p11.2 'distal', and 16p11.2 'proximal'. The overall detection rate with the synthetic MLPA probe set was about 5.3% (18 out of 338). Our experience leads us to suggest that MLPA could serve as an effective alternative first line screening test to chromosomal microarrays for syndromic obesity, allowing for a number of microdeletion syndromes loci (e.g. 1p36, 2p25, 2q37, 6q16, 9q34, 11p14, 16p11.2, and 17p11.2) known to be clinically relevant for this patient population to be interrogated simultaneously. Financial Support: CEPID-FAPESP, CNPq.

2451M

Prenatal detection of chromosomal aberrations and its reflection at adult age. *B.B. Ganguly[1], S. Mandal[1], N.N. Kadam[2].* 1) MGM Center for Genetic Research & Diagnosis, MGM Institute of Health Sciences, Mumbai, India; 2) Department of Pediatrics, MGM Institute of Health Sciences.

Heritable chromosomal abnormalities have been reported in ~50% spontaneous abortion and ~5-10% of live pregnancies with prevalence of trisomy 21. Intervention of prenatal diagnosis is generally considered in suspected cases with high risk triple screen, significant family history and/or advanced maternal age. In our previous data, Down syndrome was recorded in ~4% cases, while balanced translocation and inversion were present in 5% among 140 pregnancies. The cases with balanced rearrangements might achieve a long life span since such alterations do not contribute to major phenotypic or clinical manifestation. Therefore, chromosome aberrations are expected in ~10% of children including 5% of adults; however, these aberrations can be prevented from transmission through generations with a straightforward approach of prenatal chromosomal analysis by conventional techniques. In the present report, we present data on chromosomal status in 269 fetal samples of live pregnancies. CVS or amniotic fluid was processed for FISH and/or conventional analysis of karyotypic status. Interphase cells were considered for FISH whereas metaphases were processed for GTG-banding and karyotyping. Mitotic metaphases were obtained from long-term culture of the specimens following standard technique. IKAROS and ISIS software (MetaSystems, Germany) was utilized for conventional karyotyping and FISH analysis. The cases were categorized into three age groups of 10 years interval and the abnormalities detected by FISH and G-banding was presented in different age groups. The incidence abnormality was maximum in the advanced age group as expected; however, the youngest age group showed higher number of structural aberrations over group II. Conventional G-banding result appeared with 71.5% structural aberrations, which was not detectable by FISH. The present report highlights the importance of karyotyping over interphase FISH. Also the study recommends the intervention of karyotyping at fetal age with a view to prevention of transmission and reduction of chromosome aberrations among adults which would further reduce the burden of birth defects and/or reproductive failure.

2452T

45,X (30%); 46,X,i(Xq) (60%) mosaicism. Case report. *M. Pérez Sánchez[1, 3], A. Mora Guijosa.[1, 3], M. Lopez Melchor.[1, 3], A.R. González Ramírez.[1, 2].* 1) UGC Análisis Clínicos, Hospital Virgen de las Nieves, Granada, Spain; 2) Fibao. Hospital Clínico San Cecilio, Granada, Spain; 3) Instituto de Investigación Biosanitaria de Granada, Granada, Spain.

The commonest structural rearrament of the X is 46,X,i(Xq). An i(Xq) chromosome theoretically consists of wo copies of the entire long arm and no short arm. The gross banding patterns of most isocromosomes fits with this interpretation but in detail the situation is more complicated. Some isocromosomes have one centromere and are perfectly symmetrical, while others are symmetrical but have two centromeres close to each other, and still others have a clearly asymmetrical central portion, raising the posibility of a more complex abnormality. On the other hand, Turner mosaicism are present in an important group of Turner syndrome with a wide clinical features ranging from full-blown Turner syndrome to normal phenotype. The karyotype is the elecction technique for these cases, but for a finest detection of the rearrament point, the microarrays CGH will be of elecction. Here we present a case of a 19 years old woman that was referred for genetics studies. The clinical findings were amenorrhea with treatment response, normal secundary sexual caracteristics, hormonal status at normal levels, the right ovary was not detected and the left one was normal when magnetic resonance studies were done. No appreciable mental retardation were detected. Chromosome culture and karyotyping were realized by standard thecnics and showed karyotype of 45,X (30%); 46,X,i(Xq) (60%) mosaicism. To determine the Xp region deleted and the Xq region duplicated, GH-array 180 K (PerkinElmer Platform) was performed, with a resul of total loss of 55,17 Mb in the Xp22.33-p11.21 region (genomic coordinates: chrX296520-55466477), a partial duplication of 2,77 Mb in the Xp11.21-p11.1 (genomic coordinates: 55556815-58324786) and partial duplication of the entire Xp arm. The results obtained with CGH-Aray are in concordance with the karyotype results, but with the possibility of detec the exact rearragement point. The presence of the Xp región near to the centromere can explain the mild Turner clinical features in this patient. As a conclusión, when a rearrangement is detected by karyotype, the CGH-Array can be indicated to detect the exact rearrangement point.

2453S

Comparison of whole genome amplification (WGA) methods for detection of genomic aberrations using low coverage massive parallel sequencing. *D. Deforce[1], L. Deleye[1], D. De Coninck[1], C. Christodoulou[3], A. Dheedene[2], T. Sante[2], B. Heindryckx[3], P. De Sutter[3], B. Menten[2], F. Van Nieuwerburgh[1].* 1) Lab of Pharmaceutical Biotechnology, Ghent University, Ghent, Belgium; 2) Center for Medical Genetics, Ghent University, Ghent, Belgium; 3) Department of Reproductive Medicine, Ghent University, Ghent, Belgium.

Whole genome amplification (WGA) is currently performed on biopsied blastocyst trophectoderm cells to subsequently perform aCGH to screen for large chromosomal aberrations in a Pre-implantation Genetic Diagnosis (PGD) setting. The different currently available WGA methods lead to amplification bias resulting in over- and under-represented regions in the genome. Current WGA methods, such as PicoPLEX (Rubicon Genomics) and subsequent aCGH analysis, make it possible to detect duplications and deletions at a 10 Mb resolution.

An alternative to aCGH is low coverage Massive Parallel Sequencing (MPS). Genomic regions for which a significantly higher or lower number of sequences are generated can be called as duplications and deletions. Unlike with aCGH, there is no reference DNA used within the MPS assay that can be used for a within-assay normalization of the representation bias. WGA representation bias might thus be more critical when using MPS.

Recently, a new Multiple Annealing and Looping Based Amplification Cycles (MALBAC) WGA method has been published, claiming unparalleled performance. This method has not yet been studied in a PGD setting. The goal of this study was to compare the well established PicoPLEX and MALBAC WGA for their ability to produce optimal PGD by MPS results from a limited number of cells.

Six repeats of samples consisting of 1 cell, 3 cells and 5 cells were collected from the Loucy lymphoblastoid cell line using micromanipulation techniques. Three repeats were amplified using PicoPLEX (Rubicon Genomics), and three using MALBAC. The amplification products were used to create Illumina sequencing libraries and were sequenced on an Illumina HiSeq1500. Results show a comparable performance between the PicoPLEX and the MALBAC WGA. By subsampeling the generated sequences, we also were able to determineminimal coverage to achieve a 10 MB resolution.

Supporting the free exchange of clinical laboratory variant data through VariantWire. *S. Baxter[1,2], S. Aronson[2], L. Edelmann[3], M. Lebo[1,4], J. Lerner-Ellis[5,6,7], E. Lyon[8,9], M. Oates[2], H. Rehm[1,4,10], VariantWire Consortium.* 1) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Cambridge, MA; 2) Partners HealthCare Personalized Medicine, Cambridge, MA; 3) Mount Sinai Genetic Testing Laboratory, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, NY; 4) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 5) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada; 6) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 7) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 8) Department of Pathology, University of Utah School of Medicine, UT; 9) ARUP Laboratories, Salt Lake City, UT; 10) Pathology, Harvard Medical School, Boston, MA.

With the emergence of next generation sequencing technology, the quantity of sequencing data being produced by genetics laboratories is exponentially increasing. In the last decade, not only has the volume of clinical genetic tests been on the rise, but the average number of genes covered by those tests has also increased dramatically. The expanding scope of genetic tests is leading to more data being generated and an increased rate of variants of unknown significance being returned to clinicians. Siloed data sets restrict our understanding of the spectrum of variation for a particular disease and result in higher rates of variants of uncertain significance. Data sharing is proving to be an essential element for overcoming these challenges of the genomic era. VariantWire, a consortium supported by GeneInsight, provides a data-sharing network that allows clinical genetic testing labs to share variant and gene interpretations, and the evidence behind those interpretations, in real time. Data sharing on VariantWire occurs in a secure environment and all case information in the network is de-identified. VariantWire is governed by the VariantWire Committee, which is comprised of one member from each participating entity (listed in author affiliations). The VariantWire committee guides the content of the data sharing policy and reviews all applications from laboratories seeking to join the network. As of May 21st 2014, VariantWire is sharing 23,318 variants across 336 genes. Of the shared variants 2,973 are classified as clinically significant (pathogenic or likely pathogenic) for over 100 diseases. Another 3,907 variants are classified as unknown significance and 16,438 were determined to be either likely benign or benign. Finally, 24 somatic variants in the EGFR gene are involved with drug response. Two hundred and seventeen variants have been identified in more than one lab, with 61 of those variants being classified as either pathogenic or uncertain significance. Of those 61 clinically significant variants seen more than once, only two variants had inconsistent classifications across labs. By enabling real-time data-sharing, labs using VariantWire are assured that they have the most up-to-date knowledge from other participating labs. Finally, the GeneInsight team aids in helping labs submit their variant data to ClinVar, a freely available database, ensuring the broadest sharing of data to further our clinical understanding of the human genome.

Developing Exclusion Datasets for Genome Filtering in the MedSeq Project. *K. Machini[1,2], R. Shakhbatyan[1], H. McLaughlin[1,2], O. Ceyhan Birsoy[1,2], D. Metterville[1], M. Lebo[1,2], R.C. Green[1,2,3], H.L. Rehm[1,2].* 1) Partners Healthcare Personalized Medicine, Cambridge, MA; 2) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

A major obstacle in the clinical application of whole genome sequencing (WGS) is the difficulty in systematically interpreting the enormous amount of data generated. This includes analyzing a genome for the return of incidental findings based upon the interpretation of previously published variants as well as the interpretation of novel loss of function variants in disease-associated genes. Within the framework of the MedSeq Project, 100 participants, half healthy and half with cardiomyopathy, are undergoing WGS. Sequencing is performed at Illumina's CLIA-certified laboratory and alignment, variant calling, annotation and variant review are performed at the Partners' Laboratory for Molecular Medicine. First, annotated variants with a minor allele frequency (MAF) <5% are filtered to identify those classified as DM or DM? in the Human Gene Mutation Database (HGMD). A separate filter identifies nonsense, frameshift, and canonical splice-site (+/-1,2) variants with a MAF <1% from a list of disease-associated genes. Although this is a common strategy employed by laboratories performing incidental findings analysis, it is hindered by the plethora of variants with false claims of pathogenicity or in genes with insufficient evidence for disease causality. After full interpretation of the first 27 genomes, involving review of 1022 rare variants with claims of pathogenicity, only 74 variants (average of 2.7 per genome) reached the evidence level to be clinically reported. In the course of excluding the majority of variants, we have developed a series of filters. First, 19% of variants can now be excluded using a dataset of common variants encountered in >10% of individuals in our cohort. Second, 14% can be excluded using quality metrics derived from analyzing Sanger confirmation data to improve quality thresholds. Third, 27% of variants can now be excluded using a dataset of genes with claimed medical associations that have insufficient evidence. Finally, 15% of reported pathogenic variants can now be excluded because of evidence for a benign interpretation. This has allowed a dramatic reduction in genome review time which will continue to be reduced as further genomes are interpreted and these exclusion datasets are continually populated and queried during our review process. We propose that laboratories share their exclusion datasets and approaches to enable a community resource for collectively improving the process and efficiency of genome interpretation.

Diagnostic Exome Sequencing provides diagnoses among patients with abnormal brain MRI findings. *K.D. Farwell Gonzalez[1], L. Shahmirzadi[1], D. El-Khechen[1], Z. Powis[1], K. Radke[1], C. Mroske[1], D. Shinde[1], S.K. Gandomi[1], C. Alamillo[1], E.C. Chao[1,2], R.M. Baxter[1], B. Tippin Davis[1], S. Tang[1].* 1) Ambry Genetics, Aliso Viejo, CA., USA; 2) Department of Pediatrics, University of California, Irvine, Irvine, CA 92697.

Diagnostic exome sequencing (DES) is successful in solving the diagnostic odyssey for 30-40% of undiagnosed patients with a broad range of underlying Mendelian disorders. Among the first 500 reported DES families, 168 (34%) had a previous abnormal brain MRI. Positive findings were uncovered in 66 of these families (39%). Positive and likely positive alterations within clinically characterized genes were identified in 55 of the 168 families, for a molecular diagnostic rate of 33% among characterized genes. A novel gene finding was uncovered among 11 families (7%). The diagnostic rates among patients in this cohort are similar to the overall detection rates among all 500 referred patients (39% overall positive rate and 30% among characterized genes). Among the 66 positive findings, 43 (65%) were autosomal dominant, 12 (18%) were autosomal recessive, and 11 (17%) were X-linked molecular defects. The 66 positive patients with abnormal MRI findings were significantly less likely to have an autosomal recessive finding (18%) as compared to the entire positive cohort (51/163; 31%) (p=0.05). The most commonly observed MRI findings among the patients with positive findings were cerebellar hypoplasia, delayed myelination, cerebral atrophy, and agenesis of the corpus callosum. Several well-known molecular diagnoses were provided and/or confirmed including Leigh Syndrome, Genetic Prion Disease, and spinocerebellar ataxia. These data highlight the utility of DES in providing the most comprehensive molecular diagnosis given the diversity of genetic findings including 7% within novel genes.

2457M

Identification of a Novel De Novo Mutation Associated with PRKAG2 Cardiac Syndrome and Early Onset of Heart Failure. *M. Jurkowska[1], R. Szymanczak[1], A. Wasowska[1,2], A. Mlodzinska[1,2], M. Kania[1], M. Krawczyk[1], K. Spodar[1], A. Boguszewska-Chachulska[1].* 1) Genomed Health Care Center, Genomed SA, Warsaw, Poland; 2) Polish-Japanese Institute of Information Technology, Warsaw, Poland.

Cardiomyopathies are a group of severe cardiac diseases with a strong genetic background. More than 100 genes have been associated with them. Mutations in some of the genes can manifest as various forms of cardiomyopathy, and a significant intra- and inter-family variability exists due to penetrance and genetic modifiers. Therefore, effective genetic testing is moving from single gene and subgroup testing to large gene panels covering most of the genes causing cardiomyopathies. Purpose: A family was referred to our center whose <1 year-old boy has died in consequence of hypertrophic cardiomyopathy. The family requested testing to establish the genetic background of their offspring's clinical symptoms and to be provided with genetic counselling concerning their other child's (16 years old now) risk as well as with a risk assessment for future pregnancies. Methods: Frozen blood sample was used as a source of DNA for testing. Two NGS-based approaches were applied: 1.) HaloPlex CardioMyopathy Research Panel (ILM) that screens 34 genes involved in various cardiomyopathies 2.) Whole exome sequencing (WES) with HaloPlex Exome Target Enrichment System KIT (ILM) with subsequent analysis of 106 laboratory-selected genes reported to be involved in syndromic and non-syndromic cardiomyopathy. Results: For the cardiomyopathy gene-panel, 99.35%; of all the bases had a coverage of ≥50 reads per nucleotide and 99.48%; had ≥10. The screening results were inconclusive - no pathogenic variant was found. For 106 selected genes, the WES mean coverage was 27.5 reads/bp, 56.86%; of the bases were covered >20x and 69.63%; of the bases >10x. Despite a much less efficient coverage, a heterozygous *de novo* variant in the *PRKAG2* gene, not reported in HGMD, was identified and confirmed by Sanger sequencing. The p.Phe293Val (c.877T>G) variant was found uniquely in the index case and was classified as 'likely pathogenic' in accordance with current recommendations. *PRKAG2* pathogenic variants influence cardiac metabolism but pathological glycogen storage in heart due to mutated PRKAG2 may be potentially attenuated or significantly reversed pharmacologically. Conclusion: Despite being superior to WES in coverage efficacy and facility of result interpretation, particular NGS panels risk to be too narrow for providing with proper genetic service in the genome era, when effectiveness of testing influences not only genetic counselling, but also therapeutic options.

2458T

Targeted massively parallel sequencing in molecular diagnosis: a Brazilian report. *M. Lazar, K.M. Rocha, G.L. Yamamoto, M. Aguena, V. Takahashi, N. Lourenço, M. Varela, S. Ezquina, D.R. Bertola, R. Pavanello, M. Vainzof, M. Zatz, M.R. Passos-Bueno.* University of São Paulo, São Paulo, Brazil.

Massively parallel sequencing (MPS) has emerged as a powerful tool for investigating nucleic acids and has been applied not only for research purposes, but also for diagnosis of human disorders. The Human Genome and Stem Cell Research Center (HUG-CELL, University of São Paulo, Brazil) has implemented this methodology through a customized panel of genes associated with skeletal dysplasias, neuromuscular diseases and neurodevelopmental disorders (Nextera target enrichment for MiSeq platform - Illumina). In order to evaluate the efficiency of targeted MPS for concluding molecular diagnosis, we analyzed 92 patients presenting phenotypes compatible with neuromuscular disorders (n=50) or skeletal dysplasias (n=42). Using an average coverage of 100x to 200x, it was possible to identify pathogenic variations in 62% of individuals with skeletal dysplasias and 65% of patients diagnosed with a form of neuromuscular disorder. Particularly, in a subgroup of 14 patients clinically diagnosed with dystrophinopathy and previous normal MLPA results, the mutation detection rate was around 85%. In contrast, we obtained low detection rate (33%) for a subgroup of 9 patients affected by non-specific forms of skeletal dysplasias, indicating that high mutation detection rate is obtained if a detailed clinical evaluation and restricted diagnosis are taken into consideration. Application of this customized panel in our testing routine has provided remarkable advantages for patients affected by genetic heterogeneous disorders, where accurate categorization by clinical evaluation only is challenging. Overall, besides the high sensitivity, our experience has shown that targeted MPS is time- and cost-effective, which are mandatory criterions for molecular diagnosis. For this reason, in cases with well-defined diagnostic hypothesis, targeted MPS should be considered the first-stage in molecular investigation instead of exome sequencing. Not only has this approach higher costs, but undirected search for deleterious mutations increases frequency of incidental findings, which implies ethical dilemmas that have to be exhaustively discussed among scientific community members before defining a consensus. Financial support: Fapesp/CEPID and CNPq/INCT.

2459S

Prevalence of medically actionable findings: a summary of clinical Whole Exome Sequencing cases. *Z. Niu[1], J. Beuten[1], M. Leduc[1], W. He[1], J. Zhang[1], P. Ward[1], A. Braxton[1], T. Vaughn[1], D. Muzny[3], F. Xia[1], R. Person[1], S. Plon[1,2], J. Lupski[1], R. Gibbs[1,3], A. Beaudet[1], Y. Yang[1], C. Eng[1,2].* 1) Molecular Human Genetics, Baylor College of Medicine, Houston, TX; 2) Texas Children's Hospital, Houston TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Clinical Whole Exome Sequencing test is a powerful and effective tool to identify the genetic etiology in patients with a variety of clinical presentations. This genome wide analysis has also drawn great attention to the returning of incidental findings (we prefer the term medically actionable findings), which may greatly impact the care of the patient (and potentially family members), if the findings can lead to prevention, early diagnosis, and medical interventions. The American College of Medical Genetics and Genomics (ACMG) issued guidelines for the return of incidental findings on a core group of 56 actionable genes from clinical whole exome or genome sequence to patients. From the 2000 sequential clinical Whole Exome Sequencing cases completed at the Medical Genetics Laboratory and Whole Genome Laboratory of Baylor College of Medicine, 95 medically actionable findings were reported for an overall rate of ~4.8%. Of these, 60 findings were reported in genes on the ACMG recommended list, and 35 findings were reported in genes which met the criteria for medically actionable by expert opinion from the clinical and diagnostic team. When the consent form was updated with an opt-out from actionable findings in non-ACMG recommended gene, 2 patients out of 190 opted out of additional reporting. Majority of families requested to receive all aspects of actionable findings. 24 findings were reported in hereditary cancer predisposition genes in patients without cancer as an indication: five *BRCA1*, eight *BRCA2*, three *PMS2*, two *VHL* and single cases of *CDH1, MSH6, RAD51D, MUTYH, RET and PALB2.* 46 of the 95 mutations occurred in genes for which mutations can cause susceptibility to disorders of the cardiovascular system. Our protocol returns medically actionable findings for the proband first. Followup testing of the parents for the medically actionable findings can be ordered after disclosure of the proband's result at no cost. 33 requests from 19 families of the 95 patients with incidental findings have been received to date. In multiple cases, parental testing was requested for one parent only, typically when phenotype related to the actionable finding was noted by review of family history. Our early experience exemplified the extent of medically actionable findings uncovered from clinical Whole Exome Sequencing. Studies are needed to further evaluate the long term impact on patient care and at-risk family members when a medically actionable finding is reported.

2460M

Identification of Complex Rearrangements of the MECP2 Gene Requires a Combination of Molecular Diagnostic Techniques. *S. Ordorica, D. Lahey, O. Jarinova*, N. Carson*.* Molecular Genetics, Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

The methyl-CpG-binding protein 2 gene (MECP2; MIM#300005) is a chromosome binding protein that acts as a transcriptional repressor, located on the X chromosome. Mutations in this gene can cause mental retardation, Rett Syndrome (RTT; MIM#312750) and have also been associated with Autism Spectrum Disorders. While missense and truncating mutations are most common, complex rearrangements also occur. Here we describe three cases with complex rearrangements involving the MECP2 gene that were identified using MLPA analysis and required further molecular investigations. Case 1: MECP2 MLPA analysis in a female patient showed a reduced signal (~75% signal) for all MECP2 probes and a heterozygous deletion of CDKL5 (MIM 300203) and ARX (MIM 300382) that reside on the p-arm of the X chromosome and are implicated in Rett Sydrome and Mental Retardation. Consistent with these findings, microarray analysis showed a loss of a portion of the p-arm of the X, and a mosaic loss of the remaining X chromosome. Case 2: MECP2 MLPA analysis in a male patient showed a triplication of exons 1 and 2 and a duplication of exon 3 and 4 of the MECP2 gene. Consistent with these findings, microarray analysis showed a triplication and a duplication of the corresponding regions on Xp28. Since the patient's phenotype was indicative of the presence of two copies of MECP2 (ie: MECP2 duplication syndrome, MIM 300260), a third partial copy is likely to be non-functional. Case 3: MECP2 MLPA analysis in a female patient showed a partial deletion of exon 4. Consistent with the MLPA findings, targeted sequencing of the MECP2 gene revealed a complex rearrangement involving exon 4 of the MECP2 gene: c.[523_1075delinsCG;1161_1188del], p.[Lys175_Ala358delinsArgfs; Pro388_Ser396del]. This mutation event is consistent with the presence of deletion hot spots in this gene and is predicted to be deleterious to MECP2 gene function. The three cases presented here illustrate that while MECP2 analysis is commonly conducted using Sanger sequencing and MLPA, a combination of molecular techniques is sometimes required to confirm the presence of complex rearrangements involving the MECP2 gene and provide a clear diagnostic result.

Pathogenic mutations in genes responsible for Maple Syrup Urine Disease type 1A *(BCKDHA)*, type 1B *(BCKDHB)*, and type 3 (*DLD*) determined in a large pan-ethnic cohort. *C. Perreault-Micale, A. Frieden, S. Hallam, V. Greger.* Good Start Genetics, Cambridge, MA. 02139.

Maple Syrup Urine Disease (MSUD) is an autosomal recessive metabolic system disorder that is due to dysfunction of the branched-chain alpha-keto acid dehydrogenase (BCKD) enzyme complex. This complex is composed of subunits encoded by 4 different genes. Founder mutations in 3 of these genes, *BCKDHB* and *DLD* in the Ashkenazi Jewish (AJ) and *BCKDHA* in the Mennonites, lead to an increased prevalence of MSUD in these populations. We sequenced the coding region and intron-exon borders of these three genes in a pan-ethic population of nearly 23,000 individuals referred to us for carrier screening using next generation DNA sequencing (NGS) to identify unique variants (number of different variants detected among the carriers), known variants (those previously cited in a publication or public database), and novel variants predicted to be pathogenic (nonsense mutations, conserved splice site mutations, or indels not divisible by 3). We found 16 carriers of 12 unique variants (7 known and 5 novel) in *BCKDHA*, 40 carriers of 15 unique variants (7 known and 8 novel) in *BCKDHB* and 22 carriers of 6 unique variants (2 known and 4 novel) in *DLD*.

Overall, 78 carriers of a pathogenic MSUD mutation were identified. The AJ founder mutations, p.Arg183Pro and p.Gly278Ser in *BCKDHB*, and p.Gly229Cys in *DLD*, accounted for the majority of carriers in each subtype, even though only 6 carriers reported AJ descent. In contrast, only three carriers of the *BCKDHA* founder mutation, p.Tyr438Asn, were identified; most carriers for this MSUD subtype had other mutations. Interestingly, we identified about twice as many carriers of pathogenic *BCKDHB* variants compared to the other two genes. Four out of 6 unique *DLD* variants were novel variants that we predict to be pathogenic on the basis of their truncating nature. In contrast, the groups of *BCKDHA* and *BCKDHB* unique variants consist of about half known and half novel truncating variants. In summary, we have determined the mutation prevalence and spectrum of MSUD types 1A, 1B and 3 in a large pan-ethnic population and show that a large number of novel pathogenic variants would have gone undetected using an alternative technology that is not as comprehensive as NGS.

2462S

Molecular Genetic Determination of Maple syrup urine disease cases from southwest Iran. *A. Sedaghat[1], G. Shariati[2,3], A. Saberi[2,3], M. Hamid[2,4], M. Mohebbi[5], H. Galehdari[6].* 1) Endocrinology Dept., Jundishapour University of Medical Science, Ahvaz, Iran; 2) Narges Genetic Diagnostic Lab, Ahvaz, Iran; 3) Genetic Dept., Jundishapour University of Medical Science, Ahvaz, Iran; 4) Pasteur Institute, Tehran, Iran; 5) Internal Medicin Dept., Jundishapour University of Medical Science, Ahvaz, Iran; 6) Genetic Dept., Shahid Chamran University, Ahvaz, Iran.

Maple syrup urine disease (MSUD) affects an estimated 1 in 185,000 infants worldwide, and is most frequent metabolic disorder in southwest Iran that ranges from very mild to severe form. The frequent occurrence of MSUD (like other disorders with autosomal recessive pattern) is probably due frequent consanguineous marriage. In last twelve month we analyzed 20 families with MSUD affected children. Most our cases have been preliminarily diagnosed by tandem mass as helpful tool for this propose. Mutations in four genes BCKDHA, BCKDHB, DBT, and DLD can cause MSUD. But, we find recurrently changes in the two genes BCKDHA and BCKDHB responsible for outcome of the disease. In summary, we found in 8 cases mutations in the BCKDHA gene and in other 9 cases nucleotide changes in the BCKDHB gene. Three cases were negative, despite screening of all 4 responsible genes as have been mentioned. The negative results can be explained by two reasons: wrong diagnosis or existence of the 5th undetected gene in the pathogenesis of the MSUD. However, some detected mutations were novel in analyzed cases. In cases of novel changes in one gene, we additionally screened the other three genes to assert our results. Further, we used some predicting program such as "Predict SNP", "I-Taisser", and "Mutation Tester" to underline the pathogenicity of determined changes.

2463M

A homozygous frameshift insertion in the MRPS34 gene identified in a family with two affected boys Suffering from progressive retinal dystrophy. *G. Shariati[1,2], A. Saberi[1,2], M. Hamid[1,3], M. Sedaqat[2,4], M. Mohebbi[1,5], H. Galehdari[6].* 1) Narges Medical Genetics Lab, Ahvaz, Iran, PhD, MD; 2) Genetic Dept., Jundishapour Medical science University, Ahvaz, Iran, PhD; 3) Pasteur Institute, Tehran, Iran, PhD; 4) Endocrinology Dept, Jundishapour Medical science University, Ahvaz, Iran, MD; 5) Internal Medicine Dept, Jundishapour Medical science University, Ahvaz, Iran, MD; 6) Genetic Dept, Shahid Chamran University, Ahvaz, Iran, PhD.

Progressive retinal dystrophy covers a wide range of eye disorders including syndromic and non syndromic retinitis Pigmentosa. To date, more than 100 disease causing genes have been identified in different populations. Recently, a couple (first cousin) from southwest Iran referred us with two affected boys (8 & 6 years old) suffering from progressive retinal dystrophy as preliminary diagnosis. Genomic DNA of affected individuals was subjected for next generation sequencing (NGS) leading to the detection of numerous candidate genes including a homozygous insertion (c.320_321insAGGT) causing frameshift at codon 107 (p.Q107fs). Targeted sequencing of the MRPS34 gene exon 1 showed that both parents are heterozygous for this mutation. The MRPS34 gene codes for the mitochondrial ribosomal protein 34 that is highly expressed in eye. No clinical assertion has been found for the mentioned mutation, but we consider it as a strong candidate causative for progressive blindness in the family.

2464T

Beyond Bias: Broadening the phenotype of genetic disorders using very large gene panels. *C. Stanley, J. Eggington, P. Carmody, H. Hornung, A. Zare, S. Wong, J. Dickerson, E. Kazarinoff, K. Wright, E. Nelson, D. Neilsen, T. Foss, J. Warner, K. McKernan, R. Boles.* Clinical Genomics, Courtagen Life Sciences Inc, Woburn, MA.

Ascertainment bias is a sampling bias in genetics, where a non-random sample is collected in such a way that some members of the intended population are less likely to be included than others. In genetics, the consequence is that the most severely affected individuals (e.g. those who present in the emergency rooms) are the first to be described in the literature for most genetic disorders. This bias impacts the development of diagnostic criteria and effectively removes patients with milder or atypical presentations from diagnosis and restricts the phenotypic spectrum of disease, literally marginalizing many individuals with the same disorder and consequently leaving them without a diagnosis. This approach was dictated in part by the cost associated with Sanger sequencing, where clinical diagnostic justification was required to order a gene test. Recently, massive parallel sequencing brought both a radical drop in cost-per-gene and the advent of large comprehensive gene panels, allowing individuals who do not classically fit diagnostic criteria to be evaluated for genes with or without high clinical utility. In patients without the classic clinical criteria, or those with a milder phenotype, genetic testing may provide the definitive diagnosis. Large gene panels also allow primary care physicians to order genetic tests on patients who only meet a subset of diagnostic criteria, moving genetics to the beginning of the testing process and effectively turning the traditional paradigm on its head. For the patient, this leads to a shortcut to what was otherwise a long maze of referrals and circumvents the need for a clinical diagnosis prior to testing in many cases. For the geneticist, this provides much more information regarding the clinical spectrum of genetic disease. We report the results from over twenty cases of diagnoses confirmed by genetic panels (most de novo) identified by very large gene panels targeting patients with epilepsy, developmental delay, and mitochondrial disorders and the implications of identifying the genetic cause earlier than would have been achievable if clinical diagnostic criteria were used alone. We will also highlight how early identification has important clinical management implications for patient care.

2465S

Development of a Hereditary Spastic Paraplegia gene panel using exome sequencing. *D.J. Stavropoulos[1], C.R. Marshall[1], L. Lau[1], M. Eliou[1], J. Orr[1], P.J. Sabatini[1], A. Shlien[1,2], G. Yoon[3], P.N. Ray[1,2].* 1) Molecular Genetics, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Canada; 2) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, Canada; 3) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada.

Recent breakthroughs in next generation sequencing technologies have generated a major transformation in service delivery of genetic medicine. The ability to generate high quality sequence from thousands of genes in one experiment enables the development of comprehensive gene panel tests for genetically heterogeneous disorders, which are unattainable by Sanger sequencing. We have developed and clinically validated an in silico gene panel of 48 genes for hereditary spastic paraplegia (HSP) using exome sequencing. HSP represents a heterogeneous group of neurodegenerative disorders characterized by stiffness (spasticity) and progressive weakness (paraplegia) of the lower limbs, and may be associated with ataxia, intellectual disability, seizures, peripheral neuropathy, and visual defects. An accurate genetic diagnosis will reduce the number of patients who undergo serial investigations (such as multiple brain MRIs) or invasive investigations (such as muscle biopsy) in an attempt to establish a diagnosis. Confirmation of a genetic diagnosis is essential for comprehensive testing and genetic counseling for at-risk family members, and will make possible the availability of prenatal testing for at-risk couples. The previous strategy in the Molecular Diagnostic Lab has been to perform Sanger sequencing for nine genes with a diagnostic yield of ~ 44% (Yoon et al. 2013 Neurogenetics. 14:181-8). With implementation of exome sequencing we are able to widen our scope to all 48 genes known to be associated with HSP, and can readily expand the diagnostic panel as new HSP-related genes are discovered. This strategy also facilitates the development of additional disorder-specific gene panels with the same standardized workflow. We evaluated the performance characteristics of our exome sequencing workflow, and found high reproducibility and accuracy, with 100% detection of HSP genetic variants in our validation samples. We also explore the advantages and technical challenges of this strategy to further develop clinically relevant gene panels for genetically heterogeneous disorders.

2466M

Exome-based Neurological Region of Interest Assay for Identifying Pathogenic Sequence Variants. *J. Thompson[1], W. Gillett[1], R. Lopez[1], J. Luchetti[1], P. Milos[1], P. Park[2], Y. Shen[1], N. Vena[1], T. Yu[1].* 1) Claritas Genomics, Cambridge, MA; 2) Harvard Medical School, Boston, MA.

Identification of the genetic basis for neurological disorders is made difficult by the large number of genes that can lead to such phenotypes. Further exacerbating the situation is the highly variable presentation different mutations in the same genes can show. These issues make it challenging to decide which gene(s) to analyze in detail for proper diagnosis. Sequencing individual candidate genes frequently results in a frustrating cycle of negative results that is both time consuming and expensive. Gene panels currently available typically look at dozens of genes at a time but these are difficult to maintain given the complex phenotypes observed in neurological disorders and rapid pace of new gene discovery. To circumvent these issues, Claritas developed an approach utilizing complementary sequencing technologies to analyze the exons and adjacent intronic sequence from an exome-based region of interest. This ROI includes hundreds of genes previously demonstrated as causal in a variety of neurological disorders. The phenotype-driven set of genes makes analysis faster and more economical than analysis of a whole exome and also minimizes the challenges of presenting incidental findings. By taking advantage of the power of combining the knowldedge of clinical symptoms with the scale of massively parallel sequencing technology, patients are able to benefit with more directed and rapid results. DNA variants from the two platforms are compared to confirm novel pathogenic variants. In cases where coverage is missing on one of the platforms, possibly pathogenic variants are confirmed using Sanger sequencing. Confirmed variants are then analyzed by a team of medical directors and genetic counselors to determine clinical relevance with results reported back to physicians and patients.

2467T

RYR1 [Arg2454His] gene mutation identified in a family associated with malignant hyperthermia - an undergraduate research project. *J. Li, D. Caporale.* Biology, University of Wisconsin-Stevens Point, Stevens Point, WI.

Malignant Hyperthermia (MH) is a rare life-threatening dominant disorder that causes extreme fever, muscle rigidity, acidosis, and rapid heart rate, when exposed to general anesthesia. Researchers have previously identified four amino acid replacement mutations on the RYR1 gene in MH patients: [Arg44Cys], [Arg533Cys], [Val2117Leu] and [Arg2454His]. The RYR1 gene, located on chromosome 19, codes for membrane proteins on the surfaces of muscle cells that regulate calcium flow, which is essential for muscle contraction and relaxation. These mutations can cause symptoms of MH because they cause significant changes in the structure of the calcium channel proteins, rendering them nonfunctional. The purpose of my undergraduate research study was to screen for the aforementioned four point mutations of the RYR1 gene that may be the cause of MH in a German family that has an individual with this disorder and to identify family members that carry the mutation. With IRB approval, 15 participants filled out a survey describing whether or not they have experienced any signs of MH. DNA was extracted and purified from 10 hair follicles each. The four segments of the RYR1 gene were amplified in separate reactions by the polymerase chain reaction (PCR), cycle-sequenced using dye-labeled dideoxyterminators, and then separated by capillary electrophoresis. The DNA sequences of the family members, represented as electropherograms, were compared to a wild type DNA sequence provided by NCBI GenBank in order to detect the presence of any of the four point mutations mentioned above. Sequence comparisons revealed that four family members tested positive for the Arg2454His mutation. These findings correlated with all four experiencing symptoms of MH. A recommendation was made to family members to be screened for the RYR1 [Arg2454His] mutation, to verify these results. Currently, there are only two genotyping companies in the U.S. that provide genetic testing of the RYR1 gene, which is very costly. However, since the specific mutation has been identified, family members would only need to have their DNA screened for this mutation, which would help lower costs considerably.

2468S

An exome sequencing strategy to diagnose lethal autosomal recessive disorders. *S. Ellard[1,2], E. Kivuva[2], P.D. Turnpenny[2], M. Parker[3], A.-M. Bussell[2], K. Stals[2], R. Caswell[1], H. Lango Allen[1].* 1) University of Exeter Medical School, Exeter, United Kingdom; 2) Royal Devon & Exeter NHS Foundation Trust, Exeter, United Kingdom; 3) Sheffield Children's Hospital, Sheffield, United Kingdom.

Rare disorders resulting in prenatal or neonatal death are genetically heterogeneous. Some affected fetuses can be diagnosed by ultrasound scan but often not until mid-gestation and limited fetal DNA may be available. We used a strategy for diagnosing autosomal recessive lethal disorders in non-consanguineous pedigrees with multiple affected fetuses. Exome sequencing identified genes with rare heterozygous non-synonymous coding or splicing variants in both parents and putative mutations were tested for co-segregation. In 8 couples of European ancestry we found on average only one gene where both parents were heterozygous for different rare potentially deleterious variants. A proof of principle study detected heterozygous DYNC2H1 mutations in a couple whose 5 fetuses had short rib polydactyly. Prospective analysis of three couples with multiple pregnancy terminations for presumed autosomal recessive fetal malformations identified RYR1 mutations c.14130-2A>G and p.Ser3074Phe in one couple, GLE1 mutations p.Arg569His and p.Val617Met in the second couple and MRSP22 mutations p.Arg170His and c.878+1G>T in the third. All six affected fetuses were compound heterozygous for the respective mutations, providing molecular genetic diagnoses consistent with the fetal phenotypes. This highlights the difficulty of diagnosis as neither RYR1, GLE1 nor MRSP22 had been considered as candidate genes. Exome sequencing of parental samples can be an effective tool for the diagnosis of lethal recessive disorders in outbred couples enabling management for future pregnancies.

Molecular diagnosis of congenital hyperinsulinism improves medical management and long-term outcome. *G. Alkorta-Aranburu, A. Knight Johnson, L. Ma, V. Nelakuditi, S. Das, D. del Gaudio.* Human Genetics, University of Chicago, Chicago, IL., USA.

Congenital hyperinsulinism (CHI) is the most common cause of persistent hypoglycemia in children, which if unrecognized, may lead to severe brain damage. A prompt diagnosis and initiation of appropriate treatment is essential to prevent long-term neurological complications. Over the past 20 years there has been remarkable progress in understanding the molecular basis of hyperinsulinism (HI) and mutations in ten genes are currently known to cause HI in ~50% of the cases suggesting that continuing research will identify new genes. Inactivating mutations of beta cell ATP sensitive K+ channel genes *ABCC8* (SUR1) and *KCNJ11* (Kir6.2) cause the most common and severe type of HI, which is unresponsive to diazoxide, a channel agonist. Focal HI, also diazoxide-unresponsive, is due to the combination of a paternally-inherited *ABCC8* or *KCNJ11* mutation and a paternal isodisomy of the 11p15 region, which is specific to the islets cells within the focal lesion. It is important to differentiate these two types as surgery can cure focal but not diffuse hyperinsulinism, which frequently requires pancreatectomy. Molecular genetic testing and imaging with 18F-DOPA-PET/CT can help to diagnose diffuse or focal forms of HI.

We developed a comprehensive 2-tiered testing algorithm for the molecular diagnosis of CHI to direct the clinicians along a process of exclusion, so that rarer forms of HI would only be considered once commoner and diazoxide-unresponsive forms are ruled out. Tier-1 includes mutation analysis of genes associated with diazoxide-unresponsive HI, *ABCC8*, *KCNJ11* and *GCK* for which results are obtained within a week, allowing for rapid surgical intervention if required. If a mutation is not identified in tier-1 or the patient is known to be responsive to diazoxide, a tier-2 approach that includes targeted next-generation sequencing and array-CGH deletion/duplication analysis of all ten known genes causing HI can be performed. To date, we have identified the genetic etiology in 3/19 (16%) patients studied and likely causative mutations were identified in *ABCC8*, *GLUD1* and *GCK*. Variants of uncertain clinical significance (VOUS) were also identified in 3 patients. Parental analysis will be performed to clarify mode of inheritance of the mutations and provide insights on the nature of the VOUS. Studies are also ongoing to assess the impact of genetic testing results on patients' medical management and clinical course.

Carrier Screening in the Sephardic/Mizrachi Jewish Population for Genetic Disorders with Known Founder Mutations. *X. Cai, G. Akler, L. Shi, J. Zhang, G. Diaz, L. Edelmann, R. Kornreich.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, USA.

The Sephardic/Mizrachi Jewish (SMJ) population includes descendants of Jews from Spain, Southern Europe, North Africa and the Middle East. They are a heterogeneous group defined by a combination of geography, languages and religion. Similar to the Ashkenazi Jewish (AJ) population, recurrent founder mutations associated with autosomal recessive and X-linked genetic diseases have arisen in the SMJ population due to geographic and cultural isolation. Current genetic SMJ screening panels are limited mostly due to heterogeneity. The purpose of this study was to select diseases/mutations that may be appropriate for an SMJ carrier screening panel, and to establish accurate carrier frequencies among distinct SMJ subgroups in the New York metropolitan area. A comprehensive panel of mutations was selected based on literature review regarding diseases reported among SMJ individuals. Saliva samples were collected with informed consent and screening was performed by Sequenom MassARRAY iPLEX platform on over 500 individuals including the Iraqi, Iranian, Syrian, Moroccan, Yemenite, Tunisian, Bukharian, and Egyptian communities. To explore the differences between AJ and SMJ populations, approximately 1500 AJ anonymized DNAs were also screened using the same panel, and the carrier frequencies were compared between these two groups. Forty nine autosomal recessive and two X-linked diseases were selected for screening, including 130 mutations from 51 genes. Four diseases were determined to have a high carrier frequency (>1%), including hereditary inclusion body myopathy 2 (~1 in 10), phenylketonuria (~1 in 20), familial mediterranean fever (~1 in 25) and Wolman disease (~1 in 30). Six diseases had a low carrier frequency (<0.5%), including retinitis pigmentosa 28, Costeff disease optic atrophy, and glycogen storage disease type II with carrier frequencies of about 1 in 250. Acute infantile liver failure, retinitis pigmentosa 25 and glycogen storage disease type III all had lower frequencies of approximately 1 in 500. Several of these mutations are also recurrent in the AJ population. These findings suggest a set of candidate disorders with carrier frequencies high enough to be considered for inclusion in a prenatal SMJ carrier panel.

2471S

Clinical whole exome sequencing in a group of pediatric heterogeneous disorders: Yield and new gene discoveries. *J. Gauthier[1], I. Thiffault[1,2], JF. Soucy[1,2], FH. Hamdan[3], P. Campeau[2,3], M.E. Samuels[3, 5], E. Lemyre[2], A.-M. Laberge[2], C. Brunel-Guitton[2], S. Nizard[2], G.A. Mitchell[1, 2,3], G.A. Rouleau[1,4], JL. Michaud[1,2,3].* 1) Medical Biological Unit, Molecular Diagnostic Laboratory, Sainte-Justine University Hospital Center, Montreal, QC, Canada; 2) Division of Medical Genetics, Department of Pediatrics, Sainte-Justine University Hospital Center, Montreal, QC, Canada; 3) CHU Sainte-Justine Research Center, Montreal, Quebec, Canada; 4) Montreal Neurological Institute and Hospital, Montréal (Québec), Canada; 5) Department of Medicine, Université de Montréal, Montreal (Quebec), Canada.

It is now increasingly recognised that whole-exome sequencing (WES) is a useful diagnostic approach for the identification of disease mutations responsible for various genetic disorders but the yield of WES and the optimal methodology for its use in the clinic are not well defined. In the process of implementing WES in a clinical setting in a universal health care system, CHU Sainte-Justine, a Mother and Child University Hospital Center (Montreal, Quebec, Canada), recently launched a WES pilot project for individuals with rare conditions, unexplained despite extensive investigations. A total of 96 patients, mainly children, were recruited from genetics clinics for whom WES was performed and analysed. For patient recruitment, priority was given to clinical presentations known to have great genetic heterogeneity. We focused on rare variants known/strongly predicted to alter gene function in genes previously associated with monogenic disorders. To date, the overall diagnostic yield in 70 patients with completed analysis is 36% (25/70). It is 37% (18/49) for patients with global developmental delay / intellectual disability, 33% for other patients representing a heterogeneous group of diseases (skeletal dysplasia, retinopathy, deafness, neurodegenerative diseases, etc.). We did not identify any incidental findings but we fortuitously discovered strong candidate genes for several conditions, including Megacystis-microcolon intestinal hypoperistalsis syndrome (MYH11), congenital myopathy (PAX7) and mitochondrial diseases (TRNT1). Therefore, we conclude that our clinical WES approach is associated with a high diagnostic yield.

Towards the development of a standardized analytical pipeline for clinical whole genome analysis for rare disease diagnosis. *R.K. Iyer[1], A. Khromykh[1], D. Richards[2], G. Eley[1], S. Scott[2], B.D. Solomon[1], J.G. Vockley[1], J.N. Niederhuber[1].* 1) Inova Translational Medicine Institute, Inova Fairfax Hospital, Falls Church, VA; 2) QIAGEN Silicon Valley, Ingenuity Systems Bioinformatics, Redwood City, CA.

For many children with rare, potentially genetic syndromic disease, a clear diagnosis remains elusive, and the diagnostic odyssey continues. The successful application of whole exome or whole genome sequencing (WES/WGS) in causative gene discovery for rare Mendelian disease has the potential to vastly reduce or eliminate such situations. A very significant barrier to the routine clinical use of WES/WGS is the lack of standardized, validated and repeatable and scalable bioinformatics solutions that can facilitate the rapid annotation, filtering and classification of the large number of potentially biologically relevant variants detected by these technologies. We are currently evaluating QIAGEN's new evidence-based clinical decision support software, Ingenuity Clinical, as a potential solution for clinical interpretation and reporting by analyzing a set of whole genome data generated on 30 family trios centered on probands, afflicted with severe congenital malformation(s) that are not consistent with a known clinical diagnosis. There is no clear family history of disease, and standard genetic testing was negative. The Ingenuity Clinical software platform classifies variants using draft ACMG 2.0 assessment guidelines based on a pre-curated knowledge base of biomedical literature and clinical evidence that allows standardized and scaled annotation, filtering, classification and reporting of observed clinically relevant variants. For cases in which a genetic cause for disease is suspected based on family history, but no causal variant has been previously identified, we use QIAGEN's Ingenuity Variant Analysis to identify gene variants that may perturb biological pathways/networks upstream of known causal genes in described cases with overlapping phenotypes. Initial analysis, biological interpretation and clinical assessment of variants through these Ingenuity platforms has unequivocally identified a mutation in one proband that is clearly consistent with the clinical presentation, and facilitates a diagnosis in this patient. Initial analysis of several other cases indicates good candidates in all of them, but further assessment is required to determine their validity. The analyses on all 30 probands continue and findings will be presented.

Kohane[1, 2].* 1) Health Sciences and Technology, Harvard-MIT, Cambridge, MA; 2) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 3) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Cambridge, MA; 4) Department of Pathology, Harvard Medical School and Massachusetts General Hospital, Boston, MA; 5) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 6) Laboratory of Molecular Cardiology, Department of Cardiology, the Heart Centre, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark; 7) Division of Cardiovascular Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 8) Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, MA.

BACKGROUND—Risk stratification for hypertrophic cardiomyopathy (HCM) is an exemplar of the clinical gains attainable by targeted genetic testing. After decades of research, sequencing laboratories now identify a causal mutation in over one third of referred patients. Using these findings, clinicians routinely assess risk for the patient's relatives and may even tailor therapy for rare patients. However, the clairvoyance offered by genetic testing comes with a cost—when variants are misclassified, there is potential for harm. METHODS—Using publicly accessible large-scale exome data, we identified variants previously considered causal of HCM that were overrepresented in the general population. We studied these variants in diverse populations using complementary sequencing data, and reevaluated their initial ascertainments in the medical literature. We reviewed patient records at a leading genetic testing laboratory for all occurrences of these variants during the near decade-long history of the laboratory. RESULTS—Multiple patients, notably all of African or unspecified ancestry, received incorrect positive reports of variants classified as "pathogenic" or "presumed pathogenic" and later revised to "benign." All identified variants were significantly more common in African Americans than European Americans ($P < 0.001$). We show that if moderately diverse control sequencing data had been available to test previous pathogenicity assertions, these variants would likely have been classified sooner as benign, possibly avoiding multiple misclassifications in African-ancestry individuals and their families. We identify issues in the ascertainment process that may have led to these errors in the medical literature. CONCLUSIONS—Diverse population data can be used to identify ancestry informative yet clinically uninformative markers. These findings expand upon current guidelines, which recommend using ethnically matched controls to interpret variants. As diverse sequencing data becomes more widely available, we expect variant reclassifications to increase, particularly for groups that have historically been less well studied.

2474S

Prevalence of variants of unknown significance in a next-generation sequencing panel: an experience with autism spectrum, intellectual disability, and dysmorphic features disorders. *M. Nelson, J.E. Williamson, J.J. Evans, J.A. Carstens, E.E. Kaspar, E.J. Rief, J.L. Berry, A.C. Carter, D.L. Bishay, R.L. Barbar, J.N. Sanmann, B.J. Dave, R.T. Hagelstrom, W.G. Sanger.* Human Genetics Laboratory, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

Accurate interpretation of genetic test results to assess the phenotypic effects of genomic variants is necessary for effective patient management. Frameshift, nonsense or canonical splice site changes that yield a truncated protein product are more likely to represent deleterious variants with stronger association to disease phenotype; whereas, missense and intronic changes more often lack clinical and functional data for classification as either pathogenic or benign. Genetic test results identifying a pathogenic or likely pathogenic variant are characterized as 'positive'; those identifying variants of unknown clinical significance (VUSs) are 'inconclusive'; and those with only benign or likely benign (LB) variants are generally considered 'negative'. We analyzed the frequency of VUSs and LB changes and the specific genes and regions involved in more than 150 patients referred for a 49 gene next-generation sequencing autism/intellectual disability/multiple anomalies (A/ID/MA) panel. Approximately 1/3 of the patients had at least one VUS and more than 1/2 had at least one LB variant. While the majority of VUS and LB variants were non-recurrent and/or missense changes, greater than 30 % were represented by only 4-6% of the genes included in the panel (e.g. *KMT2D* [MIM 602113], *SHANK2* [MIM 603290], *ERCC6* [MIM 609413], *ASPM* [MIM 608716]). Within these genes, clusters of VUSs and LB variants, some within protein domain structures, were present. Fewer than 7% of patients with VUSs or LB variants had identifiable pathogenic or likely pathogenic changes. Expanding our understanding of VUSs and LB variants in A/ID/MA disorders will facilitate their reclassification. Consequently, this will increase specificity of the tests and reduce the burden resulting from information of unknown significance on the physicians, genetic counselors and patients.

Comprehensive Analyses of Causative Variants in Hereditary Nephrotic syndrome (NS) in Children: Frequency, Clinical Utility and Phenotype- Genotype Correlation. *F.E. Orkunoglu-Suer, M. Meservey, M. Jaremko, M. McCarthy, V. Storozuk, C. Hoffman, K. Liaquat, J. Lapierre, W. Zhenyuan, S. Batish, J.J Higgins.* Quest Diagnostics, Athena Diagnostics Inc, Worcester, MA., US.

Background: Hereditary nephrotic syndrome (HNS) is a genetically heterogeneous disorder representing a spectrum of inherited renal diseases that cause podocyte anomalies and resultant proteinuria. Mutations in the *NPHS1, NPHS2, WT1, PLCE1, and LAMB2* genes cause the onset of HNS in neonates, infants, and children, with progression to end-stage renal disease in later life. The relative frequencies of causative gene variants in children with HNS are unknown. **Methods:** We analyzed the frequencies of pathogenic variants (PVs) and variants of unknown significance (VUS) in a targeted panel of five genes in 273 patients referred to a clinical laboratory for HNS testing. Mutation analysis was carried out by direct sequencing of the *WT1, LAMB2, NPHS1, NPHS2, and PLCE1* genes in all cases. The study included 10 prenatal samples, samples from various childhood age groups (82 neonatal, 146 infant, 16 child), and 15 syndromic cases that were consecutively submitted. **Results:** Sequence variants (total 100 PV, 188 VUS) were detected in 159 patients. Variants were most frequent in the *NPHS1* gene (50 PV, 82 VUS), followed by the *PLCE1* gene (14 PV, 12 VUS). Variants were less frequent in the WT1 (15 PV, 14 VUS), NPHS2 (17 PV, 11 VUS), and *LAMB2* (4 PV, 42 VUS) genes. VUS were found in multiple genes in 26 cases. **Conclusions:** An analysis of 273 samples submitted for HNS testing shows that over half have variants of interest. This study confirms the clinical value of genetic testing for HNS using this panel.

2476T

Targeted Gene Panel for Diagnosis of Nephrotic Syndrome in Pediatric Patients. *J. Rousseau, L. Ambrogio, A. DiLucia, S. Hintzen, M. Kennedy, E. Mauceli, P. Milos, S. Reilly, T. Ross.* Claritas Genomics, Cambridge, MA.

The prevalence of idiopathic nephrotic syndrome (NS) is approximately 16 cases per 100,000 individuals. Recent studies show that much of the observed disease incidence can be accounted for by mutations in just 29 genes, most of which are expressed in the kidney and which play a variety of biological roles. Until recently, children with NS, steroid-resistant NS (SRNS), proteinuria, and focal segmental glomerulosclerosis (FSGS) underwent sequential, gene-by-gene testing because there were no clinical tests that simultaneously assessed mutation load across the multiple genes involved in these closely-related disorders. To allow for more rapid and cost-effective diagnosis of these patients, we validated an assay that allows detection of mutations in all exons and adjacent intronic sequences of the 29 genes most commonly found mutated in these disorders. This panel is expected to identify disease-causing mutations in 15% of cases that have a general diagnosis of chronic kidney disease and will offer a significantly higher detection rate for children with proteinuria specifically. Ordering guidance for the assay is thus based on a relatively straightforward phenotypic presentation of high protein levels in the urine, and given the panel's speed, clinical providers can now bring treatment options to their patients more quickly than with previous testing options.

2477S

A novel *EDA* splice site mutation cause hypohidrotic ectodermal dysplasia in a heterozygous female with severe phenotype. *C. Weng[1], T.Y Wei[1], F. Jin[4], P. Yu[1], M. Qi[1,2,3].* 1) School of Medicine, Zhejiang university, Hangzhou, China; 2) James D Watson Institute of genome Sciences, Hangzhou, China; 3) Department of pathology and laboratory Medicine, University of Rochester, NY, USA; 4) Department of Reproductive Endocrinology, Women's Hospital, School of Medicine, Zhejiang University, Hangzhou, China.

Hypohidrotic Ectodermal dysplasia (XHED[MIM 305100]) is a type of X-linked genodermatosis characterized by the abnormal development of sweat glands, teeth and hair. Our study aims to characterize the pathogenesis of a heterozygous female diagnosed with typical HED at molecular level. The proband underwent complete physical examination. Mutation screening was performed by Sanger sequencing on associated genes. In silico analysis was used to predict putative effect of the identified mutation, and in vitro exon trapping assay to analyze mutant transcript processing. PCR-based human androgen receptor gene assay (HUMARA) was applied to study the skewed X chromosome inactivation pattern. A novel mutation c.925-2A>G at the end of intron 7 of *EDA* gene(MIM 300451) was identified. This mutation is expected to influence the function of that splicing acceptor. The exon trapping assay indicated the first 32 bp sequence of exon 8 had been skipped abnormally in the splicing process. The resulted premature stop codon truncated 71 amino acid including the tumor necrosis factors (TNF) domain at C-terminal-end. This may lead to the deformation of the inner anti-parallel β-strand, weakening the hydrophobic interfaces and losing a number of hydrogen bonds. X chromosome HUMARA assay for the affected proband and her mother of proband, who is also a mutation carrier but with normal phenotype, showed an obvious skewed X chromosome inactivation pattern. Conclusion: A splice site mutation resulting in partial exon skipping was found in a typical hypohidrotic Ectodermal dysplasia patient. The mutation probably leads to a truncated protein with part of C-terminal skipping out, affecting the interaction properties of the *EDA* protein. The skewed X chromosome inactivation pattern is associated with the severity of the phenotype.

2478M

Follow-up of the first 250 clinical WES cases: periodic re-analyses revealed additional molecular diagnoses. *Y. Yang[1], F. Xia[1], R. Person[1], N. Niu[1], M. Leduc[1], J. Beuten[1], D.M. Muzny[2], S.E. Plon[1], J.R. Lupski[1], A.L. Beaudet[1], R.A. Gibbs[1,2], C.M. Eng[1].* 1) Dept Molec & Human Gen, Baylor College of Medicine Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine Houston, TX.

We recently reported clinical whole exome sequencing (WES) results for the first 250 unrelated patients received between October 2011 and June 2012 (Yang, et al NEJM 2013;369:1502). The patients mostly had neurological manifestations suggesting potential genetic etiology but no definitive diagnosis could be rendered despite extensive workups. Molecular diagnoses by WES were made in 62/250 patients (25%), including 4 patients with 2 molecular diagnoses resulting in blended phenotypes. The initial 25% diagnostic rate was higher than several other comparable physician ordered genetic tests including chromosomal microarray analysis and most targeted gene tests. Further, more diagnoses from the existing WES dataset are expected as new disease genes are published. We have been following up the 250 cases since the completion of the clinical reports in 2012 by performing re-analyses of the original WES variants every six months using a list of newly published disease genes. This effort, which was free of charge, resulted in additional molecular diagnoses in 4 AD disorders (genes: *AHDC1*, *ASXL3*, *KCNT1*, *KMT2A*), 2 AR disorders (genes: *SERAC1*, *SFXN4*) and 2 X-linked (XL) disorders (gene: *WDR45*, seen in 2 unrelated patients). In addition to findings in new disease genes, molecular diagnoses were also confirmed in 2 more cases by add-on parental studies and phenotype correlations. The follow-ups improved the WES diagnostic rate from 25% to 28% by adding 10 more diagnoses. Interestingly a case previously reported to carry a *de novo* truncating mutation in *ANKRD11* was now found to carry an additional *de novo* truncating change in a new disease gene *AHDC1*, making this case the fifth case with two diagnoses out of the 250 samples. It should be noted that the current process, which focused on truncating mutations and only considered missense changes with compelling evidence, was not a full-scale re-analysis. Nevertheless, every new diagnosis required ~ 2 hours on activities such as literature review, inheritance pattern and disease mechanism verification, phenotype and data evaluation, report update and communication with referrals. There is also significant time spent on evaluating and later ruling out other candidate cases. For a full-scale re-analysis, more automation is needed and the test may be offered for a fee. In our laboratory, WES patients without a clinical diagnosis were also offered the option of entering research studies for novel disease gene discoveries.

2479T

Identification of 290-bp deletion as a first report on the beta- globin gene in South of Iran. *M. Hamid[1], GH. Shariati[2], L. Dawoody Nejad[1], H. Galehdari[2], AH. Saberi[2], B. Kaikhaei[3], M. Mohammadi -Anaei[2].* 1) Department of Molecular Medicine, Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Iran; 2) Narges Medical Genetics & PND Laboratory, No. 18, East Mihan Ave, Kianpars, Ahvaz ,Iran; 3) Research Centre of Thalassemia and Hemoglobinopathies, Ahvaz Jundishapur University of Medical Sciences, Ahvaz, Iran.

In this study we describe the first report of 290-bp deletion (c.-176_92+25del) in four individuals from three unrealated families in Khuzestan province with Arabic ethnic background. They were referred for carrier detection as part of a national program for the prevention of thalassemia with anysocytosis, microcytosis and hypochromia. All the Individuals had elevated Hb A2 and normal HbF levels. One of the individual, Offspring of K.B, was 5 years old girl inherited both defects from her parents. Physical examination of this patient showed paleness, slightly hepato- and splenomegaly and she was not transfusion dependent. The 290 bp deletion characterized by DNA sequencing and MLPA test. The deletion removes the promoter region, the entire exon 1 and 5 end of IVS-1. The MLPA results confirmed the deletion by probs ranging from prob 21(Promotor) to prob 1(HBB intron 1). Diagnose of this β-thalassemia deletion can be extremely useful for prenatal diagnosis in the couple especially in the consanguineous and ethnic marriage.

2480S

PCR-based method for complete HLA gene sequencing and capture-based method for entire HLA region sequencing. *K. Hosomichi, I. Inoue.* Division of Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan.

Human leukocyte antigen (HLA) is a group of genes that are extremely polymorphic among individuals and populations and has been associated with more than 100 different diseases and adverse drug effects. HLA typing is accordingly an important tool in clinical application, medical research, and population genetics. To date, several high-throughput HLA typing methods using next-generation sequencing (NGS) have been developed. We have previously developed a phase-defined HLA gene sequencing method using the MiSeq sequencer. Our sequencing protocol and pipeline provided essentially complete phase-defined HLA gene sequences without referring IMGT/HLA database; however, it required complicated and labor-intensive workflows especially in the library preparation step. Most importantly, the method was not well adapted for processing multiple samples. Here, we developed a Bead-based Normalization for Uniform Sequencing (BeNUS) procedure using three steps of bead purification. BeNUS can easily and precisely normalize the molar concentrations of up to 96 samples. We applied long-range PCR to amplify *HLA-B* for 96 samples followed by transposase-based library construction and 300 bp paired-end sequence reads with the MiSeq. After sequencing, we observed low variation in read percentages (0.2% to 1.55%) among the 96 demultiplexed samples. On this basis, all the samples were amenable to haplotype phasing using our phase-defined sequencing method. Our HLA sequencing method optimized for 96 multiplexing samples is highly time and cost effective and is especially suitable for automated multi-sample library preparation and sequencing. In addition, we established a sequence capture method for the 3.8 Mb entire HLA region for sequencing and targeted-bisulfite sequencing to detect genetic (SNVs, small and large indels) and epigenetic (methylation variable positions) information together with the HLA haplotype map information. Only one capture step was enough to prepare the two different types of libraries, targeted sequencing and targeted-bisulfite sequencing, for 12 samples as a pooled sample. After one MiSeq run of 350 bp + 250 bp paired-end reads, more than 97% of the target region was covered by at least 20-fold in all samples, although the variation in read percentages among 12 samples was observed as 4.8% to 11.5%. Our future plan is to set these methodologies for practical application of medical research and clinical application.

Identifying disease causing variants ranging from SNVs, small InDels, single exon to whole gene deletions in the RB1 gene through a single NGS-based test. *D.L. Abramovitz[1], S. Agarwal[2], A.U. Mannan[2], A.J. Pandian[3], R. Gadkari[2], R. Ramalingam[2], S. Sankaran[2], V. Veeramachaneni[2], P. Ramamoorthy[2], R. Hariharan[2].* 1) Strand Genomics, San Francisco, CA; 2) Strand Centers for Genomics & Personalized Medicine, Bangalore, Karnataka India; 3) Vision Research Foundation, Sankara Nethralaya, Chennai, Tamil Nadu, India.

Introduction - NGS (next-generation sequencing) based tests provide clinical diagnostic labs with an attractive alternative to the traditionally employed sequential testing strategies. With the right combination of test design and analysis tools a single NGS test can identify genetic abnormalities arising from single nucleotide variations (SNVs) and structural variations (SVs) including small and large indels and copy number variations (CNVs). At Strand Centers for Genomics and Personalized Medicine, we have run hundreds of diagnostic tests ranging from whole exome to disease specific panel based NGS tests. We illustrate the clinical utility of combining efficient panel based tests with the right analysis tools in providing quick and economic diagnosis in a representative set of retinoblastoma cases. **Materials and Methods** - The samples were tested using either Illumina's TruSight Cancer panel (consisting 94 genes) or our custom designed Eye Disorders panel. In both panels, the RB1 gene is included. Paired end sequencing was done to an average coverage of >100X, the analyses were done using AVADIS® NGS software and StrandOmics™ was used for the interpretation and reporting of the variants. **Results** - We were able to provide a positive diagnosis in all retinoblastoma cases identifying the causative variants ranging from SNVs to small deletion to whole gene deletion. Performing CNV analysis using normalized read depths and z-scores from all samples previously run on the panel, we are able to pick up statistically significant changes causing heterozygous deletion of the whole RB1 gene as well as the deletion of a single exon of the gene. This NGS based method was more sensitive than FISH (fluorescence in situ hybridization) in identifying deletions. As in one case, previous analysis by FISH had identified a 13q14 deletion, however the NGS test revealed a heterozygous splice site variation as the causative variant. **Conclusions** - With the combination of panel based sequencing, AVADIS® NGS and StrandOmics™, we illustrate the ability to quickly identify disease causing variants which range from SNVs to whole gene deletions. These methods can be extended to other multi-gene diseases where sequential testing could cause significant delays in diagnosis.

Diagnoses by Clinical Exome Testing Suggest Wider than Expected Phenotypic Spectra on New Disease Genes: Implications for Choosing Testing Strategy and Interpretation of Results. *F. Xia[1], E.P. Simpson[2], C.W. Brown[1], M.F. Wangler[1], J. Zhang[1], M.S. Leduc[1], Z. Niu[1], R. Person[1], D.M. Muzny[1], A.L. Beaudet[1], R.A. Gibbs[1], C.M. Eng[1], Y. Yang[1].* 1) Baylor College of Medicine, Houston, TX; 2) Houston Methodist Hospital, Houston, TX.

Recently discovered disease genes account for a significant portion (~25-30%) of diagnoses made by clinical WES. However, some of the new genetic disorders do not have characteristic symptoms and the phenotype spectra are yet to be expanded with additional studies. The lack of knowledge and recognition in disease phenotypes can pose a challenge in making clinical diagnoses and choosing specific genes for testing, which is illustrated here with two examples. 1) Within two years, a previously asymptomatic 40 year-old female progressed to dysphagia, loss of speech, spastic quadriparesis and became non-ambulatory. WES detected a heterozygous p.A781V variant in *CSF1R*, which was recently associated with hereditary diffuse leukoencephalopathy with spheroids (HDLS). The same variant had been reported to be segregating with disease in multiple affected members of a different affected family. The age of onset and clinical presentation of HDLS is highly variable and its associated phenotypes overlap with at least 17 other genetic disorders. The deceased father and two paternal cousins of our proband were clinically diagnosed with Alzheimer, cerebral atrophy and Parkinson diseases respectively. In light of the molecular diagnosis in the proband, it is possible that those affected relatives had the same disorder. 2) A 6 year-old male had a normal growth history followed by sudden deceleration. He has additional clinical features including autism, intellectual disability, hydrocephalus, macrocephaly with frontal bossing, and a small cyst in the parieto-occipital region by MRI. By WES, a *de novo* p.Q882X pathogenic variant in a new disease gene *AHDC1* was detected. Four cases of *AHDC1*-related disease had been previously reported and each shared features of hypotonia, intellectual disability, expressive language disorder and global developmental delay. This proband showed a different regression pattern on growth, relatively normal muscle tone, and was cognitively more challenged than previous cases. Our experience indicates WES is particularly effective in making rapid diagnoses soon after disease genes are discovered. Further delineation of disease phenotypes and potential expansion of phenotypic spectra will require careful examinations of aggregated WES data and close collaborations between the diagnostic labs and referring physicians in order to distinguish causal from chance correlations between disease gene and phenotype.

Comprehensive Evaluation of Congenital Immunodeficiency by Next Generation Sequencing. *E.B. Gorman[1], H. Yu[1], S. Chen[1], A. Mangubat[1], K. Bagley[1], J. Wang[1], K.E. Berge[2], H. Sorte[2], J.R. Lupski[1], J.S. Orange[3], L.F. Forbes[3], I.C. Hanson[3], A. Stray-Pedersen[3], V.W. Zhang[1], L.J. Wong[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, United States; 2) Department of Medical Genetics, Oslo University Hospital, Norway; 3) Center for Human Immunobiology, Immunology Allergy Rheumatology, Texas Children's Hospital, Feigin Center, 1102 Bates, Suite 303, Houston, TX, United States.

Background: Congenital immunodeficiency is an inherited disorder of the immune system. Severe combined immunodeficiency (SCID), characterized by profound deficiencies of T cells and/or B cells at the time of birth, is the most severe form of congenital immunodeficiency. If not treated promptly, affected patients usually do not live beyond infancy due to severe, recurrent infections. Genetic heterogeneity of SCID frequently delays the diagnosis, which is crucial for life-saving treatment and optimal management. Methods: All targeted exons and at least 20 bp of flanking genomic sequences of 46 genes involved in SCID are enriched using SeqCap EZ solution-based capture and are subjected to Massively Parallel Sequencing (MPS) on Illumina HiSeq2000. Results: The target gene capture/MPS provides an average coverage of 1000X. Exons with insufficient coverage (<20X) or high sequence homology (pseudogenes) are complemented by PCR/Sanger sequencing using gene-specific primers to ensure the 100% coverage of all targeted regions. In a pilot study, deleterious mutations were detected in fourteen out of seventeen patients analyzed (82%). Identified mutations include compound frameshift mutations in CORO1A, a novel indel mutation in JAK3, a novel 70-bp duplication in a RNA gene, RMRP, novel missense mutations in TBX1, ZAP70, and X-linked FOXP3, as well as reported mutations in DCLRE1C and RAG1. Deep coverage of next generation sequencing revealed a c.361dupA frameshift mutation of IL7R at 82% of heterozygosity in the blood sample of a female patient. Further analysis of a buccal sample from the same patient after hematopoietic stem cell transplantation confirmed the presence of the wild-type allele at a low level (~20%), indicating possible somatic mosaicism for that patient (both in blood and in other tissue). Conclusion: High throughput deep sequencing analysis greatly increases the diagnostic yield of congenital immunodeficiency. Establishing a molecular diagnosis of immunodeficiency enables early immune reconstitution through proper treatment and guides a better management for improved long-term quality of life.

Utility of Expanded Gene Panels in Clinical Diagnostics: A Tale of a Laboratory's Experience with Two Autism Testing Panels. *R.T. Hagelstrom, M. Nelson, E.J. Rief, J.J. Evans, J.M. Carstens, J.L. Berry, J.E. Williamson, E.E. Kaspar, A.C. Carter, D.L. Bishay, R.L. Barbar, B.J. Dave, J.N. Sanmann, W.G. Sanger.* Human Genetics Laboratory, Munroe-Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

The advent of next generation sequencing (NGS) panels has become common place in clinical genetic testing strategies. Clinicians have the ability to order a single test that will interrogate tens to hundreds of genes in a time period, and at a cost, that was typical for single gene testing only a few years ago. Like all diagnostic tests, however, NGS panels should be evaluated for their clinical utility, a measurement that weighs all benefits and drawbacks of a particular test. Some general aspects of clinical utility include: analytic validity (how well the test can predict the presence or absence of a variant), clinical validity (how well the variant being analyzed is related to the presence of a specific disease), clinical utility (whether the test can provide information about diagnosis, treatment, management, or prevention of the disease), as well as the ethical, legal, and social implications (ELSI) of the test. Our laboratory has performed NGS testing for patients with autism, intellectual disability, and/or multiple congenital anomalies for several years. During this time, we have utilized two separate panels, a 49-gene panel, and then later an 86-gene panel. The larger panel increased our pathogenic variant rate by approximately 4-fold while only increasing our variants of uncertain significance (UCS) rate by approximately 1.5-fold. These results suggest that the clinical utility of the larger panel is increased over that of the smaller panel.

2485T

Important Factors in Designing Accurate and Reliable Next-generation Sequencing (NGS) Assays. *P. Mueller.* Dept NCEH/DLS/NSMBB, CDC, Atlanta, GA.

Problem: NGS applications are increasing in newborn screening (NBS), including reducing false-positives, confirming positive screens, identifying carriers, and providing timely information for appropriate initiation of treatment. NBS laboratories, commercial providers, and researchers are developing NGS assays for genes, gene panels, and the whole human exome and genome, however, there are challenges in designing accurate and reliable assays. Design and methodological challenges: New data from the GENCODE Project, an international consortium, is providing information on a large number of pseudogenes in the human genome. These pseudogenes are distributed throughout the genome and most have high homology to their parent functional genes. These data indicate that approximately 17% of the roughly 20,000 human genes have pseudogenes. The very mutations that are sought in sequencing the parent genes can be present in the normal sequence of the pseudogenes. Therefore, it is likely that false reports of mutations in the parent genes will result from these homologous regions unless appropriate methods are used. This has implications for all standard approaches to targeted, whole exome, and whole genome NGS. Additionally, special care is needed in designing 1) primers and hybrid capture arrays, 2) depth of coverage, 3) and data analysis to maximize the accuracy and reliability of NGS. Current approaches and tools: Available approaches and tools include specific long-range amplicons, software for determining primer and oligonucleotide specificity, designing appropriate coverage for the quality score used, and appropriate data trimming. Implications: New approaches are needed to improve the accuracy and reliability of NGS especially when screening newborns, children and adults, because the use of this technology in a non-symptomatic population increases the risk of a false result compared to sequencing a clinical population symptomatic or diagnosed with genetic disease.

Background: Whole-exome sequencing (WES) is a powerful tool to identify the molecular basis of clinically and genetically heterogeneous suspected Mendelian disorders. When trio-based WES strategy was preferred for gene identification, we considered proband WES as a cost-effective diagnostic strategy. **Methods:** We present a sample of 41 subjects with epileptic encephalopathy and/or severe intellectual disability (18 females and 23 males), with no diagnosis after the realization of all the conventional indicated investigations. Subjects and relatives were informed and consented for exome testing. WES was performed on index cases. We developed a standardized bioinformatic, interpretive, and validation pipelines for diagnostic WES. Variants were considered when affecting a gene referenced in OMIM as related to the subject disorder. Prioritizations of the variants lead to control familial segregation of pathogenic or probably pathogenic variants, with a maximum of 5 per subject. If no plausible variant was evidenced and if an inheritance mode could be inferred from the familial history, the whole data were considered for interpretation. **Results:** Overall, median coverage was of 86 fold and 93% of the RefSeq exons were covered at least by 10 reads. This strategy allowed the identification of 4 de novo variants (namely affecting *SHANK3*, *ARID1B*, *DYRK1A*, and *TBR1*), 2 X-linked maternally inherited variants (affecting *CUL4B* and *SLC16A2*), 2 autosomal recessive variants with consistent familial segregation (*SCN10A* and *GFER*). The diagnostic yield of this strategy was of 19% (8/41). Interpretation of the whole data in the remaining subjects lead to the identification of variants recurrently affecting *SLC13A5* gene in 2 multiplex families. Besides, candidate genes with consistent familial segregation were identified but not considered as diagnostic results. At last, anonymized pathogenic and candidate variants were uploaded on dedicated repositories (namely ClinVar, www.ncbi.nlm.nih.gov/clinvar/ and Phenome Central, https://phenomecentral.org/). **Conclusion:** In this sample, proband WES was performed as a last resort for 41 subjects. Overall diagnostic yield of this study was of 24% (10/41) and will increase with the scientific community using international repositories. Finally, a medico-economic study is being performed on this sample to evaluate this strategy's cost-effectiveness.

2487M

Whole exome sequencing in patients with intellectual disability. *M. Mila[1,2], MI. Alvarez-Mora[2,1], U. Liljedahl[3], O. Karlberg[3], L. Rodriguez-Revenga[1,2], A. Mur[4], J. Rosell[5,2], E. Guillen[6,2], M. Brannvall[3], AC. Syvänen[3], I. Madrigal[1,2].* 1) Biochemistry and Molecular Genetics Department, Hospital Clínic and IDIBAPS, Barcelona, Spain; 2) for Biomedical Research on Rare Diseases (CIBERER), ISCIII,Madrid,Spain; 3) Department of Medical Sciences, Molecular Medicine, Uppsala University, Uppsala, Sweden; 4) Servicio de Pediatría, Hospital del Mar, Departamento de Pediatría y Obstectricia de la UAB Barcelona, Spain; 5) Universitario Son Espases, Palma de Mallorca, Spain; 6) Genetic Unit, Hospital Clínico Universitario Virgen de la Arrixaca, Murcia, Spain.

Intellectual disability is characterized by substantial limitations in intellectual, functioning and adaptive behavior, diagnosed before 18 years of age. It affects 1-3 per cent of the general population with 50-60 per cent of patients remaining undiagnosed due to the great complexity and the high heterogeneity of the genetic basis. The aims of this study were: to identify mutations in known intellectual disability genes, to identify new genes responsible for intellectual disability and to provide genetic counseling to families. We sequenced 32 individuals of self-reported European ancestry from eight families presenting with moderate to severe intellectual disability using the Illumina HiSeq 2000 Sequencing System. We found four families with novel indel mutations in genes associated with intellectual disability: a compound heterozygous mutation (c.5998delCT; c.10475delAA) in the *VPS13B* gene; a deletion in the *UBE3A* gene (c.2013delG) resulting in an imprinting defect; one autosomal dominant mutation in the *DYNC1H1* gene (c.4461dupC) and one splicing mutation affecting intron 11 of the *IQSEC2* gene (ChrX:53267490_53267491delGT). We also identified two missense mutations in the X chromosome: a novel mutation in the *SMC1A* gene (c.1405C>T) and one previously described in the *OCRL* gene (c.1567G>A). In the remaining 2 families, several candidate variants were identified and require additional studies. In conclusion, these results show the high heterogeneity and difficulty in the clinical diagnosis of intellectual disability and demonstrate the high performance, reliability and cost-effectiveness of this methodology (75 per cent diagnostic success) which is now currently applied in clinical diagnosis. Acknowledements: FP7/2007-2013, grant agreement n°262055 (ESGI project) Premio discapacidad 2012 Fundació Agrupació Mutua.

Does increase in genomic microarray resolution result in increased diagnostic yield? *S. Costa, A. Krepischi, C. Rosenberg.* Genetics and Evolutionary Biology Dpt., University of Sao Paulo, Sao Paulo, Brazil.

We present data from 1,098 children with intellectual disability, obtained using different microarray platforms with increasing resolution (Table). Genomic imbalances were classified as causative (>1Mb or fulfilling criteria from Genetics in Medicine (2011) 13, 680-685) or Vous (Variants of Uncertain Clinical Significance).*

Array resolution	Patients (n)	Frequency of normal array	Total frequency of alterations	>1Mb	<1Mb causative	<1Mb Vous
44K	57	52.6%	47.4%	35.1%	10.5%	1.8%
60K	780	69.6%	30.3%	21.9%	5.1%	3.3%
180K	191	66%	34%	18.8%	5.2%	10%
850K	70	54.3%	45.7%	21.4%	4.3%	20%
Total	1,098	67.1%	32.9%	22%	5.4%	5.5%

Except for 44K platform (more stringent patient selection) we detected higher frequency of alterations with increased resolution. The difference was due to higher detection of Vous, rather than of causative variants. These results question the benefits obtained by higher resolution arrays in the diagnosis of these patients. Grants: FAPESP/CAPES.

Investigation by array comparative genomic hybridization (aCGH) in patients with syndromic retinal dystrophies: Preliminary results. *L.R.J. da Silva[1,2], F. Blanco-Kelly[1,3], N. Reyes-Rodriguez[1], C. Vélez-Monsalve[1], M.J. Trujillo-Tiebas[1], I. Sánchez-Navarro[1], A. Avila-Fernandez[1,3], R. Riveiro-Alvarez[1,3], M. Cortón[1,3], C. Ayuso[1,3].* 1) Department of Genetics, Fundación Jiménez Díaz University Hospital (IIS-FJD, UAM), Madrid, Spain; 2) Universidade de Mogi das Cruzes, São Paulo, Brazil; 3) Centre for Biomedical Network Research on Rare Diseases (CIBERER), ISCIII, Madrid, Spain.

Syndromic retinal dystrophies (SRD) are a group of inherited rare diseases with clinical and genetic heterogeneity and high disability, and great social and welfare impact. The current molecular study is complex and lengthy, with approximately 100 genes involved which make finding therapies and clinical management patients difficult. The aCGH is a technology whose implementation is allowing a change in the genetics diagnosis of various diseases. Furthermore, the investigation of amplifications, deletions and chromosomal rearrangements can detect causative factors in the intellectual disability and/or development delay associated with congenital abnormalities. The purpose of this study is to establish the molecular basis of SRD that may be caused by genomic rearrangements using aCGH technology to complete the characterization of patients. Among our cohort of SRD Spanish families, 14 unrelated cases were selected for this study. All of them had undergone previous mutation screening for genes involved in SRD and displayed intellectual disability, suggesting genomic rearrangement. Agilent SurePrint G3 human CGH+SNP microarray 2X400k was performed for all patients, followed by a custom Agilent CGH +SNP 8X60k and other techniques to confirm the results positives. Our study allowed us to preliminary characterize 4 of 14 (29%) with a suspected duplication, mechanism previously unreported for SDR. Microduplications in 1q21.1, 15q13.3, 14q24 and 11q13.2 involving genes associated with intellectual disability, neuropsychiatric disorders and retinal dystrophy were detected. No genomic rearrangement was observed in 8 (57%) patients. Furthermore large loss of heterozygosity (LOH) regions were observed in 2 additional patients (14%) on different chromosomes and different sizes (one patient showed a LOH of 17Mb and the other patient showed 8 different LOH) pointing to possible involved new genes to be further screened. Not only is this study important to help the search for new genes and pathogenic mechanisms associated with SRD, but also to provide a better prognosis and diagnosis, contributing to a appropriate genetic and reproductive counseling. Keywords: aCGH, syndromic retinal dystrophies, intellectual disability.

2490M

Retrospective comparison of SNP microarray and cytogenetics analyses of products of conception. *J.B. Schleede[1], R.D. Burnside[1], J.H. Tepperberg[1], V. Jaswaney[1], I.K. Gadi[1], H. Risheg[2], K.K. Phillips[1], A.L. Penton[1], E. Keitges[1], H. Taylor[1].* 1) LabCorp, Durham, NC., Select a Country; 2) Dynacare/LabCorp, Seattle, Washington.

Spontaneous miscarriage is a common reproductive problem that occurs in approximately 15% of all clinically recognized pregnancies. Since chromosomal abnormalities account for half of the observed first trimester reproductive failures, accurate diagnosis of chromosomal imbalance is paramount to comprehensive patient care. In this report we compare the efficacy of SNP microarray analysis to conventional cytogenetics for the identification of chromosome abnormalities associated with pregnancy loss. Conventional cytogenetic analysis of products of conception (POCs) is dependent upon tissue growth which is subject to contamination, growth failure and overgrowth of maternal tissue. We found that using microarray technology decreased failure rates from 28.7% to 1.4% and reduced the number of artifactual normal female karyotypes (71.1% female vs. 28.9% male) resulting in nearly complete balanced gender ratios. Microarray analysis also markedly improved the detection of chromosomal abnormalities (38% vs. 20% of all samples received). Another advantage over conventional cytogenetics is that SNP microarray genotyping enables the identification of normal karyotype complete moles and differentiation of digynic vs. diandric XXY triploid pregnancies. Accurate diagnosis of diandric partial moles and complete moles identifies individuals at risk of developing gestational trophoblastic neoplasia. The genotyping array also identifies the presence of maternal cell contamination, twin admixture and reveals the presence of UPD and mosaic trisomies associated with incomplete correction.

2491T

Limb-girdle muscular dystrophy 1G: how frequent are mutations in this gene? *V. Nigro[1,2], M.S. Naslavsky[3], N.M. Vieira[3,4,5,6], F. Kok[3,7], M. Vainzof[3], R.C. Pavanello[3], L.M. Kunkel[4,5,6], R. Tupler[8,9], M. Zatz[3].* 1) TIGEM & Patologia Generale, Seconda Univ di Napoli, Napoli, Italy; 2) Lab of Medical Genetics - Seconda Università di Napoli, Napoli, Italy; 3) Human Genome and Stem Cell Center, Biosciences Institute, University of São Paulo, Brazil; 4) Program in Genomics, Department of Pediatrics, Children's Hospital Boston, Boston, USA; 5) Department of Genetics, Harvard Medical School, Boston, MA, USA; 6) The Manton Center for Orphan Disease Research, Children's Hospital Boston, MA, USA; 7) Dept. of Neurology, University of São Paulo Medical School, São Paulo, Brazil; 8) Department of Science of Life, University of Modena and Reggio Emilia, Modena, Italy; 9) Program in Gene Function and Expression, University of Massachusetts Medical School, Worcester, USA.

Limb-girdle muscular dystrophies (LGMD) are a heterogeneous group of genetically determined muscle disorders with a primary or predominant involvement of the pelvic or shoulder girdle musculature. More than 30 genes with autosomal recessive (LGMD2A to LGMD2U) and autosomal dominant inheritance (LGMD1A to LGMDH) have been mapped/identified to date. We have recently identified the gene responsible for LGMD1G which had been previously mapped at 4q21 in a Caucasian-Brazilian family. Subsequently, we mapped a Uruguayan family with patients displaying a similar LGMD1G phenotype at the same locus. The inheritance is autosomal dominant, with no evidence of clinical anticipation but asymptomatic carriers were identified in both families. The initial symptoms were proximal lower limbs involvement and weakness followed by upper limbs proximal weakness. Limitation of finger and toe flexion was also a characteristic of this condition. The age of onset varied from 15 to 53 years old (36.6 ± 13.7). Interestingly, 6 out of 11 clinically affected individuals from the Uruguayan family and 2 from the Brazilian family presented cataracts with onset before age 50. None of the patients had myotonic phenomena. Muscle histological features revealed variable findings apparently related to the progression of the disease, with a mixed myopathic/neurogenic pattern. Whole genome sequencing identified, in both families, mutations in the HNRPDL gene. HNRPDL is a heterogeneous ribonucleoprotein (hnRNP) family member, which participates in mRNA biogenesis and metabolism. The coding mutations were found in the same aminoacid residue p.D378. These findings prompted us to search for mutations in a cohort of 400 Italian adult patients with a nonspecific limb-girdle presentation or facioscapulohumeral muscular dystrophy (FSHD), for which a conclusive diagnosis was not yet reached. We developed a targeted NGS analysis of the coding regions of 89 disease genes, among which the HNRPDL. We discovered two adult patients carrying new missense variants not shared by control samples or WES data. Interestingly, the variants replace Leu38Phe and Leu42Phe, but further testing is necessary to understand whether these variant may have functional impact. These data suggest that LGMD1G should have a frequency among LGMD patients <1%, in the Italian population. We are currently screening patients with LGMD or atypical FSHD to estimate the frequency of HNRPDL mutations in the Brazilian population.

An alternative method for the analysis of deletions/duplications with MLPA©using the QIAxcel© Advanced System. *S.B. Fischer[1], S. Herms[1,3], M. Attenhofer[1], K. Heinimann[1,2], I. Spier[3], S. Aretz[3], S. Cichon[1,2], P. Hoffmann[1,3].* 1) Human Genomics Research Group, Department of Biomedicine, University of Basel, Basel, Switzerland; 2) Division of Medical Genetics, Department of Biomedicine, University of Basel, Basel, Switzerland; 3) Institute of Human Genetics, University of Bonn, Bonn, Germany.

Multiplex Ligation-dependent Probe Amplification (MLPA) from MRC-Holland© is the gold standard for the detection of exonic deletions/duplications in genetic diagnostic testing. MLPA is based on a multiplex PCR, but different from a classical multiplex PCR it is a two-step process involving a hybridisation/ligation reaction for generating the amplification template as the first step. Every exon of a specific target gene is covered by one or more probe-pairs which, when both probes bind to the exon, are ligated. In the second step, the ligated probe-pairs will then be amplified and subsequently analysed using a capillary electrophoresis system. The resulting electropherogram shows a specific peak pattern for each sample. The ratio of the peak height between target and reference probes or even reference samples is used for the detection of exonic deletions/duplications. The fragment analysis is usually performed using capillary (Sanger) sequencing, which is a costly and time consuming method. In this pilot-study we present a faster and more cost effective alternative approach for the MLPA analysis by using the QIAxcel© Advanced System from Qiagen©. The QIAxcel© Advanced System is an automated DNA and RNA analyser, replacing the traditional gel analysis of DNA and RNA. For our pilot study we used two different clinical samples: a) 12 FAP (familial adenomatous polyposis coli) patients with known mutation status as well as 5 healthy controls; b) 5 HNPCC (hereditary non-polyposis colorectal cancer, Lynch syndrome) patients with known mutation status as well as 3 healthy controls. For the MLPA analysis we used the SALSA MLPA P043 APC Probemix© for the FAP samples and the SALSA MLPA P003 MLH1/MSH2 Probemix© for the HNPCC samples. The visualisation of each MLPA-generated amplification product was performed using a Sanger sequencer as well as the QIAxcel capillary electrophoresis system. Utilizing a newly developed protocol we were able to detect exonic deletion/deletions with the same resolution and accuracy as with Sanger sequencing. Based on our preliminary results using the QIAxcel Advanced system allows us to have reliable, fast and cost effective MLPA analysis.

The transformative potential of whole genome sequencing (WGS) lies in its use in individualized genomic medicine, where knowledge of an individual's genomic variants guides health care decisions throughout life, in order to anticipate, diagnose and manage disease. To pilot the implementation of genomic medicine in paediatrics we developed the SickKids Genome Clinic, a multidisciplinary test bed that supports a wide range of research into the clinical uses of WGS, from development of new bioinformatics pipelines and counselling models to health economics and bioethics studies. Our project treats an individual's genome as a source of genetic information to be repeatedly queried over time in order to manage overall health, rather than a one time test performed to diagnose a pre-existing disorder. We are recruiting 150+ children/year who are undergoing diagnostic molecular testing for suspected genetic disorders. DNA and RNA are collected from the child and both parents. Participating children undergo WGS after their parents are counselled about WGS and have declared their preferences for learning their child's pharmacogenetic variants, adult-onset secondary (incidental) medically-actionable variants and carrier status variants.

We enrolled 174 families in our first year of operation. Sequencing now has been completed for 50 children and variant analysis is underway using separate bioinformatics pipelines for primary disorder variants, structural variants, secondary variants and pharmacogenomics variants. Five of the twelve genomes analyzed to date have yielded variants that explain the presenting phenotype, four of which were not detected by the child's clinical genetic testing.

Secondary/incidental medically actionable variants are a major focus of study. ~60% of couples choose to learn their child's adult-onset and carrier variants. For those children we screen variants in >2800 disease genes listed in the NIH Clinical Genomic Database. Using stringent criteria we currently are identifying an average of 7 carrier variants and 1 medically actionable secondary variant/child for Sanger validation and subsequent return.

Our initial results support our hypothesis that WGS is superior to conventional multi-gene panels and clinical microarrays for identifying pathologic variants and can yield reportable carrier and medically actionable variants on every child.

2494T

Progress of Noninvasive Prenatal Testing (NIPT) of Mendelian disorders. *F. Chen[1], Y. Gao[1,2], H. Jiang[1], W. Xie[1], HJ. Jiang[1], J. Lu[1], XC. Li[1], W. Wang[1,2].* 1) BGI-Shenzhen, Shenzhen, Gangdong, China; 2) BGI Health, Shenzhen, Gangdong, China.

Objectives Noninvasive prenatal testing (NIPT) of Mendelian disorders has been reported as case study this year. However, most previous publications focused on sex-linked disorders and autosomal dominant monogenic diseases by assessing the fetal gender and detecting paternal inherited mutation in the maternal plasma. Only few studies showed the feasibility to detect maternal inherited mutations and practical application for autosomal recessive monogenic diseases. Our study aim to report the efficiency of a robust method of NIPT to detect sex-linked, autosomal dominant and recessive Mendelian disorders. Methods In 2012-2013 we recruited eleven families who have a proband child and genetic counseling was provided to each couple. Informed written consent was obtained from each couple. Participants as follows: 1) two families are carriers of hearing loss mutation; 2) seven families have boys with DMD; 3) one family has a 2-year old girl with maple syrup urine disease (MSUD); 4) one family with congenital adrenal hyperplasia (CAH); 5) one family with ichthyosis. Blood samples were obtained at 10-16th gestational weeks. NIPT of Mendelian disorders was performed with a haplotype-assisted strategy previously described, to determine whether the fetus is affected with the same mutation as the proband child or not. Amniocentesis was performed to get the fetal tissues and Sanger sequencing was used to confirm the results. Results Totally in five families, the fetuses were identified to inherit the same alleles as the proband. In three families, the fetal escaped from inheriting any mutations from the parents. In the rest three families, the fetal was identified to inherit the mutations either from the mother or the father. NIPT was finished in 10 days and the results were accordant with Sanger sequencing. Conclusions Noninvasive prenatal testing by maternal plasma DNA sequencing has great potential to supplement the current workflow for prenatal diagnosis of Mendelian disorders, not just for sex-linked, autosomal dominant, but also autosomal recessive. NIPT prior to invasive procedures in the second trimester will offer earlier and trustful information for the pregnant women and help to ease maternal anxiety at very early time.

Increased yield and detection of confined placental mosaicism by chromosome microarray testing of chorionic villus samples. *J. Reiner, H. Mei, N. Cohen, M. Babcock, A. Babu, S.A. Scott, L. Edelmann.* Mount Sinai Genetic Testing Laboratory, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029.

Early detection of chromosomal abnormalities and genomic imbalances remains a high priority in prenatal care. As such, first trimester chorionic villus sampling (CVS) has preferentially been performed for pregnancies with increased risk for genetic abnormalities despite the possibility of discrepancies arising from confined placental mosaicism (CPM). Although karyotype analysis historically has been the gold-standard for prenatal cytogenetic testing, chromosomal microarray analysis (CMA) increasingly is being used in conjunction with karyotyping and recently was recommended as a first-tier test for cases with abnormal ultrasound findings by the American Congress of Obstetricians and Gynecologists. To determine if the increased resolution offered by CMA influences the identification of CPM, we investigated the relative proportion of cases with confirmed CPM as well as the types of placental aberrations detected by conventional cytogenetics and CMA. In total, 4,632 chorionic villus samples were referred to the Mount Sinai Genetic Testing Laboratory from January 2010 to May 2014, and karyotype analysis, aneuploidy FISH (13, 18, 21, X and Y), and/or microdeletion FISH was performed on all cases. CMA was performed in addition to conventional cytogenetic testing on 13.8% (n=639) of these cases. The total diagnostic yield in this CVS cohort was 6.6% (n=304), which includes 21 suspected pathogenic copy number variants (CNVs) or variants of uncertain clinical significance that were detected exclusively by CMA. Of the 304 total cases with abnormal results, 45 patients (14.8%) elected to have a follow-up amniocentesis for confirmatory testing. Presumed CPM was concluded in 28 cases (62.2%), which represent 0.60% of the cohort. Importantly, eight cases of CPM harbored mosaic structural abnormalities, two of which involved confirmed interstitial CNVs detected only by CMA. Taken together, these data indicate that in addition to being able to detect submicroscopic CNVs, the increased resolution of CMA improves the detection of CPM during prenatal CVS testing. However, these data also suggest that the number of cases that require follow-up by amniocentesis may increase due to previously unidentified mosaic structural abnormalities.

Sample Identification SNP Panel for Exome, Transcriptome and Whole Genome Sequencing. *K. Duvefelt[1], A. Fungmark[1], T. Svensson[1,3], P. Magnusson[2], V. Wirta[2,3], D. Ekman[3], R. Andeer[3], J. Gruselius[3], M. Käller[3], J. Kere[1,2].* 1) Karolinska University hospital, Stockholm, Sweden; 2) Karolinska Institutet, Stockholm, Sweden; 3) Science for Life Laboratory, Stockholm, Sweden.

A panel consisting of 54 single nucleotide polymorphisms (SNPs) has been developed to enable unique identification of human samples. It will serve as a quality control step ensuring that sequence data generated in high throughput sequencing laboratories corresponds to the originally submitted sample. The panel is designed to analyze exome, transcriptome, and whole genome sequenced samples. The markers were selected based upon the following criteria: -Bi- allelic variations, excluding A-T and G-C transversions -Synonymous variants -Variants informative in the Swedish population -Analyzed successfully in HapMap CEU population -Minor allele frequency >0,3, CEU population -At least 140 bp from exon boundaries -Located towards the 3' end in coding part of transcript -Avoiding regions associated with copy number variations -Not in repetitive sequences -Not in MHC region -In regions with high sequencing coverage -Within transcripts expressed in many tissues -Eight markers for gender identification (ZFXY gene)

128 SNPs was selected using these criteria, successful design were obtained for 112 variations resulting in four pools of SNPs for the Sequenom Iplex Gold multiplex chemistry. Validation was performed on 66 samples, 44 belonged to 14 HapMap trios. Mendelian inheritance correctness, concordance with HapMap genotypes, success rate, background, HWE and robustness of genotyping scoring were evaluated. Based on this data 98 variations in four pools were selected to analyze 90 samples already high-throughput exome sequenced (Agilent Sure Select v5, Illumina HiSeq 2500 rapid run mode) as well as 64 twin samples, formerly scored for zygosity and gender, from the Swedish Twin registry. Analysis has been performed for 16 of the sequenced samples using data from 95 markers that fulfilled the quality criterias. In these variations the concordance between genotyping and sequencing was 100%. All gender markers gave concordant gender identification. Based on percent shared alleles all zygosity pairs scored correctly in the zygosity analysis as well as giving consistent gender identification. Two of the pools described which encompass 54 SNPs including three gender markers will be further used for sample identification.

Detecting copy number variations on the X chromosome in Chinese children with intellectual disability. *H. Xie[1], X.Y. Li[1,2], J. Guo[1], L.W. Wang[3], J. Wang[3], E.Z. Li[3], J.M. Zhong[2], T. Zhang[1], Y.P. Shen[4], B.L. Wu[4], X.L. Chen[1].* 1) Capital Institute of Pediatrics ,Beijing Municipal Key Laboratory of Child Development and Nutriomic, BeiJing, China; 2) Department of Neurology, JiangXi Children's Hospital, NanChang, China; 3) Department of Neurology, Affiliated Children's Hospital of Capital Institute of Pediatrics, Beijing, China; 4) Department of Laboratory Medicine, Children's Hospital Boston, Boston, MA, 02115, USA.

X-linked intellectual disability (XLID) is a genetically heterogeneous disease characterized by cognitive impairment and reduced adaptive skills. XLID is caused by copy number variants (CNVs) and single nucleotide variants (SNVs) on the X chromosome. To date, >100 XLID genes have been identified, while many more still remain unknown. In this study, seven CNVs on the X chromosome were detected from 212 Chinese children with intellectual disability using array comparative genomic hybridization (aCGH), presenting the yield of 3.3% in Chinese patient cohort. Among them, five CNVs were intellectual disability-related CNVs involving known XLID genes; three CNVs were maternally inherited and two were de novo after analyzing five available parental samples. Four known intellectual disability-related CNVs were observed segregation in the family members, including: recurrent MECP2 duplication, recurrent Xp22.31 duplication harbouring STS, Xp22.13 duplication harbouring NHS, and Xq25-26.1 deletion harbouring OCRL. A novel Xp11.4-11.23 deletion containing CASK, MAOA and KRBOX4 was detected do novo in a girl patient. The MECP2 duplication was identified in a four-generation family, in which five male ID patients and four normal females carry MECP2 duplication. The customer designed X chromosome chip and real-time quantitative PCR confirmed all nine family members carry MECP2 duplication, not MECP2 triplication. Our study promoted to identify the novel XLID genes and mechanisms involved, and showed the phenotypic and genetic heterogeneity of XLID in Chinese patients.

Miami Otogenetic Program: Implementing genomic medicine in care of patients with impaired hearing. *XZ. Liu[1,2], D. Yan[1], D. Tekin[1], M. Grati[1], S. Blanton[2], M. Tekin[2].* 1) Departments of Otolaryngology-Head and Neck Surgery, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 2) Dr. John T. Macdonald, Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL 33136, USA.

The Miami Otogenetic Program has provided a unique platform to carry out translational research on delivering genetic services to deafness patient care. Using target-enrichment/next generation sequencing (NGS), we are determining 1) the overall frequencies of different forms of genetic deafness, 2) identifying new genes for autosomal recessive non syndromic hearing loss (ARNSHL) and autosomal dominant (NSHL), and 3) creating important Genomic Deafness Database (GDD) and Personalized Sequence Profile (PSP) for the clinical care of deaf patients where data is ranked based on its clinical validity and utility. We have collected a unique cohort of multiplex families derived from three unique sources from USA, China, and Turkey, suitable for determination of molecular epidemiology of hereditary deafness and for new gene identification using "target-enrichment" methods and NGS. Our interdisciplinary and collaborative team will conduct outcome evaluation of genetic service on deafness patient care in our diversity populations. We have established the Miami Otogenetic Program including the research and the clinical components. The infrastructure of our multidisciplinary otogenetics team has being presented along with our utilization of testing algorithms when evaluating patients with sensorineural hearing loss (SNHL). We have collected DNA samples from over 800 probands from multiplex families with no mutations in the common deafness genes from the three unique cohorts. A total of 60% of small multiplex families are identified to have mutations in the known deafness genes in a pilot study and the remaining 40% have mutations in other yet-unidentified deafness-causing genes. Creation of the Genomic Deafness Database (GDD) and Personalized Sequence Profile (PSP) is in process. Using these high-throughput technologies, we have identified several new genes for non-syndromic deafness. Hearing rehabilitation and counseling of patients with genetic causes of hearing loss are provided. The combined target-enrichment/NGS and whole exome sequencing (WES) is a powerful tool in the identification of new deafness genes in small multiplex families and large multi-generational families. The multidisciplinary team approach is an effective way to bring the sequencing data to clinical practice for the clinical diagnosis and management of deaf and hard-of-hearing families.

Whole-Exome Sequencing to decipher the genetic heterogeneity of hearing loss in a Chinese family with deaf by deaf mating. *J. Qing[1,3], D. Yan[1], Y. Zhou[3], Q. Liu[1], WJ. Wu[3], ZA. Xiao[3], YY. Liu[3], J. Liu[3], LL. Du[3], DH. Xie[3], XZ. Liu[1,2,3].* 1) Departments of Otolaryngology-Head and Neck Surgery, University of Miami Miller School of Medicine, Miami, Florida 33136, USA; 2) Dr. John T. Macdonald, Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL 33136, USA; 3) Department of Otolaryngology- Head and Neck surgery, Institute of Otology, the Second Xiangya Hospital, Central South University, Changsha, Hunan, 410011, China.

Hereditary deafness is one of Mendelian diseases with a highly genetically heterogeneous trait. For many decades, linkage analysis combined with candidate genes approach have been the main tool to elucidate the genetics of hearing loss. However, this study design is costly, time-consuming and unsuitable for small families, mainly due to the inadequate numbers of available affected individuals, locus heterogeneity, as well as assortative mating. Whole exome sequencing (WES) has now become technically feasible and cost-effective method for detection of disease variants underlying Mendelian disorders due to the recent advances in next-generation sequencing (NGS) technologies. In the present study, we have combined both the Deafness Gene Mutation Detection Array and WES to identify deafness causative variants in a large Chinese composite family with deaf by deaf mating. The simultaneous screening of the 9 deafness common mutations (*GJB2*: c.35delG, c.176 del16, c.235delC, c.299-300delAT; *GJB3*: c.538C>T (p.R180X); *SLC26A4*: c.IVS7-2A>G, c.2168A>G (p.H723R); *mtDNA 12S rRNA*: c.1555A>G, c.1494C>T) in Chinese populations, using the allele-specific PCR based universal array, resulted in the identification of the c.1555A>G in the mitochondrial DNA 12S rRNA in affected individuals in one branch of the family. We then subjected the mutation-negative cases to WES and identified novel causative variants in the *MYH14* and *WFS1* genes. This report confirms the effective use of a NGS technique to detect pathogenic mutations in affected individuals who were not candidates for classical genetic studies.

2500T

Comprehensive Characterization of AML Clinical Samples Using MyAML™: A Novel AML Targeted Sequencing Strategy. *A.R. Carson[1,2], B.A. Patay[2], S.M. Graham[2], A.R. Cubbon[3,4], J.E. Miller[1,2,3,4].* 1) Invivoscribe, Inc., San Diego, CA; 2) Genection, Inc., San Diego, CA; 3) LabPMM, LLC, San Diego, CA; 4) LabPMM, GmbH, Martinsried, Germany.

While next generation sequencing (NGS) is a valuable tool in cancer genomics, most cancer panels target variant hotspots in multiple cancer types. This often compromises the sensitivity and specificity required to accurately identify low-frequency mutations in specific cancers within their clonal contexts. To mitigate this limitation, we designed MyAML™: a comprehensive and specific NGS sequencing strategy used to identify mutations in, and stratify patients with, acute myeloid leukemia (AML). MyAML utilizes oligonucleotide baits that target coding exons of 193 genes and potential genomic breakpoint hotspots within 36 somatic gene fusion partners known or predicted to be involved in AML pathogenesis. We sequenced anonymized AML patient samples from Invivoscribe's biobanks using the MyAML panel. Following DNA hybridization, target loci were sequenced on an Illumina MiSeq utilizing v3 chemistry with the 600-cycle kit to an average depth >500x. Using customized bioinformatics, we performed thorough mutation detection analyses to precisely identify and characterize single nucleotide variants (SNVs), indels, and structural variant breakpoints. We also calculated variant allelic frequencies to investigate potential aneuploidy, loss of heterozygosity and clonality. Within the AML patients, we detected known pathogenic mutations, including known and novel missense SNVs, internal tandem duplications (ITD) in *FLT3* over 300bp in size, and insertions in *NPM1*. Variants found in *FLT3*, *NPM1*, *CEBPA*, *DNMT3A*, *IDH1*, *IDH2*, and *KIT* were validated using either capillary electrophoresis or targeted amplicon NGS. Overall, more than 95% of the mutations detected by MyAML at allelic frequencies as low 5% were validated. In addition to SNVs and indels, we also identified potentially pathogenic gene fusions in patient samples, which were confirmed by FISH or cytogenetic microarrays. In order to advance personalized cancer care, diagnostic assays must be designed to maximize sensitivity and specificity such that they accurately identify all driver mutations in their clonal context. This is critical for predicting response and recurrence with various therapies. MyAML is the only comprehensive panel that optimizes variant detection by specifically targeting the genes and gene fusions known and predicted to be involved in AML pathogenesis. We demonstrate the utility of MyAML as a highly sensitive and accurate sequencing strategy for the comprehensive analysis of AML patients.

Mutations in the *PNPLA8* gene encoding the mitochondrial calcium-independent phospholipase A2 in a patient with lactic acidosis, spasticity, abnormal gait, dystonia and complex partial seizures. *I. Thiffault[1], C.J. Saunders[1, 4], S.H. Moon[2], X. Liu[2], K. Coffman[3], J.B. LePichon[3], E. Taboada[4], L.D. Smith[1], E.G. Farrow[1], N. Miller[1], S.F. Kingsmore[1, 4], R.W. Gross[2].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospitals, Kansas City, MO, USA; 2) Division of Bioorganic Chemistry and Molecular Pharmacology, Department of Medicine, Washington University School of Medicine, St-Louis, MO, USA; 3) Division of Neurology, Dept Pediatrics Children's Mercy Hospitals, Kansas City, MO, USA; 4) Division of Pathology, Dept Pediatrics Children's Mercy Hospitals, Kansas City, MO, USA.

Mitochondrial disorders are a group of clinically heterogeneous diseases, commonly defined by a lack of cellular energy due to OXPHOS defects. The majority of proteins involved in mitochondrial metabolism and maintenance are encoded by nuclear genes, with many yet to be associated with human disease. We performed whole exome trio sequencing on a young girl with mitochondrial myopathy manifested by progressive muscle weakness, hypotonia, spasticity, seizures, poor weight gain, and lactic acidosis. She was found to be compound heterozygous for two frameshift mutations, p.Asn112HisfsX29 and p.Leu659AlafsX4 in the *PNPLA8* gene, which encodes mitochondrial calcium independent phospholipase A2γ (iPLA2γ; MIM#612123). iPLA2s functions in a variety of pathways, including cellular growth, lipid homeostasis, and second messenger generation, exerting their function through the catalysis of the cleavage of acyl groups on glycerophospholipids. The clinical presentation of our patient is reminiscent of the phenotype reported in the mice null for the Pnpla8 gene. The Pnpla8 -/- mouse has cognitive dysfunction, decreased exercise endurance, mitochondrial dysfunction, enhanced insulin sensitivity, growth retardation, cold intolerance, and mild heart failure. As observed in the Pnpla8 -/- mouse model, there are unique morphologic changes observed in mitochondria of this patient's muscle biopsy, which showed an abnormal concentric disarray of internal cristae and globular dense osmiophilic inclusions. In addition, there was a significant increase in secondary lysosomes, many of which contained degenerating mitochondria. Variable fiber size was found with isolated small atrophic fibers of all subtypes; no ragged red fibers were identified. Electron transport chain function was not affected. Oxidative enzyme reactions (SDH and COX) showed no alterations in activity. These findings are consistent with a mitochondrial myopathy. Western blots showed dramatic decreases in multiple bands known to be absent in the Pnpla8 -/- mouse in muscle biopsy tissue from the patient, as would be expected from a null genotype/frameshifts. Although other iPLA2 -related diseases have been identified, such as infantile neuroaxonal dystrophy (MIM#256600) and neutral lipid storage disease with myopathy (MIM#610717), this is the first report of *PNPLA8*-related disease in a human. We suggest *PNPLA8* join the increasing list of genes involved in lipid metabolism associated with neuromuscular diseases.

2502M

Development of a Next Generation Sequencing Panel for Clinical Diagnosis and Prognostication in Hematologic Neoplasm Patients. *M. Middha, L.A. Frederick, Z. Tu, S.A. Henke, B.A. Dukek, X. Wu, L.M. Peterson, E. Klee, R. He, D.S. Viswanatha.* Mayo Clinic, Rochester, MN.

Next generation sequencing (NGS) allows investigation of multiple genes in a single test at a reduced cost compared to traditional sequencing methodologies. We design a targeted OncoHeme NGS Panel of 37 genes known to have mutations in AML, MDS, MPN, CLL, and DLBCL diseases. The genes were selected based on current literature and potential for clinically actionable findings. Here we evaluate the analytical components of the test life cycle process for developing this panel. Using a cross-platform sequencing strategy we sequenced 31 samples on Illumina MiSeq and Ion Torrent PGM instruments. To assess the effect of targeted enrichment, 20 and 11 samples were sequenced using Ampliseq PCR product library with TruSeq Nano adapters and Agilent Sure Select capture methods respectively. Ampliseq PCR products with Ion Torrent adapters were also sequenced on the PGM for all 31 samples. CLCbio Server software was used to analyze all the sequencing data. PGM data was also analyzed using TorrentSuite software to compare performance with CLCbio. We obtained about 5 million sequenced MiSeq reads per sample (average coverage ~4000x) yielding ~55 variants including Single Nucleotide Variants (SNV) and Insertions/Deletions (INDEL). The variants were detected at a minimum coverage of 100x and a minimum variant coverage of 10x. An average of ~1.7 million sequenced reads per sample from Ion Torrent (average coverage ~2000x) yielded ~38 variants using TorrentServer and ~300 variants using CLCbio. In-frame Internal Tandem Duplication (ITD) events ranging from 3 bp to more than 400 bp have been reported in the literature in 10-20% of AML patients, most ITDs are no more than 100bp. However, medium sized INDEL (20-70bp) are challenging to detect in NGS data. CLCbio identified these medium sized INDEL (up-to 42bp) for Ion Torrent sequenced samples but not for the MiSeq sequenced samples. We therefore also analyzed MiSeq data using PINDEL tool that successfully reported these medium sized INDEL. We also evaluated the effect of PCR duplication bias on variant calling using the functionality of 'mark duplicates' and 'remove duplicates' in Samtools, Picard and CLCbio plugin. To allow for testing multiple mutations with high accuracy and sensitivity we here establish an evaluated, well-defined approach for analysis and interpretation of an NGS clinical panel.

2503T

Detection of copy number variations in breast cancer samples using single-nucleotide polymorphism-targeted massively multiplexed PCR. *R.K. Swenerton, B. Hoang, J.E. Babiarz, B.G. Zimmermann, T. Constantin, E. Kirkizlar, N. Wayham, M. Rabinowitz, M. Hill.* Research and Development, Natera, Inc., San Carlos, CA.

Evaluation of copy number variation (CNV) in tumor tissues typically involves SNP microarray or aCGH. These methods have high whole-genome resolution, but require large amounts of input material, have high fixed costs, and have sub-optimal performance on formalin-fixed paraffin-embedded (FFPE) samples. Here, we employ a 28,000-plex SNP-targeted PCR methodology using next-generation sequencing (NGS), targeting chromosomes 1, 2, 13, 18, 21 and X, and regions 4p16, 5p15, 7q11, 15q, 17p, 22q11, and 22q13, to detect CNVs from fresh and FFPE samples. The assay was validated using genomic DNA from 96 human samples with known karyotype, including 71 with deletion or duplication of a region, using a minimum of 3 samples per region; 100% accuracy for copy number was observed. Single-molecule sensitivity was established by analyzing single cells. We determined the utility of this method to detect CNVs in breast cancer using both breast cancer cell lines and fresh frozen (FF) or FFPE breast tumor samples. Analysis of 5 breast tumor cell lines and matched non-tumor cell lines revealed multiple amplifications and deletions (median: 13) in all 5 tumor samples, whereas CNVs were absent in the matched non-tumor control samples. Of 31 FF and 2 FFPE breast tumor samples, 90.3% (28/31) of FF and 100% (2/2) of FFPE samples showed full or partial CNVs in at least 1 and up to 15 regions; of the 30 samples with detected CNVs, 93.3% had a CNV of either 1q or 17p, the two most common breast cancer CNVs represented on this panel. Significantly, CNVs were detected in a large proportion of samples across all evaluated tumor stages: 100% (7/7) of Stage I, 77.8% (7/9) of Stage IIA, 90.0% (9/10) of Stage IIB, and 100% (7/7) of Stage III tumors. Evidence of tumor heterogeneity was also observed. Although not investigated here, the very low DNA sample input requirements will allow this assay to determine tumor heterogeneity at the single-cell level. An assay, using our methodology, analyzing all chromosome arms would require a sequencing cost of approximately $5 per sample. Thus, this method offers a powerful, efficient, and scalable approach for investigating large numbers of FF or FFPE samples.

2504S

Automated miRNA expression profiling in FFPE tissue using nuclease protection coupled with next generation sequencing. *D. Thompson, I. Botros, M. Rounseville, H. Harrison, P. Roche.* HTG Molecular Diagnostics, Tucson, AZ.

Diagnostic pathology primarily uses formalin-fixed paraffin embedded (FFPE) tissues. Large FFPE tissue collections - both current and archival - are available, often with links to patient outcomes. A limitation to the utilization of this resource for molecular pathology is the difficulty of nucleic acid extraction from FFPE samples. Crosslinking-induced fragmentation of nucleic acids in FFPE tissue makes extraction and downstream analysis time-consuming and difficult, especially when scaling up into routine screening.

We have developed EdgeSeq, a coupling of our RNA extraction-free nuclease protection assay (qNPA) with next generation sequencing (NGS) - mediated quantification. Library preparation occurs in two simple steps: automated nuclease protection, performed on the HTG Edge Processor, followed by limited PCR cycles to prepare libraries for NGS. No RNA extraction or enzymatic processing of the sample is necessary. Sequencing of the resulting libraries allows counting for quantification of RNA in the sample. The advantages of NGS for detection include a large dynamic range with high sensitivity.

We initially used the EdgeSeq technique to develop a miRNA whole-transcriptome assay, based on Version 20 of miRBase. Application of the assay shows highly reproducible miRNA profiles are obtained from a variety of sample types including plasma, FFPE, frozen tissues, and cell lysates, with CVs of less than 10%.

EdgeSeq shows excellent correlation (R>0.97) when measuring matched frozen and FFPE cancer tissues. Importantly, poorly-expressed miRNAs are not “lost” when moving into FFPE. The high correlation demonstrates that FFPE tissue can be used in the EdgeSeq assay with full confidence that the results mirror expression in the original (generally unavailable) tissue sample. Further, studies with various FFPE samples demonstrate that tissue-specific miRNA markers are appropriately detected. The EdgeSeq miRNA assay is an excellent tool for NGS-based profiling of miRNA expression, especially for higher-throughput screening of FFPE tissues.

2505M

Non-invasive cell-free tumor DNA-based detection of breast cancer-related copy number variations. *B.G. Zimmermann[1], E. Kirkizlar[1], M. Hill[1], T. Constantin[1], S. Sigurjonsson[2], B. Hoang[1], N. Chopra[1], M. Rabinowitz[1].* 1) Research and Development, Natera, Inc., San Carlos, CA, USA; 2) Statistics, Natera, Inc., San Carlos, CA, USA.

Breast cancer screening involves mammography, which has high false positive rates and misses some cancers. Analysis of tumor-derived circulating cell-free DNA (ctDNA) for cancer-associated copy number variations (CNVs) may allow for earlier, safer, and more accurate screening. Here, we employed a single-nucleotide polymorphism (SNP)-based massively multiplex PCR (mmPCR) approach to screen for CNVs in ctDNA isolated from the plasma of breast cancer patients. The mmPCR assay targeted 3,168 SNPs on chromosomes 1, 2, and 22q, which often have CNVs in cancer (e.g., 49% of breast cancer samples have a 22q deletion). Here, we present case studies of six breast cancer patients: one stage IIa, four stage IIb, and one stage IIIb, with ctDNA fractions of 0.58-4.33%. Each tumor sample had CNVs on one or more of the targeted chromosomes. CNVs were identified in the corresponding plasma samples, including in one stage IIb sample with a ctDNA fraction of 0.58%; detection only required 86 heterozygous SNPs. This demonstrates that focal or whole chromosome arm CNVs, both common in cancer, can be readily detected. To further evaluate sensitivity, we generated 22 artificial mixtures containing a 3Mb 22q CNV, with ctDNA fractions of 0.85-14.7%. The method correctly detected CNVs in 100% of these samples with under $100 sequencing cost per sample. In numerous cancers, such as breast and ovarian, a significant proportion of tumors may only be detectable by CNVs instead of point mutations. Together, this supports that this SNP-based mmPCR approach may offer a cost-effective, non-invasive method for detecting these cancers.

2506T

High sensitivity coupled with low false positives through use of a position and sequence specific error-model in in NGS based somatic DNA sequence variant calling in a targeted cancer panel. *D. Brinza, M. Andersen, B. Johnson, N. Naturaj, K. Norman, K. Rhodes, M. Shahbazian, S. Sadis, P. Williams, P. Wyngaard, Y. Zhan, A. Lee, J. Veitch.* ThermoFisher Scientific, South San Francisco, CA.

High sensitivity combined with very low false positive variant calls are critical requirements in an NGS cancer panel. For the Oncomine® Cancer Research Panel targeting about 3800 known cancer specific variants covering 143 genes and using the Ion PGM™ Sequencer we develop an error model that achieves an average of 0.1 false positives per sample rate in the hotspots and a total of about 5 false positive variants per sample in 250 KB of non-hotspot positions when assessed with 1000 Genome samples. A DNA sample mixture was made by combining cell lines and synthetic linear DNA containing known cancer variants so that 334 hotspots were present in a single sample at 10%; allele frequency. This sample was used to create an Ion AmpliSeq™ library and was sequenced on a Ion 318™ Chip using the Ion PGM™ Sequencer. Using our new error model, a sensitivity of >97%; for SNPs and 75% for indels was observed.

2507S

Detection, estimation and correction of technical effects in copy number estimation using NGS in a targeted cancer panel. *Y. Zhan[1], B. Johnson[1], Z. Zhang[1], C. Van Loy[1], P. Williams[1], P. Wyngaard[1], A. Cani[2], D. Hovelson[2], A. McDaniel[2], C. Liu[2], S. Tomlins[2], S. Sadis[1], M. Andersen[1], J. Veitch[1].* 1) ThermoFisher Scientific, South San Francisco, CA; 2) University of Michigan, Molecular and Cellular Pathology.

We demonstrate a metric “Median Absolute Pairwise Difference” applied to assessment of the per-sample reliability of copy number estimation using the Oncomine® Cancer Research Panel that includes amplicons targeting 49 genes implicated in cancer copy number gains and 26 tumor suppressor genes with cancer related copy number losses using the Ion PGM™ Sequencer. We demonstrate the need for correction of per-sample technical effects including those based on per-amplicon GC content and length. Using mixtures of ATCC cell lines with known copy number changes we observe that detection of genes with copy number >=8 and tumor cellularity >= 30% can be identified with a sensitivity greater than 98% when the correction methods are applied.

2508M

MLPAseq: Assaying genomic copy number variation using multiplex ligation-dependent probe amplification paired with high-throughput sequencing. *D.J. Kvitek, S.A. McCalmon, S. Lin, B. Hsieh, N. McDonald, K.B. Jacobs, J.S. Paul, E.C. Olivares.* Invitae, San Francisco, CA.

As large-scale gene panels have emerged in the clinical genetic diagnostics space, it has become essential to simultaneously query the mutation state of large numbers of genes quickly, with high precision and low cost. Multiplex ligation-dependent probe amplification (MLPA) is the gold standard technique for detecting genomic copy number variation (CNV) in the clinic, but traditional MLPA is limited to detection of 40-50 targets per reaction because individual target peaks must be resolvable from one another on a capillary electropherogram. Here we report a novel extension of the original MLPA technology that enables detection of CNV events using high-throughput sequencing instrumentation, which we term MLPAseq. We demonstrate the simultaneous interrogation of ~1000 targets across 48 samples in a single Illumina Miseq run, and detect duplication and deletion events found in common reference samples and in clinical samples from our diagnostic laboratory. MLPAseq displays high sensitivity and specificity for single- and multi-exon events across >40 clinically relevant genes, including *ATM*, *BRCA1*, *BRCA2*, *CFTR*, *DMD*, *FANCA*, *MEN1*, *MLH1*, *MSH2*, *NPHP1*, *PKHD1*, *PLP1*, *PMP22* and *SMN1*. Specifically, we have used MLPAseq to identify CNVs in *BRCA1* and *BRCA2* with >99% sensitivity and >99.5% specificity, as verified by array comparative genomic hybridization (aCGH) and hybridization capture methods. MLPAseq is low cost, and both laboratory and data analysis workflows are easily automated, making it ideal for primary CNV detection or secondary CNV call confirmation for exome or Mendeliome-sized gene panels in a clinical genetic diagnostics environment.

2509T

Identification of five G6PD common deficiency variants using a novel SNaPshot method in patients of the province of Chiriqui, Panama. *O.I. Batista[1, 2], R.W. Allen[3].* 1) Ctr Gendiagnostik, David, Chiriquí, Panama; 2) CEGEN, Universidad Autónoma de Chiriquí, Panamá; 3) Department of Forensic Sciences, Oklahoma State University, USA.

The clinical, biochemical and genetic consequences of the mutations of the glucose-6-phosphate dehydrogenase (*G6PD*) gene can be important physiologically. G6PD deficiency is an enzymopathy affecting about 400 million people worldwide and biochemical testing of neonates has shown that G6PD deficiency is the metabolic disorder with the highest frequency in the province of Chiriquí, Panama. Affected individuals are usually asymptomatic, and go through life without being aware of their deficiency. They are, however, at risk of having acute hemolytic crises in response to infection, eating fava beans, and to drugs having a high oxidation potential. A SNP typing strategy was designed to simultaneously distinguish six different mutations that defined five G6PD deficiency variants. The variant with its respective mutations are the following: 1) G6PD A (+) (c.376 A>G, p.Asp126Asn); 2) G6PD A (-) (c.376 A>G/c.202 G>A, p.Asp126Asn/p.Val68Met and c.968T>C, p.Tyr222His; 3) Mediterranean (c.563 C>T, p.Ser188Phe); Canton (c. 1376G>T, p.Arg459Leu) and 5) Kaiping (c.1388G>A, p.Arg463His). This approach is based on the single-base extension of an unlabeled minisequencing primer that anneals one base upstream of the relevant SNP. In the presence of DNA polymerase, a fluorochrome-labeled dideoxynucleotide (ddNTP) gets incorporated into the SNP site. A total of 24 individual with low concentration of G6PD enzyme were screened for the six mutations mentioned before. Genomic DNA was extracted from buccal swabs of the deficient subjects using the NucleoSpin® Tissue Kit (Macherery-Nagel). PCR reactions were performed to amplify the exons containing the SNPs from each DNA sample. A six-plex of minisequencing reactions with the SNaPshot multiplex kit (Applied Biosystems) was carried out and analysis of the extension products was performed using capillary electrophoresis. The results were confirmed by restriction fragment length polymorphism (RFLP) or sequencing. The results shown that 84% of the screened patients presented the selected mutations indicating they are highly informative. The G6PD A- variant (72%) is the most frequent, followed by the Mediterranean (8%) and the Canton (4.0%) variants. 16% of individuals did not present any of the studied mutations and further sequence is recommended for them. The approach used has a higher multiplexing capacity, robustness, and extreme sensitivity.

2510S

Application of Serum miRNA Signature for Minimization of Immunosuppression and Diagnosis of Rejection Following Liver Transplantation. *B.J. Keating[1, 2], B. Chang[2, 1], T. Guettouche[2], S. Asare[3], D. Phippard[3], M. DesMarais[4], A. Shaked[1].* 1) Division of Transplantation, University of Pennsylvania, Philadelphia, PA; 2) Children's Hospital of Philadelphia, Philadelphia, PA; 3) Immune Tolerance Network, San Francisco, CA; 4) UCSF, San Francisco, CA.

Over 7,000 liver transplants are performed in the US each year with similar numbers performed worldwide. While advances in immunosuppression therapy (IST) have occurred over the last two decades, rates of acute cellular rejection (ACR) still remain significant, and co-morbidities from ISTs such as nephrotoxicity and liver damage are still major clinical issues. The ability to subclinically identify liver graft recipients who are on ACR trajectories, and those that can successfully withdraw from IST using minimally invasive, reproducible biomarkers with high specificity and sensitivity would represent a major advancement in personalized patient care. We performed miRNA profiling of 752 transcripts on 318 serum samples from 90 liver recipients transplanted from the NIH (ITN)-030 and CTOT03 studies. 48 recipients were randomized to supervised minimization and IST withdrawal, prior to a clinically indicated biopsy event, and were analyzed for prediction of rejection and for identification of those who may tolerate low, or no, IST. Serum miRNA profiles at time of biopsy from 104 samples with and without biopsy proven ACR were compared in a two-stage study. 15 miRNAs were observed to be significantly associated with ACR diagnosis after multiple testing corrections (FDR-adjusted p-value < 0.05). A logistic regression model consisting of a 3 miRNA panel to differentiate ACR from non-ACR with an AUC of 0.90 (95%CI=0.84-0.95), 92.6% sensitivity & 84.2% specificity [p=0.0001]). This 3 miRNA ACR signature was tested in an independent validation set (sera samples from 19 ACR and 16 non-ACR patients), confirming the performance of the model to differentiate ACR from non-ACR (AUC of 0.89 [95%CI: 0.83 - 0.94], 84% sensitivity and 75% specificity, p = 0.01). Statistically significant alterations in this three miRNA ACR panel preceded the rejection event by up to 40 days. The composite score of another distinct 3 miRNA panel early after initiation of IST minimization (at 75% of pre-withdrawal dose) identified recipients able to withstand significant IST reduction (<25% of pre-withdrawal dose, AUC=0.88 [95%CI: 0.80 - 0.95], sensitivity=0.82, specificity=0.90, p = 0.02). The findings in these prospective clinical trials demonstrate that 2 distinct multi-marker miRNAs signatures from sera can be used to: diagnose ACR up to 40 days before manifestation of clinical symptoms; predict rejection trajectories; & guide personalized minimization of IST.

2511M

Next generation sequencing panel for study of genes associated with Epilepsy using a novel single step enrichment and library preparation technology. *Y. Shevchenko[1], C. Naouar[1], K. Harrif[1], C. Chinault[1], L. Chan[2], M. Sanchez[2], S. Silveria[2], J. Dunne[2].* 1) GeneDx, Gaithersburg, MD, USA; 2) WaferGen BioSystems, Fremont, CA.

Epilepsy is a central nervous system disorder (neurological disorder) in which the nerve cell activity in the brain is disturbed, causing a seizure resulting in abnormal behavior, symptoms and sensations, including loss of consciousness. It is a common disorder that affects at least 0.8% of the population and can be caused by genetic disorders, metabolic diseases, trauma, infection, and structural brain abnormalities. Genetic testing for epilepsies is often complex but can be useful in certain clinical scenarios when it can help in clarifying the prognosis, assist in treatment and management of the patient, and predict the risk of a disease in family members. We set out to create a genetic test that will look at the most common causes of infantile seizures and identify mutations in genes that have treatment modifications issues. We target the test towards infants with sudden onset of seizures (possibly intractable) who will often be in the neonatal intensive care (NICU). The results of the test should be delivered within two weeks, the length of a typical NICU stay. To this end we assembled a panel of 18 genes linked with Mendelian forms of epilepsy. A genetic test based on this panel would be conducted in a CLIA lab, upon the evaluation of assay sensitivity, cost, throughput and ease of workflow. Next generation sequencing (NGS) can reduce cost and overhead in genetic sequencing but requires a similar fast, scalable and inexpensive targeted enrichment technology with sensitivity and specificity appropriate for transfer to a CLIA lab. Technologies exist which enrich targeted regions but many suffer from either protracted, expensive workflows, or uneven coverage making them poor choices to proceed to clinical testing. We tested a novel technology, Seq-Ready™ TE, which utilizes a large set of parallel singleplex PCR reactions to perform simultaneous sample enrichment and library preparation. This combined workflow can reduce total preparation time for 8 Epilepsy samples to < 4 hours with minimal hands on time. Amplicons (median size of 235bp) were designed for the 77kb region of interest (ROI) and control samples were enriched in sets of 8 per chip, extracted and purified prior to paired end 2 x 250 bp sequencing run on a MiSeq (Illumina). We will present the results of validation experiments for the Epilepsy panel using Seq-Ready TE technology.

2512T

PACTS: Development, validation and implementation of a low cost, high-throughput combination carrier screen/PGx using targeted nanofluidic PCR and massively parallel sequencing. *J. Buis, S. Birkeland, H. Wang, T. Reeder, B. Tarrier, T. Mann, J. Stoerker.* Research & Development, Progenity, Ann Arbor, MI.

The rapid decrease in the cost of massively parallel sequencing poses both opportunities and challenges for clinical molecular diagnostics. Advances in the clinical interpretation of sequence data has not been able to maintain pace with the ability to develop accurate and expansive targeted gene sequencing tests, leaving an open question as to what are the best practices for mutation screening and clinical reporting of sequence data. Here, we present data on the development and validation of a low cost, high throughput test using the Fluidigm Access Array™ and Illumina HiSeq™ 2500 Rapid Run technology to create a multi-gene sequencing based carrier screen/pharmacogenetic laboratory developed test for cystic fibrosis, spinal muscular atrophy, 18 common Ashkenazi Jewish Disorders, four cytochrome p450 genes important in common drug metabolism pathways and Factor II and Factor V Leiden. Deep multiplexing (up to 768 samples per run) and use of the rapid run technology has made high throughput sequencing on the Illumina HiSeq2500™ cost effective and fast. By combining multiple tests into one and blinding results of unordered tests in the bioinformatics pipeline, we can achieve additional operational flexibility and efficiencies of scale in a production genomic setting. Further, we present a comparative analysis of three different reporting algorithms for cystic fibrosis carrier screening. We provide data on the use of a limited, phenotypically validated set of 154 variants, an expanded clinically disease associated list of variants, and a general variant calling protocol. The data from the first 10,000 de-identified samples is evaluated to give guidance as to the benefits and drawbacks of the three different reporting paradigms.

2513S

Next-Generation Sequencing of the *"Clinome"* in a hypotensive newborn identifies novel mutations in *ACE* of the renin-angiotensinogen system. *H. Daoud[1], C. Beaulieu[2], O. Jarinova[1], N. Carson[1], B. Potter[3], C. for R. Consortium[1,4], J. Majewski[4], D. Bulman[2], P. Chakraborty[5], T. Lacazze[5], K.M. Boycott[1,2], D.A. Dyment[1,2], J. Richer[1].* 1) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 3) Department of Epidemiology, University of Ottawa, Ottawa, Ontario, Canada; 4) McGill University and Genome Quebec Innovation Centre, Montréal, Québec, Canada; 5) Department of Pediatrics, University of Ottawa, Ontario, Canada.

Next Generation Sequencing (NGS) has significantly improved our ability to make molecular diagnoses for rare disease and there is significant opportunity for its application in the neonatal intensive care setting (NICU). Here we present the case of a premature newborn with anuria and refractory hypotension. After no response to catecholamines, the neonate was able to maintain blood pressure and kidney function on vasopressin. Next generation sequencing of a comprehensive sequencing panel, targeting >4800 clinically-relevant disease genes (termed the "clinome"), identified compound heterozygous pathogenic mutations in the Angiotensin I Converting Enzyme gene (*ACE*, NM_000789.3); c.820_821delAG [p.Arg274Glyfs*117] and c.3521delG [p.Gly1174Alafs*12]. Mutations in this gene are known to cause Renal Tubular Dysgenesis (RTD; OMIM 267430), that results in failure of lung development and fetal, or neonatal, demise. The few long-term survivors with RTD have experienced chronic or end-stage renal disease. Our patient's prematurity (27 weeks) and favorable response to vasopressin potentially has spared the child significant renal pathology. At 7 months chronological age, the patient's renal ultrasound was normal. One month later, his potassium was normal on the kayexalate previously prescribed and he appeared to have nicely recovered from his neonatal acute kidney disease secondary to hypovolemia. The clinome approach provided an answer in 5 days and its focus on disease-related genes permitted pathogenicity-status of the variants to be readily evaluated, without further research study, which has obvious benefits for patients in the NICU setting.

2514M

MASTR Technology based targeted gene panels for comprehensive diagnostic MPS based analysis of inherited and acquired mutations. *J. Del Favero, S. Berwouts, K. Van der Ven, L. Heyrman, D. Goossens, A. Rotthier.* Multiplicom N.V., Niel, Antwerp, Belgium.

Multiplicom's MASTR (Multiplex Amplification of Specific Targets for Resequencing) assays enable multiplex PCR amplification of all required gene regions in a limited number of PCR reactions, resulting in the generation of highly efficient, low cost assays to establish a wide range of clinical and diagnostic applications. MASTR assays employ a simple two-step PCR protocol enabling specific amplification of the regions of interest followed by the incorporation of molecular barcodes in each amplified product to unambiguously link each read to the sample it originated from. This simple and straightforward two-step protocol enables direct compatibility with all commercially available, bench top massively parallel sequencing (MPS) platforms for cost-effective sequencing. Multiplicom currently offers sixteen targeted gene panels for diagnostic predisposition testing of cancer (e.g. breast and colon cancer) and inherited diseases (CFTR, DMD, Marfan,..). Also, MASTR based cancer panels for detection of somatic mutations in tumor tissue that target important cancer therapy related genes linked to many cancers, including melanoma, lung, colorectal, gastrointestinal, prostate, breast and ovarian cancer. Most panels are developed to amplify the complete coding region of cancer genes: the TP53 gene panel; panel containing BRAF, NRAS, KRAS and a panel containing EGFR, ERBB2, PTEN, PIK3CA and PIK3R1. The ability of these assays to use minimal amounts of precious FFPE material allows unlocking a wealth of genomic information for many tumor types using a reproducible and cost effective method. Furthermore, we developed and employed large targeted gene panels, comprising more than 500 exons, for mutation analyses in conditions such as sudden death. Pre-MPS mutation analysis of these conditions was virtually impossible due to large workload, cost and turn around time. Our data show that these large panels allow any diagnostic lab to perform these tests. Also, we showed that a substantial number of patients contain more than one disease causing mutations, not discovered before as a result of cascade based analysis, enabling better genotype/phenotype correlations. For several of these MASTR panels large validation studies have been performed or are ongoing. Results from these studies will be presented and show that multiplex PCR based gene panels enable comprehensive testing of diagnostic relevant genes which can be readily applied to large cohorts of patients.

Next-generation sequencing as a genetic diagnostic tool to improve the detection of tuberous sclerosis complex (TSC) causative variants. *H. Li[1], T. Wu[2], P. Chen[1,3,4].* 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 2) Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 3) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized with benign tumor growth in multiple organs including skin, brain, heart, lung, kidney, and other organs causing clinical symptoms such as skin abnormalities, developmental and behavioral problems, and lung and kidney diseases. Identification of pathogenetic mutation in ether *TSC1* gene at chromosome 9q34 or *TSC2* gene at chromosome 16p13 has been determined to cause TSC and is sufficient to make a definite diagnosis of TSC. The molecular genetic testing of *TSC1* and *TSC2* has been incorporated into the diagnostic criteria of TSC. However, the fact that *TSC1* gene consists of 23 exons and *TSC2* gene consists of 41 exons spanning in 53 and 45 kb of genomic DNA regions leads the genetic testing of TSC by traditional Sanger sequencing a time and labor-consuming work. In this study, we tested the use of next generation sequencing as the TSC genetic testing tool by taking the advantage of its high throughput to raise the sensitivity of mosaicisms. To enhance the detection of TSC causative variants including large deletion, insertion and inversion, we performed next generation sequencing with target enrichment strategy. The whole genomic regions containing all the exons, introns and 10 Kb of both 5' untranslated region (UTR) and 3'UTR of the *TSC1* and *TSC2* were captured by costumer designed Roche NimbleGen SeqCap EZ Choice Library. The enriched libraries were paired-end sequenced (2*300cycles) by Illumina Miseq system. Bioinformatics tools including BWA, SAMtools, Picard, GATK and ANNOVAR were applied for variants analysis. SIFT and PolyPhen2 were used to predict the biological significance of the genetic variants. Sequence data were further analyzed by Pindel and Breakdancer software to reveal the precise chromosomal breakpoints of the structural variations such as large insertion/deletion (indel) and inversion. All results were visualized by integrative genomics viewer (IGV). Among the 94 TSC families we examined, causative variants in *TSC1* or *TSC2* genes including 51 single nucleotide variants (SNVs), 20 small indels and 8 large indels were identified in total 79 families. Moreover, 2 lineal relatives from 2 TSC families turned out to be mosaic carriers of *TSC2* mutations were also detected in this study. These data suggest that next generation sequencing serving as a genetic diagnostic tool is economical and sufficient to detect the tuberous sclerosis complex causative variants.

Comparative study for the evaluation of a new technology for cystic fibrosis screening. *M. Majolini[1], M. Rongioletti[1], F. Papa[1], C. Vaccarella[1], A. Luciano[1], C. Centrone[2], B. Minuti[2], V. Mazzucchi[1], M. Belli[1], F. Torricelli[2], G. Liumbruno[1].* 1) Clinical Pathology Department, San Giovanni Calibita Hospital, Rome, Italy; 2) SOD Diagnostica Genetica, AOU Careggi, Florence, Italy.

Introduction Screening for Cystic Fibrosis Transmembrane conductance Regulator (CFTR) gene mutations, is strongly recommended in infertile couples planning a pregnancy by assisted reproductive technology (ART). This study evaluated the performance of the new Nanochip CF70 kit (Savyon Diagnostic, Israel), a microarray assay, and compared it with the Innolipa kits (Innogenetics, Belgium) Methods We analyzed 392 blood samples with Innolipa and Nanochip technologies that identify respectively 70 and 56 CFTR mutations. Discordant results were analyzed with the Devyser CFTR Core Kit (Devyser, AB, Sweden) based on PCR allele specific technology, MLPA (MRC Holland), Direct Sequencing (DS) on the 3730 DNA Analyzer (AppliedBiosystems), and Sequenom's MassArray system (Diatechpharmacogenetics, Italy) Results Innolipa and NanoChip were concordant for 371/392 samples. 21/392 (0.5%) discordant results were tested with the aforementioned technologies: DS confirmed Innolipa results in 18/21 samples and Nanochip results in 1/21, while Devyser and Sequenom did not recognize some mutations not included in their panels. DS was essential for the identification of two different homozygous deletions; although they were not present in Innolipa panels, in 2/21 samples Innolipa indicated a mutation with the warning no interpretation possible Conclusions In this study the Innolipa assay confirmed its reliability and Nanochip showed that it could become competitive with slight changes to the software.

2517M

Clinical application of an anion exchange HPLC column that distinguishes DNA methylation status. *K. Miyake[1], Y. Yamada[2], T. Yotani[2], T. Kubota[1].* 1) Epigenetic Medicine, University of Yamanashi, Chuo, Yamanashi, Japan; 2) Tsukuba Research Institute, Sekisui Medical Co., LTD.

DNA methylation is associated with gene regulation as a component of epigenetic mechanism. Abnormal methylation status alters gene expression, which results in a subset of congenital disorders including Prader-Willi syndrome (PWS) and Angelman syndrome (AS). Methylation-specific PCR (MSP) assay has currently been used for early diagnosis of PWS, which allows early start of growth hormone therapy to prevent obesity and diabetes mellitus. An HPLC column has been used to differentiate amino-acid sequences, and a new anion exchange HPLC column has recently been developed to differentiate DNA sequences, which is used for assessment of SNPs. Using the new column, we tried to differentiate DNA methylation status in PWS and AS patients using their sodium bisulfite-converted DNA samples which were PCR amplified with a primer set of *SNRPN* promoter region. As a result, control normal individuals showed a bimodal peak pattern (an early peak for the methylated allele and a late peak for the unmethylated allele), whereas PWS patients showed a single peak pattern (an early peak for the methylated allele only) and an AS patient showed a distinct single peak pattern (a late peak for the unmethylated allele only). These results were consistent with the results of MSP assay and bisulfite sequencing in the *SNRPN* region. Taken together, the new assay can clearly distinguish between 0, 50, and 100% methylation status. We are now investigating to define its sensitivity for methylation. Since the anion exchange HPLC column-based assay is a rapid and inexpensive method that can be automated on a standard type of HPLC devise, the assay will be a best high-throughput method for assessment of DNA methylation for a large number of patients with epigenetic-associated common diseases such as diabetes mellitus, and thus it will contribute to preemptive medicine of various diseases.

2518T

Development and verification of a Noonan genes Ion AmpliSeq™ panel. *M. Nelen[1], H. Yntema[1], F. Pantaleoni[2], J.C. Machado[3], C. Rossi[4], M. Tartaglia[2], J.L. Costa[3], K. Neveling[1].* 1) Dept. of Human Genetics., Radboud UMC, Nijmegen, The Netherlands; 2) Dept. of Hematology, Oncology and Molec. Medicine, Istituto Superiore di Sanità, Rome, Italy; 3) Ipatimup, Porto, Portugal; 4) Unità Operativa Genetica Medica, Policlinico S. Orsola-Malpighi, Bologna, Italy.

Noonan syndrome is a relatively common autosomal dominant congenital disorder with a high phenotypic variability. It is a clinically and genetically heterogeneous disorder that belongs to the group of Rasopathy diseases, caused by mutations in genes dysregulating the RAS/MAPK pathway. Currently, mutations in 14 genes have been described. Standard analysis using Sanger sequencing is expensive and time consuming. Prenatal analysis of all the genes is often not possible due to limited amount of material the small amount of available fetal DNA often allows the analysis of a maximum of five genes. Here we describe the development of a Noonan genes Ion AmpliSeq™ panel for Ion Torrent sequencing. It includes the coding regions of 14 known Noonan genes, plus 5 basepairs to cover exon-intron boundaries. In total, two pools including 269 amplicons were designed, allowing amplification of all the target regions with only 20 ng DNA. The amplicon sizes range between 125 and 275bps, covering 100% of the desired regions of interest. In a first pilot experiment, pre-and postnatal DNAs carrying known mutations have been sequenced. The average chip loading was 81%, and the average read length was 184bp. Coverage analysis revealed that 266 of the 269 amplicons were covered completely, whereas 3 amplicons show no coverage. The failing amplicons concern (parts of) exon 1 of the genes BRAF, CBL and MAP2K2. No pathogenic mutations have been described for these regions. Coverage depth for the other regions was good with 98% of all amplicons being covered above 100X. Mutation analysis was performed for all samples, and the described mutations (25 different mutations in 12 different genes) could be identified in all of them. The sequencing data of the prenatal samples is very much comparable to the postnatal samples. Further sequencing is ongoing, to reach a total cohort of 100 analyzed samples carrying known mutations, including both prenatal and postnatal DNAs. These preliminary results demonstrate that the Noonan Gene AmpliSeq™ panel may be used in the clinical research setting for prenatal as well as postnatal samples. The simultaneous analysis of all genes is not only attractive in case of limited DNA, but also offers a faster analysis at reduced costs.

2519S

Combined Approach of Targeted Exome Sequencing and Sanger Sequencing to Detect Pathogenic Mutations in Autosomal Dominant Polycystic Kidney Disease. *H. Park[1,2], N. Kim[3], S. Han[4], J. Jang[4], H. Kim[1], H. Jo[1], H. Ryu[1], K. Oh[1], H. Cheong[2,5], C. Ki[6], C. Ahn[1,4], W. Park[2,3,7], Y. Hwang[2,8].* 1) Department of Internal Medicine, Seoul National University Hospital, Seoul, South Korea; 2) Research Center for Rare Diseases, Seoul National University Hospital, Seoul, South Korea; 3) Samsung Genome Institute, Samsung Medical Center, Seoul, South Korea; 4) Transplantation Research Institute, Seoul National University, Seoul, South Korea; 5) Department of Pediatrics, Seoul National University Children's Hospital, Seoul, South Korea; 6) Department of Laboratory Medicine and Genetics, Samsung Medical Center, Seoul, South Korea; 7) Department of Molecular Cell Biology, School of Medicine, Sungkyunkwan University, Seoul, South Korea; 8) Department of Internal Medicine, Eulji General Hospital, Seoul, South Korea.

Background: Although genotype is the most important prognostic factor in autosomal dominant polycystic kidney disease (ADPKD), it has not been practical to perform Sanger sequencing due to high cost and technical difficulties. Recently, next generation sequencing method has been introduced in the genetic diagnosis and showed highly accurate and fast diagnostic potential. This study was performed to evaluate the efficacy of combined method of *PKD*1/2 targeted exome sequencing and Sanger sequencing in mutation detection of ADPKD. Method: We extracted DNA from whole blood of 210 ADPKD patients from 177 families. ADPKD was typically diagnosed by family history and imaging with age-dependent criteria. We used Agilent SureSelect Capture Array System for target enrichment and Illumina GAIIx for sequencing. The causal variants were identified and designated as follows: 1) stopgain SNVs, frameshift indels, or listed pathogenic variants in Mayo PKD database (https://pkdb.mayo.edu) as pathogenic, 2) non-frameshift indels or predicted as “damaging” using prediction tools as possibly causal, 3) likely neutral, 4) undetermined, and 5) no candidate. In order to validate mutations found in duplicated regions (exon 1-33 of *PKD*1 gene), we considered the alignments with mapping quality > 20 and further validated each mutation by Sanger sequencing. Results: Among 177 ADPKD families, 147 (83.1%) were found pathogenic or possibly causal variants by targeted exome sequencing alone. When we performed Sanger sequencing for 70 mutations found in the duplicated region of *PKD*1, 69 (98.6%) mutations were confirmed. Since exon 1 of *PKD*1 showed low capture efficiency (<50) due to high GC contents, we additionally performed exon 1 Sanger sequencing in the cases of undetermined significance (n =19) or no candidate (n = 14) and found 3 novel pathogenic mutations. Additional Sanger sequencing for exon 1 in *PKD*1 gene improved mutation detection rate as high as 84.2%. Among 126 pathogenic variants, novel pathogenic mutations comprised 76 (60.3%). Among pathogenic or possibly causal variants, *PKD*1: *PKD*2 were 121:28 (81.2% vs. 18.8%). Conclusion: Combined approach with customized capture-based targeted exome sequencing and additional *PKD*1 exon1 Sanger sequencing may improve mutation detection rate in ADPKD and make up for shortcomings of each method. * This study was supported by a grant of the Korean Health Technology R&D Project, Ministry of Health & Welfare, Republic of Korea (HI12C0014).

Development of panel for simultaneous screening of 98 mutations related with hearing loss. *M.C.C.M. Svidnicki, N.Z.P. Santos, S.M. Silva-Costa, G.M. Carvalho, A.M. Castilho, E.L. Sartorato.* State University of Campinas, Campinas, Brazil.

Recent advances in molecular genetics have allowed the determination of the genetic cause of non-syndromic hearing loss, but a large percentage of patients still remain with unidentified cause. It points an imminent need for new methodological strategies for the detection of an increased number of mutations in multiple genes. In this work we developed a panel of 98 mutations, previously identified, in 20 different genes for screening of hearing loss, using mass spectrometry system MassArray, Sequenom® and also evaluated the contribution of selected mutations in the etiology of deafness in Brazilian individuals. To minimize erroneous results, mainly caused by the interaction of primers in multiplex reactions, we tested and standardized the assays using 21 control samples with different mutations in GJB2, SLC26A4 and MT-RNRS1 genes. For every mutation that failed, primers were redesigned and the assays were grouped into different wells. After standardization, the values of sensitivity and specificity of the technique proved to be above 84%. A total 150 unrelated individuals affected with non-syndromic hearing loss were then screened using the developed mutation panel. The possibility of environmental factors causing HL was ruled out by historic information and medical examinations. Mutations were identified in 43 patients (28,7%) and the etiology could be concluded in 16% of the cases. All positive results were validated by other techniques. The c.35delG mutation in the GJB2 gene was the most prevalent, identified in a total of 24 individuals in at least one allele. Other mutations in the GJB2 were identified in 17 subjects, and the p.M34T mutation was the second most prevalent, detected in four cases. Mutations in SLC26A4 gene were found in five individuals, and p.V609G mutation was the most common of this gene, detected in three individuals. Mutations in MT-RNR1, MYO15A, OTOF and CDH23 genes were also identified in one patient each. The genotyping of mutations using mass spectrometry system has been shown to be faster and cheaper than Sanger sequencing and allowed to analyze a larger number of genes than those currently assessed to diagnose hearing loss. Thus, the panel developed presented promise for unraveling the etiology of hearing loss and for genetic counseling.

Genetic testing of targeted genes using next generation sequencing on PCR amplicons. *W. Yang, J. Yang, P.P.W. Lee, K.W. Chan, Y.L. Lau.* Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, 10000, Hong Kong.

Sanger sequencing of PCR amplicons has been the predominant method for genetic testing for primary immunodeficiencies (PID). Despite largely successful endeavors in finding causal mutations for this group of diseases, the method is tedious and inefficient, and suffers from false negative detections under many circumstances. Next generation sequencing (NGS) is rapidly becoming applicable to genetic testing in clinical laboratories and has been shown to be advantageous in many aspects. In this study, we report two real cases in which whole exome sequencing (WES) successfully detected the causal mutations that have been missed by previous tests based on Sanger sequencing of PCR products. In one of the cases, a somatic mutation in the NLRP3 gene that only accounted for 12 percent of the total alleles from peripheral blood mononuclear cells in a patient suffering from chronic infantile neurological, cutaneous and articular syndrome was detected by WES. In another case, a large deletion in DCLRE1C gene missed previously by Sanger sequencing due to sample contamination was also detected by WES. We also tested a method of NGS on pooled PCR amplicons coupled with extensive multiplex identifier (MID) for molecular diagnosis and genetic screening of primary immunodeficiencies and other genetic diseases, which provides flexibility, cost effectiveness, and reasonable automation and throughput (contact yangwl@hku.hk).

Classification of Incidental Finding Variants in 6503 Participant's Exomes. *L. Amendola[1], P. Robertson[2], D. Nickerson[2], M. Dorschner[2], J. Salama[1], EVS. 6500 annotation consortium[1], G. Jarvik[1, 2].* 1) Divison of Medical Genetics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

Two challenges in genomic medicine implementation are the classification of variant pathogenicity and the evaluation of incidental findings (IFs). The ACMG has proposed discovery and return of IFs for 56 genes from genomic tests. In order to explore expert crowd sourced variant classifications and estimate the rates of IFs, we classified all putatively pathogenic variants in the 6503 participants in the NHLBI exome sequencing project (ESP). The 6503 participants in the ESP included African (n=2,203) and European (n= 4,300, including 187 Ashkenazi) ancestry. We considered variants in 117 genes associated with medically actionable conditions which may be undiagnosed in adults. Briefly, the pathogenicity criteria included the requirement for published studies with multiple individuals and/or segregation or de novo mutation data or novel truncations, where that mechanism is known to cause disease. Using consistent criteria, 48 experts reviewed 628 variants that were classified as 'disease causing mutations' in the Human Genetic Mutation Database (HGMD) and had minor allele frequency < 0.005 for autosomal dominant and x-linked (612) and <0.1 for autosomal recessive (16) disorders. 67 stop and splice variants found in ESP but not in HGMD were also considered. Initially, a random 156 (25%) of the HGMD variants were blindly double-reviewed; of these 81 (52%) did not match and 53 mismatches involved pathogenic or likely pathogenic classification. We then blindly reclassified all missense variants classified as pathogenic or likely pathogenic: 56% changed classes (44/79) with 42 of 44 reclassifications moving from pathogenic or likely pathogenic to variant of uncertain significance The frequency of pathogenic, likely pathogenic, and expected pathogenic novel disruptive mutations were 0.6, 1.0, and 0.1% in those of European ancestry and 0.2, 0.5, and 0.4% in those of African ancestry. Relationships of classification to allele frequency and in silico scores were also explored. The deficit of findings in subjects of African ancestry may reflect the lack of relevant literature. 87% of HGMD 'disease-causing' mutations did not meeting our criteria for pathogenicity. Even with expert reviewers and clear criteria, there was substantial inconsistency in the classification of variants that was marked by over interpretation of variant pathogenicity. This suggests that crowd sourcing of variant annotation has limitations.

2523M

Detection, characterization, and validation of Hematological Malignancies with Archer(TM) FusionPlex(TM) Heme NGS assay. *B. Culver, B. Kudlow, J. Stahl, M. Callan, J. Amsbaugh, J. Myers.* Enzymatics, Boulder, USA.

Introduction The importance of understanding gene fusions in cancer biology is increasingly important, and may have profound impacts on next-generation drug discovery efforts. Historical testing methods such as fluorescence in-situ hybridization (FISH) are limited by scalability and subjective interpretation. Growing numbers of fusion gene partners to MLL, JAK2, and other oncogenes in hematological malignances have further complicated matters. Targeted sequencing technologies, such as Anchored Multiplex PCR (AMP), have the ability to simultaneously interrogate hundreds of targets and identify novel and known gene fusions from small amounts of input material in a single reaction. In this study, we will demonstrate the detection, breakpoint characterization, and concordance between current technologies and the targeted Archer(TM) FusionPlex(TM) Heme next-generation sequencing panel. **Materials and Methods:** Heme fusion samples were sourced from CAP-accredited tissue repository (Asterand) and through collaboration with Massachusetts General Hospital. Samples with known/unknown Hematological malignancies, as determined by existing technologies such as FISH, RT-PCR, and non-targeted sequencing, were provided for the study. The Archer FusionPlex Assay was performed according to Enzymatics package insert, and sequenced on the Illumina MiSeq platform. Sequencing analysis was performed via the Archer Analysis Pipeline, and reported fusion results were compared to current methods. **Results:** Concordance between current methods and the FusionPlex NGS results is high, with all positive samples also having a positive NGS result. In contrast to current methods, the Archer FusionPlex assay was able to characterize fusion partners previously unidentifiable via RT-PCR or other methods without prior knowledge of fusion partner or the laborious and high cost of RNA-seq screening. **Conclusions:** The Archer(TM) FusionPlex(TM) Heme panel is a powerful new tool for identifying disease relevant gene fusion events from small amounts of input material in Hematological cancers. Our initial results indicate that this targeted sequencing assay shows promise in matching the "gold standard" of FISH testing, while overcoming the obvious limitations of reflex testing. Furthermore the novel AMP-based sequencing method allows for cost-effective high-throughput identification of fusion breakpoints and fusion partners to the relevant oncogenes without prior knowledge of the partners.

Enabling Genomic Clinical Variant Assessment and Reduction of Variants of Unknown Significance through Intelligent Scoring. *C.L. Mead[1], M. Kallberg[1], T. Mann[2], S.S. Ajay[1], E. Ramos[1], D. Mote[1], S. Kruglyak[1], T.M. Hambuch[1].* 1) Illumina Clinical Services Laboratory, Illumina, San Diego, CA; 2) Progenity, 5230 S. State Road Ann Arbor, MI 49108.

Barriers to accurate human genome re-sequencing have largely been surmounted, enabling consideration of routine clinical applications. However, significant challenges remain for interpretation of whole genome data for diagnostic purposes. The shift from genetic to genomic scale testing significantly increases the interpretation burden, and yet there is a lack of cohesive information to facilitate genome scale variant assessment. Clinical assessment of whole genome sequencing (WGS) results based on literature alone produces numerous variants of unknown significance (VUS), which do not yield actionable information for clinicians. For Mendelian conditions, the relationship of disease prevalence to variant prevalence is well established and this relationship can be used to identify variants that can be confidently excluded from disease involvement. Our algorithm generates a statistical score specific to the characteristics of the variant and disease being assessed. We have established a clinical service for WGS and interpretation. The interpretation service is currently limited to exons +/- 15bp of 1600 genes whose clinical validity and involvement in 1211 monogenic conditions have been established. Here we describe our scoring algorithm that generates a statistical score for each variant to help rule out disease causality using information including disease penetrance, prevalence, inheritance mode, and variant frequency. We sequenced and interpreted 1600 genes in approximately 500 individuals and identified over 60,000 unique variants within exons +/- 15 nucleotides. Statistical analyses were performed to determine thresholds whereby variants were confidently ruled out from being associated with disease, thereby significantly reducing the number classified as VUS. WGS methods result in a significant variant assessment burden that must be addressed in order to enable effective integration into medical practice. While peer-reviewed literature sources provide the strongest evidence for variant assessment, this information is currently scarce on the whole genome level. In the context of variant assessment for monogenic diseases, where literature information is not available, our understanding of biology can enable the development of algorithms that are more refined and disease specific, which can improve interpretive reporting. A quantitative statistical score can help in the evaluation of the clinical variant assessment confidence.

2525S

Sensitive and Comprehensive Method to Detect Mutations in RB1 Gene Improves Care for Retinoblastoma Patients and Their Families. *W. Li, J. Buckley, P. Sanchez, D. Maglinte, L. Viduesky, T. Triche.* Pathology and Laboratory Medicine, Children's Hospital Los Angeles, Los Angeles, CA.

Retinoblastoma is childhood eye cancer caused by inactivating mutations in both alleles of the tumor suppressor gene, RB1. RB1 is the only gene in which mutations are known to cause heritable predisposition to retinoblastoma. Retinoblastoma can lead to the loss of vision, eye(s), and sometimes even life. Molecular identification of a germline RB1 mutation in a timely manner is very important for the effective care and management of retinoblastoma patients and their families. However, current methods to detect disease causal mutations in RB1 are lengthy, usually taking weeks or months. In this study, we report a next-generation sequencing (NGS) based method that is capable of capturing pathogenic mutations in the entire 200 kb RB1 gene, both exons and introns. The process of DNA extraction, sequence data generation, and completion of data analysis requires only 3 days. In addition, the associated bioinformatic pipeline can take NGS data and accurately measure the copy number of the RB1 gene and MYCN gene, thus enabling the NGS method to simultaneously detect point mutations, small InDels and large deletion/duplications in the RB1 gene and gene amplification of the MYCN gene on a single test platform, which was impossible previously. Because of the deep sequencing coverage of the entire RB1 gene, this method can detect even a low percentage of mosaic mutations directly from blood samples, which is essential for genetic counseling of retinoblastoma patients and their families. To assess the functional impact of mutation and other RB anomalies like promoter hypermethylation, we are developing a novel targeted NGS assay to simultaneously assay both RNA and DNA, in order to measure the transcript level of expression and DNA mutational status in the same extract. This will be complemented by development of a targeted methylation assay to complete DNA, RNA, and epigenetic profiling of the RB1 gene. Taken together, we believe that these combined NGS based methods can lead to rapid, inexpensive, comprehensive, and sensitive methods for detecting RB1 mutations and aberrant expression. This in turn will enable detection of germ line carriers who are at lifetime increased risk of a second malignancy like osteosarcoma, a decidedly more aggressive and more often fatal disease compared to retinoblastoma.

2526M

A multi-platform amplicon sequencing method for fast and reliable variant detection. *M. Toloue, L. Matzat.* NGS, Bioo Scientific Corp, Austin, TX.

The application of NGS to clinical work and patient diagnoses has been limited by several factors including cost, time, and limitation of samples. Rapid benchtop sequencing as well as multiplexing reduce both cost and time limitations of sequencing; however, sample preparation for these platforms remains a rate limiting step. Whereas target capture methods require construction of a DNA-seq library and a target capture process, amplicon libraries can be constructed by simple PCR steps that sequentially build platform-specific and barcode sequences onto target sequences. Here we present an amplicon sequencing library construction method that produces libraries in highly multiplexed reactions and is compatible with multiple platforms. Our library preparation allows accurate targeting and even coverage across amplicons. Data will be presented demonstrating amplicon coverage and SNP detection as well as the flexibility for customized amplicon panel design.

2527T

A Comprehensive Profile of Hereditary Myopathies by Next Generation Sequencing on 43 Early-Onset Patients and Subsequent Development of a Biomarker Assay by Liquid Chromatography-SRM-Mass Spectrometry. *S. Hahn[1,2,3], V. Vasta[3], S. Jung[3], Q. Zhang[4], S. Eun[5], A. Cho[6], B. Lim[7], J. Chae[7].* 1) Department of Pediatrics, University of Washington School of Medicine, Seattle, WA; 2) Seattle Children's Hospital, Seattle, WA; 3) Center for Developmental Therapeutics, Seattle Children's Research Institute, Seattle, WA; 4) Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Department of Pediatrics, Korea University College of Medicine, Seoul, Korea; 6) Department of Pediatrics, Ewha Woman's University School of Medicine, Seoul, Korea; 7) Department of Pediatrics, Seoul National University School of Medicine, Seoul, Korea.

Hereditary myopathies encompass a significant proportion of patients with chronic muscle disease. The diagnostic approach for hereditary myopathy is often difficult due to its heterogeneous genetic background and similar clinical presentations. Most patients require a muscle biopsy for the diagnosis, which is particularly challenging in infants or newborns. Unfortunately, many patients remain undiagnosed due to the lack of specific markers for many myopathies or due to ambiguous pathological results. Furthermore, Sanger sequencing of individual genes is challenging because one gene can cause a wide variety of clinical and/or pathological features, while similar clinical features can be caused by mutations in different genes. Here, we explored Next Generation Sequencing panel (~600 genes) on 43 patients with early-onset myopathy, targeting known pathogenic genes for hereditary myopathies or secondary muscle weakness. Fourteen novel/rare variants, fifteen known pathogenic variants and five VUS in 17 genes were identified in thirty two patients. Three had myasthenic myopathy (*DOK7, AGRN*, and *GFPT1*); two had peripheral neuropathy (*GARS, DYNC1H*). Incomplete penetrance was strongly suspected in four cases with variants in *COLA1, RYR1, CCDC78* and *MYBPC3* genes, indicating that careful interpretation is required in the context of clinical, laboratory and pathological findings when the rare variant is inherited from asymptomatic parents. As *COL6A* genes were most commonly affected in our cohort while no specific biomarkers are clinically available, we explored a Liquid Chromatography Selected Reaction Monitoring Mass Spectrometry (LC-SRM-MS) to identify and quantify the proteotypic peptides of Collagen VI in skin fibroblasts. We identified several candidate signature peptides for Collagen VI and are currently evaluating the method to see if the abundance in patient's fibroblasts is reduced or absent. This assay can open a valid experimental model to study the candidate drugs that are becoming available. Although our study indicates that simultaneous sequencing of multiple genes for various types of hereditary myopathies is clinically relevant, a substantial number of patients still remained without molecular diagnosis in our cohort implying that new causative genes for hereditary myopathy are to be identified. Further development of biomarker assay for hereditary myopathies is necessary and could be feasible with LC-SRM-MS in selected conditions.

2528S

Genetic Diagnosis of Duchenne Muscular Dystrophy by Clinical Exome, Whole Genome and Transcriptome Sequencing. *R.T. Wang[1,2], H. Lee[1,3], A. Eskin[1], V. Arboleda[1], K. Squire[1], J.L. Deignan[3], N. Khanlou[3], P.B. Shieh[4], S.F. Nelson[1,2,3].* 1) Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Center for Duchenne Muscular Dystrophy, University of California Los Angeles; 3) Department of Pathology and Laboratory Medicine, University of California Los Angeles; 4) Department of Neurology, University of California Los Angeles.

Duchenne muscular dystrophy (DMD; OMIM #310200) is the most common form of muscular dystrophy characterized by a progressive loss of skeletal muscle function. Roughly 1 in 5000 male births are affected worldwide. The X-linked *DMD* gene is one of the largest genes in the human genome and mutations within the 2.2 Mb gene are the unequivocal cause DMD. The mutational spectrum of DMD is heterogeneous with approximately 60-65% of affected individuals with large exonic deletions, 5-10% with large duplications and 25% with single base, small indels, or splice site mutations typically resulting in absent dystrophin expression. Although the gene responsible for DMD has been known for over 25 years, as many as 30% of affected boys have not received a molecular diagnosis in the United States, demonstrating some barriers to molecular diagnosis. Multiple ligation dependent probe amplification (MLPA) or array CGH, reliably identify exonic deletions and duplications through probe hybridization targeted to specific exons. When MLPA fails, Sanger sequencing of exons and splice sites is undertaken. The large size of the *DMD* gene, however, makes comprehensive assessment of all exonic mutations challenging and expensive, and a small portion of histologically diagnosed patients do not have a detected mutation. Here we report the use of whole exome sequencing as a clinical test to detect point mutations, small insertion and deletions, and single or multiple exonic deletions and duplications in the *DMD* gene simultaneously with high sensitivity and specificity. By sequencing to high depth of coverage, we reliably identified the disease causing point mutations, exonic deletions and duplications for 27 of 30 samples. We utilized paired end whole genome sequencing to identify duplicated breakpoints for two samples and further employed RNA-seq on biopsied muscle tissue coupled with whole genome sequencing in two refractory cases to uncover a novel genomic rearrangement and an unusual change in splicing with base-pair resolution.

Hi-Plex: a flexible, streamlined and cost-effective approach to targeted massively parallel sequencing. *T. Nguyen-Dumont[1], B.J. Pope[2,3], F. Hammet[1], M. Mahmoodi[1], H. Tsimiklis[1], M.C. Southey[1], D.J. Park[1].* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Parkville, VIC, Australia; 2) Victorian Life Sciences Computation Initiative, Carlton, VIC, Australia; 3) Department of Computing and Information Systems, The University of Melbourne, VIC, Australia.

Purpose: Massively parallel sequencing (MPS) has revolutionised biomedical research and offers enormous capacity for clinical application. We previously reported Hi-Plex, a streamlined highly-multiplexed PCR-based target-enrichment system for MPS. Here, we present its optimization to 1,000 amplicon-order multiplexing and gene panel screening of thousands of specimens.

Methodology: Hi-Plex library-building consists of a single-step, highly-multiplexed PCR, followed by size selection, using relatively inexpensive, readily available reagents in a simple half-day protocol. A given library can be sequenced with both the TruSeq and Ion Torrent chemistries. Hi-Plex does not require normalisation of barcoded libraries before pooling and sequencing. The Hi-Plex system is complemented by simple, automated primer design software that allows the uniform definition of library size, so that subsequent paired-end sequencing can achieve complete overlap of read pairs. Variant calling from Hi-Plex-derived datasets relies on the identification of variants appearing in both reads of read-pairs, permitting stringent filtering of sequencing chemistry-induced errors using our ROVER software. Comparable sequencing efficiency was achieved using material derived from lymphoblastoid cell lines and formalin-fixed paraffin-embedded tumours.

Results: Initially reported in a 60 amplicon multiplex (60-plex) setting, Hi-Plex's chemistry was improved to perform at the ~1,000-plex level. Using equal amounts of all primers, we observed that 95% amplicons were represented within 20-fold of the median coverage. Using the improved Hi-Plex chemistry and expanding on a published demonstration of Hi-Plex capabilities to perform accurate, high-throughput screening, we screened 1,285 breast cancer cases for mutations in the breast cancer susceptibility genes *PALB2* and *XRCC2*.

Conclusion: Hi-Plex is simple, accurate, low cost, modular and flexible in terms of target region design and sequencing platform. These features render the approach highly attractive for an extensive range of clinical and research applications.

2530T

GenoDENT: A targeted next-generation sequencing assay for the diagnosis and discovery of mutations in buccodental disorders. *M. Prasad[1], V. Geoffrey[1], V. Haushalter-Laugel[2], M. Paschaki[1,2], B. Gasse[3], C. Stoetzel[1], H. Dollfus[1,4], A. Bloch-Zupan[2,5,6].* 1) Laboratoire de Génétique Médicale, University of Strasbourg, Strasbourg, France; 2) Institute of Genetics and Molecular and Cellular Biology (IGBMC), Centre National de la Recherche Scientifique (UMR 7104), Institut National de la Santé et de la Recherche Médicale (U 964), University of Strasbourg, Illkirch, France; 3) Research group "Evolution et Développement du Squelette", UMR 7138-Evolution Paris-Seine, Institut de Biologie Paris-Seine, Université Pierre et Marie Curie, Paris, France; 4) Centre de référence pour les Affections Rares en Génétique Ophtalmologique (CARGO), Hôpital Civil, Strasbourg, France; Service de Génétique Médicale, Hôpital de Hautepierre, Strasbourg, France; 5) Faculty of Oral Medicine, University of Strasbourg, Strasbourg, France; 6) Reference Centre for Orodental Manifestations of Rare Diseases, Pôle de Médecine et Chirurgie Bucco-dentaires, Hôpitaux Universitaires de Strasbourg (HUS), Strasbourg, France.

Genetic disorders of the oral cavity and teeth, whether present in isolation or as part of a syndrome, encompass a wide range of disease phenotypes and numerous genetic loci. Furthermore, several of the constituent phenotypes show considerable locus heterogeneity, with evidence for the involvement of novel loci, thus rendering the molecular diagnosis of these phenotypes challenging. We have developed a targeted next-generation sequencing assay, GenoDENT, for the diagnosis and discovery of mutations in 560 known and candidate genes in orodental diseases. We demonstrate the utility of this assay for the molecular diagnosis of a wide variety of syndromic and non-syndromic dental disorders, such as amelogenesis imperfecta, dentinogenesis imperfecta, selective tooth agenesis, and ectodermal dysplasia. In eight patients with a known molecular diagnosis, GenoDENT was able to identify 100% of the mutations, including a ~3 Mb heterozygous deletion on the X chromosome. The target enrichment allowed a mean coverage of 371X, with 95% of targeted nucleotides being covered at ≥50X. Furthermore, in eight patients without a molecular diagnosis, we were able to identify known and/or novel mutations in known genes in 6/8 patients (75%). These included a frameshift mutation in *DSPP* (dentinogenesis imperfecta), missense mutations in *WNT10A* (selective tooth agenesis) and *EDA* (ectodermal dysplasia), and nonsense and missense mutations in *WDR72* (amelogenesis imperfecta). The mutations were validated by Sanger sequencing and their pathogenicity was established by segregation analysis in family members for whom DNA was available. Bioinformatic analyses predicted the novel missense mutations identified to be pathogenic. In the two patients in whom no mutations were identified in known genes, the GenoDENT pipeline allowed us to prioritize potentially novel pathogenic loci for further investigation. In conclusion, we have developed a reliable targeted sequencing assay for the genetic diagnosis of a wide variety of orodental disorders. This assay also provides the potential to identify novel loci underlying rare orodental disorders. This EU-funded project (ERDF) A27 "Oro-dental manifestations of rare diseases", is supported by the RMT-TMO Offensive Sciences initiative, INTERREG IV Upper Rhine program www.genosmile.eu.

2531S

A new approach to target capture for genetic testing: a novel DNA enrichment method for next-generation sequencing applied to clinically-relevant genes. *C. Richard[1], Y. Bei[1], B. Galvin[1], L. Apone[2].* 1) Directed Genomics, Ipswich, MA; 2) New England Biolabs, Ipswich, MA.

As next-generation sequencing expands from basic research into clinical applications, target enrichment protocols need to be simple, robust, and cost effective. To address this need, we have developed a new technique for target capture that offers significant advantages over traditional in-solution hybridization and multiplex PCR protocols. This method utilizes rapid hybridization of short probes to genomic DNA or cDNA fragments, to define the regions of interest, followed by enzymatic removal of off-target sequence, ligation of NGS platform specific adaptors, and PCR amplification. This method can individually tag DNA molecules with unique identifiers for duplicate filtering, is easily performed within one day, and is compatible with FFPE samples. To demonstrate this technique, we have designed a panel to capture over two hundred exons from oncogenes and tumor suppressor genes, covering several thousand COSMIC mutations. Analysis of the libraries sequenced on an Illumina MiSeq demonstrates the high specificity and uniformity of the target sequences generated by this approach.

2532M

Nijmegen breakage syndrome detected by newborn screening for T cell receptor excision circles (TRECs). *A.N. Adhikari[4], J. Patel[1], R.A. Gatti[2], C. Brown[2], U. Sunderam[3], K. Kundu[3], R. Srinivasan[3], S.E. Brenner[4], J.M. Puck[5], J.A. Church[6].* 1) Department of Pediatrics, Children's Hospital of Los Angeles, Los Angeles, CA; 2) Departments of Human Genetics and Pathology & Laboratory Medicine, David Geffen University of California Los Angeles School of Medicine, Los Angeles, CA; 3) Innovations Labs, Tata Consulting Services, Hyderabad, AP, India; 4) University of California, Berkeley, CA; 5) Department of Pediatrics and Institute for Human Genetics, University of California, San Francisco, CA; 6) Department of Pediatrics, Keck School of Medicine, University of Southern California and Children's Hospital, Los Angeles, CA.

Severe combined immunodeficiency (SCID) is a group of disorders characterized by reduced or absent T-cell number or function. Newborn screening for SCID utilizes quantification of T cell receptor excision circles (TREC). These circular DNA byproducts of thymic T cell receptor rearrangements correlate with numbers of circulating T cells. Although TREC screening was developed to identify patients with SCID, it has identified T lymphopenia in newborns with disorders that may not otherwise present until later in life. We present a case of an infant patient with Nijmegen breakage syndrome, an autosomal recessive disorder characterized by microcephaly, a distinct facial appearance, short stature, immunodeficiency, radiation sensitivity, and a strong predisposition to lymphoid malignancy. Low newborn TREC led to confirmatory testing that demonstrated persistently low T cells from birth. Whole exome sequencing (WES) was performed on the infant and his healthy parents to look for causative genetic variant(s) potentially associated with the observed phenotypes in the infant.

The sequencing data were processed through our analysis pipeline. The first several steps employed standard tools for mapping and variant calling, but integrated two different carefully-tuned callers to yield high quality sets of variants. Comprehensive variant annotation was performed to flag the compound heterozygous, de novo, uniploidal disomy, and X-linked recessive variants with potential clinical importance. After filtering the variants and prioritizing genes based on an immunological disorder associated gene list, we found two previously unreported compound heterozygous nonsense mutations in the gene for nibrin (*NBN*) (c.1140C>T;p.Gln344*, c.952T>G;p.Leu281*), predicted to cause nonsense-mediated mRNA decay of transcripts from both alleles in the infant patient. The identified *NBN* variants were confirmed experimentally using Sanger sequencing in a CLIA-approved Medical Genetics laboratory. Immunoblotting showed absence of nibrin protein and a colony survival assay demonstrated radiosensitivity comparable to patients with ataxia telangiectasia. Thus, WES after abnormal SCID newborn screening made the early diagnosis of Nijmegen breakage syndrome.

Establishing distinctive criteria for reporting genomic sequencing results in healthy versus ill newborns: The BabySeq Project. *O. Ceyhan-Birsoy[1, 2, 3], S.S. Kalia[4], P.J. Park[3], T.W. Yu[2, 3, 5], P.B. Agrawal[2, 3, 6], R.B. Parad[7], I.A. Holm[2, 3], A. McGuire[8], R.C. Green[1, 4], A.H. Beggs[2, 3], H.L. Rehm[1, 9].* 1) Laboratory for Molecular Medicine, Partners Center for Personalized Medicine, Cambridge, MA; 2) Division of Genetics and Genomics, Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 3) Department of Pediatrics, Harvard Medical School, Boston, MA; 4) Department of Medicine, Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) Department of Neurology, Boston Children's Hospital, Boston, MA; 6) Division of Newborn Medicine, Boston Children's Hospital, Boston, MA; 7) Department of Pediatric Newborn Medicine, Brigham and Women's Hospital, Boston, MA; 8) Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX; 9) Department for Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Newborn genomic sequencing may enable detection of a wide range of conditions for which knowledge can improve health outcomes. At the same time, to mitigate the risks of ambiguous information, distinct criteria need to be defined for return of results in healthy versus ill newborns. We developed different genome analysis protocols and reporting strategies for these two populations in the BabySeq project, a randomized controlled trial exploring the use of newborn genomic sequencing. 240 healthy newborns and 240 sick newborns in the NICU will be enrolled and randomized to receive exome sequencing. All newborns in the sequencing group will receive a Genomic Newborn Sequencing Report (GNSR) with variants in genes that have strong evidence to cause a highly penetrant childhood-onset disorder. To determine which genes meet these criteria, over 1,000 genes have been curated and categorized with respect to multiple attributes, including strength of evidence for disease association, mode of inheritance, age of onset, and penetrance. To minimize risks associated with reporting difficult-to-interpret variants, only pathogenic and likely pathogenic variants will be returned on the GNSR. In addition to the GNSR, newborns in the NICU will also receive an Indication Based Genome Report (IGBR), which will focus on genes with strong or moderate evidence for the indication. We have created lists of genes associated with 20 of the most common presentations in the NICU, including hypoglycemia, seizures, and hypotonia. If results from these predefined lists are non-explanatory, genes with novel loss-of-function or biallelic rare variants will also be considered. Consistent with a diagnostic testing approach, the IBGR will return pathogenic, likely pathogenic, and uncertain significance variants in genes with a clear causal relationship to the indication. Multiple IBGRs may be requested as the clinical scenario evolves or if new indications arise. Finally, standardized report formats consisting of a one-page results summary followed by detailed explanation of variants and diseases have been generated to communicate results efficiently to medical geneticists as well as non-geneticist providers. We will monitor the understanding of our reports by patients and physicians, and their impact on clinical outcomes, healthcare utilization, and safety. These assessments will contribute to elucidating the potential risks and benefits of genomic sequencing in newborns.

2534S

Detection of Low Level Mixed Chimerism Using High Throughput SNP Genotyping. *A.A. Nakorchevsky[1], E. Flores[1], X. Li[2], T. Hong[2], A.O.H. Nygren[1].* 1) Agena Bioscience, San Diego, CA, USA; 2) Hackensack University Medical Center, Hackensack, NJ, USA.

Patients diagnosed with blood malignancies often receive allogeneic bone marrow transplant or stem cell transplants following the regimen of chemotherapy. Status of the post-transplant patients has to be monitored carefully to allow for early diagnosis of such post-transplant adverse effects as transplant rejection, graft vs. host disease or hematologic relapse. Triaging of the transplant recipients in clinical and research settings is achieved by monitoring the Minimal Residual Disease (MRD) or measuring the amount of mixed chimerism in peripheral blood lymphocytes (PBL) of the patients. Mixed chimerism is a phenomenon where in addition to the donor cells the recipient white blood cells are detected post allogeneic transplant indicating that the possibly malignant recipient cells have evaded cytoreductive treatment and are undergoing hematopoiesis. While MRD molecular techniques target disease-specific markers such as mutations and translocations, mixed chimerism is detected via PCR-based typing techniques such as Short Tandem Repeat (STR) and Variable Number Tandem Repeat (VNTR) analysis. We created a single nucleotide polymorphism genotyping method to detect mixed chimerism in PBL and circulating cell free DNA. The panel targets 92 independent SNPs with a minor allele frequency 0.45-0.55 via multiplex PCR followed by single base extension into the SNP site and detection with MALDI-TOF mass spectrometry. Identification of low percentage mixed chimerism is achieved by analyzing the cumulative skew in genotyping data across a cohort of 92 markers. The feasibility of the panel and algorithm was verified using artificially created mixed chimeric samples from both related and unrelated individuals. Using this model system we achieved a 1% limit of detection with an analytical sensitivity and specificity of 0.95 and 0.9 respectively. Finally we evaluated a set of pre-validated clinical chimeric samples and obtained 100% concordance with an orthogonal technology. The advantages of this SNP-based method compared to already established methodologies is that it has higher sensitivity than STR-based methods and it does not require disease specific markers or prior knowledge of either donor or recipient genotypes. Results are obtained within 8 hours with no library preparation and the experimental workflow can be multiplexed to increase sample throughput. The panel and the analysis algorithm can also be used with other genotyping or sequencing technologies.

2535M

Silver-Russell syndrome and segmental UPD(7q) detected by array CGH. *P. Tavares[1], A. Vaglio[2], R. Lemos[1], C. Ventura[1], A. Pereira[1], A. Sousa[1], J. Sá[1], J. Pinto Basto[1], R. Quadrelli[2], P. Rendeiro[1].* 1) CGC Genetics, Porto, Portugal (www.cgcgenetics.com); 2) Instituto de Genética Médica, Hospital Italiano, Montevideo, Uruguai.

Introduction: 20 to 60% of cases of Silver-Russell syndrome (SRS) are caused by the epigenetic changes of DNA hypomethylation at the telomeric imprinting control region (ICR1) on chromosome 11p15, involving the H19 and IGF2 genes. About 10% of cases are due to maternal uniparental disomy (UPD) of chromosome 7 [Penaherrera et al 2010]. A few cases are due to segmental UPD7 [Hannula et al 2001 and Eggermann 2008]. Objective: We report a SRS clinical case due to a maternal segmental UPD7 and will compare the clinical and molecular data with the published segmental UPD7 SRS clinical cases. Results: The clinical diagnosis was confirmed by the identification of a run of homozygosity at 7q11.22 to 7q31 with 38.7 Mbp (Cytoscan 750k, Affymetrix) with abnormal methylation pattern on genes GRB10 and MEST (MS-MLPA ME032-A1, MRC Holland), confirming a maternal UPD7. Conclusions: This clinical case supports the association between segmental UPD7 and SRS. Despite the fact that segmental mUPD7 is restricted to 7q arm, imprinted genes on 7p arm are also involved, enlightening the complexity of this disease. This clinical case can contribute for a better understanding of the molecular mechanisms of SRS.

Leber Congenital Amaurosis (LCA) is the most common cause of incurable childhood blindness. Non syndromic LCA is characterized by a clinical, genetic and physiopathological heterogeneity. Hitherto 18 genes are identified which mutations cause a stationary and dramatically severe cone-rod dystrophy with very poor visual performances or a progressive, yet severe, rod-cone dystrophy with low but measurable visual acuity in the first two decades of life. LCA genes are involved in variable retinal functions; cilia dysfunctions are the leading cause of the disease (7 cilia genes; ca. 30% of the cases). Patients with LCA occasionally develop renal, neurologic and or skeletal symptoms defining a series of syndromes which hallmark is cilia dysfunction. So far, 19 cilia genes are identified which cause syndromic type 1 or 2 LCA. With the exception of CEP290 and IQCB1 which mutations cause non syndromic or syndromic LCA, the identification of disease causing mutations in an infant with LCA is of great help to make a prognosis with respect to the retinal and extraocular outcome. Considering the prevalence of cilia dysfunction in syndromic and non syndromic LCA, we used ciliome sequencing as a molecular diagnosis and progonosis tool and a research tool to identify novel LCA genes. The DNA of 60 unrelated children with LCA was subjected to ciliome sequencing using a custom 5.3 Mb Agilent SureSelect Target Enrichment library which captures 32,146 exons of 1,666 genes selected form cilia databases. Biallelic disease-causing mutations in known genes were identified in 17/60 patients: CEP290 (n = 4), CRB1 (n = 4), RPGRIP1 (n = 2), LCA5 (n = 1), IQCB1 (n = 2), IFT140 (n = 2), AHI1 (n = 1), ALMS1 (n = 1). Single heterozygote disease-causing mutations were detected in 9/60 individuals but Sanger sequencing failed to detect a mutation on the second allele. Finally, 3/60 patients harbored biallelic mutations in three novel genes. In summary, ciliome resequencing allowed identifying the disease-causing gene in 33 % of the patients addressed for LCA making targeted sequencing an interesting alternative to expensive whole exome sequencing. The identification of mutations in genes responsible for Mainzer-Saldino syndrome (IFT140), Joubert syndrome (AHI1) and Alström syndrome (ALMS1) before extraocular expression become obvious demonstrates the importance of NGS-based molecular diagnosis to set-up a rational and efficient follow-up of patients.

2537S

Somatic mosaicism for a novel PDHA1 mutation in a male with severe pyruvate dehydrogenase complex deficiency: a case report and literature review. *S. Zhang[1], K. Deeb[1], J. Bedoyan[2], R. Wang[3], L. Sremba[3], M. Schroeder[1], G. Grahame[2], M. Boyer[3], S. McCandless[2], D. Kerr[2].* 1) Dept. of Pathology, University Hospitals Case Medical Center, Cleveland , OH.,; 2) Center for Inherited Disorders of Energy Metabolism, University Hospitals Case Medical Center; 3) Division of Metabolic Disorders, CHOC Children's Hospital, Orange, CA.

Mutations in the X-linked PDHA1 gene encoding the pyruvate dehydrogenase complex (PDC) PDH-E1α subunit are mostly responsible for PDC deficiency. Males harboring hemizygous PDHA1 mutations are clinically more severely affected, while females often display variable clinical manifestations due to skewed X-inactivation. Mosaic PDHA1 mutations are less frequently reported and may manifest in milder phenotypes. Here, we report a novel mosaic mutation in a male patient with a severe phenotype. The patient is a 4 ½ year old boy with a clinical history of congenital microcephaly, significant brain abnormalities including agenesis of the corpus callosum, colpocephaly, hypoplasia of the cerebellar vermis and Dandy-Walker variant, persistent seizures, profound developmental delay, and failure to thrive. He exhibited persistently elevated blood lactate, pyruvate, and alanine with normal lactate to pyruvate ratio, suggestive of PDC deficiency. PDC activities in cultured skin fibroblasts (SF) from this patient (0.63 and 0.76 nmol/min/mg protein) were below the reference range (mean 2.42; range 1.26-4.42, n = 329), corresponding to 26% and 31% of the mean, respectively. The patient was found to be mosaic for a novel, missense mutation, c.523G>A (p.A175T), confirming the clinical and biochemical findings of PDC deficiency. Molecular analysis of the PDHA1 gene from peripheral blood of the proband's mother did not reveal the same change, consistent with a de novo event in this patient. This is the seventh reported case of male somatic mosaicism for a PDHA1 mutation, but notably with a significantly severe clinical phenotype.

2538M

Performance evaluation of inherited disease panels for Korean patients with Limb-girdle muscular dystrophies (LGMD). *H. Kim[1], N.J. Kwon[1], J. Kim[1], M.W. Seong[2], H. Park[2], S.H. Seo[2], D.D. Seol[2], S.I. Cho[2], K.S. Yang[1], S.S. Park[2], J.S. Seo[1,3].* 1) Macrogen Inc., Seoul, Korea; 2) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 3) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, Korea.

The genomic data produced by next-generation sequencing (NGS) are widely used to better understand disease development and drug response. Recently, numerous companies have developed and commercialized targeted sequencing panels that focus on specific disease of interest. In this study, the performance of three commercialized inherited disease panels were evaluated on 16 Korean patients, suspected to have Limb-girdle muscular dystrophies (LGMD). The TruSight One sequencing panel and TruSight Inherited Disease (Illumina), which utilizes prbobes to capture the target regions, and Ion AmpliSeq Inherited Disease Panel (Thermo-Lifetechnologies), which utilizes the amplicon system, were evaluated. The TruSight One sequencing panel provides comprehensive coverage of more than 4800 clinical relevant genes and focuses on the exonic regions, which harbor the disease-causing mutations. On the other hand, TruSight Inherited Disease and Ion AmpliSeq Inherited panel are more inherited disease specific. TruSight Inherited Disease sequencing panel focuses on the coding region and intron-exonic boundaries of 552 genes of pediatric-onset Mendelian disorders, while Ion AmpliSeq Inherited Disease sequencing panel focuses on the coding exons of over 300 genes associated with over 700 unique inherited diseases, including neuromuscular, cardiovascular, developmental, and metabolic diseases. The sequencing data were produced using MiSeq, HiSeq2500 (Illumina), and Ion Proton (Thermo-Lifetechnologies). The basic analysis for sequencing quality and disease associated variants of each panels were performed through our internal analysis pipeline. We analyzed common targeted regions of the three panels, and all identified mutations were confirmed using Sanger Sequencing. Additionally, the data produced by HiSeq2500 and MiSeq were compared to identify mutation that were found at high depth of HiSeq2500 data but not present in MiSeq Data. We evaluated the accuracy of each panels to validate NGS technologies for clinical diagnosis. We show that inherited disease panels are able to detect rare mutation in the disease samples, and our data provides good foundation for further clinical studies.

2539T

Expanding the phenotype of genes encoding the components of the PI3K pathway. *M.A. Walkiewicz[1], A. Dang Do[2], N.L. de Macena Sobreira[2], J. Beuten[1], J. Zhang[1], Z. Niu[1], F. Xia[1], J.N. Bodurtha[2], B.H. Graham[1,4], F. Scaglia[1,4], D.M. Muzny[3], A.L. Beaudet[1], R.A. Gibbs[1,3], Y. Yang[1], C.M. Eng[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Texas Children's Hospital, Houston, TX 77030.

Mutations in genes encoding the components in the PI3K pathway, namely *AKT3*, *PIK3R2*, and *PI3KCA*, have been recently reported in individuals with megalencephaly-capillary malformation (MCAP - MIM 602501), megalencephaly-polymicrogyria-polydactyly-hydrocephalus (MPPH - MIM 603387), CLOVES (MIM 612918), and Cowden (MIM 615108) syndromes. The first proband is a 22 month old female who presented with poor feeding since birth, stiffness of extremities, megalencephaly, communicating hydrocephalus, and electroclinical seizure by EEG. The initial course was complicated by sepsis leading to hyperlactatemia, hypoglycemia, metabolic acidosis, and thrombocytopenia. Brain MRI revealed multiple foci of T1 hyperintensity in the cerebral white matter thought to represent heterotopias. By WES we identified a *de novo*, heterozygous c.1393C>T (p.R465W) mutation in the *AKT3* gene. The same mutation was previously reported in a patient with congenital megalencephaly, somatic asymmetry, connective tissue dysplasia, and umbilical hemangioma. The second proband is a 2.6 year old male born prematurely at 36 weeks. He has global developmental delay, macrocephaly, dolichocephaly, and hepatomegaly. MRI of the brain demonstrated perisylvian polymicrogyria. By WES we identified a *de novo*, heterozygous c.1669G>T (p.D557Y) variant in the *PIK3R2* gene. The third proband is a 24 month old female who presented with global developmental delay, macrocephaly, asymmetric facies, nevus flamus, atrial tachycardia, omphalocele, left hydronephrosis, multiple other dysmorphic features including 2-3 toe syndactyly, and recent accelerated weight gain. Brain MRI revealed small posterior fossa with crowding of the cerebellum, ventriculomegaly, and mild parietal periventricular T2 hyperintensity. By WES we identified a *de novo*, mosaic (mutant 27: wild type 185) c.1093G>A (p.E365K) mutation in the *PIK3CA* gene. This change was previously reported in a patient with megalencephaly. In summary, we report three additional individuals with mutations in the components in the PIK3-pathway. Although all three patients had megalencephaly, abnormal brain imaging, and global developmental delay, other clinical findings confounded a definitive clinical diagnosis. This further demonstrates the utility of WES in confirming clinical diagnosis and expanding disease phenotype.

2540S

CLINICAL ADVANTAGES OF HIGH COVERAGE COMPREHENSIVE NGS PANELS IN THE MOLECULAR DIAGNOSIS OF HEREDITARY CANCER MUTATIONS. *H. DAI, G. DOUGLAS, E. GORMAN, S. CHEN, X. TIAN, Y. FENG, F. LI, J. WANG, V. ZHANG, L. WONG.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX., United States.

Introduction: Accurate assessment of hereditary cancer risk by molecular diagnosis of predisposing mutations is essential for disease management and genetic counseling. When ordering such genetic tests, it may be challenging to single out relevant genes while still aiming to obtain evaluations as comprehensive as possible. High coverage capture-based Next Generation Sequencing (NGS) panel analysis provides a promising solution to meet clinical demands in a cost-efficient way. Methods: 61 hereditary cancer-associated genes, grouped into 12 disease-specific panels and one comprehensive panel, were targeted with in solution capture followed by next generation sequencing. Exons with coverage <20X, or with possible pseudogene(s), are complemented by amplicon/Sanger sequencing to reach 100% coverage. Mutations/unclassified variants detected by NGS were further confirmed by Sanger sequencing. Potential copy number variation (CNV) suggested by our NGS assay are confirmed by either array CGH or MLPA methods. 10 phase I samples (commercially available plus internal control gDNA from different types of tissues) and 13 phase II samples (with known mutations) were used for validation. Results: The mean coverage is 1255X/750X for phase I and II validation, respectively. Phase I samples have an average of 97 variants in the comprehensive panel, which are 100% concordant with amplicon/Sanger sequencing results. In phase II samples, all known point/indel mutations in BRCA1, MEN1, MUTYH, VHL, APC and PTEN were successfully detected. Furthermore, pathogenic exonic CNVs in VHL, MLH1, TP53, PTEN, EPCAM and a whole gene deletion in APC gene were also identified successfully and confirmed. As an example of highlighting the advantage of our NGS assay, we were able to detect both a point mutation (c.65C>A) and an exon 14 deletion of PMS2 gene in one sample simultaneously, despite the well-known PMS2 pseudogene interference. Conclusions: This capture based deep coverage NGS panel provide accurate and comprehensive analysis for hereditary cancers genes. The combination strategies of both deep coverage of all coding regions and Sanger confirmation/complementation allows accurate identification of a wide spectrum of mutation types, including point mutations, small indels, mosaicism. In addition, CNVs at the exon level can be analyzed simultaneously. Our data underscore the important clinical utility of NGS-based analysis in the molecular diagnosis of hereditary cancer.

2541M

Mutations in *STK11* identified exclusively in individuals with clinical histories suggestive of Peutz-Jeghers syndrome. *J.S. Dolinsky[1], S.B. Keiles[1], T.F. Pesaran[1], C. Horton[1], M. Umali[1], K. McGoldrick[1], S. Li[1], E. Chao[1,2].* 1) Ambry Genetics, Aliso Viejo, CA., USA; 2) University of California, Irvine, School of Medicine, Irvine, CA.

Pathogenic mutations in *STK11* are detected in an estimated 80% of individuals clinically diagnosed with Peutz Jeghers syndrome (PJS). PJS is characterized by gastrointestinal PJS-type hamartomatous polyposis, mucocutaneous pigmentation, and cancer predisposition including breast cancer, which can occur at early ages in PJS with up to a 57% breast cancer risk by age 70. Due to the risk of early onset breast cancer, it has been proposed that family members could develop breast cancer prior to polyposis symptomatology. Thus, *STK11* has been included on a number of commercially available and academic research hereditary breast cancer (HBC) multigene panel tests. In this study, we sought to identify individuals with a *STK11* mutation detected on HBC multigene panels offered by Ambry Genetics from March 2012 through May 2014. We hypothesized that some individuals with HBC in the absence of other PJS features will harbor a *STK11* pathogenic mutation. 12,928 individuals underwent panel testing with BRCAplus (*BRCA1*, *BRCA2*, *CDH1*, *PTEN*, *STK11*, *TP53*) or BreastNext (BRCAplus genes and *ATM*, *BARD1*, *BRIP1*, *CHEK2*, *MRE11A*, *MUTYH*, *NBN*, *NF1*, *PALB2*, *RAD50*, *RAD51C*, *RAD51D*). Clinical data submitted via test requisition form and subsequently verified by the clinician was assessed for individuals with a *STK11* mutation. Clinical data from an additional 73 individuals with mutations in *STK11* identified through single gene testing or another multigene panel was also assessed. Several probands had histories consistent with HBC, however those probands met clinical criteria for PJS. Remaining individuals with a *STK11* pathogenic mutation had a clinical diagnosis of PJS or features consistent with PJS, including one individual identified through a HBC panel. The remaining 12,927 individuals referred for HBC multigene panel testing did not harbor a *STK11* pathogenic mutation. While variants of unknown significance (VUS) are not common in *STK11*, having been identified in approximately 0.44% of the HBC multigene cohort, there are significantly more VUS than mutations identified in *STK11* on HBC panels ($p<0.001$). This analysis does not support our hypothesis, but rather suggests that inclusion of *STK11* may not be appropriate on multigene HBC panels, introducing more uncertain results without improving diagnostic yield. *STK11* testing should be reserved for broad spectrum hereditary cancer panels, polyposis panels or single gene analysis in individuals with a history suggestive of PJS.

2542T

Risks associated with utilizing molecular data to guide tumor surveillance in BWS. *C. Shuman[1,2,3], S. Choufani[2], L. Steele[3,4], N. Parkinson[3,4], J. Lauzon[5], J. Tagoe[6], P. Ray[3,4], R. Weksberg[1,2,3,7,8].* 1) Clinical & Metabolic Genetics, Hosp for Sick Children, Toronto, ON., Canada; 2) Genetics and Genome Biology Program, Research Institute, The Hospital for Sick Children; 3) Department of Molecular Genetics, University of Toronto; 4) Paediatric Lab Medicine, Molecular Genetics, The Hospital for Sick Children; 5) Department of Medical Genetics, Alberta Childrens Hospital; 6) Genetic Services, Alberta Health Services; 7) Institute of Medical Science, University of Toronto; 8) Department of Paediatrics, University of Toronto.

In general, it is well accepted that tumor risk assessment can be significantly improved by incorporating epigenomic/genomic data. In this regard, recent publications (Brioude et al. 2013; Scott et al. 2006) recommend tailoring tumor surveillance for children with Beckwith-Wiedemann syndrome (BWS) based on the specific molecular etiology, when identified. However, technical limitations of the test in determining somatic epigenetic mosaicism can lead to negative health outcomes. BWS is an etiologically heterogeneous, pediatric overgrowth syndrome associated with an increased risk (~ 4 - 21%) for embryonal tumor development. This risk led to tumor surveillance recommendations including 3 monthly abdominal ultrasounds. (Epi)genetic alterations involving the telomeric imprinting centre, IC1 (i.e. gain of methylation [GoM]at IC1or paternal uniparental disomy [UPD] of 11p15.5) have the highest risks for tumor development. Those with alterations involving the centromeric imprinting centre, IC2 (i.e. loss of methylation [LoM] at IC2 or mutations in CDKN1C) have significantly lower risks and no cases of Wilms tumor (WT) have been reported. These findings led to new molecular group specific recommendations to discontinue ultrasound screening for WT in children with demonstrated IC2 LoM. We present 3 cases of children with BWS and IC2 alterations on initial MS-MLPA testing who subsequently were found to have renal tumors/nephrogenic rests detected by abdominal ultrasound. Pt 1: Nephrogenic rests (stable) were detected in a 16 month male with IC2 LoM in DNA from saliva and blood, on repeat testing. Pt 2: WT was found in a 15 month old female with LoM in DNA from blood. Retesting on a new blood sample revealed borderline findings of IC2 LoM and IC1 GoM consistent with UPD. Pt 3: Unilateral WT was detected in a 9 month old female. Repeat testing on DNA obtained from blood and skin showed borderline IC2 LoM. No evidence of UPD was found. Pyrosequencing these cases in the research lab demonstrated methylation indices most consistent with low level mosaicism for UPD. Therefore, we would advocate caution in revising medical management guidelines especially when the etiology involves mosaicism and/or the testing technology generates data that are not definitive. Technological advances may resolve some of these issues to support stratification of tumor risk assessment and surveillance by molecular test results.

2543S

Universal Lynch syndrome screening in an integrated health care system: Assessment of patient perspectives on benefits and barriers. *J.E. Hunter[1], J. Zepp[1], M. Gilmore[1], J. Davis[1], E. Esterberg[1], K.R. Muessig[1], S.K. Peterson[2], S. Syngal[3], L. Acheson[4], G. Wiesner[5], K.A.B. Goddard[1], J. Reiss[1].* 1) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 2) Department of Behavioral Science, University of Texas MD Anderson Cancer Center, Houston, TX; 3) Dana-Farber Cancer Institute, Boston, MA; 4) Departments of Family Medicine and Community Health, Reproductive Biology, and Oncology, Case Western Reserve University, Cleveland, OH; 5) Vanderbilt Hereditary Cancer Program, Department of Medicine, Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN.

Lynch syndrome (LS) is the most common form of hereditary colorectal cancer (CRC) and accounts for 2-3% of all CRC cases. A diagnosis of LS has significant impact on clinical management of patients and their at-risk family members. Universal screening for LS using either microsatellite instability (MSI) or immunohistochemistry (IHC) testing among CRC patients is increasingly implemented in clinical practice. The aim of this study was to assess knowledge of and attitudes toward MSI screening among newly diagnosed CRC patients. Participants were recruited through Kaiser Permanente Northwest and were administered a phone survey regarding MSI screening. The study population consisted of 74 men and 50 women age 39 to 87 years. Only 3% of participants had any prior knowledge of MSI screening, and 8% anticipated having an abnormal screening result. However, most participants expressed interest in MSI screening: 92% wanted to know their risk of hereditary CRC and 93% agreed that MSI screening should be available to anyone. Overall, participants endorsed the benefits of screening for themselves and their families: 87% agreed they would be glad that their doctor ordered this test, 94% would like information that could benefit their family, and 99% responded they would share their screening results with their family. Older participants were less likely to be worried about their family's risk of CRC and lower income participants were more likely to report that MSI screening would not help them or their family. The most commonly reported barrier to MSI screening was worry regarding the cost of additional testing and surveillance, endorsed by 72% of participants. In particular, younger and lower income participants were more likely to be worried about additional costs associated with an abnormal screening result. Another potential barrier to screening was a concern about privacy and confidentiality of the test result, endorsed by 30% of participants. Few participants (10%) indicated concern about losing their health insurance; however, younger and lower income participants were more likely to be concerned. Although CRC patients in our study had little a priori knowledge about MSI screening, they responded positively to undergoing screening and recognize the potential benefits to themselves and their families. However, concern regarding additional out-of-pocket healthcare costs may be a barrier to MSI screening, particularly among younger and lower income patients.

2544M

Diagnostic Exome Sequencing as the Foundation of Building Pharmacogenomics Based Therapeutic Models for the Treatment of Ion Channel Epilepsy. *S.K. Gandomi, K. Waller, K.D. Farwell Gonzalez, L. Shahmirzadi, R. Baxter, B. Tippin-Davis, S. Tang.* Clinical Genomics, Ambry Genetics, Aliso Viejo, CA., USA.

Diagnostic exome sequencing is currently the most comprehensive clinical genetic testing option available to patients with neurological disorders. Historically, individuals presenting with features suggestive of an underlying genetic syndrome had limited options in the diagnostic process, especially in regards to their subsequent management. With the recent advancement of Next Generation sequencing techniques, and the rapid growth in clinical utility of diagnostic exome sequencing (DES) in the clinical neurology setting, the diagnostic and treatment options available for epilepsy patients is progressively changing. Here we present our institution's DES data to show the effectiveness of DES in diagnosing ion channel related epilepsy, which therefore lays the foundation for potential pharmacogenomic treatment protocols in the near future. In the first 496 cases sent to our institution for DES, 131 (27.93%) patients were diagnosed with epilepsy as a major clinical feature upon referral. Approximately 43 (32.8%) of these patients were found to have positive, pathogenic alterations, and an additional 11 (8.4%) patients were found to have "likely positive" alterations in a variety of genes. In both of these cohorts combined (n=54), 1 patient had an alteration in a calcium-activated chloride channel gene (ANO3[610110]), 3 patients had alterations in sodium channel genes (SCN3A [MIM 182391], SCN1A[MIM 182389]), and 3 additional patients had alterations in potassium channel genes (KCNQ2 [602235], KCNC3 [176264]). As the current literature suggests, there are rapidly increasing therapeutic possibilities for epilepsy, especially for disorders involving major ion channels such as SCN1A (MIM 182389). We anticipate the continued and increased use of DES in identification of pathogenic alterations for patients with ion channel-related epilepsy, and recommend the integration of DES technology into research and clinical settings for the long-term development of targeted therapies.

2545T

Next-generation sequencing diagnostics for inherited arrhythmogenic cardiac disorders. *C. Marschall, I. Vogl, HG. Klein.* Center for Human Genetics, 82152 Martinsried, Bavaria, Germany.

Inherited arrhythmogenic cardiac disorders are composed of primary arrhythmia syndromes such as long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT) and Brugada syndrome (BrS) and the cardiomyopathies with structural changes leading to an arrhythmia risk such as hypertrophic cardiomyopathy (HCM), dilatative cardiomyopathy (DCM) and arrhythmogenic right ventricular cardiomyopathy (ARVC). All these diseases are associated with significant morbidity and mortality and are a known risk factor for sudden cardiac death. The presymptomatic diagnosis is essential as for most of the cases a therapy is available. Mutation detection in the index cases followed by cascade screening of the family members could be life saving. As some cardiomyopathies may present with only little structural symptoms, the differential diagnosis of these arrhythmogenic disorders may be difficult. Unfortunately some arrhythmogenic disorders are extremely heterogeneous. A Nextera sequence capture in solution target enrichment assay was designed for the capture of coding regions including splice sites of 61 genes known to be associated with arrhythmogenic disorders. Target enrichment followed by re-sequencing on the Illumina MiSeq was used for mutation detection. More than 40 clinical samples with a suspected inherited arrhythmogenic disorder were analyzed with a minimum coverage of 30-fold. Data analysis was performed with the CLC Genomic Workbench software. Potentially disease causing variants and regions with an insufficient coverage were re-analyzed with Sanger sequencing. Disease causing mutations were detected in over 40% of the cases and less than 20% showed ambiguous variants.

2546S

Genetic testing leads clinical care in neonatal diabetes: a new paradigm. *E. De Franco[1], S.E. Flanagan[1], J.A.L. Houghton[1], H. Lango Allen[1], D.J.G. Mackay[2,3], I.K. Temple[3], S. Ellard[1], A.T. Hattersley[1].* 1) University of Exeter Medical School, Exeter, United Kingdom; 2) Wessex Regional Genetics Laboratory, Salisbury Health Care Trust, Salisbury, UK; 3) Human Genetics and Genomic Medicine, Faculty of Medicine, University of Southampton, Southampton, UK.

Traditional genetic testing focusses on analysis of one or a few genes according to clinical features; this testing paradigm will now change as next-generation sequencing allows simultaneous analysis of multiple genes. Neonatal diabetes is the presenting feature of many discrete clinical phenotypes defined by different genetic aetiologies. The genetic subtypes differ in treatment requirements and associated clinical features. We investigated the impact of early, comprehensive testing of all known genetic causes of neonatal diabetes. We studied 1020 patients with neonatal diabetes diagnosed before 6 months of age referred from 79 countries between 2000 and 2013. Mutations were identified by comprehensive genetic testing including targeted next-generation sequencing of 21 neonatal diabetes genes. A genetic diagnosis was obtained in 840 patients (82%). The most common cause were potassium channel mutations (n=390), which were less common in consanguineous families (46% vs 12%, p<0.0001). Transfer from insulin to sulfonylurea therapy with improved glycaemic control was observed in most of these patients. Median time from diabetes diagnosis to referral for genetic testing decreased from over 4 years before 2005 to less than 3 months (2011-2013). Early referral altered the clinical phenotype at time of genetic testing. In patients with a genetic diagnosis of transient neonatal diabetes remittance was seen only in 10% with early referral (less than 3 months from diagnosis) compared to 100% with late referral (more than 4 years from diagnosis, p<0.001). Similarly in patients with genetically diagnosed Wolcott-Rallison syndrome 11% with early referral had syndromic diabetes compared to 82% (p<0.001) with late referral when skeletal/liver involvement was common. Patients are now referred for genetic testing close to presentation with neonatal diabetes. Comprehensive testing of all aetiologies identifies causal mutations in over 80% of cases. The genetic result predicts optimal diabetes treatment and development of related features. This represents a new paradigm for clinical care with genetic diagnosis preceding development of clinical features and guiding clinical management.

2547M

Identification and characterization of *CFTR* deletion and duplication mutations among nonwhite patients with cystic fibrosis. *I. Schrijver[1,2], L. Pique[1], S. Graham[3], M. Kharrazi[4].* 1) Department of Pathology, Stanford Medical Center, CA; 2) Department of Pediatrics, Stanford Medical Center, CA; 3) Sequoia Foundation, La Jolla, CA; 4) California Department of Public Health, Richmond, CA.

Even with the implementation of newborn screening programs across the United States, there remains an inequitable identification of cystic fibrosis (CF [OMIM #219700]) in nonwhite groups. Diagnosis can be improved by determining the type and estimated frequency of individual mutations in nonwhite populations. We specifically investigated the prevalence of deletion and duplication mutations, which are not detectable by Sanger sequencing, in CF patients in the U.S. with African, Native American, Asian, East Indian or Middle Eastern backgrounds. Of the approximately 500 eligible nonwhite CF patients in the Cystic Fibrosis Foundation (CFF) Patient Registry database with zero or one *CFTR* [OMIM *602421] mutation(s) instead of the expected two, 142 probands were enrolled into our study. Of the enrolled probands, 89 were fully genotyped by direct sequencing of *CFTR*. However, 26 had only a single mutation and 27 had no mutations detected. These patients were subsequently analyzed by Multiplex Ligation-dependent Probe Amplification (MLPA) and novel deletion/duplication breakpoints were further characterized by a walking PCR technique. MLPA testing of the 52/53 probands for whom DNA remained available identified 15 del/dup mutations in 13 probands: two were identified in two probands each, one of whom already had a pathogenic mutation identified by sequencing (c.1521_1523delCTT, p.Phe508del). Thus, only 14/15 of these mutations accounted for unidentified alleles (14/78 = 18%). Six of the rearrangements were novel and included one simple deletion, three complex deletions containing short (2-12 bp) insertions, one duplication and a multigenic deletion of exons 19-24 of *CFTR* that extends into the neighboring *CTTNBP2* gene on chromosome 7. Two previously reported rearrangements - a deletion of exons 2-3 and a complex deletion of exons 17a-17b that includes a 62 bp insert - were detected in four probands each (~5% of unidentified alleles). Deletions and duplications in the *CFTR* gene appear to be relatively common in nonwhite CF patients and account for ~18% of unidentified alleles after Sanger sequencing. MLPA should be routinely applied in diagnostic *CFTR* testing, and is an especially valuable part of the testing algorithm in nonwhite individuals. Inclusion of such mutations facilitates early diagnosis and can help improve the quality of life of nonwhite and mixed ethnicity individuals affected with this condition.

2548T

Predicted management implications of CytoScan Dx® Assay in a consecutive cohort of patients suspected of Developmental Delay, Intellectual Disability, and/or Congenital Anomalies. *A. Chaubey[1], R. Pfundt[2], K. Kwiatkowski[3], A. Roter[3], B. DuPont[1], E. Thorland[4], R. Hockett[5], A. Shukla[3], E.T. Fung[3].* 1) Cytogenetics, Greenwood Gen Ctr, Greenwood, SC; 2) Human Genetics, Radboud University, Nijmegen, The Netherlands; 3) Clinical Applications, Affymetrix, Santa Clara, CA; 4) Cytogenetics, Mayo Clinic, Rochester, MN; 5) Cytogenetics, CombiMatrix, Irvine, CA.

Background: The prevalence of developmental disability is 13.87% and occurs across all racial, ethnic, and socioeconomic groups. Establishing an underlying diagnosis early has the potential to reduce health care costs, provide physicians and families with knowledge of which disorder is affecting the child, prognosis, and comorbidity information, all of which have implications beyond only medical treatment. Although microarrays are now common first tier tests in this patient population and supported by the medical guidelines, payer reimbursement for testing is inconsistent. Methods: In a consecutive and unselected cohort of 960 patients who had previously undergone regular genetic testing for suspicion of a genetic disorder related to developmental delay, intellectual disability, congenital anomalies, and/or dysmorphic features, we assessed the diagnostic yield of the CytoScan® Dx Assay as compared to historical patient reports. To then understand how this relates to management implications we assessed the clinical utility of CytoScan Dx Assay by applying the Rigg's criteria of actionability to the chromosomal abnormalities identified by CytoScan Dx Assay. Results: 61.7% of all samples were male with an average age of 7.8 ± 11.3. Overall, 86% of the subjects were assessed using a microarray as part of routine patient care. Abnormal or pathogenic findings were reported similarly for RPC (13.3% or 128/960) and CytoScan Dx Assay (13.8% or 132/960). 33% or 43/132 of the abnormal patients (comprising 51 CNVs) identified by CytoScan Dx Assay had predicted clinical management implications. Conclusions: This is the first study to assess the clinical performance of CytoScan Dx Assay within a consecutive cohort of patients with developmental delay, intellectual disability, and/or congenital anomalies that were referred for whole genome chromosomal testing. CytoScan Dx Assay diagnostic yields are similar to previous studies and one-third of the patients with pathogenic chromosomal identified by CytoScan Dx Assay are predicted to have clinical management implications which may improve health outcomes.

2549S

Comprehensive evaluation of the FBN1, LTBP2 and ADAMTSL4 genes in 667 patients with ectopia lentis. *B. Callewaert[1], L. De Potter[1], S. Van Nuffel[1], E. Debals[1], J. De Backer[1], O. Vanakker[1], H. Van Esch[2], M. Biervliet[3], J. van den Ende[4], J. Désir[5], A. De Paepe[1], P. Coucke[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Ghent, Belgium; 2) Center for Medical Genetics, University Hospital of Leuven; 3) Center for Medical Genetics, University Hospital of Brussels; 4) Center for Medical Genetics, University Hospital of Antwerp; 5) Department of Medical Genetics, Hôpital Erasme, Université Libre de Bruxelles.

Introduction: Ectopia lentis (EL), a displacement of the lens of the eye, has an estimated prevalence of 6.4 per 100 000 live born children. EL can present as an isolated phenomenon or within a syndromal constellation with multisystemic involvement. The most prevalent congenital cause of EL is Marfan Syndrome (MFS), which requires a lifelong cardiovascular follow-up. Because of the evolving phenotype, the diagnosis of MFS is difficult to make at young age and *FBN1* testing is often requested. When no detectable *FBN1* mutation is found, the absence of a definite diagnosis may cause psychological distress and sometimes unnecessary examinations. Recently, mutations in *LTBP2* have been implicated in congenital glaucoma and microspherophakia with EL. *ADAMTSL4* mutations have been implicated in EL and EL et pupillae. This study evaluates the contribution of mutations in *FBN1*, *LTBP2* and *ADAMTSL4* mutations in isolated EL in a large study group. Methodology: Over a 22 month time period a total of 667 probands with EL were referred for *FBN1* analysis. We analyzed the *FBN1*, *ADAMTSL4* and *LTBP2* genes in these patients using a step-wise next-generation approach. Mutations were confirmed with Sanger sequencing. Results: 616 out of 667 probands harbored an *FBN1* mutation (of which 44 did not fulfill the 2010 Ghent revised criteria for MFS) and 51 did not (of which 19 patients did fulfill clinical criteria for MFS) resulting in a detection rate of 92.4% (616/667). In the remaining 51 patients, homozygous or compound heterozygous mutations in *ADAMTSL4* were found in four patients. (c.767_786del; c.2237G>A, c.2021_2022delCT, c.2977C>T, c.963dup). One proband showed a homozygous mutation in *LTBP2* (c.4964A>G). In another proband only one mutation (c.3850C>T, p.Arg1284Cys) was found. Conclusions: *FBN1* is by far the primary gene to screen upon the diagnosis of EL. However, our results show that the clinical spectrum resulting from *LTBP2* and *ADAMTSL4* mutations includes isolated EL. Therefore, if no *FBN1* mutation is found, screening of *ADAMTSL4* and *LTBP2* is advised as this may reveal a final diagnosis for 12% of the remaining patients and even up to 20% if the MFS criteria are not met. In addition, our data indicate that *LTBP2* mutations are no likely cause of *FBN1* negative MFS with EL.

2550M

Barriers to Cytogenetic Testing in Adults with Congenital Heart Disease. *J. Vengoechea Barrios[1], L. Carpenter[1], R.T. Collins[2].* 1) Division of Genetics, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Medicine and Department of Pediatrics, University of Arkansas for Medical Science.

The University of Arkansas for Medical Sciences adult congenital heart disease (ACHD) interdisciplinary clinic began in August of 2012. The clinic includes an ACHD cardiologist, an internist/geneticist, and a genetic counselor. A recent retrospective study of cytogenetic testing in children with syndromic and non-syndromic CHD reported a 15% rate of clinically significant results (1). We sought to determine the rate of clinically significant cytogenetic findings in our ACHD population. A retrospective review was performed of all records of ACHD patients seen in our clinic by both the cardiologist and geneticist. 51 patients were identified for the study as of April 1, 2014. The majority of patients (64.7%; 33/51) were female, as many patients came to care due to pregnancy. The most common diagnoses were bicuspid aortic valve (with either coarctation or aneurysm of the aorta) and Tetralogy of Fallot, each seen in 10/51 patients (19.6%). Other diagnoses included pulmonary stenosis (4/51), isolated coarctation of the aorta (4/51), transposition of the great arteries (4/51) and AV canal defect (4/51). One patient had a previously established diagnosis of Turner syndrome. A cytogenetic test was offered to 37 (74%) of the remaining 50 patients (SNP microarray in 35 patients, a high-resolution karyotype in one patient and a 22q11 FISH in 1 patient), 8/37 patients did not consent to genetic testing (21.6%). Of the remaining 29 patients, testing was completed in 12 cases (41.3%) of which 8 were women (66.7%). The results of the 12 patients included: 1 22q11 deletion, 1 incidental finding of Klinefelter, 1 6q27 gain of uncertain significance, 1 benign variant, and 6 normal microarrays. Two results are pending at this time. Of those patients who gave consent for genetic testing, 17/29 (59%) did not receive testing: 4 patients had no insurance; 3 had insurance that denied coverage; 6 declined due to out-of-pocket cost; and 4 patients did not follow-up after consent was obtained. The present study demonstrates the difficulties in performing cytogenetic testing in ACHD patients. Barriers to access for genetic testing include lack of insurance, restrictive insurance policies with genetic testing exclusions, out-of-pocket costs and difficulties in follow-up after insurance has approved testing. Optimized workflow for single cell copy number profiling using high resolution oligo CGH arrays. *S. Basehore, P. Costa, N. Novoradovskaya, A. De Witte, S. Fulmer-Smentek.* Agilent Technologies Genomics, Santa Clara, California.

Microarray-based comparative genomic hybridization (aCGH) is a powerful technique used in cytogenetic and cancer research for genome-wide detection of DNA copy number (CN) changes. As a consequence of cell and tissue heterogeneity, there has been an increasing focus in single cell analysis in tumors and micrometastases characterization, and in pre-implantation and noninvasive prenatal (fetal cells circulating in maternal blood) investigation. Traditional FISH and PCR based techniques, and more recently BAC arrays, have been used to provide insights into a single cell's genome, with limited resolution. Here we describe a same day, cost-effective, analysis workflow that combines whole genome amplification (WGA), with CN profiling using high-resolution oligo CGH microarrays for single cell research. To assess the accuracy of aberration detection, a single cell model system was built from a set of normal and aberrant cell lines with varying sizes of known CN changes. As references, lymphocytes isolated from normal male and female individuals were used. Due to the minute amounts of genetic material contained within each cell, all samples and references were subjected to a multiple displacement amplification-based WGA to increase the amount of DNA while maintaining its genomic representation. Amplified samples were then differentially labeled and combined in 7 pairs of test vs. test samples and 1 pair of reference vs. reference per 8-pack microarray slide. This eliminates the use of a reference for every array and allows the processing of 14 samples on one slide. Combined samples were hybridized for 2-6 hours to an 8x60K CGH microarray containing probes optimized for single cell WGA and analysis. Following hybridization, microarray slides were washed and scanned. The data were extracted and analyzed for CN alterations using algorithms and a single cell specific analysis method implemented in Agilent CytoGenomics 2.9. Using an optimized workflow for sample processing and analysis in 7-11 hours, CN changes were accurately assessed in the single cell model system. Aberrations affecting whole and portions of chromosomes, as small as 6 Mb, were confidently identified and confirmed by gDNA CN profiling. This short workflow enables researchers to obtain reliable results at a high resolution while remaining cost-effective.

2552S

Performance comparison between low coverage semiconductor sequencing and array comparative genomic hybridization to analyze copy number variation. *B. Min, M. Seo, J. Kim.* Seoul National University, Seoul, South Korea.

Copy number variations are alterations of the DNA and have an important role in the pathogenesis of human disease including cancer and genetic disorders. Array comparative genomic hybridization is the most widely used analytical method for genetic identification of copy number. Next generation sequencing technologies provide an opportunity to detect copy number by comparing the number of sequence reads between patients and control samples. To evaluate the use of semiconductor sequencing for copy number variation diagnosis, Detection of copy number using the Agilent 4 X 180k aCGH platform was compared with low coverage semiconductor sequencing on the patients with genetic disorders. Detected changes in copy number using low coverage sequencing were validated by using aCGH results data and Sanger sequencing. Most copy number variants detected among patients using the aCGH method were successfully detected by low coverage sequencing. In the diagnostic setting, A balance of low coverage sequencing cost and diagnostic sensitivity and specificity should be considered. Turnaround time of experiment also should be considered to challenge array comparative genomic hybridization method. semiconductor sequencing method is alternative sequencing platform with a reduced turnaround time and cost of sequencing. We propose that low coverage semiconductor sequencing can be used as a diagnostic procedure for the patients with CNVs.

Effects of clinician guided genomic risk assessments: HelloGene. *H. Jin[1], T. Kim[1], K. Ahn[1], J. Bhak[2], H. Joo[1], S. Dong[3].* 1) TheragenEtex, Suwon, Gyeonggi, South Korea; 2) Personal Genomics Institute, Genome Research Foundation, Suwon, South of Korea; 3) Kyung Hee University School of Medicine, Seoul, South of Korea.

Genome wide association studies (GWASs) on common diseases have been reported increasingly since 2005. These results were applied for the personalized genomic risk assessments tests by several corporations, such as 23andMe, Navigenics, DeCODEme and so on. These companies offer direct-to-consumer (DTC) tests without the obligatory involvement of the health care provider. Since DTC is illegal in Korea, the test results of personalized genomic risk assessments test; HelloGene by Therabio Inc., should be delivered and explained by clinician. HelloGene service was launched in January, 2013 in Korea. However, genomic risk assessments test were not popular in the healthcare facilities, and social awareness about risk assessment test was limited among clinicians. To overcome these circumstances, Therabio Inc. has initiated the clinical trial with 18 university hospitals via academic society, the Korean Society of Health Screening and Promotion, in January, 2014. The trial consists of two survey questionnaires which are given before and after the HelloGene service. The first questionnaire consists of the ten questions regarding basic understanding and personal impression about the test such as previous experience, knowledge and so on. After the test, the subjects were surveyed with the second questionnaire, which have 20 questions mainly about the satisfaction and change in perspective about the genomic risk assessments test. Up to now, 55 subjects were completed both questionnaires. Interestingly, 54 out of 55 subjects were responded that it was helpful to have genetic counseling by clinician. In addition, 54 out of 55 subjects showed willingness for changing their lifestyle according to the results to prevent diseases. Even though the trial is on-going, it is already producing important information regarding general populations' impression and perspective towards genomic risk assessment tests and it is predicted to showing positive aspects for genomic risk assessment tests in Korea.

Rare finding of non-transient congenital extra and intra-medullary acute myeloid leukemia with Beckwith-Wiedemann syndrome. *G.A. Jervis, H. Monforte, R. Ortega, L. Harris, M.J. Sutcliffe.* Department of Pathology and Laboratory Medicine, All Children's Hospital, John Hopkins Medicine, St. Petersburg, FL.

A male neonate presented with macrosomia, hepatosplenomegaly, right ventricular hypertrophy, macroglossia, neutropenia, and "blueberry muffin rash". Extramedullary myelomonocytic leukemia cutis was diagnosed by pathology from skin biopsy with a concomitant involvement of acute myeloid leukemia (AML), FAB subtype M5 in the bone marrow. Constitutional SNP HD array revealed a terminal 4.8 Mb gain of 11p15.5, a terminal 3.7 Mb deletion of 8p23.3, and a mosaic 10.5 Mb deletion between 17q21.31-q22. Cytogenetics and FISH confirmed an unbalanced der(8)t(8;11)(p23.3;p15.4) with duplication of the Beckwith Wiedemann syndrome (BWS) region; an overgrowth and tumor predisposition syndrome. MS-MLPA detected an imprinting abnormality with hypermethylation of the *H19* locus and normal methylation of the *KCNQ1OT1* locus, consistent with the diagnosis of BWS, likely due to a paternal duplication. This mechanism, found in <1%; of BWS cases, may be associated with an even higher risk for tumor development (Wilms tumor/ hepatoblastoma) and developmental delay. Cytogenetic bone marrow analysis confirmed the der(8)t(8;11)© but also revealed an acquired balanced t(5;17)(q35;q22) in 7/20 cells. Unexpectedly, the 17q© deletion was not detected in the bone marrow (cytogenetic and array negative). Possible explanation for this discrepancy may be tissue specific mosaicism. The clinical effects of this mosaic deletion are unknown. The acquired translocation is interesting because: 1) the *RARA* (retinoic acid receptor alpha) gene had normal signal pattern by FISH, differing from the t(5;17) described in AML M3 that disrupts this gene, 2) 5q35 region is part of a childhood AML translocation, t(5;11)q35;q15.5), that contains the *NPM1* gene, with mutations in AML, and 3) 17q22 region was involved in both the constitutional deletion and acquired translocation, suggesting regional instability. Although there are reports of leukemias (ALL, AML) in older children secondary to BWS, literary search found no references of congenital leukemia with this condition. This may be the first reported case of neonatal AML in a patient with BWS, adding to the complexities of defining this condition.

Screening Results From 79424 Patients Tested by CFnxt, a 147 Mutation Cystic Fibrosis Screening Assay Built on the Illumina BeadXpress® Platform. *C. Holland, R. Tinawi-Aljundi, M. Weindel, J. Stoerker.* Progenity, Ann Arbor, MI.

Introduction: In March 2011, the American College of Obstetricians and Gynecologists (ACOG) updated its screening recommendations for cystic fibrosis to include offering CF screening to all women of reproductive age. The current ACOG mutation panel offers a comparatively limited risk-reduction for racial minority patients. We developed a CF screening assay that interrogates 147 mutations and 4 variants and provides greater risk reduction across all ethnicities. Methods: The assay consists of 12 multiplex PCR reactions, treatment of the product with a SAP/Exo I mixture, 12 multiplex allele-specific primer extension (ASPE) reactions with biotinylated CTPs, consolidation of ASPE reactions, hybridization onto the VeraCode® Bead set (Illumina), binding of the streptavidin-Alexa Fluor® (Invitrogen) conjugate, and scanning of the beads by the BeadXpress®. 96 samples and controls are run per batch in 384-well plates. Sample transfer is assisted by automated liquid handling. All putative positive samples are repeated for confirmation. The run-time for CFnxt is approximately 12 hours. Results: Through 2 June 2014, Progenity has completed testing on 79,424 patients. A total of 2484 heterozygotes and 17 compound heterozygotes were confirmed, resulting in an overall confirmed positive rate of 3.15%. Of the heterozygotes detected, 1944 were part of the ACOG panel (77.7%), and 557 were non-ACOG panel mutations (22.3%). A total of 22 out of 23 ACOG mutations were identified, along with 67 non-ACOG mutations. This includes 557 patients that would not have been otherwise identified. The most common mutations observed were deltaF508 (1368), R117H (237), W1282X (62), G542X (61), D1152H (60), G551D (36) and 3849+10kbC>T (27). In addition, out of the top 20 mutations identified, 5 were non-ACOG mutations. A total of 251 samples resulted in failed analysis (0.32%). Conclusions: The CFnxt assay provides robust screening across a broad range of CF mutations, thereby delivering significantly increased carrier detection for all ethnicities, compared to the ACOG panel, and an improvement in identification over other expanded panels.

2556M

A novel StripAssay identifies genetic variants modifying beta-thalassemia disease severity. *C. Oberkanins, B. Rauscher, H. Puehringer.* ViennaLab Diagnostics, Vienna, Austria.

Background: The clinical phenotype of patients with beta-hemoglobinopathies is extremely heterogenous, ranging from nearly asymptomatic forms of thalassemia intermedia to severe transfusion-dependent thalassemia major. The wide phenotypical variability is associated with the type of beta-globin mutation, the co-inheritance of alpha-thalassemia and the ability for persistent production of fetal hemoglobin (HbF) in adult life. For the latter, three different quantitative trait loci, accounting for 20-50% of HbF variation, have been identified by now. Single nucleotide polymorphisms (SNPs) in the gamma-globin gene promoter (HBG2), in the BCL11A gene and the HBS1L-MYB intergenic region lead to increased residual HbF levels in adults. Methods: A teststrip-based reverse-hybridisation assay was developed for the simultaneous detection of SNPs in the HBG2 (g.-158 C>T), BCL11A (rs1447407, rs10189857), HBS1L-MYB (rs28384513, rs9399137) genes. Results: The new StripAssay enables the concomitant identification of genetic variants known to influence beta-thalassemia disease severity. Based on the presence of positively modifying alleles, and combined with alpha- and beta-globin genotyping, it allows the prediction of patients likely to display less severe phenotypes. Favourable properties, such as the rapid DNA extraction protocol, ready-to-use reagents and teststrips, as well as the potential for automation of the hybridisation/detection and interpretation steps, make the StripAssay convenient and easy to perform within less than six hours. Conclusions: Testing for genetic modifiers influencing disease severity will lead to more specific and effective treatment, and support clinical decisions regarding the beginning of transfusion therapy in beta-thalassemia patients. Furthermore, the knowledge about prognostic markers has implications for genetic counselling and prenatal diagnosis.

2557T

A multidisciplinary approach to the evaluation and care of patients with inherited lung disease. *B. Raby[1,2], D. Toledo[3], L.M. Yonker[4], E. Henske[1], T.B. Kinane[4].* 1) Division of Pulmonary and Critical Care Medicine, Brigham & Women's Hospital, Boston, MA; 2) Channing Div. Network Medicine, Brigham & Women's Hospital, Boston, MA; 3) Partners Center for Personalized Medicine, Boston, MA; 4) Massachusetts General Hospital, Boston MA.

Like other medical disciplines, clinical pulmonary medicine is entering the post-genome era, where increased accessibility to genetic testing, converging with greater public awareness of the role of genetics in health, poses new challenges to pulmonologists. Moreover, most clinical training programs provide little exposure to monogenic conditions other than alpha-1-antitrypsin deficiency and cystic fibrosis. To address this, we established the Brigham and Women's Hospital Pulmonary Genetics Center, a multidisciplinary program that centralizes the diagnosing, managing, and counseling of patients and at-risk family members with genetic lung diseases. All patients are evaluated by a pulmonary geneticist in conjunction with a certified genetic counselor. Patients are triaged for appropriate genetic testing, and for subsequent evaluations by specific subspecialists, including pediatric pulmonologists, adult medical geneticists, a diverse team of pulmonary subspecialists with expertise in rare lung diseases, and the lung transplant team. Clinical fellows from both the pulmonary and medical genetics fellowship programs formally attend the clinic as part of their training. Partnering with the Laboratory for Molecular Medicine (LMM) of the Partner's Center for Personalized Medicine, we developed a CLIA-certified next-generation sequencing panel capable of evaluating more than 60 genes related to diverse inherited lung diseases, including familial forms of cystic disease, pulmonary fibrosis, bronchiectasis, and pulmonary hypertension. All patients are counseled both prior to and following testing. Here we describe the first 75 referrals to the center, outlining the spectrum of patients evaluated, their experiences undergoing genetic testing, and clinical outcomes resulting from this testing. The most common reasons for referral were for evaluation of patients with fibrosis or cystic lung disease with a family history of similar, and for young adults presenting with unusual constellations of clinical findings suggesting rare genetic disease. Pathogenic variants have been identified for the majority of patients tested. The most common diagnosis, made in 10% of referred patients, has been fibrosis caused by short telomere syndrome. The initial case series also includes families with Birt-Hogg-Dube Syndrome, Blau Syndrome and Primary Ciliary Dyskinesia. The implications of confirmed diagnoses are described, highlighting the utility of this approach.

Identification of truncating mutations in the *CHD8* gene in patients with autism spectrum disorders by clinical whole exome sequencing (WES). *J. Zhang[1], M.S. Leduc[1], Z. Niu[1], R.E. Person[1], W. Alcaraz[1], E.E. Roeder[3], T. Moss[4], J.M. Nguyen[5], M.R. Wagle[6], P.A. Ward[1], A.A. Braxton[1], T.R. Vaughn[1], D.M. Muzny[2], A.L. Beaudet[1], R.A. Gibbs[1,2], C.M. Eng[1], F. Xia[1], Y. Yang[1].* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) The Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Department of CHSA Pedi-Genetics, Texas Children's Hospital, TX; 4) Genomic Medicine Institute, Cleveland Clinic, OH; 5) Department of Pediatrics, University of Texas at Houston, TX; 6) Department of Pediatrics-Neurology, Texas Children's Hospital, TX.

Autism spectrum disorder (ASD) is a complex neurodevelopmental disability characterized by impaired social interactions, communication difficulties and restricted and repetitive stereotyped behaviors, with an overall prevalence of 62 cases per 10,000 people. Genome-wide studies such as chromosomal microarray and whole exome sequencing (WES) have identified *de novo* changes in numerous genes in patients with ASD. While most of those genes have yet to be validated as candidate autism genes, a few such as *CHD8* and *ADNP* have been better defined. *CHD8* encodes chromodomain helicase DNA binding protein 8 and was previously linked to autism in nine patients in one report in 2012 (PMID 23160955). Here we report four additional cases referred for clinical WES who were found to harbor novel truncating mutations in *CHD8*. Patient 1 was a 5.5 year old female with clinical phenotypes including expressive language delay, dyspraxia, motor delay, hypotonia, dysmorphic features, tall habitus, macrocephaly, obesity, strabismus, and scoliosis. She was found to carry a heterozygous *de novo* c.4611dupA (p.V1538fs) mutation in the *CHD8* gene. Patient 2 was a 14 year old male presented with autism, intellectual delay with regression, attention deficit disorder, hypotonia, ataxia, tremors, tics, dysmorphic features, nausea, constipation, seizures, retinal disease and scoliosis. This patient had a heterozygous *de novo* c.2565del (p.N855fs) mutation in the *CHD8* gene. Patient 3 was a 4.5 year old female with autism, global developmental delay, speech delay, hypotonia, dysmorphic features and macrocephaly and a heterozygous c.4468dupT (p.C1490fs) mutation in the *CHD8* gene. The parental samples were not available for study. Patient 4 was a 5 year old female with autism, severe intellectual disability, speech delay, hypotonia, dysmorphic features, macrocephaly, and hyperextensibility. WES revealed a heterozygous c.6518C>A (p.S2173X) in the *CHD8* gene, Sanger sequencing showed that the mother is negative for this mutation; the father was not available for study. Overall, the four cases with truncating *CHD8* mutations identified by WES further expand the phenotypic spectrum of *CHD8*-related disorders. The occurrence of *CHD8* mutations in our clinical WES samples is four out of a total of 1800 unrelated patients referred for autism spectrum disorder and intellectual disability with or without other organ system involvement.

2559M

Use of a Patient-Centered Conceptual Framework to inform the development of the ClinGen Resource. *M.S. Williams[1], S. Aronson[2], H.L. Rehm[3], S. Goehringer[1], A. Milosavljevic[4], E.M. Ramos[5], Clinical Genome Resource Consortium.* 1) Genomic Med Inst, Geisinger Health System, Danville, PA; 2) Executive Director of Information Technology, Partners HealthCare Personalized Medicine Boston, MA; 3) Dept. of Pathology, Brigham & Women's Hospital and Harvard Medical School Director, Laboratory for Molecular Medicine, Partners Personalized Medicine Boston, MA; 4) Department of Molecular and Human Genetics Baylor College of Medicine Houston, TX; 5) Division of Genomic Medicine, National Human Genome Research Institute, NIH Bethesda, MD.

Background Healthcare systems represent a complex 'system of systems' resulting in challenges in coordination, access, communication and integration that need to be addressed in order to improve the quality and decrease the cost of care. One such system is the Clinical Genome Resource, a product of the NIH-funded Clinical Genome Resource consortium (ClinGen). The ClinGen resource will provide information about actionable genomic information to clinicians at the point of care. As the integration of the resource into the healthcare system was being contemplated, the consortium agreed to explore a patient-centered conceptual framework. The key insight in this framework is that the only constant in the care delivery system is the patient and the patient's caregivers. Following this framework, we reimagined the ClinGen resource information delivery process from the patient/caregiver perspective—so-called patient-centered care. **Methods** The patient-centered framework created by the UK National Health System Heart Improvement Programme was used. The interaction of the patient/caregivers with their providers within this framework is termed the clinical microsystem. A workgroup of ClinGen was convened to use this framework to conceptualize the organization and relationship of the elements that would interact with the ClinGen resource either directly or indirectly. **Results** The workgroup used an iterative approach to develop a draft 'system map'. This was presented to the ClinGen Consortium steering committee for comment and discussion which were incorporated into a final draft. This draft defined the critical applications in the ecosystem such as Electronic Health Records and Laboratory Information Systems, dbGaP, ClinVar, and other external data sources and identified key interactions and data flows that needed to occur to achieve optimal utility. The final design was approved by the steering committee. **Conclusion** The approved system map will be used to construct and implement the ClinGen resource. This means that the project is committed to effectively delivering information to the clinical microsystem such that the goal of improving health through the use of evidenced-based genomic information can be realized. Currently the various ClinGen workgroups are taking ownership of the different interactions and data flows to determine the specifications and standards that will be needed to optimize each interaction and system dependency.

2560T

Mutation analysis of *CYP21A2* and correlation between genotype - phenotype in 163 Vietnamese patients with congenital adrenal hyperplasia due to 21-hydroxylase deficiency. *V. Dung[1], K. Tran[2], P. Le[2], K. Nguyen[1], H. Le[1], M. Fukami[3], V. Ta[2].* 1) Medical Genetics and Metabolism, National Hospital of Ped, Hanoi, Viet Nam; 2) Hanoi Medical University, Research Center of Gene and Protein, Hanoi, Vietnam; 3) National Research Institute for Child Health and Development, Department of Molecular Endocrinology, Tokyo, Japan.

Background: Congenital adrenal hyperplasia (CAH) is one of the most common inherited metabolic disorders. The most common form of CAH (95%) is caused by mutations in *CYP21A2*, the gene encoding the adrenal steroid 21-hydroxylase enzyme (21-OHD; OMIM 201910). Objective: To identify the mutations in the *CYP21A2* gene in Vietnamese patients with CAH and attempt a genotype-phenotype correlation. Methods: Molecular analysis was performed using PCR, multiplex ligation dependent probe amplification and direct sequencing of PCR products of the *CYP21A2* gene in 163 CAH patients. Correlation between phenotype and genotype was evaluated based on identified mutations and clinical manifestations. Results: Mutations were identified in 321 alleles. Twelve different causative mutations with 29 different genotype were identified in *CYP21A2* including two novel mutations. The most frequent genetic defect was c.293-13A/C>G (115 alleles; 35.8%) mutation, followed by Large deletion (88 alleles; 27.4%); c.1066C>T (p.R356W) (49 alleles; 15.3%); c.515T>A (p.I172N) (33 alleles; 10.3%). The rarer mutations were c.952C>T (p.Q318X) (9 alleles; 2.8%); c.1276C>T (p.R426C) (7 alleles; 2.2%); c.920_921insT (L307fs) (7 alleles; 2.2%); c.1447_1448insC (p.R483fsX541) (6 alleles; 1.9%); c.737delA (E246fs) (1 allele; 0.3%); c.3G>A (p.M1I) (1 allele; 0.3%); and novel mutations p.I112X (1 allele; 0.3%) and p.S125X (4 alleles; 1.2%). The majority of patients (127 cases; 77.9%) were homozygotes. Sixteen cases were compound heterozygous. Genotype accurately predicted phenotype in 97.3 and 95.3% of patients with salt-wasting (SW) and simple virilizing (SV), respectively. 44 cases with homozygous mutation c.293-13A/C>G are associated with SW phenotype and 3 patients present with SV form. Conclusions: The spectrum of mutations of the *CYP21A2* gene in Vietnamese patients is comparable to the reported in other populations. Large deletion accounts for nearly one-third of the genetic defects. Therefore, laboratory should include methods for detecting point mutations as well as large deletions. Genotype-Phenotype correlation was high in the studied patients.

2561S

Preventive effects of α-tocopherol on telomere shortening in human buccal cells. *S. Yabuta, Y. Shidoji, M. Masaki.* Graduate School of Human Health Science, University of Nagasaki, Nagasaki, Nagayo, Japan.

[Background and Objectives] Telomere shortening is considered as a solid index for senescence of human cells. However, telomere length may be affected by both physical aging and oxidative stress. In as much as telomere shortening is caused by oxidative stress, it should be preventable with meal intervention (Blackburn, E et al., JAMA 2010;303:250-257). According to the previous results, oxidative stress may cause genomic DNA damages as well as suppression of telomerase activity, which is also active in certain somatic cells. In this context, habitual intake of antioxidant nutrients such as β-carotene and vitamin E may be important to prevent telomere shortening. The present study addresses interactions between the relative telomere length (RTL) in buccal cells and anti-oxidant vitamin-related genes including BCMO1, SR-B1, and ISX genes. These three gene products are involved in intestinal uptake and metabolism offat-soluble vitamins. Finally, we analyzed a relationship between buccal RTL and daily intake of antioxidant nutrients. [Methods] The subjects consist of Japanese men and women (n=70, aged 20-59y) voluntarily recruited with a written informed consent. Telomere length was measured by monochrome multiplex quantitative PCR method with buccal cells. The telomere length was expressed as a relative telomere length (RTL) comparing with a reference sample. BCMO1 (rs6564851), SR-B1 (rs2278986), and ISX (rs362090) weretypedby real-time PCR method with TaqMan probes. The data of nutrient intake were collected by food frequency questionnaire(FFQ). [Results and Conclusions] Allele frequencies of G and T in rs6564851 were 0.836 and 0.146, respectively and these values fit into those of Japanese population uploaded in SNP database. In association of RTL with the gene polymorphisms, there was a positive and significant correlation between buccal RTL and daily intake of α-tocopherol in men of BCMO1 T-carriers ($p<.05$). When BCMO1 T-carriers were further classified by ISX AA type and ISXG-carrier type, only the ISX AA type showed a positive correlation between buccal RTL and α-tocopherol intake ($p<.05$). Further in vitro experiment is under way to validate a protective effect of α-tocopherol on the telomere shortening, where the role of hydrogen peroxide as oxidative stress may be modified by combined genotype of BCMO1 T-carrier and ISX AA homozygote in a human cell line.

Expanded Screening for Pathogenic Mutations in the Ashkenazi Jewish Population. *B. Baskovich[1], S. Hiraki[2], K. Upadhyay[2], P. Meyer[2], S. Carmi[3], N. Barzilai[2], A. Darvasi[4], K. Offit[5], S. Bressman[2], L. Ozelius[6], I. Peter[6], J. Cho[6], G. Atzmon[2], L. Clark[3], T. Lencz[2], I. Pe'er[3], H. Ostrer[1,2], C. Oddoux[1,2].* 1) Montefiore Medical Center, Bronx, NY; 2) Albert Einstein College of Medicine, Bronx, NY; 3) Columbia University, Manhattan, NY; 4) Hebrew University of Jerusalem, Givat Ram, Jerusalem; 5) Memorial Sloan Kettering Cancer Center, Manhattan, NY; 6) Mount Sinai School of Medicine, Manhattan, NY.

Introduction: A number of founder and recurrent mutations are prevalent in the Ashkenazi Jewish population. Screening for these mutations has reduced the incidence of many autosomal recessive diseases. Yet, only 22 conditions are available on current Ashkenazi Jewish screening panels. The purpose of this study is to expand the knowledge base of pathogenic mutations in this population and develop an expanded screening panel. **Methods:** Whole-genome sequencing was performed by Complete Genomics on 128 disease-free Ashkenazi Jews, which identified 13,768,157 variants. These variants were passed through a pipeline which queried the Online Mendelian Inheritance in Man (OMIM) and ClinVar databases. The pipeline yielded 201 variants that were called pathogenic in these databases. These variants were manually curated through literature review and scored for pathogenicity. The literature was also reviewed for known Ashkenazi Jewish mutations. The results were combined and weighted by clinical utility and allele frequency. **Results:** In addition to the 22 conditions that are currently screened for, an additional 69 conditions that have pathogenic alleles were identified. In total, 168 significant pathogenic mutations were established for 52 autosomal recessive, 34 autosomal dominant and 5 X-linked disorders. The diseases include those that inform risk to offspring, which are generally autosomal recessive, and range from very severe, such as glycine encephalopathy and Leigh syndrome, to milder, such as hyperoxaluria and ichthyosis. Some of these disorders are informative for adult-onset conditions that may convey risk of future cancer (*BRCA1/2* and mismatch repair testing), obesity, or macular degeneration or may have atypical presentations. Some mutations convey different phenotypes in the monoallelic and biallelic states; thus, testing would offer information pertaining to both personal risk as well as risk to offspring. **Conclusions:** As screening for a larger number of mutations becomes possible, we need to reframe our goals of population screening and genetic counseling. An expanded panel can further reduce the incidence of autosomal recessive conditions, reduce morbidity and mortality by offering earlier diagnosis, and satisfy a need for information and enable planning for future life events. The number of mutations identified could be feasibly screened for on a population-wide basis and are individually selectable following genetic counseling.

2563T

Clinical exome sequencing: Initial experience in a pediatric and biochemical genetics clinic. *J.A. Bernat[1], A. Ahmad[1], M.C. Hannibal[1], C.E. Keegan[1,2], B.C. O'Connor[1], K.M. Owens[1], S.C. Quinonez[1], J.L. Schuette[1,2], A.H. Seeley[1], J.G. Thoene[1], B.M. Yashar[2], D.M. Martin[1,2], J.W. Innis[1,2].* 1) Division of Pediatric Genetics, Metabolism, and Genomics, Department of Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Technological advancements in next-generation sequencing have allowed whole exome sequencing to become feasible as a clinical test in cases of suspected genetic disease when initial tests have failed to yield a molecular diagnosis. Although many single case reports exist, there is limited data regarding molecular diagnostic success rates of exome sequencing in a medical genetics clinic setting. Initial estimates have suggested a diagnostic yield of 15-30% in select cases. Recent publications relevant to incidental findings (pathogenic variants in genes unrelated to the patient's phenotype) have also shown that this test has a broad and complex potential impact. We quantified the diagnostic yield and incidental findings in exome sequencing cases in the University of Michigan Pediatric and Biochemical Genetics Clinics, from October 2012 to the present. Cases were identified in which clinical exome sequencing tests were sent by UM Pediatric Genetics faculty. Clinic notes were reviewed for phenotype information, previously-ordered studies, and family history. Research-based testing and next-generation sequencing-based focused gene panel testing were excluded. To date, results have returned for 39 tests. In 12 cases (31%), pathogenic variants in disease-causing genes related to the patients' phenotypes were identified. New diagnoses included Bainbridge-Ropers syndrome (MIM 615485), Kabuki syndrome (MIM 147920), Myhre syndrome (MIM 139210), Opitz-Kaveggia syndrome (MIM 305450), triosephosphate isomerase deficiency (MIM 615512), and Van Maldergem syndrome (MIM 615546). 23 of the 27 remaining cases had variants of uncertain significance (VUSs) reported. No patients or families opted out of receiving a report of incidental findings. 5 cases (13%) had incidental findings in one of the 56 genes recommended to be reported by the ACMG, with pathogenic variants identified in *BRCA1*, *BRCA2*, *MYBPC3*, and *MYH7*. Early results suggest that clinical exome sequencing is a promising new technology that can lead to a molecular diagnosis in a subset of select cases. When applied properly, such testing may lead to a diagnosis more quickly and likely at less cost in both monetary and psychological terms. An understanding of the limitations of this testing and the possibility of incidental findings is necessary for its proper application. Additional work will be required to determine the molecular etiologies for cases in which exome sequencing is negative.

2564S

Implications of Massively Parallel Sequencing in screening for Autosomal Recessive conditions: the risk of being a "genetic wallflower". *L. Burnett[1,2,3], D. Chesher[1], L. Nguyen[1], R.M. Lew[4], A. Proos[1], L.C. Ding[1], L. Koe[1].* 1) NSW Health Pathology North, Sydney, NSW, Australia; 2) Sydney Medical School, University of Sydney, NSW, Australia; 3) School of Information Technologies, University of Sydney, NSW, Australia; 4) Department of Obstetrics and Gynaecology, QEII Research Institute for Mothers and Infants, University of Sydney, NSW, Australia.

Introduction Genetic screening for autosomal recessive (AR) genetic carriers is available in many communities "at risk" due to high prevalence of pathogenic variants. Examples include Tay-Sachs disease, thalassaemia and cystic fibrosis. The range of tests included in screening programs is broadening, and will accelerate with the introduction of Massively Parallel Sequencing. As more genes are included in screening programs, a risk emerges of being a "genetic wallflower", rejected by every suitor because of the AR genes they carry. We recently modelled the frequency of autosomal dominant (AD) genetic conditions arising as Incidental Findings (IF) in Whole Genome Sequencing. We found that the proportion of tested individuals with significant IFs plateaus to a limit even as the number of genes tested increases beyond those in the ACMG IF Recommendations.

Aim To model the rate of increase in AR genetic carriers with increasing numbers of AR genes in test menus. We also explore the likelihood of genetic wallflowers emerging.

Methods A mathematical model based on binomial distribution was used to predict the number of AR carriers based on prevalence of pathogenic variants and number of tested conditions. Monte Carlo simulation was used to calculate the probability of any two individuals in this screened population being carriers of exactly the same AR genetic conditions.

Results The model was validated using known rates of AR genetic carriers found in Australian Ashkenazi Jewish community screening programs. We have found that the numbers of AR genetic carriers will rise as the number of tested conditions is increased. We also report the likelihood of genetic wallflowers emerging in AR genetic carrier screening programs.

Conclusions As the number of AR conditions included in testing panels is increased, the number of AR genetic carriers identified in a population will increase. This behaviour is in marked contrast to that for AD conditions, where the proportion of a population with a reportable IF will plateau. These findings have significant implications for health economic evaluation and planning. Finally, we report on the ethical and social implications of genetic wallflowers emerging.

2565M

Analyses of *TSC* genes among Brazilian tuberous sclerosis complex (TSC) patients. *L.G. Dufner-Almeida[1], J.P.G Almeida[2], L. Masulk[3], M. Richartz[3], M. Miranda[3], S.A. Antoniuk[3], S. Rosemberg[2], L.A. Haddad[1].* 1) Department of Genetics and Evolutionary Biology, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 2) Department of Pediatrics, Division of Child Neurology, Faculdade de Medicina da Santa Casa de São Paulo, São Paulo, Brazil; 3) Department of Pediatrics, Universidade Federal do Paraná, Curitiba, Brazil.

Tuberous sclerosis complex (TSC) is a multisystem disorder, with variable expression and autosomal dominant inheritance. Clinically it is due to hamartia and hamartoma development in different tissues, notably in the brain, kidneys, heart, skin and lungs, causing organ dysfunction. Mutations in either tumor suppressor genes *TSC1* or *TSC2* are responsible for TSC. TSC1/TSC2 protein heterodimer inhibits the mammalian target of rapamycin (mTOR) complex 1, controlling cell growth and proliferation. Although TSC diagnosis is basically clinical, since the 2012 specialist panel review, the finding of a *TSC1* or *TSC2* pathogenic mutation has been considered sufficient for the definite diagnosis of the disease. In addition, mTOR inhibitors have been clinically approved to treat under specific guidelines three hamartomas that afflict TSC patients. To set up the basis for molecular diagnosis of TSC and functional analysis of *TSC1* and *TSC2* mutations in São Paulo, Brazil, an ongoing project aims to establish and compare at long term Sanger and massively parallel technologies for *TSC1* and *TSC2* DNA sequencing. As a preliminary step, we conducted Sanger sequencing of the *TSC1* gene, encompassing its full coding sequence, an average of 132 bp of intronic segments next to exon boundaries, in addition to the gene core promoter of 28 Brazilian patients with definite TSC diagnosis. Seven patients (25%) displayed *TSC1* nonsense/frameshift mutations. Among 31 other DNA variants identified, 27 were DNA polymorphisms. Two and one additional DNA point variants from the same patient flanked a putative, specific transcription factor binding site, 5' to the *TSC1* core promoter. In addition, a novel DNA variant residing in the *TSC1* noncoding exon 2 was predicted to change the sequence potential to behave as a splicing enhancer. In summary, we describe 25% of TSC patients with pathogenic mutations in the *TSC1* coding sequence. Moreover, our data disclose four novel DNA variants in *TSC1* potentially regulatory regions that are likely to unravel novel pathogenic mutations, and thus need to be experimentally tested.

The Implementing Genomics in Practice (IGNITE) Network: A Coordinated Effort to Study and Improve Implementation of Genomics in Clinical Practice. *S.E. Kimmel[1], G.S. Ginsburg[2], E.P. Bottinger[3], J.C. Denny[4], D.A. Flockhart[5], T.I. Pollin[6], E.B. Madden[8], K. Weitzel[7], M. Alexander[1], C. Horowitz[3], L.A. Orlando[2], N.S. Calman[3], P.R. Dexter[5], M. Levy[4], A.R. Shuldiner[6], H.A. Junkins[8], J.A. Johnson[7], IGNITE Network.* 1) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA., United States; 2) Duke University Medical Center, Duke University, Durham, NC; 3) Icahn School of Medicine at Mount Sinai, Mount Sinai School of Medicine, New York, NY; 4) Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN; 5) Indiana University School of Medicine, Indiana University, Indianapolis, IN; 6) University of Maryland School of Medicine, University of Maryland, Baltimore, MD; 7) College of Pharmacy, University of Florida, Gainesville, FL; 8) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Purpose: Despite great progress in understanding the impact of genomics on patients' health and outcomes from therapy, implementation of genomics in practice remains challenging. There is an urgent need to better understand the methods of incorporating patients' genomic information into clinical care, evaluating implementation efforts, and measuring outcomes of genomics implementation. Methods: The aims of the Implementing Genomics in Practice (IGNITE) Network, funded by the National Human Genome Research Institute and the National Cancer Institute of the NIH, are to assess methods of implementation of genomic information in practice within specific projects, to rigorously evaluate these methods across projects in order to create generalizable knowledge, and to provide proofs of concept of the value of genomics in medical care. Special interest has been placed on partnering between established and less experienced groups; inclusion of diverse settings and underserved populations; and optimal utilization of electronic medical records (EMR) and clinical decision support (CDS) tools. Demonstration projects and a Coordinating Center have been funded to incorporate genomic information (genetics, pharmacogenetics, and family history) into the EMR and provide CDS for implementation of appropriate interventions or clinical advice across multiple and diverse sites. IGNITE projects include incorporation of structured family history tools, genotyping protocols for more accurate diagnosis and customized treatment of disease, and germline and somatic pharmacogenomics. With the assistance of a Coordinating Center, the projects are using established frameworks for implementation research to define barriers to implementation, develop and disseminate solutions to these barriers, and assess outcomes, especially those most important to ensuring rapid and sustained adoption, such as patient and provider satisfaction, clinical outcomes, and cost effectiveness. Summary: The IGNITE Network's goal is to determine what works and what does not in genomic medicine implementation in practice and to provide generalizable knowledge that can be used to foster similar implementation in other settings, for other diseases, and for the myriad of potentially useful genetic-based testing and histories. Details of the IGNITE projects and the challenges and lessons learned from implementation can benefit the scientific and clinical community.

Clinical exome sequencing identifies a novel gene, LINS, associated with intellectual disability, failure to thrive, seizures, dysmorphology, and language regression. *I. Lu[1], L. Shahmirzadi[1], R. Baxter[1], S. Tang[1], K. Gonzalez[1], E. Rosebrough[2], O. Abdul-Rahman[2].* 1) Ambry Genetics, Aliso Viejo, CA; 2) University of Mississippi Medical Center, Jackson, MS.

Clinical Whole Exome Sequence analysis of an 8 year-old Caucasian female affected with intellectual disability (ID), failure to thrive, myopia, microcephaly, seizures, dysmorphic features, and language regression with aphonia identified two compound heterozygous alterations in LINS, the human homolog of the Drosophila segmentation lins protein, which is involved in the Wnt signaling pathway. The paternally-inherited c.2020dupA frameshift alteration and maternally-inherited c.1394+1G>T splice site alteration are both expected to result in a deleterious effect on the LINS gene. The patient evaded diagnosis through clinical evaluation and extensive genetic testing over many years including negative chromosome analysis, FISH for Smith Magenis syndrome, CGH/SNP microarray, Angelman syndrome methylation analysis, MECP2 and CDKL5 analysis for Rett syndrome, mitochondrial DNA array and gene sequencing panel, as well as uninformative biochemical results. The two LINS gene alterations we identified are likely to provide an explanation for the patient's symptoms and no other likely candidate gene alterations were identified to explain the patient's phenotype. LINS is a newly characterized gene involved in human cognition and brain development. Mutations in LINS have been described in only two cases of autosomal recessive ID and microcephaly. In one previously reported case, a homozygous frameshift mutation was identified in an Iranian family with four children affected with moderate ID and microcephaly. In a separate case, a 5-nucleotide homozygous deletion affecting a donor splice site was identified in a Yemeni male and female sibship affected with early onset ID, developmental delay and head nodding behavior. Consanguinity was present in both of the previously reported cases. Phenotypic overlap with the current case include microcephaly and intellectual disability; however, there appears to be a spectrum of clinical symptoms associated with LINS mutations. Diagnostic exome sequence analysis is an effective method for contributing to the mutational and phenotypic spectrum of LINS-related diseases.

2568M

Genetics of beta thalassemia in Iran: Still requires consideration? *N. Mahdieh[1], B. Rabbani[2], R. Shiri Heris[3].* 1) Deputy of Research and Technology, Ministry of Health and Medical Education, Tehran, Iran; 2) Medical Genetic Group, Qazvin University of Medical Sciences, Qazvin, Iran; 3) Faculty of Paramedicine, Ilam University of Medical Sciences, Ilam, Iran.

Beta thalassemia is observed in many countries. Prevalence of thalassemia-causing mutations is different among various parts of the world and even within different ethnic groups living in Iran. In addition to clinical, biochemical and hematologic diagnostic methods, molecular diagnostics is used for prenatal diagnosis of thalassemia. We analyzed all published data about the frequency of beta globin mutations among Iranian subjects. Mutation frequency was calculated in more than 5000 at risk couples studied in pre-marriage counseling of screening strategies in Iran. Furthermore, the frequency of HBB gene mutation was determined in 2003 major beta thalassemia. On the basis of the present study, more than ninety mutations have been reported to cause beta thalassemia the country. Ten following mutations were common: IVS I-5 (G>C), IVS II-1 (G>A), FSC36/37 (-T), IVS I-110 (G>A), FSC 8/9 (+G), IVS I-1 (G>A), FSC8 (-AA), IVSI-25 bp, CD30 (G>C) and FSC44 (-C), contributing 80 % of all mutations. IVS II-1 (G>A) is common across the country but other mutations might be common among specific ethnic groups. Our results showed the current prevention strategy is an efficient way to reduce the allele frequency of disease.

Diagnostic Yield of Genetic Testing in the Children's Hospital of Colorado Autism Genetics Specialty Clinic. *N.J.L Meeks[1,2], K. Brown[1,2], B. Miller[1].* 1) Children's Hospital Colorado, Aurora, CO; 2) University of Colorado, Anschutz Medical Campus, Aurora, CO.

Background: Autism spectrum disorders (ASDs) are a group of neurodevelopmental disorders characterized by deficits in social communication, restricted interests, repetitive patterns of behavior and symptom onset early in development. Several well-defined genetic disorders have been identified in patients with ASDs; however, clinical genetic testing is diagnostic in only a minority of cases. The purpose of this study was to determine the diagnostic yield of genetic testing in a population of children with ASDs seen at the Autism Specialty Genetics Clinic, part of the Autism Treatment Network, at the Children's Hospital Colorado. Methods: A retrospective chart review was performed of patients seen in the Autism Genetics Clinic. Patients who met inclusion criteria had the following: an initial or follow-up genetics evaluation within the past six years; a diagnosis of an ASD through formal evaluation; and at least one molecular genetic test completed and resulted. Results: Of 130 charts reviewed, 107 patients met study criteria. The average number of molecular tests ordered per person was 3.05 [95% CI: 2.74-3.35]. Eighteen patients (16.82%) had molecular genetic testing that was diagnostic. Copy number changes found on chromosomal microarray (CMA) accounted for 67% of all pathogenic findings with a yield of 13.9%. Other pathogenic findings included mutations in the PTEN, MECP2 and PTPN11 genes, positive FISH testing for a familial mutation, and two patients with abnormalities detected on karyotype. Biochemical screening for metabolic conditions, FMR1 testing, and multi-gene intellectual disability panels evaluating for more than one genetic condition did not yield any pathogenic findings. Of all molecular testing completed, 21.5% identified a variant of uncertain significance. Discussion: The results of this chart review are comparable to previously published studies on genetic evaluations of children with ASDs with an overall diagnostic yield of genetic testing at 16.82%. Unlike previously published studies, almost every patient (95%) had a chromosomal microarray as part of their evaluation. These results continue to support the use of CMA as a first line evaluation in children with ASDs. Also, 1 in 5 molecular or cytogenetic tests resulted in a variant of uncertain significance. Incorporating this information in clinic visits will improve pre-test genetic counseling in this population.

2570S

Whole exome sequencing as a diagnostic tool for complex neurological disorders. *G.R. Monroe[1], G. Frederix[2], S. Savelberg[1], K. Duran[1], M.M. van Haelst[1], G. Visser[1], P.M van Hasselt[1], P. Terhal[1], H. Kroes[1], J. van der Smagt[1], A. Hövels[2], G. van Haaften[1].* 1) UMC Utrecht, Utrecht, Netherlands; 2) Utrecht University Pharmacoepidemiology and Clinical Pharmacology, Utrecht, Netherlands.

Whole exome sequencing (WES) provides a straightforward detection of rare variation including de novo mutations in parent-child trios, but a systematic interpretation of the diagnostic yield and an assessment of the costs associated with implementing WES in the clinic is currently lacking. We determine the increased diagnostic yield and provide a thorough cost analysis of the clinical care with and without the use of WES. This study will serve as a guide for centers intending to implement WES and provide a clear diagnostic benefit versus the associated costs of obtaining this increased diagnostic yield. Twenty children of healthy, unrelated parents were randomly selected from the 2011 patient population at the Sylvia Toth Center (STC) in Utrecht, the Netherlands. The STC is a specialized center for children with complex neurological disorders and diverse phenotypes. DNA libraries were prepared using Kapa Biosystems reagents, enriched using Agilent Sureselect All exon V5 with a custom pooling protocol, and sequenced on the Illumina HiSeq 2500. A list of exonic variants was obtained by filtering against public and our in-house database according to the expected *de novo* inheritance model as well as for recessive and compound heterozygote variants. In parallel, the clinical records of patients were obtained and a cost summary of medical treatments, hospital visits, care, and all other resource use was compiled per patient. This cost was then compared to the cost of care using WES, assessed retrospectively on each patient. Comparing the diagnosis and costs with and without the use of WES gives a clear picture of the economic feasibility of putting WES into standard diagnostic practice at the STC and similar centers. The diagnostic yield from the 13 patients sequenced thus far is 23%, confirming past studies diagnostic yields on intellectual disability cohorts. The three variants found are in genes recently associated with intellectual disability (*ANKRD11, CTNNB1, ANDP*), and the variants are all frame-shift deletions resulting in protein truncation. On average these patients have had numerous visits to the hospital, overnight stays and different diagnostics to unravel the genetic cause of their neurological disorder. It is therefore deemed very plausible that the total cost of the current diagnostic pathway is many times higher compared to WES, indicating the economic feasibility of implementing WES early in the diagnostic pathway.

Genetic investigation of cystic fibrosis transmembrane regulator mutations in a cohort of consecutive patients candidate for assisted reproductive techniques. *F. Papa[1], M. Rongioletti[1], MB. Majolini[1], C. Vaccarella[1], I. Simonelli[2], V. Mazzucchi[1], A. Luciano[1], P. Pasqualetti[2], G. Liumbruno[1].* 1) Clinical Pathology Department, San Giovanni Calibita Hospital, Rome, Italy; 2) Medical Statistics & Information Technology Fatebenefratelli Association for the Research, Rome, Italy.

Introduction. The present study, investigated the frequency of mutations in the CFTR gene, in a group of consecutive patients candidate for assisted reproductive techniques with the aim of identify subjects carriers of the most severe ones. Methods. 22,416 alleles were screened for 56 CFTR gene mutations utilizing the CFTR INNO-LiPA Results. CFTR mutations were detected in 6.2% of the screened alleles. In the large group of alleles analyzed 93.4% were wt, 4.4% were characterized by mild mutations, and 1.7% by severe or severe/mild mutations. Indeed, the most common severe mutation was ΔF508/N observed in 192/22,416 (0.86%) of all alleles analyzed, followed by the N1303K mutation with the frequency of 36/22,416 (0.16%). Whereas regarding mild mutations, the most frequent was the 5T polymorphism present in 916/22,416 (4.1%). Conclusions.Our results together with previous studies, reinforce the importance of an accurate determination of mutations in the CFTR gene, including the 5T polymorphism, in order to inform the couple of their carrier risk and the possibility on having affected child. Moreover, our findings highlight the potential of genetic screening as a tool to identify possible compound heterozygous subjects without CF-like symptoms.

2572T

Next-generation sequencing for the diagnosis of autism spectrum disorders using genomic capture targeting multiple candidate genes. *L. Rodriguez-Revenga[1, 2, 3], MI. Alvarez-Mora[1, 3], I. Madrigal[1, 2, 3], R. Calvo[4], O. Puig[4], M. Mila[1, 2, 3].* 1) Biochemistry and Molecular Genetics Department, Hospital Clinic, Barcelona, Spain; 2) CIBER de Enfermidades Raras (CIBERER), Barcelona, Spain; 3) IDIBAPS (Institut d'Investigacions Biomèdiques August Pi I Sunyer), Barcelona, Spain; 4) Psychiatry and Child and Adolescent Psychology Service, Hospital Clinic, Barcelona, Spain.

Autistic spectrum disorders (ASD) is one of the most common neurodevelopmental disabilities, with an average estimated global prevalence of 62 cases per 10,000 children and an approximate 4:1 male to female ratio. Over the past few years, the genetic basis of ASDs has been pursued aggressively using all kind of high-throughput genomic analysis technologies: SNP-array, CGH-array, next generation sequencing based techniques and genome-wide association studies. Despite the progress in the identification of several candidate genes and causative genomic copy number variations (CNVs), the vast majority of ASD cases still remain unexplained. An obstacle for molecular diagnosis of ASD patients has been clinical and genetic heterogeneity of patient cohorts in combination with a recently pointed out multihit model of the disease. This model is based on the observation that most of the abnormalities identified have been associated with highly variable phenotypes and seems insufficient to cause ASDs on their own, supporting the hypothesis that CNVs contribute to ASDs in association with other CNVs or point variants located elsewhere in the genome. In this study, we developed a next-generation sequencing-based screening based on the capture of a panel of genes involved, or suspected to be involved in ASD, on pooling of indexed DNA and on paired-end sequencing in an Illumina MiSeq platform, followed by confirmation by Sanger sequencing. A cohort of 44 ASD patients with negative result for arrayCGH was screened to evaluate this strategy in terms of sensibility, specificity, practicability and cost. In silico analysis was performed using DNAnexus® software. Sequencing data provided, on average, 99.75% coverage of the 44 genes selected at more than 100-fold mean depth of coverage. Disease causing mutations were identified in 10 patients resulting in a molecular diagnosis rate of 22.7%. These results demonstrate the efficiency of NGS in performing molecular diagnosis of ASD. The failure of finding recurrent mutations highlights the genetic heterogeneity of ASD. Acknowledgments: This study was supported by Fundación Alicia Koplowitz (AKOPLOWITZ11_006). The CIBER de Enfermedades Raras is an initiative of the ISCIII.

2573S

Prevalence of ACMG Incidental Findings in The Cancer Genome Atlas Germline Samples. *S. Sanga, A. Vladimirova, R.D. Goold, T.M. Klingler.* Station X, Inc., San Francisco, CA.

Our genomes are going to be an integral part of our future health care. Already, exome and genome sequencing are rapidly being integrated into the practice of medicine presenting opportunities in characterizing rare diseases, managing patient-specific treatment in cancer, prenatal screening for disease risk, and identifying novel pharmacogenomic biomarkers. Such sequencing has the potential to reveal medically-valid or useful findings that might be unrelated to the indication under investigation, In recognition of this, the American College of Medical Genetics and Genomics recently published their recommendations for reporting incidental findings in clinical exome and genome sequencing [Green et al., 2013]. The ACMG has recommended that laboratories performing germline clinical sequencing seek and report mutations of the specified classes or types in a select set of genes. They also encourage dialog among stakeholders and the creation an ongoing process for updating these recommendations over time as their use clinical practice provides more information on their utility. Here, in an effort to help assess the clinical utility of the ACMG guidelines for reporting on incidental findings, we apply the recommended guidelines to more than 4,000 germline exomes and genomes currently available as part of The Cancer Genome Atlas, and report our findings. In order to accomplish this analysis rapidly across thousands of samples, we developed a structured query based on the ACMG guidelines and have made it available for general use in GenePool, a genomics software platform designed for cohort-scale genomics data management, analysis, and collaboration.

Fabry disease diagnosed through family screening. *G. Sarca[1], C. Dragomir[2], E. Severin[3].* 1) Professor C.Angelescu Hospital, Bucharest, Romania; 2) Genetic Lab, Bucharest, Romania; 3) Carol Davila University of Medicine and Pharmacy, Bucharest, Romania.

Background. Early recognition of Fabry disease (FD) is difficult due to the clinical variability, the non-specific signs and symptoms and the rarity of the disease. In the same time, early recognition involves early initiation of enzyme replacement therapy (ERT) known to delay the time and prevent the disease progression. Our study describes the screening for FD using genetic testing after a diagnosis of Fabry disease in a male family member.-Objectives. To detect the disease causing mutation and to clarify the genetic status of asymptomatic family members.Subjects and methods. All 7 family members (both males and females) were genetically tested. Genetic testing included isolated DNA from blood samples and sequence analysis of all coding exons and all intron-exon boundaries of the GLA gene.Enzyme activity levels were evaluated too. Results. The disease causing mutation in the family was the pathogenic GLA mutation (c.485G>A) present in exon 3. Two males were found hemizygotes having one copy of GLA gene mutation and no enzyme alpha GAL activity. All five females were found carrier of the same mutation and had alpha-Gal A activity in the normal range.Younger male received early ERT and expressed a mild disease phenotype (no cardiac and renal involvement) comparing with his older male relative. Conclusion. Measurement of alpha-Gal A enzyme activity is unreliable for carrier detection. Early genetic testing should be considered in younger persons with a family history of Fabry's disease.

Translating allelic heterogeneity of GJB2 gene to clinical practice in Romanian population with congenital isolated hearing-loss. *E. Severin[1], C. Dragomir[2], A. Stan[2], D.T. Stefanescu[2], L. Savu[2].* 1) Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; 2) Genetic Lab, Bucharest, Romania.

Background. Different alleles within the same gene can cause a similar variant phenotype. Previously published studies showed the allelic heterogeneity of GJB2 gene as main genetic cause of isolated congenital hearing-loss phenotype. The proportional distribution of the different mutations within GJB2 gene varies in different ethnic groups. Objectives. The aim of the present study was to provide a complete and updated spectrum of mutations in GJB2 gene and to identify the most prevalent mutations in Romanian population. Subjects and Methods. To overcome our aims, we used consecutive sample selection in order to obtain a better representation of entire Romanian population. All available persons with congenital hearing-loss were included based on the inclusion criteria (clinical records of congenital sensorineural hearing loss, non-syndromic hearing loss, no related findings, patients with affected siblings but unaffected parents). Testing protocols included ARMS-PCR and DNA sequencing techniques for detection of known mutations or identification of mutations within two genes associated with hearing loss, GJB2 and GJB6. Results. Most prevalent mutation was c.35delG (40.0%) in both homozygotic and heterozygotic forms. The second mutant allele was W24X (8.75%) also founded in homo- or heterozygotic forms, followed by c.-23+1G>A originally named IVS1+1G>A and R127W mutations with lower frequencies. Conclusions. The study reveals: c.35delG mutation as most common one in Romanian population; absence of GJB6 gene deletions; genetic background of congenital hearing-loss in local population; supports improvement of testing protocols (newborn screening, carrier screening) and treatment choices (cochlear implant or other hearing device). In addition, genetic information is used for more precise genetic counselling services.

Where's the Benefit? Views on Genetic Testing for ASD. *K.B. Shutske[1], H. Starks[1,2,3,4], H.K. Tabor[1,2,3,4], W. Burke[1,2].* 1) Institute for Public Health Genetics, University of Washington, Seattle, WA; 2) Bioethics and Humanities, University of Washington, Seattle, WA; 3) Department of Pediatrics, University of Washington, Seattle, WA; 4) Treuman Katz Center for Pediatric Bioethics, Seattle Children's Research Institute, Seattle, WA.

Background: Autism Spectrum Disorders (ASD) comprise a clinically heterogeneous group of disorders with a strong genetic component. Current guidelines from ACMG and others recommend genetic testing for all individuals diagnosed with ASD, using aCGH (array Comparative Genomic Hybridization) testing as the first tier test, yet genetic testing for ASD is not consistently implemented in the clinical setting. **Methods**: We conducted semi-structured interviews with 13 parents of children diagnosed with ASD, and 15 providers from multiple specialties involved in the care of patients with ASD to identify how parents and providers define the benefits of and barriers to genetic testing for ASD. **Results**: Although parents were open to testing, it was often a low priority compared to other aspects of their child's care. Some parents expressed confusion about the test and reasons for conducting it, but they were willing to have their child tested, based primarily on their provider's recommendation, to ensure that they were doing "all they could" for their affected child. Wanting a causal explanation for ASD or information for reproductive decision making were motivators for some parents, but for the majority the motivator was "crossing it off the list" of things tried. While some providers were supportive of testing, many providers were ambivalent. Providers often made the decision to offer testing on a case by case basis. Barriers to testing mentioned by both providers and families included difficulty in conducting the blood draw, concern that information might create guilt or blame, and the cost of the test, especially when insurance would not cover it. Additional concerns from providers were stigma, variants of uncertain clinical significance, incidental findings, the added burden to the family with possible waste of time and energy, and the fact that the testing is too complex for many families to understand. The biggest barrier for families was not being aware of it. **Discussion**: Currently there is variability in provider attitude and practices toward genetic testing for ASD, as well as parental uncertainty about the value of testing. When providers recommend testing, parents generally follow their advice but they do so primarily to ensure that they are providing all recommended care. Further discussion among stakeholders is needed to clarify the purpose of genetic testing and its appropriate use in ASD care.

Pediatric neurodevelopmental disabilities refractory to traditional diagnosis: Diagnostic rate, cost and change-in-care of whole genome versus exome sequencing. *S.F. Kingsmore[1], S.E. Soden[1], C.J. Saunders[1], E.G. Farrow[1], L.K. Willig[1], L.D. Smith[1], J.B. LePichon[1], N.A. Miller[1], D.L. Dinwiddie[2], G. Twist[1], A. Noll[1], B.A. Heese[1], L. Zellmer[1], A.M. Atherton[1], A.T. Abdelmoity[1], J.E. Petrikin[1], N. Safina[1], S.S. Nyp[1], B. Zuccarelli[1], I.A. Larson[1], A. Modrcin[1], S. Herd[1], M. Creed[1], Y. Zhaohui[3], Y. Zuan[3], R.A. Brodsky[3].* 1) Center for Pediatric Genomic Medicine, Department of Pediatrics, and Department of Pathology, Children's Mercy Hospital, Kansas City, KS 84108; 2) University of New Mexico Health Science Center, Albuquerque, NM 87131; 3) Department of Medicine, Johns Hopkins University, Baltimore, MD 21205.

Neurodevelopmental disabilities (NDD), including global developmental delay, intellectual disability, epilepsy and neurobehavioral disorders, affect more than 3% of children and are attributable to single gene mutations at over 1,000 loci. Traditional methods yield molecular diagnoses in less than one half of children with NDD. Whole genome sequencing (WGS) and whole exome sequencing (exome sequencing) can enable diagnosis of NDD, but their clinical and cost effectiveness are not known. In 100 families, with 119 affected children, 41% received molecular diagnoses by exome sequencing or rapid WGS. 11 of 15 (73%) families with critically ill infants were diagnosed by WGS. 30 of 85 families (35%) that were refractory to traditional diagnosis, received diagnoses by exome sequencing. Prior to enrollment, the latter were symptomatic for an average of six years, and their families had expended an average of $18,504 in negative diagnostic tests. Referring physicians reported a change in clinical management and/or clinical impression of the pathophysiology in 46% of newly diagnosed families. If performed at symptom onset, exome sequencing/WGS would have reduced the time to molecular diagnosis by an average of 64 months. It is suggested that trio WGS should be part of the initial diagnostic work-up of NDD.

2578T

Whole exome sequencing identified a *RP2* mutation in a large Turkish family. *E. Koparir[1], O.F. Karatas[1,2], A. Sarac[3], B. Yuksel[3], M.S. Sagiroglu[4], B. Ozer[4], M. Solak[5], M. Ozen[1,6].* 1) Department of Medical Genetics, Istanbul University, Cerrahpasa Medical School, Istanbul, Turkey; 2) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 3) Genetic Engineering and Biotechnology Institute, TUBITAK Marmara Research Center, Kocaeli, Turkey; 4) Information Technologies Institute, TUBITAK Marmara Research Center, Kocaeli, Turkey; 5) Department of Medical Genetics, Afyon Kocatepe University, Afyon, Turkey; 6) Department of Pathology & Immunology, Baylor College of Medicine, Houston, TX, 77030, USA.

X-linked retinitis pigmentosa (RP) is a clinically and genetically heterogeneous disorder accompanied by abnormalities of the rod and cone photoreceptors or the retinal pigment epithelium of the retina leading progressive vision loss. Affected individuals suffer from night blindness, constriction of peripheral visual fields and later loss of central vision. All 16 patients have vision loss, however, the disease onset time and severity for each patient are variable. WES has been commonly used as a diagnostic tool to identify the molecular basis of this genetically heterogeneous disorder. We performed WES in a three-generation large Turkish family with 16 affected individuals to screen all retinitis pigmentosa-related genes and to look for novel candidate genes. R282W missense mutation was detected in exon 3 of *RP2* gene and confirmed by conventional Sanger sequencing. Although R282W was initially presented as a polymorphic variant, recent studies suggested that this missense variant might have a pathological potential and affects RP2 expression, its interactions and intracellular localization. Our findings support this hypothesis and strengthen the pathogenic potential of R282W mutation albeit the fact that additional mutations in other genes might be necessary for compete penetrance of retinal degeneration phenotype.

2579S

Whole exome sequencing as a tool to enhance patient care: Experience in a midsize academic clinical genetic setting. *A. Pandya, K. Withrow, T. Causey, V. Pallante, J. Propst, M. Jaworski, R. Lewandowski.* Dept Human & Molecular Genetics, Med Col Virginia, VCU, Richmond, VA.

Whole exome sequencing (WES) is expected to revolutionize the practice of clinical genetics with a paradigm shift in how clinicians reach a diagnosis in patients with an unknown etiology. It holds tremendous potential thereby raising expectations of physicians and families to provide an etiologic diagnosis. We report on our experience in a small subset of patients offered WES to identify an etiology. WES was preauthorized and offered to fifteen patients in the past 18 months since its clinical availability. All families were eager for testing and some initiated conversation about WES. A rigorous consent process followed regarding pros and cons of WES and the potential for incidental findings. All the patients had negative single gene molecular testing and SNP microarray. Results from twelve patients are presented (three pending). A pathogenic variant was identified in five patients (41% yield). Two have changes in an established disease gene: ATRX, associated with alpha thalassemia X-linked MR syndrome and ARID1A, associated with Coffin-Siris syndrome, although the phenotype was not evident clinically. In an adult with ataxia, a variant in the KCND3 gene confirmed a diagnosis of SCA19. One patient had a change in a newly described gene DYNC1H1, allowing a better genotype -phenotype correlation. Although the initial report in another patient suggested no clear pathogenic changes, discussion between the clinician and laboratory personnel resulted in attributing clinical significance to a variant of unknown significance (VOUS), with diagnosis of a rare type of congenital disorder of glycosylation. In two patients a de novo change in novel genes was identified but lack of supporting data or functional studies prevents attribution of clinical significance. In the remaining six patients four have a negative result and two have a VOUS. This report demonstrates some of the challenges and benefits of WES in a clinical setting and offers a learning opportunity to enable wider utility. The yield for an etiology in our sample is high (41%), although far from 100% as expected by families. We have not had an incidental finding reported to date, but the families are open to receiving this information. Despite the paradigm shift brought about by WES with test results guiding the phenotypic delineation, we highlight the importance of a thorough clinical evaluation which guides interpretation of sequence variants of unknown significance.

2580M

Diagnostic exome sequencing establishes molecular diagnoses among patients with gastrointestinal disease. *L. Shahmirzadi[1], K.F. Gonzalez[1], D. El-Khechen[1], Z. Powis[1], C. Alamillo[1], C. Mroske[1], D. Shinde[1], K. Radtke[1], R.M. Baxter[1], B. Tippin-Davis[1], S.K. Gandomi[1], E.C. Chao[1,2], S. Tang[1].* 1) Ambry Genetics, Aliso Viejo, CA, 92656; 2) Department of Pediatrics, University of California, Irvine, Irvine, CA 92697.

Diagnostic exome sequencing (DES) has proven to be an effective and efficient diagnostic tool for patients with undiagnosed genetic diseases. This test often indicated when a patient has a suspected genetic diagnosis and where prior genetic testing has been uninformative, when there are multiple genes/diseases in the differential, or when the phenotype is not consistent with a known genetic disorder. DES has been instrumental in providing a diagnosis for patients among a broad range of indications. The five most common indications for testing in our cohort have included patients with neurological, musculoskeletal, craniofacial, ophthalmologic, and gastrointestinal phenotypes. In a retrospective analysis of the first 500 reported patients who underwent DES at one laboratory, we identified 125 patients who presented with syndromic gastrointestinal (GI) disease. Among these patients, 8 presented with GI symptoms as the main feature, while GI issues were among other indications for testing in the remaining patients. Some of the most common GI symptoms included irritable bowel syndrome (IBS), gastroesophageal reflux disease, constipation, diarrhea, intestinal hypomobility, abdominal distension, eosinophilic esophagitis or colitis, omphalocele and colon/rectal lesions. A positive or likely positive findings was identified in 35/125 patients, providing a 28% diagnostic rate for syndromic gastrointestinal indications. 30 molecular diagnoses were established within well-characterized genes, while 5 cases identified pathogenic mutations in novel genes. These novel genes included: *IL21R, MYH10, CACBA1E, ITSN1*, and *PURA*. The positive findings among characterized genes included the following genes: *TRPS1, ANKRD11* (2 cases), *TUBB4A* (2 cases), *ALG1, PTCHD1, SHANK3, STXBP1, ACTG2* (2 cases), *ARHGEF9, SCN1A, KAT6B, PKD1, FOXG1, SYNGAP1, NDUFA1, PCNT, SMC3, TMEM231, OFD1, ANO3, COL3A1, AMPD2, GARS, COL4A1, HMBS, and NGLY1.* Although GI disease is not the most common indication for DES, these findings highlight the clinical utility of DES for patients with potentially syndromic disease involving the GI tract and GI disease alone.

2581T

Assessment of a next generation sequencing panel to detect mutations in 40 genes causing renal tubulopathies. *E. Ashton[1], D. Bockenhauer[2], W. van't Hoff[2], R. Kleta[2], N. Lench[1].* 1) Regional Genetics, Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom; 2) Department of Nephrology, Great Ormond Street Hospital NHS Foundation Trust, London, United Kingdom.

The renal tubule regulates blood pressure, as well as water, acid-base and electrolyte homeostasis and there are currently mutations described in around 40 different genes associated with these disorders. We describe here evaluation of a 40 gene panel (including autosomal dominant, autosomal recessive and X-linked genes) that was developed within the EURenOmics consortium (www. Eurenomics.eu) in 92 patients by next generation sequencing. The Multiplicom MASTR ™ technology (Multiplex Amplification of Specific Targets and Resequencing) was used for library preparation. Nine multiplex PCR reactions were performed for each patient followed by pooling of products to produce amplicons for all regions of interest in the 40 genes in the panel. This was followed by a second round of PCR to add patient-specific barcodes and adaptors for sequencing. Sequencing was carried out using the Illumina MiSeq system using the version 3 2 x 300 bp sequencing chemistry (generating between 13.2 and 15 Gb of data per sequencing run). Data analysis was performed with an in-house bioinformatics pipeline using BWA for alignment, VarScan for variant calling and Variant Effect Predictor (VEP) for variant annotation (Ensembl). All mutations identified by next generation sequencing were confirmed by Sanger sequencing. Included in the patient cohort were 10 positive controls with previously known mutations in *AVPR2* (MIM 300538), *CLCN5* (MIM 300008), *CLDN19* (MIM 610036), *HSD11B2* (MIM 614232), *KCNJ1* (MIM 600359), *KCNJ10* (MIM 602208), *OCRL* (MIM 300535), *SLC12A1* (MIM 600839) and *SLC4A1* (MIM 109270) to assess the sensitivity of the methodology.

We have simultaneously screened a group of patients diagnosed with renal tubulopathies for mutations in 40 different genes using a Multiplicom MASTR ™ panel. Most of these genes are currently not available for testing in UK diagnostic laboratories. The testing described here allows screening of multiple genes simultaneously to provide a faster diagnosis for patients at reduced cost, with mutation-specific testing then available to other family members. The flexibility of the Multiplicom MASTR™ method means that any other genes identified to be causative of renal tubulopathy could be included in the design in future.

2582S

Effective diagnosis of genetic disease by computational phenotype analysis of the disease-associated genome. *T. Zemojtel[1,2], S. Köhler[1], L. Mackenroth[1], M. Jäger[1], J. Hecht[1], P. Krawitz[1], L. Graul-Neumann[1], S. Doelken[1], N. Emke[1], M. Spielmann[1], N.C. Oeien[1,5], M.R. Schweiger[1], U. Krüger[1], G. Frommer[6], B. Fischer[1], U. Kornak[1], A. Ardeshirdavani[7], Y. Moreau[7], S.E. Lewis[8], M. Haendel[9], D. Smedley[10], D. Horn[1], S. Mundlos[1,3,4], P.N. Less than half of patients presenting with suspected genetic disease receive an etiological diagnosis. Though next-generation sequencing (NGS), and in particular whole exome sequencing (WES), has enabled an unprecedented acceleration in the pace of Mendelian disease gene discovery, extensive challenges remain to integrate NGS, bioinformatics, and clinical data into effective diagnostic workflows. Because only variants in the ~2800 established Mendelian disease genes can be interpreted in a clinical context, we have established an approach that targets variants in these causative genes, which we will refer to as the disease-associated genome (DAG), developing a targeted enrichment DAG panel (7.1 Mb), for which we achieved a coverage of 20-fold or better for 98% of bases. Furthermore, we established a computational method termed Phenotypic Interpretation of eXomes (PhenIX) that evaluates and ranks variants based on variant pathogenicity and semantic similarity of patients' phenotype profiles described by Human Phenotype Ontology (HPO) terms to those of 3991 Mendelian diseases associated with the ~2800 disease genes. In computer simulations, ranking genes based only on the variant score put the true gene in first place less than 5% of the time; in contrast PhenIX placed the correct gene in first place over 86% of the time. We retrospectively tested PhenIX on 52 patients with previously identified mutations and known diagnoses, achieving a mean rank of 2.1 for the correct gene. In a prospective study on a group of 80 individuals who had remained without a diagnosis despite intensive clinical workup and targeted genetic testing, PhenIX analysis enabled a diagnosis in 23 cases (~29% at a mean rank of ~2.4). An experienced clinical geneticist needed an average of ~1.5 hours per patient to evaluate the ranked list produced by PhenIX. Thus, the combination of targeted NGS investigation of the DAG followed by phenotype-driven bioinformatic analysis provides the means for quick and effective differential diagnostics in medical genetics.

2583M

Genomic diagnosis in children with developmental delay/intellectual disability. *K. Bowling[1], K. East[1], M. Amaral[1], C. Penfold[1], J. Whittle[1], C. Henegar[1], S. Simmons[2,3], E.M. Bebin[2,3], E.J. Lose[2,3], K. Brothers[4], G.S. Barsh[1], R.M. Myers[1], G.M. Cooper[1].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) North Alabama Children's Specialist, Huntsville, AL; 3) University of Alabama at Birmingham, Birmingham, AL; 4) University of Louisville, Louisville, KY.

Developmental delay, intellectual disability, and related congenital defects (DD/ID) affect ~1-2% of children who are born worldwide. DD/ID phenotypes greatly impact affected individuals and their families, and constitute a costly public health burden. Genetic diagnosis of DD/ID-affected children comprises an ideal exploratory arena to address the challenges and unanswered questions facing the widespread use of DNA sequencing in clinical contexts. While cytogenetic and microarray-based platforms have been used extensively for DD/ID diagnostics, causal genetic variation remains undetermined in a large proportion of DD/ID-affected individuals. Therefore, as part of the Clinical Sequencing Exploratory Research Consortium, we are conducting whole exome sequencing in ~450 parent-offspring trios over a period of 4 years to establish a genetic diagnosis for unexplained cases of DD/ID. Primary genetic results (DD/ID causative) as well as secondary findings (pathogenic variation detected in parents) are being returned to probands and their parents in a clinic setting, and follow-up studies are underway to determine how genomic test results affect the well-being of participants. To date, we have enrolled and consented 99 parent-offspring trios (some with DD/ID-affected siblings), and have completed exome sequencing and analysis for 29 of these trios. Among children with no diagnosis after standard clinical testing (e.g., clinical microarrays), we have successfully identified DD/ID pathogenic variants in 6 probands (21% of our total) including mutations in *TCF4*, *SCN2A*, *MECP2*, *ARX* and *GRIN2B*. We have also found variants, that while not definitively causal, are plausible candidates; for example, compound heterozygosity for impactful variants in *PCNXL2* shared by affected siblings, and de novo variants in *EBF3*, a conserved transcription factor known to be important in brain development. Further, we have identified potentially pathogenic variation in 15 of the 58 exome-sequenced parents (26%). Secondary findings include variation in *RYR1* (malignant hyperthermia susceptibility) and *DSP* (arrhythmogenic right ventricular cardiomyopathy), as well as carrier status for *HEXA* (Tay-Sachs disease) and *CFTR* (cystic fibrosis). The results of our clinical sequencing project demonstrate, thus far, that large-scale DNA sequencing improves the rate of definitive diagnoses in DD/ID-affected children and thereby meets a valuable clinical need.

2584T

Autosomal Dominant Hypertrophic Cardiomyopathy (HCM) is an important modifier of the cardiomyopathy of Fabry Disease (FD): Implications for α-Galactosidase A replacement therapy. *D. Doheny[1], R. Desnick[1], D. Macaya[2], C. Antolik[2], H. Rehm[3], A. Alfares[3], T. Callis[4], J. DaRe[4], S. Garman[5].* 1) Dept Gen & Genomic Scienc, Icahn School of Medicine at Mount Sinai, New York, NY; 2) GeneDx, 207 Perry Pkwy, Gaithersburg, MD; 3) Harvard Medical School, Laboratory for Molecular Medicine, 65 Lansdowne Street, Cambridge, MA; 4) Transgenomic, 5 Science Park, New Haven, CT; 5) Department of Biochemistry and Molecular Biology, University of Massachusetts, 710 North Pleasant street, Amhurst, MA.

Hypertrophic Cardiomyopathy (HCM) is a common autosomal dominant disorder of the myocardium that affects ~1 in 500 individuals world-wide and is the most common cause of sudden cardiac death in individuals under 35 years. To date, variants in >20 genes have been identified that cause HCM, most encoding sarcomere proteins. The cardiac features of HCM are indistinguishable from the cardiomyopathy of FD due to α-galactosidase gene (GLA) mutations. Screening panels that sequence the most common HCM-causing genes also include GLA, detecting pathogenic (P) and likely pathogenic (LP) variants. We hypothesized that previously unrecognized FD patients, particularly those with the "later-onset" phenotype, would be detected by these panels. In 6486 HCM patients referred for panel sequencing, GLA variants were identified and stratified by sex and phenotype, including "classic" or "later-onset" phenotypes, benign variants (BV), and variants of unknown significance (VUS). The presence of HCM variants was also recorded. Of the 6486 HCM patients tested, 96 (1.5%) were identified with a GLA variant. Of these 96, 27% also had a P or LP HCM variant, most being in the β-myosin heavy chain (MYH7) and the myosin binding protein C (MYBPC3) genes. When stratified by Fabry phenotype and sex: 1) 13 patients had the "classic" phenotype, but only one, a heterozygote, had a P/LP HCM variant, indicating that the cardiomyopathy in most was due to FD; 2) among the other Fabry phenotypes, a higher percentage of patients had a P/LP HCM variant suggesting that the cardiomyopathy was due primarily to HCM variants: among 32 patients with the "later-onset" phenotype, 25% had a HCM variant; among 43 with GLA BVs, 35% had a HCM variant; and among 8 with GLA VUSs, 25% (both females) had a HCM variant. Of those with GLA BVs, 79% had the pseudodeficient D313Y lesion of which 38% had a HCM variant. These findings are the first to indicate that variants in other genes may modify or underlie the pathogenesis of the major life-threatening manifestations of FD. Clearly, all patients with FD and left ventricular hypertrophy or HCM should be tested for HCM-causing genes, and those with HCM found to have GLA mutations: 1) should be evaluated by a FD specialist, 2) at-risk family members should be tested, and 3) affected males considered for early intervention by enzyme replacement therapy. Additionally, identification of P/LP HCM variants in FD patients may also have implications for treatment options.

2585S

Characterization of Malaysian children with Beckwith-Wiedemann syndrome and Silver-Russell syndrome using methylation specific - multiplex ligation-dependent probe amplification. *M. Thong[1], K. Thurga[2], R.Y.Y. Poh[2], I. Taufik[1], H.B. Chew[3], G.S. Ch'ng[3], W.T. Keng[3].* 1) Department of Paediatrics, Faculty of Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia; 2) Department of Biomedical Science, Faculty of Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia; 3) Department of Genetic, Hospital Kuala Lumpur, 50586 Kuala Lumpur, Malaysia.

Introduction: Beckwith-Wiedemann syndrome (BWS [MIM 130650]) and Silver-Russell syndrome (SRS [MIM 180860]) cause gigantism and growth retardation, respectively. Imprinting centre (IC) 1 controls the expression of IGF2 and H19 whereas IC2 controls the expression of CDKN1C and KCNQ1OT1. Methodology: Blood samples were collected from 13 BWS and 18 SRS patients based on clinical features. Genomic DNA was extracted. The DNA of patients and controls were subjected to multiplex ligation-dependent probe amplification (MLPA) to detect the copy number and methylation status in imprinted genes of chromosome 11 for BWS and SRS. The resulting PCR products were sent for fragment analyses. Results and discussion: Out of 13 BWS patients, three patients had IC2 hypomethylation with normal IC1 methylation. The IC2 hypomethylation may be implicated in KCNQ1OT1 activation and CDKN1C inhibition, leading to the gigantism. Six patients had IC2 hypomethylation and IC1 hypermethylation simultaneously which indicated paternal UPD at chromosome 11p15.5. One patient had both IC1 and IC2 hypomethylation and two patients had IC1 hypermethylation with normal IC2. One mutation was identified in CDKN1C at position 78 in one BWS patient. One had normal methylation at both IC's. Among the 18 SRS patients, five showed normal methylation at both IC's. One showed hypomethylation at both IC1 and IC2, and two showed IC1 hypomethylation with IC2 hypermethylation. Hypomethylation of IC1 causes the biallelic expression of H19 and biallelic silencing of IGF2, resulting in growth restriction. However, one had normal IC1 and IC2 hypermethylation and one had normal IC1 with IC2 hypomethylation. Three had hypermethylation at both IC1 and IC2 and five had IC1 hypermethylation with normal IC2. None of our SRS samples showed UPD in chromosome 7. Conclusion: The patients in this study presented with gain and loss of methylation, duplication and deletion in both BWS and in SRS, in different imprinted genes, emphasizing the heterogeneity of these two growth disorderd syndromes.

An age-based categorical framework to guide informed decision-making about next generation sequencing results in newborn screening. *L.V. Milko, J. O'Daniel, K. Foreman, C. Turcott, J. Booker, L. Boshe, M. Gucsavas-Calikoglu, A. Aylsworth, J. Muenzer, D. Frazier, B. Powell, M. Roche, N. Strande, N. Vora, C. Powell, J.S. Berg.* University of North Carolina Chapel Hill, School of Medicine, Chapel Hill, NC.

A tenet of newborn screening (NBS) is the potential for early detection and prevention of diseases prior to clinical manifestation of symptoms. Although next generation sequencing (NGS) offers great promise in increasing the number of conditions that can be presymptomatically screened, it also presents significant ethical complexity for conditions where efficacious treatment may not be available, or where avoiding the "diagnostic odyssey" might be the only benefit. The NC NEXUS (North Carolina Newborn Exome Sequencing for Universal Screening) project is developing a modified "binning" classification framework to characterize different categories of information that parents might be interested in learning, and to study the psychosocial impacts of their choices. The framework is divided into four quadrants that balance a semi-quantitative scale of "clinical actionability" (a measure of the likelihood and severity of disease outcomes, and the efficacy and potential harms of interventions), against the age of onset of disease or age of implementation of preventative intervention. The core panel ("NGS-NBS") is composed of clinically actionable genes that are implicated in childhood-onset disorders, including conditions on standard newborn screens. All parents of screened newborns will receive results of the core NGS-NBS panel. Given the lack of empirical data on how to present other types of genetic information, parents will be randomized into either a control arm receiving only results of the NGS-NBS panel, or an experimental arm tasked with deciding whether to learn additional information from three categories: 1. clinically actionable conditions with typical disease onset or interventions beginning in adulthood (eg. Lynch syndrome); 2. childhood-onset, non-medically actionable disorders with no known effective interventions (eg. Rett syndrome); and 3. carrier status for recessive disorders. Information about adult-onset disorders with no known interventions (eg. Alzheimer disease) will not be returned. We hypothesize that classifying the types of results that parents may opt to learn into clear categories will assist physicians and parents in engaging in informed decision-making in the complex setting of genome-scale sequencing of healthy newborns. It will also be useful in understanding how and why parents choose whether to participate in sequencing of their child's DNA, what results they elect to receive, and the impacts of their decisions.

Targeted resequencing in intellectual disability and epilepsy in routine diagnosis, preliminary results. *D. Lederer, V. Benoit, Ch. Verellen-Dumoulin, I. Maystadt.* Centre for Human Genetics, IPG, Gosselies, Belgium.

Epilepsy is a common neurological disorder with a lifetime incidence rate of 3%. Intellectual deficiency affects 1-3% of children. Microarray CGH detects a chromosomal abnormality in 10-15% of individuals with intellectual disability and in 8% of patients with epileptic encephalopathy. Extensive metabolic study and brain imaging techniques lead to a diagnositc in respectively 5% and 0,8% of cases. There are many conditions that associates epilepsy and mental retardation, caused by mutations in more than 100 genes, making genetic diagnosis expensive and challenging in the absence of other congenital anomalies. With the recent advances in genetics, it is becoming easier to analyse panel of genes responsible for a condition. In order to simplify the genetic diagnosis in epilepsy and intellectual deficiency, we have gathered in one analysis 150 genes. The coding regions are amplified with a customed Ampliseq protocol and we sequence the fragments on an Ion Proton®. Mutation calling is done with Life technologies variant caller and Cartagenia. Here, we present the preliminary results. To date, we have tested more than 120 patients. The inclusion criteria to this study are intellectuel deficiency or developmental delay and epilepsy. We have confirmed mutations in few genes: STXBP1, FOXP1, KCNQ2, SCN2A, RFT1, ATRX, GLDC, NRXN1, NLGN3, SHANK3, SYNGAP1, MAGI2, SLC9A6, KDM5C. Overall, we are expecting a causal mutation rate of 15-25%. We will present the clinical and metabolic data of patients with causal mutations. Moreover, other substitutions detected were already described in the litterature in patients with specific epilepsy with or without intellectual disabilty and were sometimes inherited from a healthy parent (SCN1A, KCNQ3, SCN8A, SCN1B). They could act as modifier genes inducing epilepsy in patients affected by a second mutation responsible for the intellectual phenotype. We need more data to confirm this hypothesis. In conclusion, gene panel analysis could be a first line diagnostic test in patients with intellectual deficiency and epilepsy in view of low cost and high mutation pick up rate.

Should the ACMG expand the required reportable disorders or findings on Exome Sequencing? Reporting a recent experience. *R.M. Zambrano, Y. Lacassie.* Department of Pediatrics, LSUHSC, New Orleans, LA. and Children's Hospital of New Orleans.

Exome and Genome sequencing are becoming the standard in the Genetic clinics for the evaluation of patients with rare disorders. These technologies are allowing the identification of the molecular bases of many syndromes and also uncover incidental or secondary findings that could be of medical value for the patient and their family. The ACMG has published a statement listing the recommendations for reporting incidental findings in Clinical Exome and Genome Sequencing. Based in a recent experience in which the use of incidental clinical Exome data supported the clinical diagnosis of severe primary hyperparathyroidism in a neonate, we propose to include disorders that can cause severe neonatal diseases and also recommend that the laboratories performing these tests do report all the recessive genes in which both parents are heterozygotes. We report a 5-day-old Caucasian female born to a 29-year-old father and a 32-year-old consanguineous G5P2 mother. The 2nd and 3rd pregnancies were miscarriages. Their 4th pregnancy resulted in a child presenting congenital scoliosis and mild developmental delay. Because of consanguinity, Exome sequencing was requested. It didn't find an expected autosomal recessive disorder but identified a previously unreported de novo mutation in the TRPS1 gene (AJMG 2014, in press). Their last pregnancy was detected early. Only complications included polyhydramnios and premature labor requiring bed rest for 8 weeks. The baby was born NSVD at 374/7 WGA. The newborn was discharged home at DOL 2 but had to be re-admitted after 2 days due to hyperbilirubinemia, poor feeding, weight loss, hypotonia and lethargy. Laboratory work-up showed severe hypercalcemia with a serum calcium level of 33.7 mg/dL. Repeated was 36.8 mg/dL and PTH was elevated at 867 pg/mL (nl 15-65 pg/mL). We suspected neonatal severe hyperparathyroidism (NSHPT) caused by mutations in the CASR gene. As the parents had been sequenced, we contacted the laboratory which quickly confirmed that both parents were heterozygous for a mutation in the CASR gene: c.206G>A (p.R96H). This allowed us to further support our clinical diagnosis of NSHPT. Sanger sequencing confirmation on the proband is pending. Reporting biparental heterozygosity for genes causing severe neonatal disease or disorders with available treatment is recommended. This would allow genetic counseling, prenatal testing, and the prompt therapy after birth or later.

Exploration of the benefit of risk-stratified colorectal cancer screening based on common genetic variants - current status and future potential. *S.K. Naber[1], S. Kundu[2], K.M. Kuntz[3], Z.K. Stadler[4], R.W. Burt[5], M.S. Williams[6,7], N. Calonge[8], D.T. Zallen[9], T.G. Ganiats[10], E.P. Whitlock[11], E. Webber[11], K.A.B. Goddard[11], N.B. Henrikson[12], M. van Ballegooijen[1], A.C.J.W. Janssens[2], A.G. Zauber[4], I. Lansdorp-Vogelaar[1].* 1) Department of Public Health, Erasmus Medical Center Rotterdam, Rotterdam, Netherlands; 2) Department of Epidemiology, Emory University, Atlanta, GA, United States; 3) Department of Health Policy & Management, University of Minnesota, Minneapolis, MN, United States; 4) Memorial Sloan-Kettering Cancer Center, New York, NY, United States; 5) Department of Medicine, University of Utah, Salt Lake City, UT, United States; 6) Intermountain Healthcare, Salt Lake City, UT, United States; 7) Genomic Medicine Institute, Geisinger Health System, Danville, PA, United States; 8) The Colorado Trust, Denver, CO, United States; 9) Department of Science and Technology in Society, VirginiaTech, Blacksburg, VA, United States; 10) Department of Family and Preventive Medicine, University of California, San Diego, CA, United States; 11) Center for Health Research, Kaiser Permanente Northwest, Portland, OR, United States; 12) Group Health Research Institute, Seattle, WA, United States.

Background. Common genetic variants contribute to colorectal cancer (CRC) risk and can be used to stratify the population into CRC risk categories. However, the discriminatory performance of such risk-stratification algorithms is currently limited. In this study, we investigate the current and potential future benefits of using risk-stratified colonoscopy screening, based on common genetic variants, versus uniform colonoscopy screening at ages 50, 60 and 70. **Methods.** We used the MISCAN-Colon microsimulation model to determine cost-effective colonoscopy screening strategies for people with a relative risk (RR) for CRC of 0.1, 0.2, ..., 9.8, 9.9 and 10. The costs and effects of risk-stratified screening in the population were determined based on the current discriminatory performance of common genetic variants (area under the ROC curve (AUC) of approximately 0.6) compared to uniform screening at ages 50, 60 and 70 for all. Because it is expected that the discriminatory performance of risk-stratification based on common genetic variants will increase in the future, we also estimated costs and effects for risk-stratified screening based on hypothetical common genetic variants with higher levels of discriminatory performance (AUC of 0.65, 0.70, ..., 0.90). **Results.** With current discriminatory performance, the optimal colonoscopy screening strategy ranged from no screening for people with a RR of 0.1 to screening every 3 years from age 40 until age 85 for people with a RR of 5.4 - 10. Screening at ages 50, 60 and 70 was optimal for people with a RR between 0.9 and 1.3. This stratification resulted in 1% more life years gained than uniform screening (less than 1 life year per 1,000 individuals) for the same overall costs. With increased discriminatory performance, the gain in life years increased from almost 4% for an AUC level of 0.65 to more than 18% for an AUC level 0.90. **Conclusions.** Given the very modest discriminatory performance of common genetic variants in risk-stratification for CRC, the current benefits of risk-stratified CRC screening based on these variants are limited. New variant discoveries are needed to yield a substantial improvement in discriminatory performance, and are necessary for risk-stratified screening to become clinically significant.

2590T

HCV infection and interferon-based treatment induce p53 gene transcription in chronic hepatitis C patients. *J. Nowak[1], B. Swiatek-Koscielna[1], E. Kaluzna[1], J. Rembowska[1], I. Mozer-Lisewska[2], I. Bereszynska[2], J. Wysocka-Leszczynska[1], A. Kowala-Piaskowska[2], J. Wysocki[1], D. Januszkiewicz-Lewandowska[1, 2, 3].* 1) Inst Human Gen, Polish Academy Sci, Poznan, Poland; 2) University of Medical Sciences, Poznan, Poland; 3) Department of Medical Diagnostics, Poznan, Poland.

It is suggested that tumor suppressor p53 gene is implicated in the interferon (IFN)-mediated innate immunity against viruses. This study aims at examining transcriptional response of p53 gene to HCV infection and IFN-based therapy in chronic hepatitis C (CHC) patients. p53 gene expression was quantified by TaqMan real-time PCR in peripheral blood mononuclear cells (PBMCs) of 63 CHC patients (HCV genotype 1 and 4) treated with pegylated IFN-α and ribavirin and of 51 healthy individuals. Analyses were performed before, at week 4 and 12 of treatment. p53 gene expression was significantly upregulated in CHC patients before and at week 4 of anti-HCV therapy. No significant differences in p53 mRNA expression between rapid virological responders (n=23), complete early virological responders (n=17) and non-responders (n=23) were found. Moreover, no significant correlation between p53 gene expression and HCV-RNA viral load was observed. The results obtained indicate that HCV infection and IFN-based treatment induce p53 gene transcription in PBMCs. It can be suggested that p53 gene may play a role in HCV infection but is not directly involved in treatment-induced HCV elimination. Moreover, variations in p53 gene expression not determine on-treatment anti-HCV response in CHC patients with 'difficult-to-treat' HCV genotype 1 and 4.

2591S

Assisted reproductive treatment is not a risk factor for chromosomal abnormalities in spontaneous abortion. *s. Shim.* Dept of Ob and Gyn, CHA Gangnam Medical Center, seoul, South Korea, MD.

Background: The causes of miscarriage include fetal and maternal factors. More than half first-trimester pregnancy losses are attributed to fetal chromosomal abnormalities, in which autosomal trisomy is known to be the most frequent cause (about 60%). Maternal risk factors for first-trimester pregnancy losses are maternal obesity, old age, and prior history of pregnancy loss. Recently, ART is more frequently utilized with an increase in infertility rate. However, there is a paucity of data about the frequency of embryonic chromosomal abnormalities in first-trimester miscarriage after assisted reproductive treatment (ART). We examined whether or not embryonic chromosome aberration in first-trimester pregnancy losses is more frequent in pregnant women with ART than in those with natural pregnancy. Methods: We conducted a retrospective study in CHA Medical Center. Study population consisted of 511 pregnant women (natural pregnancy group 31.31% <160/511> vs. ART pregnancy group 68.49% <350/511>) who underwent either spontaneous abortion or surgical dilatation and curettage between 2011 and 2012 with the diagnosis of missed abortion during first trimester (gestational age < 14wks). We compared the frequency of embryonic chromosome aberration according to natural pregnancy group or ART pregnancy group, BMI >= 25 or BMI < 25, the presence or absence of prior history of pregnancy loss, and maternal age >= 35 or < 35. Results: The overall rate of aneuploidy was 51.6%, and mean maternal age 35.0 years. There was no significant difference in abnormal karyotypes between ART pregnant group and natural pregnancy group (P=0.154). However, abnormal karyotypes were significantly more frequent in patients with maternal age >= 35 years than those with maternal age < 35 years, in patients with BMI >= 25 than in those with BMI < 25, and in pregnant women with prior history of pregnancy loss than in those without prior history of pregnancy loss (each for P<.05). Conclusions: ART treatment is not a risk factor for chromosomal abnormalities in the first trimester miscarriage. However, maternal age more than 35 years, maternal obesity (BMI >= 25) and prior history of pregnancy loss are associated with abnormal karyotyping in first trimester miscarriage.

A workflow based information system infrastructure to support translational science: The NIH Undiagnosed Diseases Program experience. *A.E. Links[1], D. Draper[1], E. Lee[1], V. Lebedev[2], M. Didenko[2], D. Adams[1], M. Brudno[3], S. Dumitriu[3], M. Girdea[3], W.P. Bone[1], B. Coessens[4], S. Verhoeven[4], C.F. Boerkoel[1], W.A. Gahl[1], M. Sincan[1].* 1) Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD; 2) RURO Inc., Frederick, MD; 3) Department of Computer Science, University of Toronto, Ontario, Canada; 4) Cartagenia NV, Leuven, Belgium.

The Undiagnosed Diseases Program (UDP) is a translational medicine initiative focused on bridging the gap between the patient bedside and the research bench. The application of translational medicine presents two major challenges: “translational research,” or bench-to-bedside integration, and conduction of complex and multidisciplinary research through collaborative research networks. Moreover, the UDP deals with many independent cases that each have individual research and clinical life cycles. In an effort to overcome these two challenges and manage the complexities of the UDP, clinical and research processes were mapped and used for development of a Translational Research Information System (TRIS) known as the Undiagnosed Diseases Program Integrated Collaboration Server (UDPICS). The UDPICS ecosystem includes a workflow based translational research information management server, an ontology based phenotyping application, a biosample management system, an animal tracking system, a cloud-based genomic analysis platform, and an electronic laboratory notebook. It contains a complicated data structure with over 80 active workflows and over 2000 discrete data elements for efficient tracking of research projects and clinical services. In addition, the UDP has designed a collaborator instance of UDPICS to allow external collaborators to work with non-personally identifiable information (non-PII) specific to the individuals involved in the collaboration, upload reports for easier feedback to the clinical staff, and engage in recorded discussions with members of the UDP team. In conclusion, the UDP has developed a system that is capable of supporting both translational research and clinical services while providing a collaboration platform to allow the research consortia to tackle the complex and diverse scientific problems posed by the many different undiagnosed diseases.

2593T

Assessment of the variant annotation interpretive gap among major variant databases. *M. Lee, B. Vecchio-Pagan, G.R. Cutting.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

The interpretive gap is a growing divide between variants which have been identified and those which have been annotated. This gap is a significant obstacle when seeking to assign disease liability to variants detected by exome sequencing and when interpreting sequencing results in diagnostic laboratories. The breadth of the interpretive gap may be assessed by evaluating the consistency and depth of data across traditional disease-focused as well as "normal" variation databases. We surveyed five databases: OMIM (curates disease phenotypes), HGMD (curates disease variants from the literature), ClinVar (inventories variants from user submissions), LOVD (inventories variants from user submissions), and The 1000 Genomes Project (inventories variants detected in "normal" individuals). There were 2780 genes curated in OMIM, 4733 in HGMD, 18645 in ClinVar, 20172 in LOVD, and 17406 in 1000 Genomes. Across the inventory databases (ClinVar, LOVD, and 1000 Genomes), 67.7% of genes were present in all three; however, only 10.4% of genes were found in all five. To assess variant depth, 2179 genes annotated in all five databases were extracted. Variant counts reported for each gene differed by as much as an order of magnitude per gene. To determine consensus and quality of variant annotation, we selected the 30 disease-implicated genes with the highest number of variants in OMIM and extracted variant data for each gene from OMIM, HGMD, ClinVar, and 1000 Genomes. MAF data from dbSNP and 1000 Genomes revealed that 60.0 ± 39.2% (range: 17.1-99.1%) of variants reported in the 30 genes had a dbSNP rsID, and 26.8 ± 45.9% (range: 0.114-95.0%) had population MAF, indicating that high quality feature data is missing for a substantial fraction of variants in genes with strong disease associations. Remarkably, only 41 (0.437%) of 9383 unique variants are annotated by all four databases. Furthermore, variant type (e.g. SNV, deletion, insertion, indel) distributions of the 30 genes in HGMD, ClinVar, and 1000 Genomes were strikingly different among the curated variant types. A suspected overrepresentation of SNVs was seen, and represented 72.6% of variants in HGMD, 82.6% in ClinVar, and 98.5% of variants in 1000 Genomes. These findings reveal that the interpretive gap is both wide and multidimensional, as there is an absence of consistency regarding the number, composition, and associated feature data of variants annotated in widely used variant databases.

2594S

Clinical whole exome sequencing (WES) production update at Baylor Whole Genome Laboratory (WGL): Improved procedures for faster TAT and better disease gene coverage. *Y. Ding[1], S. Matakis[1], C.J. Buhay[1], M. Wang[1], N. Veeraraghavan[1], T. Chiang[1], A.C. Hawes[1], W. Liu[1], N. Saada[1], J. Ma[1], L.K. Dolores-Freiberg[2], J. Chandarana[2], C.J. Qu[2], R. Najjar[2], M.N. Bainbridge[1], Y. Han[1], H. Dinh[1], J.V. Korchina[1], Q. Wang[1], E. Boerwinkle[3], J.R. Lupski[2], S.E. Plon[2], A.L. Beaudet[2], C.M. Eng[2], R.A. Gibbs[1], D.M. Muzny[1], Y. Yang[2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Baylor WGL has been providing clinical WES services since October 2011. To date, approximately 3800 WES cases including 3650 germline WES, 150 cancer WES as well as ~3100 mitochondrial genomes have been sequenced on the Illumina HiSeq2500 or HiSeq2000. The current sample volume is approximately 200 samples per month. NGS sequencing of mitochondrial genomes has been included in the clinical WES test starting with samples received on 10/15/2012. The mitochondrial genome was amplified by a single long-range PCR before subjecting to paired-end library constructions. Mitochondrial and WES libraries from the same sample were barcoded and sequenced in the same lane (1:30) on Illumina's HiSeq platform. This process eliminates virtually all sequencing cost for the mitochondrial genome. Paired-End library constructions for WES and mitochondrial genome were automated using Beckman Biomek NXP/Span-8 robots, and show high throughput (up to 400 samples per month), data quality and reproducibility. The enrichment for exome sequences utilized a solution based whole exome capture probe set, VCRome 2.1, which covers approximately 200,000 coding exons (35 Mb). An average of >10 Gb data were generated for each WES and 95% of the targeted exome regions were sequenced at a depth of >20X (average coverage >140X). The mitochondrial genome was sequenced at >20,000X to facilitate the detection of large deletions. Further, we have validated and implemented additional procedures initially developed at the Baylor Human Genome Sequencing Center (HGSC) in order to achieve better sequencing coverage and shorter turnaround time (TAT) (Muzny et al. 2014 ASHG abstract). First, by applying the "spike-in" reagents (version 1) targeted at 1800 GeneTests genes, the number of 100% covered genes increased by 200-300 for samples with 10 Gb output. Starting from April 2014, all clinical samples (450 so far) are captured using the "spike-in" exome reagents. Second, the newly implemented rapid hybridization procedure reduces the probe capture time from 72 to 24 hours. Further validation of additional quick WES (QWES) procedures developed at HGSC will enable the completion of the wet lab exome sequencing process within 5 working days at WGL. Improved clinical WES protocols and automation have enabled Baylor WGL to produce higher quality WES data with better disease gene coverage and shorter TAT and prepared the lab for more challenging services such as WES for prenatal or neonatal ICU samples.

2595M

Clinical actionability of incidental findings: application of a semiquantitative metric to assess actionability of over 1200 genes. *A.K.M. Foreman[1,2], J.K. Booker[1,3], L. Boshe[1,2], K.R. Crooks[1,3], J.P. Evans[1,2], B.C. Jensen[1,4], K. Lee[1,2], D.K. Nelson[1,5], J.M. O'Daniel[1,2], B.C. Powell[1,2], C.M. Powell[1,6], M.I. Roche[1,6], C. Skrzynia[1,2], N.T. Strande[1,2], K.E. Weck[1,3], K.C. Wilhelmsen[1,7,8], J.S. Berg[1,2].* 1) UNC Chapel Hill School of Medicine, Chapel Hill, NC; 2) Department of Genetics; 3) Department of Pathology and Laboratory Medicine; 4) Department of Medicine, Division of Cardiology; 5) Department of Social Medicine; 6) Department of Pediatrics, Division of Genetics and Metabolism; 7) Department of Neurology; 8) Renaissance Computing Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC.

As exome and genome sequencing are increasingly applied in clinical scenarios, incidental findings (IFs) are discovered as a matter of course. Debate about the most appropriate handling of such findings is ongoing, but it is widely recognized that IFs vary in their clinical utility or actionability. Evaluating actionability is critical to identifying genes for routine return and enabling informed decision-making by patients. The NCGENES (North Carolina Clinical Genomic Evaluation by NextGen Exome Sequencing) study returns "clinically actionable" IFs to patient-participants undergoing exome sequencing. To define these IFs for NCGENES, we developed a semiquantitative metric to assess actionability of gene-phenotype pairs by scoring five elements of actionability on a 0-3 scale: (1) **severity** and (2) **likelihood** of the adverse outcome, (3) **efficacy** and (4) **burdens or risks** of the proposed intervention, and (5) level of **knowledge**. Higher scores suggest greater actionability. We initially scored 161 genes selected from OMIM as plausible candidates for routine return as medically actionable IFs. The median score was 11, and 73 genes scored 12 or higher. To investigate the robustness of the metric, we scored a random sample of 1000 genes in RefSeq. The majority of genes scored 0 by default because an associated phenotype either did not exist in OMIM or OrphaNet, was caused by somatic mutation, or was simply a modest influence on disease risk based on association studies. The remaining 114 genes were formally scored using the metric, with a relatively flat distribution of scores from 5-10 and a median of 8. We then applied the metric to the 56 genes recommended by the ACMG for routine return when discovered as IFs. The median score was 11 (range 7-14). High-scoring genes included *MLH1* (with its associated phenotype, Lynch syndrome) with a score of 13, and *RYR1* (malignant hyperthermia) with a score of 12. The *NTRK1* gene, which was dropped from the ACMG list after being included on a preliminary version, scored 10. The ACMG 56 contains nineteen genes with a score ≤10. Our proposed metric promotes transparency in decisions about return of IFs, provides a basis for comparing genes with disparate phenotypes, and is customizable. We evaluated the impact of weighting individual elements, such as efficacy or knowledge, on the scores and discuss challenges to use of the metric, including pleiotropy, and factors important to return of IFs not captured by the metric.

Project of Iwate Tohoku Medical Megabank Organization toward preemptive medicine. *A. Shimizu[1], T. Hachiya[1,2], K. Tanno[3,4], A. Fukushima[5,6], Y. Shiwa[2], H. Ohmomo[1], R. Furukawa[2], K. Yamamoto[6], K. Ono[1], M. Satoh[1,2,3,7], J. Hitomi[8,9], K. Sobue[10,11].* 1) Division of Biomedical Information Analysis, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 2) Division of Biobank and Data Management, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 3) Division of Community Medical Supports and Health Record Informatics, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 4) Department of Hygiene and Preventive Medicine, School of Medicine, Iwate Medical University; 5) Division of Innovation and Education, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 6) Department of Clinical Genetics, School of Medicine, Iwate Medical University; 7) Division of Cardioangiology, Department of Internal Medicine and Memorial Heart Center, School of Medicine, Iwate Medical University; 8) Deputy Executive Director, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 9) Department of Anatomy, School of Medicine, Iwate Medical University; 10) Executive Director, Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University; 11) Department of Neuroscience, Institute for Biomedical Sciences, Iwate Medical University.

The Tohoku Medical Megabank Organization was established building upon a partnership between two Japanese Universities: Tohoku University and Iwate Medical University as a national project to promote recovery from the Great East Japan Earthquake and the establishment of an advanced medical system. The organization has established a biobank that integrates the medical information of 150,000 participants and genome information collected from over 1,000 participants and is conducting a large-scale genome cohort study in order to develop and provide preemptive medicine; and at the same time, it also provides health checkups to the participants free of charge and dispatches doctors to the disaster-affected area. Iwate Medical University Tohoku Medical Megabank Organization is carrying out the following studies on its own: 1) technical examination of integration of several cohorts; 2) technical examination of transportation of the specimens and information stored in the cohorts and the biobanks; 3) technical examination of the use of information on polymorphism, DNA methylation and gene expression for predicting disease risks; 4) consideration of informing the participants of their disease risks estimated with the use of their genetic information; and 5) questionnaire surveys to study the impacts that this project has had on the health of the participants. We would like to integrate these studies in an organic manner, proceed with the technical examinations so that our genome cohort research will contribute to improving the health awareness of the participants, and eventually realize preemptive medicine in the future.

The ClinGen framework for defining the clinical validity of monogenic disease associations for use in research and clinical analyses. *J.S. Berg[1], O. Birsoy[2], A.J. Butte[3], M. Giovanni[4], K. Goddard[5], A. Hamosh[6], L. Milko[1], M.F. Murray[4], E. Riggs[4], P.N. Robinson[7], W.S. Rubinstein[8], A. Santani[9], A. Scott[6], T. Sneddon[3], N. Strande[1], H.L. Rehm[2], S.E. Plon[10], C.L. Martin[4].* 1) Genetics, UNC Chapel Hill, Chapel Hill, NC; 2) Laboratory for Molecular Medicine, Partners Healthcare Center for Personalized Genetic Medicine, Boston, MA; 3) Genetics, Stanford University, Stanford, CA; 4) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 5) Center for Health Research, Kaiser Permanente Northwest, Portland, OR; 6) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 7) Institute for Medical Genetics, Charité Berlin, Germany; 8) National Center for Biotechnology Information, Bethesda, MD; 9) Children's Hospital of Philadelphia, Philadelphia, PA; 10) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The rapid pace at which new gene-disease associations are reported for monogenic disorders poses a tremendous challenge to the clinical interpretation of genome-scale sequencing data in patients and research participants. The NIH-funded ClinGen consortium is working with the NCBI to generate a publicly available resource for delineation of clinically relevant genes and variants. As part of this effort, a workgroup was assembled to develop standardized procedures for curating genes and their relationship to monogenic disorders, in order to provide well curated, up-to-date information for use in research and clinical analyses. The workgroup first addressed the problem of categorizing the clinical validity of gene-disease associations according to strength of evidence.

The workgroup established seven categorical designations for strength of evidence for a causal role in disease: Definitive, Strong, Moderate, Limited, No Reported Evidence, Disputed, and Evidence Against. These categories are defined according to the type and strength of evidence provided in the published literature or other public sources, the presence or absence of contradictory evidence, and whether the initial report of disease-gene causality has been replicated.

This framework is initially being applied to genes relevant to three clinical domains: hereditary cancer, cardiology, and inborn errors of metabolism. We are actively curating target genes within these areas and evaluating results of the categorization, consistency between reviewers and frequency of category change. Our overall goal is to provide the categorization and supporting evidence for every gene implicated in monogenic disorders, and to develop a standardized system for community curation in order to support updated gene-disease relationships and associated evidence as new information is published. This framework will be useful to researchers investigating human genetic disorders, so that they can apply consistent criteria when claiming evidence of disease association, and to highlight those claims of disease association that require more data. Categorization of the clinical validity of gene-disease associations will also be of substantial clinical benefit given the increasing use of large multi-gene panels and genome-scale analysis in diagnostic genetic testing.

PCRstable: Chemical stabilization technology for ambient genetic testing. *G. Dodson, V. Liberal, S. De los Rios, R. Muller.* Research & Development, Biomatrica, Inc., San Diego, CA.

The need for cold storage and shipping of genetic screening reagents makes the use of these reagents difficult in regions where access to freezers and dry ice is either non-existent or undependable. PCRstable is a novel technology developed to stabilize PCR-based testing components dry at ambient temperatures. We have developed and tested the stability and functionality of stabilized PCR and RT-PCR reagents for genetic screening, which are described in this study. We combined the test reagents with proprietary biostability compounds and applied a simple air drying procedure for stabilization. Following accelerated aging studies at elevated temperatures, we performed both PCR and RT-PCR reactions to assess the ability of the stabilized reagents to perform the respective reactions. For both PCR and RT-PCR assays, we found excellent stability at ambient temperatures for both end-point and quantitative PCR. Preservation of PCR and RT-PCR reagents with PCRstable biostability compounds lead to high retention of both reagent stability and activity at ambient and elevated temperatures. These procedures could be applied to PCR-based genetic screening methods to eliminate their cold chain requirements. This would allow such genetic testing in locations currently lacking access to reliable cold storage by significantly reducing storage and associated shipping costs .

Public perceptions of disease actionability and severity and their potential utility for making decisions about Genomic Testing Results.

P.S. Sinicrope[1], K.D. Graves[2], Y. Zhou[2], J.B. McCormick[3], S.T. Vadaparampil[4], N.M. Lindor[1]. 1) Health Sciences Research, Mayo Clinic , Scottsdale, AZ; 2) Lombardi Comprehensive Cancer Center, Georgetown University, Washington D.C; 3) Divisions of General Internal Medicine and Health Care Policy & Research, Biomedical Ethics Program , Rochester MN; 4) Moffitt Cancer Center, Tampa, FL.

Background: While much research highlights disease actionability and severity as important factors informing the return of genomic results, few studies actually address public perceptions of these concepts. We examined perceptions of disease actionability and severity and their relationship to clinical, attitudinal, and sociodemographic characteristics. We also explored individuals' perceptions of the utility of disease actionability and severity in making hypothetical decisions about general genomic testing results. Methods: We conducted a cross-sectional online survey with a representative sample of US adults using the YouGov opt-in panel. Our survey was informed by focus groups, the multi-disciplinary investigative team, and cognitive interviews. The survey contained 136 items and 3 videos covering the basics of genetics and disease actionability and severity. Sections included: 1) Overview and Motivations for Genetic Testing; 2) Perceptions of Severity; 3) Perceptions of Actionability; 4) Perceptions of Severity/Actionability combined; 5) You do the Binning; and 6) Assessing the Binning Process/Demographics. Results: Respondents included 900 adults (51% Female, 65% White, 12% Black, and 15% Hispanic) with an average age of 45 (SD=17). About 64% reported knowing "something, but not very much" about genetic testing and 60% preferred to make their own decisions about genomic results they would want to learn about vs. letting medical experts decide. The majority (>85%) found the concepts of actionability and severity to be useful individually and combined; 46.6% indicated a preference for using actionability over severity. Over half (53.8%) reported being very/extremely confident in their ability to score for actionability and severity. Participants' scoring of actual medical scenarios varied for both actionabilty and severity ($p<0.0001$). Conclusions: We found that actionability and severity are perceived quite variably, raising the question of how meaningful current binning efforts are for patients. Despite the challenges of scoring disorders, respondents indicated confidence in their ability to score, to make decisions for themselves versus expert decisions, and to receive results of all types, with only a minority want to be more selective. These results may inform development of patient-centered approaches to decision making in genomic testing.

2600S

Conductive, Sensorineural, and Mixed Hearing Loss in Patients with Down Syndrome. *A. Musso[1], A. Umrigar[1], K. Foley[1], D. Mercer[1], M. Marble[1,2], F. Tsien[1].* 1) Genetics , LSUHSC New Orleans, New Orleans , LA., USA; 2) Genetics, Children's Hospital of New Orleans, New Orleans, LA, USA.

According to the Centers for Disease Control and Prevention, an estimated 75% of patients with Down syndrome suffer from some form of hearing loss. The hearing loss can be conductive hearing loss (CHL), sensorineural hearing loss (SNHL), or mixed hearing loss, which is a combination of CHL and SNHL. CHL in Down syndrome patients is usually due to otitis media with effusion which is managed medically with antibiotics and pressure equalization (PE) tubes. Causes of SNHL in the Down syndrome population are congenital inner ear abnormalities including internal auditory canal hypoplasia, enlarged vestibular aqueducts, cochlear nerve hypoplasia, and others. Due to the irreversible nature of SNHL, hearing aids and speech therapy are the optimal intervention for patients with Down syndrome. The incidence of SNHL in Down syndrome children ranges from 4% to 55%. We are conducting a retrospective study of at least 200 patients evaluated in the Down syndrome clinic at Children's Hospital of New Orleans and their satellite genetics clinics throughout the state of Louisiana. Based on audiograms of the hearing loss, we will discern whether the hearing loss is conductive, sensorineural, or mixed. We will evaluate the following standard audiological procedures: otoscopy, tympanometry, otoacoustic emissions, and pure tone audiometry. Hearing loss type and severity will be determined by comparing air conduction and bone conduction pure tone thresholds. This study will provide further data on the incidence of hearing loss in children with Down syndrome. Geneticists can play an important role in enhancing the communicative outcomes of Down syndrome patients through referral for early hearing and speech intervention.

2601M

HUMAN COMMUNICATION DISORDERS IN PATIENTS WITH DOWN SYNDROME. *A. Romero-Diaz[1], J.M. Aparicio-Rodriguez[2].* 1) Phoniatrics Otoneurology; 2) Genetics, Hospital para el Nino Poblano, Puebla, Mexico.

Down syndrome is one of the most frequent chromosomal abnormalities live births. Most patients with a trisomy of a portion or all of the chromosome. Its prevalence is approximately 1/800 live births. The human communication disorders are common in patients with Down syndrome. Morphological abnormalities of the head and neck frequently in patients with Down syndrome as midface hypoplasia, characterized by malformation of the eustachian tube, short palate, macroglossia, and narrowing of the oropharynx and nasopharynx, joined as systemic factors associated with muscular hypotonia, results in a high incidence of recurrent otitis media and sleep apnea syndrome in these patients. HEARING.- The prevalence of hearing loss in children with Down syndrome is high, especially the transmission or conductive hearing loss since between 50-70% of cases have chronic serous otitis media between 3 and 5 years; the neuro-sensory deafness represents only 4%. LANGUAGE DEVELOPMENT.- Language development is usually delayed. This delay correlates with cognitive ability; Most oral communication, which may be more or less significant defects language is obtained; and in some cases can not develop oral language and require augmentative and / or alternative communications. CHANGES IN THE VOICE.- Typically have a high palatal vault, large tongue, generalized hypotonia and maxillary hypoplasia. No skeletal abnormalities affecting craniofacial features. Although his brain is structurally normal can be observed brachycephaly and a flattened shape in the center of the face due to a malformation of the frontal bone. DOWN SYNDROME AND STUTTERING.- Have certain degrees of learning difficulties that can affect the ability to understand and produce speech and language. One of the biggest problems for some people with Down syndrome is the unintelligibility of their speech toward others. Unintelligibility and disfluency often go hand in hand. MEMORY.- Children with Down syndrome usually show memory skills short better than visual-term verbal memory. This means that they will learn more easily if the information presented to them visually if they are presented verbally. ATTENTION.- In Down syndrome there are alterations in the brain mechanisms involved when changing focus of attention. So often have difficulty sustaining attention for extended periods of time and ease of distraction from diverse and novel stimuli.

2602T

Corpus Collosum Agenesis and Psychomotor Retardation in a Female Patient with 15.4 Mb Deletion of 14q12→q21.2 and 550 kbp deletion of 18p11.23; Microarray Delineation of Imbalanced Chromosomal Rearrangement. *D. Torun[1], M. Arslan[2], H. Akar[1], Y. Tunca[1].* 1) Dept. of Medical Genetics, Gulhane Military Medical Faculty, Ankara, Turkey; 2) Dept. of Pediatric Neurology, Gulhane Military Medical Faculty, Ankara, Turkey.

Agenesis of the corpus callosum (ACC) is characterized by the partial or complete loss of the nerve fibers that connect the cerebral hemispheres. ACC is one of the most common central nervous system abnormalities and the etiology of ACC is associated with several chromosomal, single gene and environmental causes. A 9 month female patient from non-consanguineous healthy parents has been referred for psychomotor retardation and ACC detected by cranial MRI in postnatal period. Prominent forehead, hypertelorism, upslanted palpebral fissures, nystagmus, depressed nasal bridge, prominent philtrum, thin upper lip, deep palmar creases observed on her clinical examination. Physical exam revealed that height, weight and head circumference was below the 3th percentile. She treated for congenital hypothyroidism. Abdominal ultrasound, echocardiography was normal. Karyotype analysis of patient revealed a de nova apparently balanced translocation between chromosomes 14 and 18 [t (14; 18) (q13; p11)]. To investigate if the translocation was really balanced, analysis on the Affymetrix Cytoscan 750K was done. Microarray analysis revealed a deletion spanning about 15.4 Mb at the chromosomal region 14q12-14q21.2 {arr[hg19] 14q12q21.2(28,431,057-43,915,132)x1} and 550 kbp deletion at 18p11.23 chromosomal region { arr[hg19] 18p11.23(7,281,346-7,816,276)x1}. Deleted regions on chromosome 14 and 18 were consisting of 40 and 1 OMIM genes, respectively. The presence of ACC and microcephaly is in agreement with previously published report [PMID: 18627055]; however, seizure has not been detected in current case. This case further shows haploinsufficiency of multiple genes resulting in ACC and developmental delay. Microarray analysis is a sensitive method to detect imbalances in reciprocal translocations.

2603S

Deletion of 17p11.2 encompasses *FLCN* with increased risk of Birt-Hogg-Dubé in Smith Magenis Syndrome: Recommendation for Cancer Screening. *A.C.M. Smith[1], L.R. Fleming[2], A.M. Piskorski[3], A. Amin[3], C. Phorphutkul[4], S. de la Monte[4], E. Stopa[4], W. Introne[1], T. Vilboux[1], F. Duncan[1], J. Pellegrino[5], B. Braddock[5], L.A. Middelton[6], C. Vocke[6], W.M. Linehan[6].* 1) Office Clinical Dir, NHGRI/NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 3) Department of Pathology, Warren Alpert SOM Brown Univ., Rhode Island Hosp., Providence, RI; 4) Department of Pediatrics, Warren Alpert SOM Brown Univ., Rhode Island Hosp., Providence, RI; 5) Medical Genetics, Upstate Medical University, Syracuse, NY; 6) Urologic Oncology Branch, NCI/NIH, Bethesda, MD.

We report two unrelated adults with Smith Magenis syndrome (SMS) who were confirmed to have renal histology consistent with Birt-Hogg-Dubé (BHD) syndrome. These two cases suggest the need to expand previous management recommendations for SMS to include cancer surveillance starting at 21 years of age.

BHD is an autosomal dominant disorder characterized by increased risk of cutaneous fibrofolliculomas, pulmonary cysts, spontaneous pneumothorax, and renal tumors. BHD renal tumors are most commonly chromophobe or hybrid renal cell carcinoma, although clear cell RCC or oncocytoma may also occur. Haploinsufficiency for folliculin (*FLCN*), a gene that maps within the common SMS del 17p11.2 region, poses a risk to develop BHD. While 88% of BHD cases are attributed to *FLCN* point mutations, deletion or duplication of *FLCN* in BHD has been described. As the majority of SMS cases result from a 3.7Mb deletion in 17p11.2 which includes *FLCN*, there has been a theoretical concern about increased cancer risk in SMS patients. However, these two cases constitute the first known association of BHD characteristic tumors in SMS patients.

Case 1 was a 50-year female cytogenetically diagnosed with SMS (del 17p11.2) after undergoing radical nephrectomy for bilateral chromophobe renal cell carcinoma and hybrid tumors. Her history was negative for skin lesions or lung cysts. Case 2 was a 45 year old adult male with SMS, who presented with a high grade B-cell lymphoma; chemotherapy was declined and he died one month later. A full autopsy revealed diffuse lymphomatous involvement of all major organs, oncocytosis of the right kidney, and incidental oncocytomas of the left kidney. Molecular SNP analysis confirmed a 7.1 kb 17p11.2 deletion (14,374,758-21,539,613; HG Build 18) that encompassed *RAI1* and *FLCN* with a second *FLCN* mutation (c.736delA; S246fs) seen in the renal specimens.

Conclusion: Given these observations, we propose clinical surveillance for BHD-associated renal tumors by baseline abdominal and pelvic MRI or CT scan with/without contrast for SMS adults beginning at age 21 years and every 3 years thereafter.

AMMECR1 gene disruption and expression impairment in a balanced X-autosome translocation patient. *M.M. Oliveira[1], R.S. Guilherme[1,2], V.A. Meloni[1], N. Kosyakova[2], T. Liehr[2], G. Carvalheira[1], M.I. Melaragno[1].* 1) Departamento de Morfologia e Genética, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 2) Institute of Human Genetics, Jena University Hospital, Friedrich Schiller University, Jena, Germany.

Detailed molecular characterization of women with balanced X-autosome translocations has proven to be valuable in searching candidate genes for diseases. Patients with balanced chromosomal rearrangements involving an X-chromosome generally present a skewed X inactivation, with the normal X-chromosome being preferentially inactivated. Thus, a gene disruption in X-chromosome frequently results in absence of a functional copy of the affected gene. Here we report a seven year old female patient who presented with karyotype 46,X,t(X;9)(q23;q12)dn, disproportionate short stature, microsomia, minor facial dysmorphisms, septal atrial defect with thin aneurysmal septal tissue, scoliosis, diffuse bone demineralization with peripheral osteopenia, recurrent sinusitis, and normal cognition. Replication banding showed a preferential inactivation of the normal X-chromosome in lymphocytes, and genomic array indicated for a balanced translocation. The autosomal breakpoint affects a heterochromatic region. X-chromosome breakpoint mapping was performed by array painting technique using a glasneedle-microdissection derived DNA probe, exclusively of the derivative chromosomes. Array painting determined the disruption of AMMECR1 gene at intron 1, within the genomic coordinates chrX:109,509,444-109,552,503 (GRCh37/hg19). The breakpoint localization was validated by FISH using the BAC probe CTD-3066N24. AMMECR1 mRNA whole blood expression was assessed by qRT-PCR in the patient and eight female controls. Two TaqMan assays were used and both showed absence of AMMECR1 expression in the patient and high gene expression levels in all controls. Therefore, AMMECR1 gene function impairment may be related to her clinical abnormalities. Although AMMECR1 gene function is unknown, its expression is ubiquitous in human organs and tissues, with exception of the nervous system. AMMECR1 gene expression occurs primarily in organs and cell types that were affected during the patient's development. AMMECR1 protein is highly conserved throughout evolution, presents nuclear localization, several phosphorylation sites and similar conformation as proteins that interact with nucleic acid, suggesting a regulatory role. This patient may represent a unique model for the evaluation of the phenotypic consequences of AMMECR1 impairment in humans and the claim of this gene as a candidate for the observed phenotype requires further functional and genetic validation. Financial support: FAPESP.

2605T

GENETIC BASIS OF AGING, TELOMERES AND TELOMERASE. FOUR PEDIATRIC PATIENTS WITH PREMATURE AGING OR COCKAYNE'S SYNDROME. *M. Barrientos- Perez[1], J.M. Aparicio-Rodriguez[2,3].* 1) Endrocrinology; 2) Genetics, Hosp para el Nino Poblano, Puebla; 3) Estomatology Benemérita Universidad Autónoma de Puebla, México.

There has been a direct relation between Telomere, telomerase and aging due to multiple investigations that are carried out on them, so it has been associated with human youth and the cure of cancer. There is a direct relationship in the alteration of the Telomeres and Telomerase with stress and inbreeding. With respect to consanguinity there is a syndrome of premature aging called Cockayne syndrome. Four cases of cockayne syndrome (CS) from two families with first degree consanguinity living in a small town where radioactive uranium (UR) mines were found. The clinical manifestation of CS were analyzed in the Hospital Para el Niño Poblano (HNP) by a multidisciplinary study. The main clinical manifestations were dermatological alterations as photosensitivity to sunligth and predisposition to skin cancer "xeroderma pigmentosum" (XP); endocrinology alterations as dwarfism and senile appearance; ophthalmological findings from cataracts to pigmentary retinal degeneration; neurological alterations as mental retardation and sensorial hearing loss; and upper limbs, lower limbs and vertebral column degeneration was also found. Four cases with Cockayne Syndrome were diagnosed in two Mexican families with consanguinity from an area with radioactive contaminants, showing that consanguinity is the etiological factor of this syndrome. Keywords. Consanguinity, autosomal recessive inheritance, Cockayne's syndrome, Telomeres, telomerase, uranium, xeroderma Pigmentosus.

2606S

Copy Number Variation in Oculoauriculovertebral Spectrum. *M. Colovati[1], S. Bragagnolo[1], R.S. Guilherme[1], A.G. Dantas[1], C.A. Kim[2], A.B. Perez[1], M.I. Melaragno[1].* 1) Genetics Division, Department of Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Genetics Unit, Instituto da Criança, Universidade de São Paulo, São Paulo, Brazil.

Oculoauriculovertebral spectrum (OAVS, OMIM 164210) is a clinically heterogeneous condition that includes unilateral or bilateral ear anomalies, hemifacial microsomia, ocular defects, conductive and/or sensorineural hearing loss, orofacial clefts, vertebral malformations, and more rarely, cardiac, renal and cerebral malformations and intellectual impairment. Most cases are sporadic with rare familial cases exhibiting autosomal dominant inheritance with incomplete penetrance and variable expressivity. Several chromosomal abnormalities have been associated with OAVS but no recurrent abnormalities were identified to define candidate regions. We described 62 patients with OAVS clinical diagnosis that fit in the minimal criteria according to Tasse et al. (2005), including seven familial cases. All showed normal karyotypes, except one: 46,XX,inv(12)(q15q24.1). One patient presents a der(4) from a critical maternal translocation t(X;4)(p22.31;p15.33) detected by FISH. Genomic arrays identified 13 potentially pathogenic copy number variations (CNV): 7 deletions (4p16.3p15.33, 4q13.3q21.1, 8q13.3, 10q26.2q26.3, 16p13.3, 22q11.21, Xp22.33) and 6 duplications (2q32.1, 4p16.1.1, 16p13.11, 17q11.2, Xp22.33). The 4p16.1 duplication (~950 kb) was observed in two non-related patients. Two patients showed overlapping CNVs in Xp22.33 (~3,2 Mb deletion and ~9 Mb duplication). None of these CNVs were described in the Database of Genomic Variants (DGV), except the duplication 4p16.1 that was possibly relevant because involves HMX1 gene. Some variants of unknown clinical significance (VOUS) were also identified when DGV and the internal control database were considered. In this study some deleted and duplicated regions comprise genes with relevance to the OAVS phenotype, such as BAPX1 in 4p15.33, responsible for hemifacial microsomia; HMX1 in 4p16.1, involved in the oculoauricular syndrome; EYA1 in 8q13.3, important for the craniofacial development; YPEL1 and ERK1 in 22q11.2, involved in branchial arch development. Besides, larger deletions, duplications and VOUS found in our patients include many genes described in OMIM and genomic regions which may be related to the phenotype. These candidate genes and/or regions will deserve further investigation. The identification of the OAVS genes and genomic position are important to understand better the molecular pathways and clinic heterogeneity of the syndrome. Financial support: FAPESP, Brazil.

2607M

A rare combination: mosaic Turner syndrome by isochromosome Xq with 17p13.3p13.2 microduplication and congenital cataract with autosomal dominant inheritance and incomplete penetrance in the same individual. *J.A. Rojas Martínez[1], J.C Acosta Guio[2,3].* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá, Colombia; 2) Instituto de Ortopedia Infantil Roosevelt. Bogotá. Cundinamarca. Colombia; 3) Instituto de Investigación en Nutrición, Genética y Metabolismo. Universidad El Bosque. Bogotá. Cundinamarca. Colombia.

The combination of Turner syndrome with congenital cataract with autosomal dominant inheritance and incomplete penetrance has not been reported, since even this form of cataract in isolated presentation is exceptionally rare. There are also no reports presentations with rearrangements on chromosome 17. Next, we present the case of a twenty month old girl born in Bogotá (Colombia), product of first pregnancy maternal, non-consanguineous parents. She was diagnosed a month living with bilateral congenital cataract and also has a history of neurodevelopmental delay and background in the family of mother, grandmother and maternal uncle with bilateral congenital cataract. Physical examination found multiple minor facial anomalies, and other abnormalities. Neurological examination with generalized hypotonia with truncal predominance, and scarce and unclear language. Suspecting chromosomal abnormalities, diagnostic study begins with high resolution BG karyotype reporting: mos 46,X,iso(Xq)[82]/45,X[18], with the presence of a mosaic given by major cell line with a isochromosome of the long arm of the X chromosome and another cell line with complete monosomy of the X chromosome. Comparative Genomic Hybridization (CGH) was performed, confirming the previous cytogenetic analysis. Additionally, a 274 Kb duplication was identified in 17p13.3p13.2 (with breakpoints in 3561131-3835801) that compromises 8 genes. Congenital cataract with clear autosomal dominant inheritance present in this patient exhibits incomplete penetrance, as the mother of the patient must have the mutated allele, because she transmits to her progeny, but is not expressed in her phenotype. Furthermore 8 genes were identified in the region corresponding to the duplicate 17p13.2p13.3 segment in this patient. One of these genes, GSG2 encodes a protein called haspina whose overexpression has been shown to be associated with genomic instability and aneuploidy, so the authors suggest that the microduplication 17p13.2p13.3 ontogenetically preceded and probably contributed to the development of aneuploidy and abnormality of the X chromosome present in this case. As in other reports of chromosomal abnormalities that occur simultaneously, in the above case the clinical manifestations result from the superposition of two phenotypes, therefore this report contributes to a better definition of the clinical features of 17p13.3 microduplication syndrome.

2608T

Polycystic kidney disease and multiple malformations in a patient with tetrasomy 2q13q21.1. *L. Dupuis[1], C. Roadhouse[1], R. Badilla-Porras[1], D.J. Stavropoulos[2], R. Mendoza-Londono[1].* 1) Clinical Genetics, Hospital for Sick Children and University of Toronto, Toronto, Ontario, Canada; 2) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children and University of Toronto, Toronto, Ontario, Canada.

Autosomal tetrasomies are rare events which typically cause a severe clinical phenotype. Well characterized autosomal tetrasomies include cat-eye syndrome (tetrasomy 22), Pallister Killian (tetrasomy 12p) and tetrasomies of 9p and 18q. We describe a case of chromosome 2q13-q21.1 triplication, resulting in tetrasomy for this segment. This is the first report of a liveborn with a triplication of chromosome 2 of this magnitude (19.876 Mb). The patient presented at day two of life with dysmorphic features, bilateral hip dislocation, overlapping toes and bilateral pneumothoraces. Abdominal ultrasound revealed didelphys uterus, large polycystic ovaries and dysplastic cystic kidneys that led to end stage renal disease and kidney transplant. At her most recent evaluation at the age of four years, medical issues included global delay, lung hypoplasia, bilateral hip dislocation, G-tube dependence, strabismus and mild sensorineural hearing loss. MRI of the brain revealed appropriate myelination and prominent lateral and third ventricles but no evidence of hydrocephalus. Microarray analysis (44,000 oligo) showed that the area of tetrasomy involved 115 RefSeq genes and 13 OMIM Morbid Map genes. A thorough review of the literature revealed two previous cases of tetrasomy of chromosome 2q that partially overlapped the area involved in our patient. Mercer et al (2009) reported an adult female with a 7.28Mb triplication of 2q12.3-q13 with infertility and had left polycystic kidney, patent ductus arteriosus, left streak ovary, bicornuate uterus and deafness. Wang *et al* (1999) reported a stillborn with a larger area of tetrasomy 2q11.2-q21 with brain malformations, multicystic kidneys, absence of the right thumb and cleft lip and palate. The area of overlap between these three cases comprises a 3Mb region on 2q13 (chr2:111,158,401-114,416,131 hg18) that harbors four OMIM genes. These include *MERTK* a tyrosine kinase that when absent can result in retinitis pigmentosa, *IL1B* and *IL1RN* which participate in the immune system, and the transcription factor *PAX8* that when mutated can result in lesions of the excretory system and thyroid dysplasia. This case series narrows the critical region for renal cyst and genital malformation susceptibility on chromosome 2 and expands the phenotype of patients with tetrasomy of this region. It is not presently clear which genes in excess dosage from this area of triplication may be responsible for different aspects of the phenotype.

Neurodevelopmental Profile and Cognitive Variability in Two Females with the Rare 48, XXXX Chromosomal Disorder. *D.C. Gibbs[1], A.L. Gropman[2,4], T. Sadeghin[3], C. Samango-Sprouse[1,2,3,4].* 1) The Focus Foundation, Davidsonville, MD; 2) George Washington University School of Medicine, Washington, DC; 3) Neurodevelopmental Diagnostic Center, Davidsonville, MD; 4) Children's National Medical Center, Washington, DC.

48, XXXX is a rare chromosomal aneuploidy associated with neurocognitive deficits, speech and language disorders and executive dysfunction. Less than 60 cases have been reported in the literature however limiting our understanding of the 48, XXXX neurodevelopmental phenotype. To our knowledge, this is the first study to report on the neurodevelopmental, cognitive and behavioral profile of two females with 48, XXXX of similar ages. Patient 1 (age=11.0) and patient 2 (age=10.9) were evaluated using the Wechsler Intelligence Scale for Children-4th Ed. (WISC-IV), the Leiter International Performance Scale (LIPS-R), Expressive and Receptive One-Word Vocabulary Tests-4th Ed. (ROWPVT-4/EOWPVT-4) the Beery Buktenica Test of Visual Motor Integration-5th Ed. (Beery-VMI), the Child Behavioral Checklist (CBCL) and the Behavioral Rating Inventory of Executive Function (BRIEF). Verbal IQ's were 44 and 68 on the WISC-IV and 56 and 80 on the LIPS-R for patient 1 and 2, respectively. Overall vocabulary was stronger in patient 2 than patient 1, but receptive vocabulary was stronger than expressive in both patients (Patient 1: 62 / 55; Patient 2: 83 / 79; ROWPVT-4, EOWPVT-4). Both 48, XXXX girls had significantly impaired visual motor capacities in graphomotor and perceptual domains (<5th percentile Beery-VMI subtests) as well as significant executive dysfunction and behavioral/social deficits (<10th percentile on CBCL and BRIEF subtests). Patient 1 had an extensive history of family learning disabilities (FLD) likely contributing to her more severely delayed cognitive development. We hypothesize that the co-existing ADHD in both subjects compounded their existing social and behavioral deficits. The visual-motor deficits are novel findings in 48, XXXX and likely to contribute to patients' delayed cognitive development. These distinct and overlapping features are characteristic of other X and Y chromosomal variations and may be of great use in the diagnosis, treatment and counseling of 48, XXXX patients and families.

2610M

48,XXYY Syndrome: a wide spectrum of phenotypic presentation. A case report. *L.F. Imbachi[1], A.I. Sanchez[1], P.M. Hurtado[1, 2].* 1) Pontificia Universida Javeriana Cali, Cali, Colombia; 2) Centro Medico Imbanaco Cali, Colombia.

Introduction: Sex chromosome aneuploidies are the most common chromosomal abnormalities with an incidence of 1 in 400 births. Tetrasomy and pentasomy conditions (48,XXYY, 48,XXXY, 49,XXXXY) are less frequent with an incidence of 1:18,000-1:100,000 male births. 48,XXYY syndrome is the most common of these three occurring in 1:18,000-1:40,000 male births and is related to a wide spectrum of physical findings, congenital malformations, cognitive impairment, developmental delay and behavioral problems. Case Presentation: This is a 3-year-old (y/o) male patient who was born by cesarean section from non-consanguineous parents after a first full term uneventful gestation. Maternal and paternal ages were 29 y/o. No significant family history. He started to have myoclonic, afebrile seizures at 4 months old. EEG showed generalized discharges. He was started on anticonvulsants with complete remission of seizures. At 2 and a half y/o aggressive behavior and motor stereotypies were noticed. Clinical examination revealed global developmental delay with plagyocephaly, hypertheloríism, severe truncal hypotonia with head lag communication problems. MRI spectroscopy revealed symmetric signal abnormality in thalamus, basal ganglia and brainstem. Urine organic acids were negative; pyruvate, plasma aminoacids and Acylcarnitine profile were normal. Mutations or deletions were not detected in mitochondrial DNA screen or in FOXG1/MECP2 sequence analysis. Karyotype showed 48,XXYY chromosome abnormality. Discussion: This is a male patient with 48,XXYY syndrome who has physical and neurodevelopmental features consistent with it. Common findings include hyperthelorism, dental problems, clinodactyly and hypogonadism. The first two were evident in our patient as well as hypotonia, which occurs in 75% of patients. Congenital malformations like cleft palate, heart and kidney defects were ruled out in this patient. About 10-15% of individuals have seizure disorders, like this child. Elevated rates of autism (28-45%), mood disorders (46,8%) and attention deficit and hyperactivity disorder (70%) have been seen. Therefore this could explain patients' aggressive behavior and repetitive conducts. Conclusions: 48,XXYY syndrome has a wide spectrum of phenotypic presentation. It is important to identify the variability in physical features and cognitive functions to establish an early diagnosis, initiate management and to offer appropriate genetic counseling and therapies for rehabilitation.

2611T

Clinical features of 5p13 duplication syndrome. *T. Kuchikata, S. Itou, H. Yoshihashi.* Division of Medical Genetics, Tokyo Metropolitan Child Medical Center, Tokyo, Japan.

5p13 duplication syndrome (OMIM #613174) is newly recognized chromosomal microduplication syndrome characterized by developmental delay and intellactual disability, facial dysmorphisms. NIPBL in the duplicated region is known as a part of causative gene. Loss-of-function mutations in NIPBL cause cohesin abnormality, which leads to chromosome segregation abnormality during the mitotic and meiotic cell cycles. A part of cohesinopathy causes Cornelia de Lange syndrome (CdLS). Here,we describe a Japanese case with 5p13 duplication syndrome. Subject: 4y-male. He was delivered at term without any critical problems during the perinatal period ,except for a birth weight of 1.9kg. His unrelated parents and siblings are healthy. He had a delay in psychomotor development with aging. At the age of 3 month old, brain MRI revealed there was no definitive abnormality and myelination was not retarded. At the age of 2 year old, the weight was 11.2kg (25th percentile) and the height was 83.3cm (25th percentile). He had mild bilateral auditory disorder, strabismus, right cryptochidism, left accessory ear and dysmorphic features which are prominent forehead, downslating palpebral fissure, hypomalar, broad nasal root, long philtrum and long slender fingers. The gestalt was suggestive of Kabuki syndrome. KMT2D and KDM6A mutations were not detected. Radiological survey for skeletal dysplasia revealed no definitive abnormality. A peripheral karyotype was 46,XY and there was no submicroscopic subtelomeric chromosomal rearrangements. Array-CGH(ISCA:CGH180K, Agilent)showed an arr[hg19]5p13.2(36374209-37331912)×3. The chromosomal abnormality arose de novo. The duplicated region contains NIPBL and SCL1A3, C5orf43, NUP155. Discussion: This is the first case of 5p13 duplication syndrome in Japan. This syndrome is a counterpart of CdLS with many characteristic features,but has no cardinal feature of diagnostic value. Although the phenotype in this case overlaps those of cases with the 5p13 duplication syndrome in previous reports, it seems to be difficult to recognize this syndrome from the point of view of dysmorphic features. The phenotypic effect of NIPBL haploinsufficiency is well known as CdLS and the other diseases related to cohesion abnormality in clinical and research work. However, to our knowledge, there is no sufficient scientific knowledge about the gene dosage effect of NIPBL. Further cases may provide insight into the consideration of clinical information.

2612S

Klinefelter Syndrome (48, XXXY) in a Patient With Mild Mental Retardation and Psychotic Personality Traits. *H. Pachajoa[1, 2], M.F. Hernandez[1].* 1) Centro de Investigaciones en Anomalías Congénitas y Enfermedades Raras (CIACER), Universidad Icesi, Cali, Colombia; 2) Fundación Clínica Valle del Lili, Cali, Colombia.

Introduction: Klinefelter syndrome is the most common aneuploidy in males with a prevalence of 0.1-0.2% in the general population, which rises up to 3% in males with fertility issues, although only 35% of cases are diagnosed. The affected males tend to be tall, have narrow shoulders, wide hips, sparse body hair, gynecomastia and small testis; they present androgen deficiency and azoospermia. Besides the previous physical characteristics, there have been reports on the expression of behavioral and cognitive traits that tend to be very variable, possibly according to the type of aneuploidy, with an established association between the number of extra X chromosomes and cognitive deficit, and a not so clear association of different chromosomal variants of Klinefelter and psychotic behavior, with some authors proposing the origin of the extra chromosome as a determinant of different behavioral traits. Case report: 13 year old male with karyotype 48,XXXY, who besides presenting the classical physical features, is under psychiatric treatment because of presenting trouble at home and at school for being aggressive and impulsive. A review on the literature is made. Conclusion: When approaching a patient with Klinefelter syndrome is necessary to acknowledge the importance of an opportune start of hormonal therapy and a multidisciplinary approach including endocrinology, pediatrics, genetics, neuropsychology and psychiatry when needed.

2613M

Maternal Uniparental Disomy Prader-Willi Syndrome in an XYY boy. *P. Phowthongkum[1], J. Berkowitz[2], A. Schneider[2].* 1) Internal Medicine, Einstein Medical Center Philadelphia, Philadelphia, PA; 2) Genetics Division, Einstein Medical Center Philadelphia, Philadelphia, PA.

Prader-Willi Syndrome (PWS) is a neurodevelopmental disorder characterized by neonatal hypotonia, failure to thrive, intellectual disability, hyperphagia, short stature, and characteristic behaviors. PWS is associated with chromosome 15q11-13 deletions, maternal UPD or an imprinting abnormality. 47,XYY is a sex chromosome disorder which is usually subtle. We report long term follow up of a ten year old boy with PWS and 47,XYY. He was born at term by emergency C-section for fetal distress to a 27-year old G1P0 mother and 30-year old father. At delivery he was hypotonic with poor gag reflex. Examination revealed cryptorchidism and subsequent feeding difficulty. Karyotype of 47,XYY did not explain his phenotype and prompted testing for PWS. Methylation study was consistent with PWS. FISH for del15q12 was negative. Microsatellite studies confirmed maternal UPD. He was started on growth hormone at 6 months. His height is at the 75th percentile, which may be attributed to the 47,XYY. After having some periods of hyperphagia and food searching behaviors as a toddler, he demonstrated very good self-control with his eating until recently. He has developed general anxiety and obsessive behaviors, and is exhibiting aggression due to frustration from being unable to keep up with peers. He has become more self-aware of his condition and is having more difficulty with peer-to-peer interaction. His neurodevelopmental evaluation revealed an IQ of 72. He performed very well on math and expressive reading but poorly on language comprehension and sound awareness. He does not have autistic spectrum features. There are few reports about genotype-phenotype correlation for PWS. Maternal age is considered a risk factor for UPD15 PWS, but his mother was only 27 at delivery. Evaluation of PWS individuals who developed psychosis, found the majority have matUPD15. Further longitudinal study is required to establish the natural history and clinical course for this subgroup of patients prone to neuropsychiatric issues. In terms of XYY involvement, as non-disjunction happens independently in maternal oogenesis and paternal spermatogenesis, the odds of recurrence of this mixed phenotype is extremely low. The evolution of this child's PWS manifestations and how XYY syndrome may have mitigated some of the physical features will be discussed. We will also explore how XYY may be adding to the neuropsychiatric manifestations.

2614T

The Extended Phenotypic Spectrum of 7p14.3-15.3 deletion syndrome. *M. Michelson-Kerman[1,2], D. Lev[1,2], C. Vinkler[1,2], L. Blumkin[1,3].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic clinic, Wolfson Medical Ctr, Holon, Israel; 3) Pediatric Neurology Unit, Wolfson Medical Ctr,Holon, Israel.

Structural aberration of chromosomes are associated with various syndromes. Microdeletion of the short arm of chromosome 7p is rare. Phenotypic presentation is variable and include craniofacial malformations, hypoplastc ears, heart defects, hypotonia, short fingers with tapering phalanges and severe developmental delay. Most of the cases are de novo deletions. Few cases are due to unbalanced rearrangements. We present a twenty months-old girl with severe developmental delay, dysmorphic features, hypoplastic ear cruses, tapering fingers, hypotonia, severe ataxia and congenital alacrima. Karyotype in leucocytes was normal, 46 XX. Affymetrix Cytogenetics Whole-Genome HD Array chip revealed a 10375.473 KBP loss in chromosome 7, between p14.3 and p15.3. This region harbors 96 known genes, including HOXA gene cluster and several cytogenetic regions associated with genetic disorders . Parental studies are normal. Although most of phenotypic features were previously described in patients with 7p microdeletion, our patient presents with distinct features including severe congenital alacrima and severe ataxia. These features have not been described previously.

2615S

Pigmentary mosaicism type Ito in a balanced X-autosome translocation with no gene disruption at the breakpoint. *M. Melaragno[1], R.S. Guilherme[1], C.E. Steiner[2], G.M. Carvalheira[1], N. Kosyakova[3], T. Liehr[3], M.M. Oliveira[1].* 1) Disciplina de Genetica, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 2) Department of Medical Genetics, Universidade Estadual de Campinas, São Paulo, Brazil; 3) Institute of Human Genetics, Jena University Hospital, Friedrich Schiller University, Jena, Germany.

Pigmentary mosaicism type Ito (PMI) is a heterogeneous symptom complex characterized by hypopigmented whorls and streaks following Blaschko's lines, with neurological deficits, epilepsy and/or asymmetric abnormalities in other organs. Although its etiology is not fully understood, PMI is typically associated to apparently balanced X-autosome translocations involving Xp11, especially the band Xp11.2. Several hypotheses have been proposed to explain this association, such as disruption of X-linked genes, effect position, mosaic functional Xp disomy and functional autosomal monosomy due to a random X-inactivation pattern. We report the first patient with PMI and balanced X-autosome translocation involving Xp11 that was submitted to a high resolution breakpoint definition. An 18-year-old girl presented with karyotype 46,X,t(X;21)(p11.22;p11.1), Blaschko linear hypopigmentation in the trunk, neurodevelopmental delay, and electroencephalographic abnormalities. The normal X-chromosome was preferentially inactivated in lymphocytes, genomic array indicated for a balanced translocation, and the autosomal breakpoint affects a heterochromatic region. X-chromosome breakpoint mapping was performed by array painting technique using a glasneedle-microdissection derived DNA probe, exclusively of the derivative chromosomes. Array painting determined the Xp11.22 breakpoint as intergenic, within the genomic coordinates chrX:51,760,718-51,776,770 (GRCh37/hg19). The breakpoint localization was validated by FISH using the BAC probe RP11-1129M7. There are no breakpoint neighboring genes that could be a candidate for pigmentary dysplasia. Although we observed a skewed X inactivation pattern in lymphocytes, the hypopigmented skin may present a random X-inactivation pattern causing a functional Xp disomy. Therefore, the X-inactivation pattern study only in lymphocytes is not sufficient to assess the pathogenic mechanism leading to PMI in patients with rearrangements involving X-chromosome. Most descriptions of balanced X-autosome translocation associated with PMI date back to the 80's and 90's, when the rearrangement investigation was limited to low resolution techniques and interpretation of a rearrangement's clinical impact was based upon a broad chromosome region. The report of a patient with PMI and balanced X-autosome translocation involving Xp11.22 with an intergenic breakpoint reduces the strength of the hypothesis of an X-linked loci disruption. Financial support: FAPESP.

Down syndrome before Lejeune, Gauthier, and Turpin: Historical myths and reality. *E.B. Hook[1,2].* 1) School of Public Health, University of California, Berkeley, CA., USA; 2) Department of Pediatrics, UCSF, San Francisco, CA, USA.

A critical review of the literature reveals that a number of historical aspects of Down syndrome are often misrepresented or misunderstood. i) (J. Langdon) Down's report (1866) of those with the syndrome, which classified some types of "idiocy" as atavistic reversions of Europeans to those of a "lower" race, is usually regarded as an unchallenged example of Victorian racism. But at the very same meeting at which he presented his conclusions, they were criticized forcibly. At the height of the Victorian era there were from the first those who rejected Down's racial interpretation. ii) Even before Down, Seguin (1846) had reported the syndrome, but as a type of "cretinism". And primarily because of the superficial similarity of those with Down syndrome and cretinism, some kind of causal association of hypothyroidism with Down syndrome has been the longest lasting and most prevalent hypothesis until the cytogenetic era. iii) While Waardenburg (1932), Bleyer (1934), and Fanconi (1939) suggested a chromosome abnormality, there was nothing forcing about their hypothesis. Moreover, Mittwoch (1952) could not find a chromosomal abnormality when she searched. iv) Other genetic theories were offered which seemed at the time to explain the etiology just as well. Macklin (1929), an early specialist in medical genetics, proposed 5 separate recessive genes or 2 dominant and 4 recessive, and Penrose 2 dominant genes. v) Some investigators who suggested genetic explanations also posited interactions with non-genetic factors, e.g. Baroff (1958), a year before the report of Lejeune et al., because of both the low average familial proportion of those affected and the maternal age association. vi) Bleyer (1961) attributed his (correct) cytogenetic hypothesis to "deductions...from close clinical study", but as McKusick (1961) implied, many incorrect theories were also derived from close clinical study. Wallin (1949) and Engler (1949) reported several dozen for Down syndrome. McKusick noted many are absurd. Some, like racial theories reflect contemporary prejudices, but others when proposed, appeared plausible and defensible to many based on existing knowledge at the time. vii) Many past outstanding clinicians drew incorrect inferences about the cause of the condition. We cannot judge these past investigators because we lack detailed knowledge of their perspectives and their limits in time and place.

IMPLEMENTATION OF HIGH-RESOLUTION SNP ARRAYS IN THE INVESTIGATION OF PATIENTS WITH NEURODEVELOPMENTAL DISORDERS: 6 YEARS OF CLINICAL EXPERIENCE. *O. PALUMBO, P. PALUMBO, R. STALLONE, M.P. LEONE, T. PALLADINO, L. ZELANTE, M. CARELLA.* MEDICAL GENETICS UNIT, IRCCS CASA SOLLIEVO DELLA SOFFERENZA, SAN GIOVANNI ROTONDO, FG, Italy.

Genomic copy number variations (CNVs) contributes to the etiology of global developmental delay (DD), intellectual disability (ID), autism spectrum disorders (ASDs), and multiple congenital anomalies (MCAs). Chromosomal microarray analysis (CMA), with a 10-20% diagnostic yield, can identify CNVs≤1 Mb and now is considered the first-tier clinical test for detection of CNVs among patients with developmental disabilities. We report our experience with the use of the Affymetrix SNP Arrays in 1800 Italian patients during the past 6 years (2008-2013). Blood samples were analyzed with CMA at a resolution ranging from 10 kb to 1 kb. CNVs have been considered pathogenic if the variant was responsible for a known syndrome, if involved gene/s reported in association with the clinical phenotypes of the patients, if occurred de novo or, when inherited, if the parent was variably affected. We identified CNVs with a high score of pathogenicity in 486 (27%) patients. Among them 167 (34.4%) showed a CNV overlapping with a known syndrome, 319 (65.6%) a likely pathogenic rearrangement. Of particular interest, we found some CNVs useful to further delineate the clinical features associated with deletions in 8q12.1q12.3, in 15q25.2, in 17q21.31, in 2q24.1q24.2, in 22q11.2, and duplications in 16p13.3 and in 11p13. Some CNVs were useful to describe new syndromes such as a 1.7 Mb deletion in 3q13.2q13.31. Also, we have identified a large group of small CNVs (<1.0 Mb) encompassing, either in whole or in part, functionally related genes to the phenotypes such as CASK, CNTN6, SNTG2, HIP1, DLG2, NRXN1, MCPH1 and CHL1. Among these small CNVs, we have reported a FOXP1 gene microdeletion in an adult patient with autism and speech delay, and a de novo interstitial deletion of 0.122 Mb at 2q24.2 region harboring only TBR1 gene in a boy with moderate to severe intellectual disability. Variants of uncertain significance (VOUS) because unreported, containing genes of uncertain clinical significance or non-genic but potentially regulating nearby gene expression, were identify in 144 individuals (8%). Interestingly, using SNP arrays, we were also able to identify some copy neutral events including uniparental disomy (UPD), run of homozygosity (ROH) and low level mosaicism revealing in some cases important clinical correlations.

2618S

Idic(15) syndrome: clinical studies of 32 new individuals. *A. Battaglia, T. Filippi.* Dev Neurosciences, Stella Maris nst/Univ Pisa, Pisa, Italy.

Chromosome region 15q11q13, known for its instability, is highly susceptible to clinically relevant genomic rearrangements, such as supernumerary marker chromosomes formed by the inverted duplication of proximal chromosome 15. Inv dup(15) results in tetrasomy 15p and partial tetrasomy 15q. The large ones, containing the Prader-Willi/Angelman syndrome critical region (PWS/ASCR), are responsible for the inv dup(15) or idic(15) syndrome. Diagnosis is achieved by standard cytogenetics and FISH analysis, using probes both from proximal chromosome 15 and from the PWS/ASCR. Microsatellite analysis on parental DNA or methylation analysis on the proband DNA, are also needed in order to detect the parent-of-origin of the idic(15) chromosome. Array CGH has been shown to provide a powerful approach to detect the duplication and its extent. Differential diagnosis concerns the possible occurrence of double supernumerary isodicentric chromosomes derived from 15, resulting in partial hexasomy of the maternally inherited PWS/ASCR. Large idic(15) are nearly always sporadic. Antenatal diagnosis is possible. Here, we report on 32 new idic(15) patients; all sporadic. 1/32 had a double idic(15). Phenotypic features were quite variable, and 60% presented with a distinct "autistic-like" profile, providing a behavioral signature for ASD arising from the proximal 15q. Epilepsy occurred in 90%, and in only 20% could be controlled by AEDs. The interictal EEG showed slow/sharp waves, and/or biphasic spikes-polyspikes, spike/wave complexes, and an excess of fast activity over both fronto-temporal areas. Intellectual disability was severe-profound in 85%, with expressive language limited to dysillabic sounds/single words. Structural CNS defects were seen in 30%. Early central hypotonia was present in all. Follow-up ranged from 2 to 24 years.

2619M

Large distal duplication of chromosome 22q. *D. Ortiz, L. Karger, M. Babcock, L. Edelmann, A. Babu, L. Mehta.* Dept. of Genetics & Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

About 25 cases of live-born trisomy 22 have been reported in the literature with characteristic dysmorphic features and major organ anomalies typically resulting in demise soon after birth (Heinrich et al, 2012). Other microduplication syndromes of chromosome 22 include Emanuel syndrome [der(22)t(11;22)], cat-eye syndrome (tri- or tetrasomy 22q11.2) and 22q11.2 microduplication syndrome. We describe a live-born female infant with a large 27.3 Mb duplication of chromosome 22q11.23q13.33 resulting in trisomy 22q11.23→qter. During the pregnancy there was persistent asymmetric IUGR with severe microcephaly (<3rd percentile) and oligohydramnios. Fetal echocardiogram was normal. Amniocentesis was offered and declined. The patient was born at 36.3 weeks gestation and had dysmorphic features, poor tone and poor respiratory effort. Additional features included a secundum atrial septal defect, bilateral hip dislocation, and tracheomalacia. No renal or brain anomalies were found. Karyotype revealed a derivative chromosome 22, 46,XX,der(22)t(22;22)(p12;q12.1), with no duplication of the DiGeorge region TUPLE1 probe but with duplication of the 22q13.3 ARSA probe. Array CGH further defined the duplicated region as 22q11.23q13.33 (22201006-49525123) (NCBI36/hg18). Parental studies were normal. The patient died on day of life 77 due to respiratory failure. Her facial appearance was strikingly similar to patients with complete trisomy 22 including microcephaly, cranial anomalies, hypertelorism, flat nasal bridge, dysplastic ears and shortened neck, and she shared many additional features including IUGR, near-term delivery, genital anomalies, congenital heart lesion and respiratory issues. A patient with a similarly large partial trisomy 22 (23.5 Mb between 22q11.1-22q13.1) has been described, but had findings consistent with cat-eye syndrome, including coloboma, preauricular ear tag, hypospadias and renal anomaly (Karcaaltincaba et al, 2010). Our patient expands the literature on complete and partial trisomy 22, abnormalities with limited viability, and helps clarify the contribution of the distal duplication to this distinctive phenotype and associated malformations.

2620T

Prader-Willi syndrome: Toward Automated Identification of Phenotypic Differences. *L. Wolf[1], C. Clericuzio[2], S.B. Cassidy[3], J.E. Allanson[4].* 1) FDNA, Herzliya, Israel; 2) Department of Pediatrics, University of New Mexico Health Sciences Center, Albuquerque, New Mexico; 3) Division of Medical Genetics, Department of Pediatrics, University of California, San Francisco, San Francisco, California, USA; 4) Hospital of Eastern Ontario, University of Ottawa, Canada.

In Prader-Willi syndrome (PWS), the two common etiologies are paternal deletion of chromosome 15q11-13 (~70% of affected persons) and maternal uniparental disomy15 (UPD) (~25%). Cassidy et al. [Am J Med Genet 68; 433-440, 1997] evaluated 37 individuals with deletion PWS and 17 with UPD to determine if there were phenotypic differences and reported that those with UPD have a higher likelihood of an atypical face, often rounder displaying a broader forehead and a flatter/broader nasal bridge. Allanson et al. [Proc Greenwood Gen Ctr 19: 117, 2000] followed up with an objective study of 109 individuals with PWS. Measurements of eyes, ears, nose, mouth, facial widths, depths, lengths and circumferences were taken. Results showed agreement with the previous study: persons with UPD have a longer face, more protuberant nose with a narrower base, smaller mouth, and broader or more prominent mandible. In this study we revisited the 2000 study to validate the analysis using different statistical machinery, examine the age-related differences between the two etiologies, and evaluate image-based differentiation. 73 persons are included in our retrospective study, 37 under the age of 8 (7 UPD, 30 deletion), and 36 above (15 UPD, 21 deletion). The R Matching package was used to match individuals based on gender and age. The results reveal that, in the younger age group, nasal base and mouth width are significantly reduced in UPD, while in the older, inner canthal distance and ear length are larger in UPD. After normalizing measurements by ofc, these results remain significant. Reduced minimum frontal distance is another differentiator of UPD under the age of 8, while reduced mouth width differentiates above age 8. The successful utilization of normalized measurements supports the future use of ratios of distances extracted from images. Next, facial images of 16 persons (4 UPD, 12 deletion) from the same cohort were evaluated with automatic image analysis tools for UPD/deletion differentiation. This type of analysis provided good discrimination between UPD and deletion individuals. Since UPD is the less prevalent etiology and has a subtly different phenotype, there is a risk of under diagnosis. In a future study we plan to test this hypothesis using blinded dysmorphologist assessment and automatic facial analysis tools. We would assess whether this risk could be reduced by training automatic systems to identify the individual etiologies.

2621S

Wiring the Brain in Down Syndrome: Unique Identical Twins Discordant for DS. *J.R. Korenberg[1], L. Dai[1], J.O. Edgin[3], C. Vachet[2], J. Anderson[4], G. Gerig[2].* 1) Center for Integrated Neuroscience and Human Behavior, Department of Pediatrics, Brain Institute, University of Utah, Salt Lake City, UT; 2) School of Computing, University of Utah, Salt Lake City, UT; 3) Department of Psychiatry, University of Arizona, Tucson, AZ; 4) Department of Neuroradiology, University of Utah, Salt Lake City, UT.

Genetic disorders as Down syndrome (DS) provide a solution to the challenge of human neuroscience, to develop a unified view of the brain across spatial, temporal and functional levels integrated with emergent properties such as cognition. However, subtle brain and cognitive phenotypes are obscured by genome-wide variation. We report a multimodal analysis including genetics, cognition, structural and functional MRI of the only living pair of Identical male twins, age 22, discordant for DS. These resulted from an extra chromosome 21 in an otherwise identical genome, with the remainder of variance contributed by environmental and stochastic effects. We established MZ identity by Illumina genomic arrays, and established typical clinical and chromosomal features of DS in one, >96% trisomy 21 in cord blood, blood and fibroblasts, and in the other a normalized phenotype, >92% normal karyotype in these tissues. The twins completed the Arizona Cognitive Test Battery for DS, an assessment including neuropsychological measures of hippocampal and prefrontal function. The 8% mosaic twin had a full-scale IQ of 123, typical performance on a frontal measure (CANTAB IDED), but impaired spatial working and associative memory (CANTAB Spatial Span and Paired Associates Learning (PAL)), markers of hippocampal dysfunction. Early language delay was noted; at baseline testing he presented with a 24 point split in verbal and performance IQ. The 96% mosaic twin showed scores typical for the DS range (full scale IQ=42), with prominent impairments in (PAL). The twins were also scanned on high resolution MRI/DTI and compared with 22 typical DS and 17 controls. Overall, normalized volumes of the 96% mosaic twin were very close to the volumes of the DS group, and the 8% mosaic twin volumes were similar to controls. An exception was DS-like volume in the 8% mosaic twin of the right fusiform gyrus, involved in visual memory and language. Integration of MRI with cognition in full trisomy, revealed correlation of hippocampal volumes with PAL results. Only the 96% mosaic twin demonstrated increased internetwork synchrony across networks seen in typical DS during functional MRI. The twins are a graphic vision of how a simply trisomy for 21 disturbs brain wiring and the results implicate the hippocampal and fusiform gyrus formation in the neural systems responsible for visual-spatial (PAL) and linguistic deficits of DS.

2622M

Congenital Myasthenia Syndrome: Uniparental disomy of chromosome 2 and homozygous mutation of GFPT1. *S. Rangasamy[1,2], R. Richholt[1,2], K.M. Ramsey[1,2], A. Siniard[1,2], J.J. Corneveaux[1,2], I. Schrauwen[1,2,3], J. Krate[1,4], A. Kurdoglu[1,2], M. De Both[1,2], S. Szelinger[1,2,5], B.E. Hjelm[1,2], S. Swaminathan[1,2], M. Huentelman[1,2], D. Craig[1,2], V. Narayanan[1,2].* 1) Neurogenomics Division, Translational Genomics Research Institute, Phoenix AZ, USA; 2) Dorrance Center for Rare Childhood Disorders, Translational Genomics Research Institute, Phoenix AZ, USA; 3) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 4) University of Arizona College of Medicine, Tucson, AZ; 5) Molecular and Cellular Biology Interdisciplinary Graduate Program, School of Life Sciences, Arizona State University, Tempe AZ, USA.

Congenital myasthenia syndrome (CMS) includes a group of genetic disorders involving genes encoding components of the neuromuscular junction. We describe an unusual case of a child with CMS who was found to have long stretches of homozygosity on chromosome 2. The female child was born full term but required emergency C-section, followed by prolonged intubation. She was later diagnosed with hypotonia, weakness with reduced spontaneous movement, and was areflexic. Genetic testing for spinal muscular atrophy, Prader-Willi syndrome, and congenital myotonic dystrophy were negative. Muscle biopsy study at 1 month of age showed normal fiber type size and grouping, but there was coarse staining of the T-tubule system suggestive of a mitochondrial disease with reduced cytochrome C oxidase levels. EMG showed an electrodecremental response, and she had a partial response to treatment with pydostmine. Gene testing for SURF1, SCO1, SCO2, and CO×10 were negative and the chromosomal microarray test showed normal gene dosage. Chromosomal microarray identified a long (57.6 Mb and 90 Mb) contiguous regions of homozygosity restricted to chromosome 2: arr 2p21q11.2 (45,013,724 - 102,641,201) hmz; 2q22.1q36.3 (140,091,291 - 229,908,245) hmz. The Congenital Myasthenia Group at the Mayo Clinic confirmed a CMS diagnosis. At the time, CMS gene panel was negative. Family trio based whole-exome sequencing (WES) was performed at the Dorrance Center for Rare Childhood Disorders as a part of research study. Exome data identified a homozygous, frameshift, c.865-866insG insertion on chr2, at exon 9 of GFPT1 gene; a low coverage region by WES. Insertion was confirmed by Sanger sequencing which demonstrated that father was homozygous reference and mother was heterozygous. Based on our findings, we propose that this child had two identical (maternal) copies of large segments of chromosome 2, implying maternal uniparental disomy, harboring the GFPT1 insertion that causes autosomal recessive congenital myasthenia. Previously reported patients with recessive GFPT1 mutation show reduced GFPT1 levels and decreased protein glycosylation. Glycosylation at neuromuscular junctions is important for key intracellular signaling protein function and compromised glycosylation in GFPT1 mutation leads to altered neuromuscular phenotype. The precise pathogenic mechanism for our observed GFPT1 insertion will be determined with future studies.

2623T

CRANEOFACILALES AND FEATURES ASPECTS ORAL OF CHILDREN WITH THE POBLANO CHILD HOSPITAL GOLDENHAR SYNDROME IN THE PERIOD 2013-2015. *D. Reyes Ramirez[1,2], R. Aparicio[1,2], G. Muñoz Quintana[1].* 1) Pediatric Estomatology, Benemerita Universidad de Puebla, Puebla, Puebla; 2) Genetics, Hospital para el niño Poblano, Mexico.

The facial skull malformations and chromosomal aberrations are considered alterations in the phenotypic and secondary structure error of the birth. All these changes must be observed during childhood and confirmed by chromosomal karyotype or deficiency in DNA repair. Pediatric patients were evaluated and showed different congenital and chromosomal alterations. These changes at the level of its multiple system and organic structure, chromosomes were analyzed and classified as numeric and structural alterations respectively. Another group of genetic disorders known as mutations and they are inherited in different generations. A wide range of pediatric patients with congenital and genetic diseases by alterations mainly associated with craniofacial development during pregnancy, prenatal, or at birth are described in this study to analyze characteristics clinical, medical, or surgical procedures and medical evolution according to the syndrome of malformation in study. The wide variety of Craniofacial anomalies often makes them unclassifiable. Goldenhar, also known as the first Syndrome and is second Gill arch or oculo-auriculo-vertebral spectrum, is a complex of Craniofacial and vertebral anomalies. These findings can be found in solitary or usually associated with microtia, mandibular hypoplasia, or congenital vertebral malformations. The incidence is limited and varies between 1 in 45,000 to 2 in 100,000 inhabitants. Currently it should be considered as a bilateral malformation, which would differentiate it from the Microsomía Hemifacial. Know the relationship of oral diseases in children with Goldenhar Syndrome, as well as craniofacial features will give us a broad overview in order to provide better care odonto/stomatological pediatric patients. The earlier and excellent medical and surgical treatment is important to improve their life quality.

2624S

Intragenic *CNTN4* Deletion in a Child with Profound Speech Apraxia and Absence of Autistic Features. *J. Fleischer[1], H. Al-Kateb[2], M. Shinawi[1].* 1) Genetics, Washington University, St. Louis, MO; 2) Department of Pathology and Immunology , Washington University School of Medicine, St. Louis, MO.

Background: Contactin 4, a cell adhesion molecule and a member of the immunoglobulin super family, is expressed primarily in the nervous system. Deletions and duplications encompassing the *CNTN4* gene have been reported in children with autistic spectrum disorder and developmental delay. Intrestengly, all previously documented cases were inherited form unaffected fathers raising questions regarding reduced penetrence and pathogenenicity of these rearrangements. Methods: Clinical and molecular cytogenetic characterization studies were performed on a 2-year-old boy who presented with severe speech apraxia, mild gross motor delay and absence of autistic features. The findings in the proband are compared with previously reported cases. Results: The proband is non-verbal, but displays age appropriate receptive speech skills, cooperative play, joint attention, and eye contact. Additional findings include intrauterine growth retardation, premature birth, a large secundum atrial septal defect, and mild facial dysmorphisms. Chromosomal microarray analysis revealed a 128Kb deletion within the *CNTN4* gene corresponding to the coordinates chr3: 2,878,363-3,006,381 (hg19). The deletion takes out exons 7-12 and introduces a frame-shift mutation at amino acid S154 resulting in a termination codon 22 amino acids downstream the deletion site. Two splice variants (4 and 5) are not affected by this deletion. Fluorescence in-situ hybridization studies revealed a paternal origin of the deletion. Conclusion: Although the *CTNT4* intragenic deletion in our proband is predicted to result in loss of *CNTN4* function, the child did not exhibit autistic features, the hallmark of *CNTN4* microdeletion-associated phenotype. Our data provide additional support for the significance of *CNTN4* gene in language development and emphasize the phenotypic heterogeneity. We discuss potential factors contributing to reduced penetrence and attempt to find possible phenotype genotype correlation.

2625M

A 284kb microduplication at 7q21.11 involving SEMA3A possibly linked to agenesis of corpus callosum and visual impairment in a patient with spastic quadriparetic cerebral palsy. *D. Ma[1], N. Singh-Bhatia[2], P. Levy[2], R. Marion[2], R. Naeem[1].* 1) Pathology, Montefiore medical center, Bronx, NY; 2) Genetics, Children Hospital at Montefiore, Bronx, NY.

A 284kb heterozygous duplication was identified by array comparative genome hybridization (aCGH) on chromosome 7q21.11 in a patient with spastic quadriparetic cerebral palsy, cerebral dysgenesis including agenesis of corpus callosum, visual impairment and severe global developmental delay. This duplicated region, involving the regulatory elements of SEMA3A along with its exon 1 and the transcriptional start point, has not been documented in any publicly available case or control databases. Within the family, another two brothers and one sister also presented with cerebral palsy and global developmental delay, suggesting a candidate gene in a possibly autosomal dominant inheritance mode with variable expressivity and penetrance. An in depth examination of the SNP data revealed five loss of heterozygosity (LOH) regions on 2q23.2-q24.1, 3q25.2-q26.31, 6q14.2-q14.3, 6q22.1-q22.31 and 8q11.21-q11.23 with various lengths from 3.1Mb to 16.8Mb. A search for potential disease-causing genes in a recessive inheritance mode did not reveal obvious candidates that could explain the clinical features. A literature review of SEMA3A indicated a high expression of the gene in all adult and fetal brain regions and heart as well as fetal skeletal muscle. Gene expression has been associated with the growth of the human corpus callosum and the effect on retinal pigment epithelial cell activity, which is quite well matched with the multiple congenital anomalies in this patient. In addition, a recent case report has linked the deletion of the similar region with a novel type of syndromic short stature. Though the gene dosage of SEMA3A appears to be critical for the normal development of brain, the functional impact of the duplication on its regulation of gene expression remains to be elucidated.

2626T

Craniosynostosis in Williams Syndrome. *N. Okamoto, K. Ueda.* Dept Medical Genetics, Osaka Med Ctr/Res Inst, Osaka, Japan.

Williams syndrome (WS) is caused by a microdeletion on chromosome7q11.23 encompassing the elastin gene. WS is characterized by distinctive facies, congenital cardiovascular malformations, connective tissue abnormalities and intellectual disability. Craniosynostosis has seldom been described as a complication of WS. We identified seven patients with craniosynostosis. They showed abnormal cranial morphology, prominent microcephaly or headache. Four had sagittal craniosynostosis (dolichocephaly), one had metopic craniosynostosis (trigonocephaly), and two had both. Two of them underwent cranioplastic surgery. Patients with WS often show hyperactivity together with developmental delay. If craniosynostosis remains undiagnosed, disabilities may be worse. Increased intracranial pressure may modify behavioral abnormalities. Therefore, proper diagnosis and neurosurgical intervention are necessary. If patients with WS show prominent microcephaly or cranial deformation including dolichocephaly or trigonocephaly, neuroradiological evaluation including 3D-CT of the cranium is necessary. We suggest that craniosynostosis is an important complication of WS. Craniosynostosis should be considered in every patient with WS and cranial deformation.

2627S

Neurodevelopmental and neurobehavioral characteristics in males and females with CDKL5 duplications. *P. Szafranski[1], S. Golla[2], W. Jin[1], P. Fang[1], P. Hixson[1], R. Matalon[3], D. Kinney[4], H-g. Bock[5], W. Craigen[1], P. Magoulas[1], J.L. Smith[1], W. Bi[1], A. Patel[1], S.W. Cheung[1], C. Bacino[1], P. Stankiewicz[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Departments of Pediatrics and Neurology, University of Texas Southwestern Medical Center, Dallas, TX; 3) Division of General Academic Pediatrics, Department of Pediatrics, The University of Texas Medical Branch at Galveston, Galveston, TX; 4) Memorial Children's Hospital Navarre Pediatrics South Bend, IN;; 5) Department of Pediatrics, University of Mississippi Medical Center, Jackson, MS.

Point mutations and genomic deletions of the *CDKL5* (*STK9*) gene on Xp22 have been reported in patients with severe neurodevelopmental abnormalities, including Rett-like disorders characterized by early-onset seizures, infantile spasms, severe intellectual disability with absent speech, and microcephaly. The phenotypic resemblance to Rett syndrome has been proposed to result from similar functions or interactions in the neuronal molecular pathways between CDKL5 and MECP2. In contrast to *MECP2*, the clinical consequences of increased dosage of *CDKL5* are poorly understood. To date, only larger-sized (8-21 Mb) duplications harboring *CDKL5* have been described. We report six females and four males from seven unrelated families with *CDKL5* duplications ranging in size between 540 kb and 935 kb. Three families of different ethnicities had identical 665,915 bp duplications of complex genomic structure containing only the shorter *CDKL5* isoform expressed at low levels in the fetal brain but not the adult brain, indicating that it had likely arisen many generations ago. Four affected boys, ages 9-14, and three affected girls, ages 8-9, manifested autistic behavior, developmental delay, language impairment, and hyperactivity. Of note, two girls and one boy had macrocephaly. Two carrier mothers of the affected boys reported a history of problems with learning and mathematics while at school. None of the patients had epilepsy. Consistent with *CDKL5* mutations and deletions, the X-inactivation pattern in all six studied females was random. We propose that the increased dosage of *CDKL5* might have affected its interactions with MECP2, leading to perturbation of synaptic plasticity and learning; manifestations of this perturbation include autistic behavior, developmental and speech delay, hyperactivity, and macrocephaly.

2628M

Subtelomeric investigation in individuals with microform of HPE. *L. Ribeiro-Bicudo[1,2,3], V. do Ó[2], B. Gamba[3], A. Richieri-Costa[2].* 1) Genetics, Goias Federal University, Goiania, Goias, Brazil; 2) Hospital for Rehabilitation of Craniofacial Anomalies, Bauru, Sao Paulo, Brazil; 3) Genetics, Sao Paulo State University, Botucatu, Sao Paulo, Brazil.

Holoprosencephaly (HPE) is a malformation sequence where the cerebral hemispheres fail to separate into distinct left and right haves. Three levels of increasing severity are described in HPE: lobar, semi-lobar and alobar. Another milder subtype of HPE called the middle interhemispheric variant (MIHF) or syntelencephaly, has been recognized. A new phenotype was first delineated in a series of Brazilian patients, the so-called holoprosencephaly-like (HPE-L) phenotype. The etiologies and the variable clinical spectra of HPE and HPE-L, also called HPE minor form or microform, seem to be related and extremely heterogeneous. Data about frequencies of classic HPE are well known. It is considered one of the most common human malformation, with an estimated prevalence of at least 1/16,000 live births and in 1/250 conceptuses, and it is usually classified according to type of CNS involvement or facial anomalies observed. On the other hand, similar statistics concerning HPE-L and/or microforms are unknown, but certainly it represents a challenge in several areas, such as clinical findings, differential diagnosis, prognosis, and genetic counseling. HPE-L can be seen as a condition important to the understanding of many of the mechanisms involved in normal and abnormal craniofacial development. Attention should be given to newborn babies with isolated large cleft lip/palate where the definitive diagnosis only will be possible with the phenotypic evolution. It is estimated that the cause of HPE is due to cytogenetic anomalies in 30-50% of indivuduals, to their environmental causes and unknown genetic alterations in 10-15%, and to mutations in HPE genes in 5-10%. The present work was based on the observation of previous data showing subtelomeric aberrations in HPE individuals. We selected individuals presenting the microform of HPE with normal MRI and no developmental delay. These individuals had facial characteristics such as hypotelorism, single central incisor, flat nose, and cleft lip/palate. We performed MLPA screening based on the P036 kit on 64 DNA samples. No subtelomeric aberrations was found in the samples analyzed. Even considering that the sample is small, it seems that the subtelomeric aberration is not a common event in the microform of HPE.

2629T

Discontinuous microdeletion at 1p13.3 involving NBPF4 but not ALX3 in a patient with severe frontonasal dysplasia. *A. Ali[1], R. Patel[1], S. Jaiswal[1], S. Singh[2], R. Raman[1,3].* 1) Centre for Genetic Disorders, Banaras Hindu University, Varanasi, Uttar Pradesh, India; 2) GS Memorial Plastic Surgery Hospital Hospital, Varanasi; 3) Department of Zoology, Banaras Hindu University, Varanasi, Uttar Pradesh, India.

Frontonasal dysplasia (FND) arises due to improper embryonic development of head and face. It is defined by at least two of the following features; hypertelorism, broad nose, clefts of nose, absent nasal tip, cleft lip and/or cleft palate, anterior cranium bifidumoccultum, or a widow's peak hairline. Three types of frontonasal dysplasia are reported; type-1 and type-2 which are correlated with mutations in ALX3 (1p13.3) and ALX4 (11p11.2) genes respectively, whereas type-3 is correlated with mutations in ALX1 gene (12q21.31). Here, we report a sporadic case of FND with some overlapping features of all the three types of FND, characterized by hypertelorbitism, absent cupid bow, cleft of bilateral nostrils, lacking midline bony nasal septum, deviation of nasal septum to right side, frontal bossing with depression in centre, left eye anophthalmia and right eye micropthalmia, left orbit without lens, bilateral epicanthal folds, overjet teeth, flexion deformity of little finger of left of left hand and unilateral cryptorchidism (left side). Cytogenetic microarray analysis using Affymetrix CytoScan® HD array was performed for the patient, both the parents, and 7 unaffected controls. A deletion of 125 kb region at locus 1p13.3 was detected in the patient only and none of the parents and unaffected controls. The deleted region contains two genes SLC25A24 and NBPF4. SLC25A24 encodes a carrier protein that transports ATP-Mg which exchanges it for phosphate. NBPF4 is a neuroblastoma breakpoint family gene known to be associated with a number of developmental and neurogenetic diseases such as microcephaly, macrocephaly, autism, schizophrenia, mental retardation, congenital heart disease, neuroblastoma, and congenital kidney and urinary tract anomalies. ALX3, a known candidate gene for FND, is close to the deleted region but is in normal copies. This study suggests, deletion of NBPF4 as the cause of frotonasaldysplaia in the patient due to the following two reasons. One, NBPF4 is known to cause variable phenotypes including cranial abnormalities. Second, hypermetyhylation of ALX3, a known candidate for FND, cause neuroblastoma, and since NBPF4 is also known to cause neuroblastoma, we hypothesize that ALX3 probably regulates NBPF4 expression and therefore ALX3 mutation cause FND through downregulation of NBPF4. Therefore haploinsufficiency of NBPF4 causes FND. Investigation is underway to further confirm the role of NBPF4 in FND.

Growth Standards for Children and Adolescents with Smith-Magenis Syndrome. *L.R. Fleming[1], F. Duncan[2], W. Introne[2], J. McGready[3,5], K. Schulze[4,5], A. Alade[5,6], J. Hoover-Fong[5,6], A.C.M. Smith[2].* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Office of the Clinical Director, NHGRI/NIH, Bethesda, MD; 3) Dept of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 4) Center for Human Nutrition, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 5) Greenberg Center for Skeletal Dysplasia, Johns Hopkins University, Baltimore, MD; 6) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Background: Smith-Magenis syndrome (SMS) is a complex genetic disorder, with an incidence of 1/15,000, characterized by distinctive craniofacial features, cognitive impairment, sleep disturbances, and neurobehavioral abnormalities. Poor linear growth and weight gain are common in infancy and short stature has been reported in 50-78% of individuals. However SMS-specific growth curves have not been available previously to allow clinicians to assess growth. Methods: Anthropometric data (height, weight and head circumference) were collected by clinician measurement, review of the medical record and parent submission for 143 individuals (82 Females, 61 Males) with SMS in Europe, the USA and Australia. Of these, 138 (96.5%) had deletions and 5 (3.5%) had point mutations in *RAI1*. Penalized cubic smoothing splines were used to estimate SMS curves for height and weight for periods of 0-36 months and 2-12 years. These curves were compared to WHO (0-36 month) and CDC (2-18 year) norms. Results: At birth, the majority of term infants with SMS are within the clinically normal range for weight and length. Infants with SMS exhibit a decline in height velocity, with the median height tracking < 5th centile of average stature by 3 years of age. Females with SMS show a more gradual decline in height velocity than males. Relative short stature persists through early adolescence, with median height for individuals with SMS through age 12 near the 25th centile for sex specific CDC age norms. By 6 months of age there is substantial attenuation of weight velocity in SMS males. A more gradual attenuation in weight velocity over the first year of life is seen in SMS females. Weight curves for 2-12 years of age show accelerated weight gain beginning in late childhood (~7 yrs). In comparison to CDC norms, the median weight in SMS males and females falls above the CDC 50th centile through 12 years of age. Discussion: This study represents the first set of standardized growth curves created for individuals with SMS. Syndrome specific growth curves can be used to set expectations for growth and to manage syndrome related symptoms. These curves can also be used in future research to better understand the natural history of SMS and the genotype-phenotype relationships in these patients.

2631M

Phenotype of double de-novo Williams and DiGeorge microdeletion syndromes. *A. Shukla[1], K. Mandal[2], SJ. Patil[3], SR. Phadke[2], KM. Girisha[1].* 1) Medical Genetics, Kasturba Medical College, Manipal, Karnataka, India; 2) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India; 3) Naryana Hrudayalaya Institute of Medical Sciences, Bangalore, Karnataka, India.

DiGeorge syndrome (DGS, chromosome 22q11.2 deletion syndrome, OMIM 188400) and Williams syndrome (WS, chromosome 7q11.23 deletion syndrome, OMIM 194050) are well characterized microdeletion syndromes. Here, we report a child with de novo deletions in both these regions with the resulting unique phenotype that has not been reported till date in the literature. This 6-years-old child presented with speech delay and history of persistent hypocalcemia with seizures in the neonatal period. He is born to non-consanguineous healthy parents and has a healthy younger sister. The development was markedly delayed with independent walking achieved at 3 years of age. He does not speak even a single word though is able to communicate his basic needs non-verbally. He is yet to achieve bowel and bladder control. He has severe growth retardation with microcephaly. The height is 98 cm (-4 SD below the mean) and OFC is 46.5 cm (-5 SD below the mean). The craniofacial features are a mixture of both syndromes. He has the typical features of full lower cheeks with malar flattening and thick vermillion as in Williams syndrome but the nose and ears are similar to those of DGS. The hooding of the upper eyelids too resembles that of DGSS. Surprisingly, though congenital heart defect is a major feature of both these syndromes, he has a normal echocardiography. The behavioral phenotype matches more with that of DGS and he lacks the sociable behavior of the Williams syndrome. The persistent hypocalcemia can be attributed to the 22q11 deletion. Interestingly, he was clinically diagnosed to have Williams syndrome by one clinical geneticist and DiGeorge syndrome by the other. Detection of microdeletion was done using Multiplex Ligation Dependent Probe Amplification (MLPA) technique (MRC Holland, Amsterdam) using Probe mix P245-Microdeletion-1. Deletion was noted at 22q11.21 (all 3 probe sets in this probe mix for that region) and also at 7q11.23 (both of 2 probe sets in this probe mix for that region) suggesting co-existing DiGeorge syndrome and Williams syndrome. Either parent lacks these deletions. The case illustrates chance occurrence of two common microdeletions at these two regions and the resulting combined phenotype with overlapping features of these two syndromes.

2632T

One cannot presume siblings with similar clinical findings result from the same underlying genetic cause!—familial genome instability, leaky proof reading mechanism, or true diagnosis? *A. Tsai, K. kovak, K. keller, J. kushner, C. rogers, S. Moore.* Molecular and Medical genetics, OHSU, Portland, OR.

When siblings present with similar clinical findings, we usually presume they result from the same etiology. It is not uncommon for a clinical geneticist to order all testing on one child in the family, and subsequently offer siblings specific testing for the revealed genetic disorder. For a cytogenetic anomaly identified by microarray, a reference lab often suggests a FISH study for parents or at-risk individuals in the family rather than a full microarray. We present three families in which multiple children within the family are affected with similar clinical features. Family 1 is fraternal twins. They were born SGA with similar dysmorphic features. A 180k oligo array revealed a copy gain of 1.94 Mb: 5q35.2q35.3 (175,491,045-177,427,809)x3 in the female twin, which includes the entire NSD1 gene (deleted in Sotos syndrome). Her result and features were consistent with the previously reported reverse-Sotos phenotype. A maternal half brother has a similar gain of 1.98 Mb: 5q35.2-q35.3 (175,491,045-177,470,488)x3 and similar features. The male twin's array showed a single copy gain of 435.7 kb (maximum size 458 kb) in 5q35.2q35.3 (176,700,522-177,136,262)x3 that resides within/overlaps with a portion of the sister's, is predicted to disrupt several exons of the NSD1 gene and present with Sotos syndrome. Family 2 is fraternal twins, both with autism and small optic nerves. Microarray in one twin revealed a distal deletion 22q11.21 (19,408,946-19,790,658) x1 and the brother showed a 16p13.11 duplication (15126709-16292235) x3, 1.166-2.133 Mb. Family 3 is 2 maternal half siblings with dysmorphic features and intellectual disability. The brother has a 969.6 kb duplication at 1p13.3, and the sister has a 598 kb deletion at 16p11.2 consistent with the 16p deletion syndrome and the 969.6 kb duplication. Siblings only share 25-50% of genes that are subject to recombination, individual epigenetic exposures and stochastic events. One cannot presume siblings with similar clinical findings result from the same underlying genetic cause. Family 1 shows co-existence of 2 different CNVs from different parental origins. Families 2 and 3 reveal different CNVs and, if only FISH were offered, the anomalies in siblings of the proband would have been missed. CNV can be a red herring. Further investigation is required if the phenotype cannot be explained by known microarray anomalies. Appropriate genetic causes should be considered individually, especially in half siblings.

2633S

An interstitial microduplication in 17q11.2 encompassing the NF1 gene, in a girl presenting with a Prader Willi like syndrome: expanding the NF1 microduplication. *C. Vinkler[1], T. Lerman-Sagie[2,3], D. Lev[1,2,3].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Metabolic Neurogenetics Service, Wolfson Medical Center, Holon Israel; 3) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Interstitial microduplication of chromosome 17q11.2 is rare condition with less than 20 reported cases. In most cases described so far, the microduplications include the NF1 gene. Previous reports trying to delineate the phenotype classified the patients according to the size and breakpoints of the microduplication. Type 1 with 1.4 Mb duplication, type 2 with 1.2 Mb duplication and type 3 with 1Mb duplication. The clinical phenotype includes developmental delay, facial dysmorphism and sometimes seizures. Eating disorder with severe obesity has not been described in this group of patients. We present a 14y old girl who was followed in our clinic for several years. She had dysmorphic features, obesity, hypotonia, global developmental delay and atrioseptal heart defect. Prader-Willi syndrome was ruled out by molecular tests. Family history is unremarkable. At 14y of age she is still overweighed (due to eating disorder) intellectually disabled and has verbal dyspraxia. Her dysmorphic features include round face, short and narrow forehead, small orbital fissures, broad and sparse eyebrows, short and small nose, widely spaced inverted nipples, camptodactyly and clinodactyly of the 5th finger bilaterally. Brain MRI is unremarkable except for a mild enlargement of the left atrium. CMA test showed a de novo 8.746Mb duplication on chromosome 17q11.2 encompassing the NF1 gene along with other 14 OMIM morbid genes. None of the genes has been associated with eating disorders. Obesity has been mentioned in two other cases of 17q11.2 duplication. We propose that CMA test should be considered in cases of eating disorders. More cases might allow to define the common critical area of eating disorder and perhaps help in understanding this abnormality.

2634M

Bilateral absence of the ulna in 4q terminal deletion syndrome. *M. Marble[1], T. Meaux[2].* 1) Dept Ped/Clinical Gen/LSUHSC, Children's Hosp New Orleans, New Orleans, LA; 2) LSUHSC.

We report a patient born with bilateral absence of the ulna who was found to have a terminal deletion involving the long arm of chromosome 4. The deletion was identified by chromosome microarray analysis and determined to be 21.98 Mb in size and to involve 4q32.3-4qter. The molecular coordinates encompassed by the deletion were 4:169,154,141-191,133,858. The patient was born at 38 weeks gestation by spontaneous vaginal delivery. The pregnancy was complicated by intrauterine growth retardation, oligohydramnios, and maternal hepatitis C. Birth weight was 3000 grams. Other clinical features included atrial septal defect, patent ductus arteriosus, micrognathia, cleft palate, inner epicanthal folds and long philtrum. At 2 years of age, weight was 10.6 kg (10-25th percentile) and height was 80 cm (5th percentile). She had delay in language skills with an approximately 15 word vocabulary and no sentences. She could sit on her own and could pull up on furniture but was not yet able to walk. The atrial septal defect and patent ductus arteriosus closed spontaneously. Radiographs showed a short humerus and absent ulna bilaterally. On the upper extremities there was only a single digit. The digit was noted to have a hypoplastic metacarpal, a small well-developed proximal and distal phalanx, but apparent absence of the mid phalanx. Past reports have suggested an association between chromosome 4q deletions and variable ulnar ray defects but most of these reports used traditional cytogenetic methods. We found a few cases in the literature with absent ulna associated with 4q terminal deletions but very few for which comparative genomic hybridization was documented. We compared the deletion in our patient to previous reports in the literature. The findings in our patient, along with other reports, suggest that the terminal 4q chromosomal segment contains a region important for ulnar ray development.

2635T

Congenital heart disease and Sturge-Weber syndrome in a young female with 22q11.2 triplication. *L. Mota-Vieira[1,2,3], L.M. Pires[4], S. Vaz[5], P. Maciel[5], I.M. Careira[4], R. Pires[1,2].* 1) Molecular Genetics and Pathology Unit, Hospital of Divino Espirito Santo of Ponta Delgada, Azores Islands, Portugal; 2) Centre for Biodiversity, Functional and Integrative Genomics (BioFIG), Faculty of Sciences, University of Lisbon, Portugal; 3) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 4) Laboratory of Cytogenetics and Genomics, Faculty of Medicine, University of Coimbra, Portugal; 5) Department of Pediatrics, Hospital of Divino Espirito Santo of Ponta Delgada, Azores Islands, Portugal.

In the scope of the population-based epidemiological study on congenital heart disease (CHD) performed in the São Miguel Island (Azores archipelago, Portugal), we are investigating the genetic basis of these complex diseases which are a major cause of serious morbidity and mortality in childhood. Since 22q11.2 deletions and duplications are frequently implicated in CHD, we carried out a systematic analysis of this genomic region in CHD patients from this Atlantic Island. The analysis consisted of clinical evaluation and searching for copy number variations (CNVs) by Multiplex Ligation-dependent Probe Amplification (MLPA), according to MRC-Holland protocol. The MLPA results detected in a female patient higher doses than 22q11.2 duplication, suggesting the presence of a double disomy (2:2, *i.e.*, two chromosomes with 22q11.2 duplication) or a tetrasomy (1:3, *i.e.*, one normal chromosome and a 22q11.2 triplication in the other). These two hypotheses were investigated by FISH analysis which confirmed a tetrasomy. Further, we screened parental samples, by both techniques, in order to ascertain if the 22q11.2 triplication was inherited or acquired *de novo*. The results showed that her non-affected father presented 22q11.2 duplication (1:2). Therefore, the triplication here described could be explained by an unequal crossing-over of 22q11.2 region that triggered an expansion of the duplication to a tandem triplication during spermatogenesis, in a non-allelic homologous recombination mechanism mediated by the presence of low-copy repeats. To the best of our knowledge, the present study reports the second documented case of 22q11.2 triplication, being the first one described by Yobb and collaborators (2005). Our patient displays the dysmorphic facial features, cognitive deficit and heart defect (restrictive interventricular communication and membranous sub-aortic stenosis) usually seen in patients with 22q11.2 deletion and microduplication syndromes, as well as phenotypic characteristics of Sturge-Weber syndrome (in particular the presence of nevus flammeus — port-wine stain —, behavioral disorders, and visual fields defects). Taking this into consideration, we propose that 22q11.2 triplication is a variation of 22q11.2 microduplication syndrome, with aggravated phenotype due to the major dosage of implicated genes.

2636S

Familial 17q12 duplication presented as SGA/IUGR and microcephaly during pregnancy: A counseling dilemma. *A. Singer[1], I. Maya[2], C. Vinkler[3].* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Tel Aviv, Israel; 2) Institute of Medical Genetics, "Rabin" Petah-Tikva, Israel; 3) Institute of Medical Genetics,"Wolfson" Holon, Israel.

Recurrent genomic rearrangements of chromosome region 17q12, ranging from 0.3 to 2.1 Mb, have been described to be associated with different clinical phenotypes. Patients carrying a 17q12 duplication present with intellectual disability, developmental delay of various degree, epilepsy, schizophrenia, autisim, brain abnormalities, esophageal atresia and various renal and urinary tract abnormalities. In the normal population, duplication of 17q12 is quiet rare (<0.02%) and it penetrance estimate is around 21%. Hence, prenatal counseling poses a dilemma. We present a baby boy with prenatal and postnatal microcephaly and IUGR/SGA. He was born to a healthy nonconsanguineous couple. Late amniocentesis (32 week) because of symmetric SGA/IUGR, microcephaly and echogenic intracardiac focus found 1.4 MB 17q12 duplication. Parents' CMA showed that it was inherited from his father. During counseling the father was found to have normal HC but he has dyslexia and some speech disturbances. Counseling in this case posed a dilemma since 17q12 duplication is known to have a variable phenotype and incomplete penetrance. The parents decided to continue with the pregnancy. The boy was born at term. Examination was normal except for microcephaly (HC< -2Sd). Prenatal microcephaly has not been previously described in 17q12 duplication syndrome. The clinical significance of this prenatal finding adds to the counseling dilemma.

2637M

Atypical 22q11.2 deletion at the distal end of the common 3Mb deletion. *N. Bhatia[1], T. Goldwaser[2], P. Reingold[2], S. Klugman[2], P. Levy[1], B. Morrow[3].* 1) Children's Hospital at Montefiore, Bronx, NY., USA; 2) Montefiore Medical Center, Bronx, NY, USA; 3) Albert Einstein College of Medicine, Bronx, NY, USA.

Background: 22q11.2 deletion syndrome is a contiguous gene deletion characterized by congenital heart disease, palatal defects, immunodeficiency, hypocalcemia, renal anomalies, developmental delay and facial dysmorphisms. Up to 64%; of individuals with 22q11.2 deletion syndrome exhibit psychiatric disorders, including bipolar disorder and schizophrenia, with wide phenotypic variability. Deletions in the 22q11.2 region usually include a common 3Mb deletion (~90%) or a proximally nested 1.5Mb deletion (~7%). Other atypical deletions include distally nested deletions and deletions distinct from the 3Mb region. The 3Mb and 1.5Mb deletions both include the *TBX1* gene, associated with the congenital heart disease seen in this syndrome.

Case: A 20-week primigravid was referred to our prenatal genetics department for counseling after the fetus was noted to have a Dandy-Walker variant on 16 week anatomy scan. The proband was the product of a nonconsanguineous union between a 23 year old mother and 37 year old father. The mother has a history of bipolar disorder, ADD, OCD, and developmental delay, diagnosed in adolescence. Amniocentesis was performed and arrayCGH revealed a 0.369Mb maternally-inherited deletion in chromosome 22, specifically, arr [hg19] 22q11.21 (21081260-21449911) x 1 mat. At birth, FISH with cosmid probes Tuple1 and N25 were normal. Brain MRI noted a minimally prominent cisterna magna. The proband presented to our pediatric genetics department at 13 months of age. Physical exam was normal and the child was developmentally appropriate with no medical issues. Postnatal arrayCGH confirmed the prenatal finding. Simultaneously, the mother presented to our prenatal department for her second pregnancy, desiring an amniocentesis after anatomy scan revealed a polycystic kidney. This fetus was also found to carry the same familial 22q11.2 deletion, and the mother is currently in her third trimester of pregnancy.

Discussion: This case presents an atypical deletion of the 22q11.2 region, with notable phenotypic features of 22q11.2 deletion syndrome - namely, psychiatric issues as well as velopharyngeal insufficiency and craniofacial dysmorphisms. Further study will aid in an improved genotype-phenotype correlation and enhance our understanding of distal deletions of the 22q11.2 region.

2638T

A novel microdeletion affecting *SNRPN* but preserving distal gene expression leads to Prader-Willi Syndrome. *T. Diallo[1], R. Begay[1], D. Slavov[1], S.L. Graw[1], T. Boyle[2], M.R.G. Taylor[1], P.R. Baker II[3].* 1) Adult Medical Genetics Clinic, University of Colorado Denver - Anschutz Medical Campus, Aurora, CO., United States; 2) Departments of Medicine and Pathology, University of Colorado Denver - Anschutz Medical Campus, Aurora, CO., United States; 3) Clinical Genetics and Metabolism, The Children's Hospital, Denver, CO., United States.

Background: Prader-Willi Syndrome (PWS) is an imprinting disorder characterized by initial neonatal hypotonia, feeding problems, and failure-to-thrive, followed by hyperphagia, obesity, and developmental delay. The most common causes of PWS are 5-7 Mb class I or II deletions of paternally expressed genes at the 15q11.2 locus. Atypical microdeletions have implicated various genes as critical for the development of pathology and continue to shed light on our incomplete understanding of PWS. **Methods and Results:** A 23 year-old woman with typical features of Prader-Willi Syndrome was evaluated clinically. As a neonate she was severely hypotonic with early feeding problems and failure-to-thrive. By 8 years of age her parents noted lack of satiety, obesity, and food hoarding. She exhibited delayed puberty, mild developmental delay, unique behavioral characteristics, and her IQ was considered to be low-normal. Her overall PWS clinical score was 13 (based on Holm et al. 2002 criteria). Methylation analysis, classic PWS FISH, and clinical *SNRPN* expression studies were normal, but oligoarray studies revealed a microdeletion of up to 132 kb. SNP homozygosity analysis narrowed the deletion to approximately 70 kb between intron 2 and intron 4 of *SNRPN*, and to not extend into the *SNURF* transcript. RT-PCR analysis was compatible with loss of *SNRPN* and retention of *SNURF* transcripts. Importantly, the patient's deletion did not include the *SNORD116* cluster or the imprinting center, with preserved expression of transcripts distal to *SNRPN*. **Conclusion:** Rare cases of PWS with attenuated phenotypes have been associated with microdeletions in snoRNA clusters within the *SNRPN/SNURF* locus (Sahoo et al. 2008, DeSmyth et al., 2009; Duker et al. 2010). In these cases methylation testing and *SNRPN* expression testing were still diagnostic. Our proband, with a striking, albeit attenuated, clinical picture represents the first patient with a PWS phenotype and a microdeletion involving only a small part of *SNRPN* (exons 2&3) which tested falsely negative on methylation, FISH, and expression analysis. Because of the size and location of the deletion the use of oligoarray was invaluable in the diagnosis of this patient. Further, and more mechanistically important, we have demonstrated a PWS phenotype with preserved expression of the *HBII-85/SNORD116* snoRNA cluster, challenging the hypothesis that this is the only PWS critical region.

2639S

Overgrowth in association with 3q25 microdeletion. *K. Enomoto[1,2,3], N. Kurosawa[2], R. Satomi[1], Y. Sugawara[3], A. Watanabe[2], S. Watanabe[2], K. Kurosawa[4].* 1) Department of Pediatrics, JA Toride Medical Center, Toride, Ibaraki, Japan; 2) Department of Pediatrics, Tsuchiura Kyodo General Hospital, Tsuchiura, Ibaraki, Japan; 3) Department of Pediatrics and Developmental Biology, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 4) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan.

Prevalence of congenital disorders associated with overgrowth is not so much compared to what with growth failure. Generally speaking, the rare and specific physical features should sometimes reduce the difficulty with diagnosis in some unknown cases. However, the diagnosis in association with overgrowth is often difficult because of few of other distinctive symptoms or nothing but nonspecific or confusing dysmorphic faetures. It's not easy to detect disease-causing alterations of chromosome with traditional investigations such as karyotype, though some characteristic syndromes can be analyzed by using technic of molecular biology or genetics, e.g. fragile X syndrome, Beckwith-Wiedemann syndrome (BWS), and Simpson-Golabi-Behmel syndrome. We have limited cases showing overgrowth previously reported associated with chromosome anomalies, e.g. duplication in 4p, deletion in 5q35 (Sotos syndrome), duplication in 11p15 (BWS), duplication in 12p, 22q13 deletion syndrome, and Pallister-Killian syndrome (mosaic 12p tetrasomy). We herein present a new case of 3q25 microdeletion extending to 700kb involving *SHOX2* and some other genes identified by microarray CGH examination: arr 3q25.32(157,649,680-158,323,134)x1 (hg19). The patient who is 5-year-old boy at present was born at 38 weeks gestation. His birth weight, length, and head circumference were 3,828g (+2.89 SD), 53.0cm (+2.66SD), and 36.0cm (+2.25SD), respectively. He was transferred to our hospital in early newborn owing to his systemic angioma including facial invasion without hemihypertrophy or limb asymmetry. He had not been complicated by any other problems in newborn to early childhood. He exhibits obvious overgrowth especially in his postnatal weight and head circumference (macrocephaly), mild developmental delay, and facial dysmorphism. Facies is characterized by frontal bossing, downslanting palpebral fissures, bulbous nose, and mildly dysplastic external ears. Angioma is now getting thinner and fairly disappearing. Our investigation reveals that he has the smallest deletion range in the previously reported cases. As our observations delineate the phenotypic spectrum associated with a clearly defined deletion of chromosome 3q25, we suggest that the haploinsufficiency of the genes involving the deleted region contributes to the above mentioned some characteristic features, and this part of chromosome can be the almost critical lesion of 3q25 microdeletion syndrome.

2640M

Diamond-Blackfan anemia and intellectual disability: a new contiguous gene syndrome at 15q25.2. *M. Gorce[1], A. Guichet[1], A. Donzeau[2], A. Ziegler[1], M. Barth[1], I. Pellier[2], D. Bonneau[1], E. Colin[1].* 1) Department of Biochemistry and Genetics, CHU Angers, ANGERS, France; 2) Department of Pediatrics, CHU Angers, Angers, France.

15q25.2 microdeletion is an emergent CNV locus for intellectual disability, dysmorphic features and congenital anomalies. Two distinct microdeletions have been described at this locus: 1) a distal deletion (11 cases) responsible for neurodevelopmental and neuropsychiatric disorders and 2) a proximal deletion (8 cases) which is a susceptibility locus for cognitive deficit, diaphragmatic hernia and possibly Diamond-Blackfan anemia (DBA). This proximal deletion is said to predispose to DBA because it contains the gene RPS17 encoding for a ribosomal protein, responsible for 2% of DBA. Until now, however, DBA has been diagnosed with certainty in only one case of 15q25 proximal deletion. The additional case reported here had a history of intrauterine growth retardation. At age 18 months, he had a moderate developmental delay, dysmorphic features and musculoskeletal anomalies. He had a normochromic macrocytic aregenerative anemia with elevated erythrocyte adenosine deaminase activity and elevated HbF (3,2%) highly suggestive of DBA. A 15q25.2 microdeletion of 2.2Mb including RPS17 was identified using SNP array and the deletion of RPS17 was confirmed by FISH using a specific probe. The deletion was absent in patient's father and was impossible to test in mother. To date, only few mutations in RSP17 have been reported in patients with DBA. Anemia was mentioned in 4 cases among the 8 previous reported cases of 15q25.2 proximal deletion but the definite diagnosis of DBA was made in only 1 case. The present report confirms that patients with 15q25.2 deletion involving RSP17 are at risk for DBA and possibly DBA-associated malignancies.

2641T

Expanding the Phenotypic Profile of Kleefstra Syndrome: a Female with Near-Normal Intelligence and Developmental Dyspraxia. *D. Sisson[1], D.C. Gibbs[1], A.L. Gropman[2,3], C. Sprouse[2], T. Sadeghin[3], C. Samango-Sprouse[1,2,3,4].* 1) The Focus Foundation, Davidsonville, MD; 2) Children's National Medical Center, Washington, DC; 3) George Washington University School of Medicine, Washington, DC; 4) Neurodevelopmental Diagnostic Center for Young Children, Davidsonville, MD.

Kleefstra syndrome is a rare neurogenetic disorder most commonly caused by deletion in the 9q34.3 chromosomal region and is associated with intellectual disabilities, severe speech delay and behavioral problems. To our knowledge, this is the first patient with a 9q34.3 deletion that is not intellectual disabled but has a developmental disorder with overlapping features expanding the phenotypic profile and prognosis for patients with Kleefstra syndrome. The patient is a 6 year-old female whose neurodevelopmental and cognitive profile was assessed using the Beery-Buktenica Visual Motor Integration tests (Beery-VMI), the Expressive and Receptive One Word Picture Vocabulary Tests-Revised (EOWPVT-R/ROWPVT-R), Preschool Language Scale-4th Ed. (PLS-4), the Wechsler Intelligence scales (WPPSI-III) and the Social Responsiveness Scale (SRS-2). Verbal IQ was 81 and Global IQ was 94 on WPPSI-III. Beery subtests indicated severe visual motor deficits (0.08 percentile, VMI; 0.05 percentile, Visual Perception; 0.02 percentile, Motor Coordination). Receptive vocabulary (standard score=99, ROWPVT-R) was within normal range and significantly stronger than expressive vocabulary (standard score=82, EOWPVT-R). Auditory Comprehension and Expressive Communication were within normal limits for age but in the low-average range. SRS-2 indicated delays in social cognition (T-score=89) social communication (T-score=81) and autistic features (T-score>90) but the patient did not meet criteria for an Autism Spectrum Disorder. These results confirm the patient's previous diagnosis of developmental dyspraxia associated with motor planning deficits affecting her speech, oculomotor and graphomotor abilities for which the patient received early intervention services. These services may have contributed to the patient's above average speech and intellectual capabilities than previously reported cases with a 9q34.3 deletion, expanding the phenotypic profile associated with Kleefstra syndrome. Thus, dyspraxia should be considered in the diagnosis and prognosis of patients with a 9q34 deletion as this case-report suggests that targeted intervention therapies may significantly improve patients' cognitive outcome.

Craniofacial Dysmorphism And Mild Intellectual Disabilities In A Child With A Paternally Inherited 14q32.1 Deletion. *Y. Wang, J. Martinez.* Dept Pathology, Univ South Alabama, Mobile, AL. 600 Clinc dr. Mobile, AL 36688.

Deletions in chromosome 14q32 have been reported in association with intellectual disabilities and congenital anomalies. This is an imprinted genomic region with paternally and maternally expressed genes. We present a child with dysmorphic features and mild intellectual disabilities associated with a paternally inherited 14q32.1 chromosomal deletion. This is a 9 yr old white male seen in the Genetics clinic with history of developmental delay and unusual features. The child was born at term to the first pregnancy of a 20 yr old mother from a pregnancy complicated by oligohydramnios. Birth weight was 8 pound 6 ounces. Birth length was 20 and ¾ inches. He had no neonatal problems but he was later noted to have global developmental delay, feeding and sensory processing difficulties and speech abnormalities. He was attending school at the 3rd grade level within an I.E.P and he is having learning difficulties. He was also evaluated for constipation and GI studies revealed a "small colon". A rectal biopsy was negative for Hirschsprung disease. The family history is significant for the child's father who has similar craniofacial features but he does not have intellectual disabilities. Physical examination revealed an OFC of 51 cm (25th%); Height of 129.5 cm (25th%) and Weight of 28.6 Kg (50th%). He has craniofacial dysmorphism including a narrow bifrontal diameter, high nasal bridge, downslanted palpebral fissures, puffy cheeks, thick lips and a high and narrow palate. There is also increased joint laxity and skin elasticity. Otherwise the physical examination is negative. A CGH microarray revealed a paternally inherited 14q32.12q32.13 encompasses 1.3 Mb and thirteen genes including RPS6KA5, GPR68, CCDC88C, FBLN5, TRIP11, NDUFB1, CPSF2, SLC24A4, RIN3, LGMN, GOLGA5 and CHGA. The common phenotype of 14q32 deletion syndrome includes varying degrees of developmental delay or intellectual disabilities, speech and communication abnormalities and dysmorphic features. Our patient has similar clinical findings previously identified in individuals with deletions of chromosome 14q32.2. Furthermore, the chromosome 14q32 region harbors a cluster of imprinted genes. Deletions affecting this cluster could disrupt regulatory elements increasing the recurrence risk. Deletions of chromosome 14q32.1 region however have not been reported and in that context, our family offers are rare opportunity of understanding mechanisms that alters genetic expression in this region.

2643M

Clinical features and molecular characterization in a subject with an interstitial deletion of 2q24.2. *H. Yoshihashi[1], S. Ito[2], T. Kuchikata[1].* 1) Div Med Gen, Tolyo Metropolitan Childrn's Hos, Fuchu-shi, Japan; 2) Div Nursing, Tolyo Metropolitan Childrn's Hos, Fuchu-shi, Japan.

Microarray analysis has identified an interstitial deletion syndrome in 1q21, 9q22.3, 15q13.3, 15q24 and 16p11.2. A deletion of 2q24.2 is rarely reported cytogenic aberration in patients with developmental delay(DD)/intellactual disability(ID). However, there have been only a few reports describing characteristic findings on the basis of molecularly defined breakpoints. Here, we present clinical manifestations and review current reports of a deletion in 2q24.2. Subject: 7-year-old male. He was born at term after an uneventful pregnancy and postnatal period, except for low-birth-weight infant (2392g), mild hypotonia and VSD. He had moderate delay in psychomotor development with aging. Conventional chromosomal study showed normal male karyotype. At the age of 3 year old, he represented the facial dysmorphism, including a broad forehead, arched eyebrows, long eye lashes, up-turned nares, long philtrum, full lips, thick ear lobes and low hair line. Further genetic testing using array CGH (ISCA 180K manufactured by Agilent) revealed an interstitial deletion (approximately 6.5Mb) of 2q24.2. Parental analysis showed no clinically significant CNVs. The precise breakpoints were determined [arr2q24.1q24.2 (157,612,737-162,620,308)x1 dn]. Discussion: At least 10 patients with a deletion of 2q24.2 have been reported and partly delineated clinical features and breakpoints, but it may be difficult to be suggestive of this cytogenic aberration from dysmorphic features without microarray analysis. The deleted region in our subject encompassed 23 genes and the smallest overlapping region (SOR: approximately 1.8Mb) indicated by Yokoyama et al.(2014), which involved eight genes (LY75, PLA2R1, ITGB6, RBMS1, TANK, PSMD14, TBR1, SLC4A10). The haploinsufficiency of genes in SOR will be responsible for common phenotypic features, including low birth weight, DD/ID and hypotonia in most patients with a deletion of 2q24.2. TBR1 and SLC4A10, critical for early cortical development and regulation of the intracellular pH of neurons respectively, may have an influence on pathogenesis of psychomotor development. RMBS1 and PSMD14, associated with decreased cell proliferation and severe IUGR in animal models respectively, may be noteworthy as causative genes of growth failure. The clinical features and molecular characterization in our subject support that an interstitial deletion of 2q24.2 may cause an emerging deletion syndrome.

2644T

22Q11 DELETION SIZE IN CHILEAN PATIENTS AND ASSOCIATION WITH CLINICAL FEATURES. *G.M. Repetto[1,2], C. Vial[1], L. Leon[1], K. Espinoza[1], F. Benavides[1], M.L. Guzman[1], T. Guo[3].* 1) Center for Genetics and Genomics Clin Alemana- Univ Desarrollo, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Department of Genetics, Albert Einstein College of Medicine at Yeshiva University, New York, USA.

Three common deletion sizes have been reported in the majority of patients with chromosome 22q11 microdeletion syndrome (22q11DS): 3Mb in more than 90% of patients, 2Mb and 1.5 Mb in a smaller proportion. Their correlation with clinical phenotype is unclear, in part due to the limited number of patients with small deletions. We evaluated precise deletion size and location in a large group of Chilean patients with 22q11DS, correlated the findings with the presence of congenital heart disease (CHD) and palate anomalies (PA) and compared the results with similar data from the literature. We analyzed DNA samples from 218 individuals with Affymetrix v6.0 SNP array and with MLPA P250 DiGeorge probemix. There was concordance between the array and MLPA results. We found that 201 patients (92.2%) had a 3Mb deletion, 5 (2.2%) had a 2Mb deletion and 12 (5.5%) had a 1.5Mb deletion. In ten individuals, proximal regions PRODH to DGCR10 were found to be non-deleted by SNP array. These findings were not identified by MLPA, as expected by the probemix composition. When precise breakpoints were analyzed, we observed variation within the low copy repeats that flank the common breakpoints. The frequency of CHD was significantly higher in the individuals with the 3 Mb deletion in comparison with the 1.5 Mb deletion (58.9% vs 25%; p 0.045; OR 4,308, 95% CI 1.025-20.787). This difference was not observed for the presence of PA. We then aggregated our results with data from the literature that described deletion size and pertinent clinical data (Kurahashi et al 2007; Michaelovsky et al 2012). This resulted in information from 360 patients: 330 with 3Mb deletion, 9 with 2Mb and 21 with 1.5 Mb. We confirmed the association between the presence of CHD and the 3Mb deletion, compared with 1.5 Mb (p=0.005; OR 4.0, 95% CI 1.46-11.30). This large cohort of Chilean patients confirms that the large 3Mb deletion is the most common one in this syndrome, and that there is variation within the common breakpoints. Individuals with the 3Mb deletions had greater frequency of CHD compared with the ones with 1.5 Mb deletions, suggesting the existence of modifiers in the non-overlapping region in 22q11. The implications of the presence of both copies of the proximal region in a small group of patients need to be carefully evaluated, particularly given the apparent role of PRODH and proline metabolism in the psychiatric phenotype. Funded by Fondecyt-Chile grant #1130392.

Unknown CNVs found in 52 Bulgarian patients with intelectual disability and congenital malformations. *S.P. Hadjidekova[1], D. Avdjieva-Tzavella[1, 2], B. Rukova[1], R. Staneva[1], D. Nesheva[1], R. Tincheva[1], D. Toncheva[1].* 1) Department of Medical Genetics, Medical Faculty, Medical University- Sofia, Bulgaria; 2) State University Pediatrics Hospital "Prof. Ivan Mitev", Medical Faculty, Medical University- Sofia, Bulgaria.

Introduction: The evergrowing resolution of the DNA microarrays and the optimization of the technique allow detection of larger aberrations and a variety of small copy number variations (CNVs) whose clinical significance is unknown in some cases. Methods: We studied 52 patients with congenital anomalies and intellectual disability. Whole-genome oligo-array CGH was performed using the BlueGnome CytoChip oligo 2×105K microarray, v1.1. Results: We found a total of 247 CNVs, of which 15 pathogenic (7 deletions, 8 duplications), 124 benign (62 deletions, 62 duplications) and 108 with unknown clinical significance (68 deletions, 40 duplications). The unknown CNVs were detected among 34 patients with the following distribution in size : 52.7% less than 100Kb; 37% from 100 Kb to 500Kb; 9.2% from 500Kb to 1 Mb; 0.9% larger than 1Mb. We applied a specific algorithm in the interpretation of the unknown variants. Conclusion: The rates of unknown CNVs in our study were notably high: This indicates that some of these variations may be probably benign for the Bulgarian population and cannot be found in the studied other populations. It is speculated that the Bulgarians are characterized by high genetic heterogeneity. This demonstrates the obvious need for large population studies and mapping of variations in the Bulgarian population for enabling the precise interpretation of unknown CNVs in the clinical praxis. The protocol and informed consent documents were reviewed and approved by the local ethics committee and prepared according the Declaration of Helsinki and local country laws. 2646M

A rare case of speech sound disorder with a heterozygous BCL11A deletion. *A. Huang[1], B. Peter[1], . Center for Mendelian Genomics[2], Z. Brkanac[3], A. Stocco[4], M. Matsushita[5], J. Wolff[5], W. Raskind[3, 5].* 1) Speech & Hearing Science, Arizona State University, Tempe, AZ; 2) Genome Sciences, University of Washington, Seattle, WA; 3) Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA; 4) Psychology, University of Washington, Seattle, WA; 5) Medicine, University of Washington, Seattle, WA.

Speech sound disorder (SSD) interferes with a child's ability to acquire clearly intelligible speech. One proposed subtype is childhood apraxia of speech (CAS), thought to result from faulty programming of movement sequences for speech. CAS is often comorbid with reading disorder (RD), a disorder of written language. We recently described a child with CAS with a de novo heterozygous microdeletion of BCL11A and 100 kb of surrounding noncoding sequences. Speech and gross motor development showed evidence of poor motor programming and low muscle tone. In eight of ten previously reported cases with microdeletions in 2p15-p16.1, multiple genes including BCL11A were deleted; phenotypic involvement was more severe. BCL11A regulates fetal hemoglobin and is located in an RD candidate region; its role in speech, reading/spelling, and motor development is not yet well understood. A previous study reported 16 CNVs in 12 children with CAS but causality could not be established (Laffin et al., 2012); none of the reported CNVs involved BCL11A. We investigated the role of CNVs of BCL11A and other regions, including candidate regions for CAS and RD, in 9 individuals with CAS and 3 individuals with RD. One control individual had tongue thrust (TT), an SSD subtype unlikely to share biological etiologies with CAS or RD. Also included were three unaffected individuals, biologically related to two CAS participants, and two families with familial CAS, with 9 and 4 affected individuals, respectively. DNA was extracted from buffy coat. Genotyping was performed with 964 k SNP arrays. CNVs were analyzed with cnvHap and PennCNV algorithms. No participant had CNVs involving BCL11A. Overlaps with two CNVs in the Laffin et al. (2012) study were found to be common CNVs. Five participants (1 RD, 1 TT, 1 CAS, 2 controls) carried four copies of an identical region of the FOXP2 gene. Two participants (1 RD, 1 CAS) had a CNV in an identical region of CNTNAP2. There was no evidence that these CNVs segregated, however, and they are unlikely to be pathogenic. Two or more participants with CAS and RD shared 64 other CNVs. We conclude that BCL11A deletions are uncommon in CAS. In future studies, we will evaluate the coding and regulatory roles of this gene in RD and CAS and follow up on CNVs from the present study. - Genotyping and CNV analyses were provided by the University of Washington Center for Mendelian Genomics (1U54HG006493 to Drs. D. Nickerson, J. Shendure and M. Bamshad).

2647T

Congenital asplenia in a patient with chromosome 1p36 deletion. *L. Pisani[1], P. Zachariah[2], A. Gomez[2], J. Reiner[1], N. Cohen[1], L. Mehta[1].* 1) Dept. of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, NY; 2) Dept. of Pediatrics, Columbia University College of Physicians and Surgeons, NY.

Chromosome 1p36 deletion syndrome is a well-described microdeletion, with an incidence of about 1/5000 newborns. Common manifestations are typical facial features, intellectual disability, hypotonia, seizures, structural brain abnormalities, congenital heart defects, ocular anomalies and hypothyroidism. Immunodeficiency has not been previously associated with this syndrome. We report a 2-year-old girl who presented with a complex partial seizure in the setting of an acute febrile illness. She had a history of global developmental delay and was noted to have frontal bossing, open anterior fontanel, low set ears, flat nasal bridge, short palpebral fissures and overlapping 2nd-3rd toes bilaterally. Blood and CSF cultures at admission were positive for Streptococcus pneumoniae. The patient and her siblings had not received any immunizations due to religious reasons. Family history was negative for intellectual disability, consanguinity or birth defects. Microarray revealed the presence of a pathogenic 5.33 Mb deletion of chromosome 1p36.31-p36.33(736471-6070487, build hg18), including 112 genes and transcripts and overlapping the critical region for 1p36 deletion syndrome. The deletion was confirmed by FISH. In addition, a 91.6 kb duplication on chromosome Xp22.31(8557747-8658299) was noted, encompassing exon 2 of KAL1, considered likely benign. Testing of parents is pending. She received a 2-week course of Ceftriaxone but was then lost to follow up. Four months later, the patient was readmitted with new fever and lethargy. Blood culture was positive for Hemophilus influenzae with CSF analysis suggestive of meningitis. Her peripheral smear was notable for Howell-Jolly bodies and abdominal ultrasound showed a 2.5 cm structure at the site of the spleen. Echocardiogram was normal. She was discharged on amoxicillin prophylaxis after completing a course of Ceftriaxone with recommendations for catch-up vaccinations. This is the first report of congenital functional asplenia in 1p36 deletion. The deletion does not include any known genes implicated in heterotaxy, and is of a commonly reported size. Unmasking of a recessive allele could be considered as a potential mechanism, but no relevant genes could be identified in the deletion interval. This report highlights the presence of a rare birth defect in a relatively well characterized microdeletion syndrome.

2648S

De novo deletion of 5q23.2-q31.1 in a boy with global developmental delay, contractures and dysmorphic features: a contiguous gene deletion syndrome involving morphogenesis and DNA repair. *A. Guerin[1], R. Gatti[4], C. Brown[4], M.S. Meyn[2,3], M. Carter[2,3].* 1) Division of Medical Genetics, Department of Pediatrics, Kingston General Hospital, Kingston, Ontario, Canada; 2) Division of Clinical and Metabolic Genetics, Department of Pediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Program in Genetics and Genome Biology, SickKids Research Institute, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) UCLA School of Medicine Department of Pathology and Laboratory Medicine, Los Angeles California.

Contiguous gene deletion syndromes represent a diagnostic dilemma in interpreting complex phenotypes. Genes that are deleted can have important roles in morphogenesis, which can result in malformations, but genes with ongoing expression, which are essential for cell survival, can also be affected. We present a patient with a de novo 8.4 Mb deletion of 5q23.2-q31.1, a rare microdeletion syndrome. The patient presented with congenital contractures, dysmorphic features, symmetric growth retardation and global developmental delay. The deletion encompassed 12 OMIM genes, including FBN2, which is expressed in early morphogenesis. Deletions of FBN2 have been reported in patients with Beals syndrome (MIM 121050); this is likely the cause of our patient's congenital contractures; however, he did not have the other characteristic features (arachnodactyly, Marfanoid habitus). Our patient also had haploinsufficiency for the RAD50 gene, whose product is part of the MRN complex, required for repairing DNA damage. Complete RAD50 deficiency leads to a Nijmegen breakage syndrome-like disorder (#613078), characterized by microcephaly and growth retardation, "birdlike" facies and chromosome instability. Given the possibility of decreased production of key repair proteins, chromosome breakage and colony survival (radiosensitivity) assays were performed on a lymphoblast line. These studies were within normal limits. Western blot showed normal levels of ATM, NBS, and RAD50. Hetero- zygous missense variants in RAD50 may be low penetrance risk factors for breast cancer, so it remains uncertain if there is an impact of this deletion on future cancer risk. Contiguous gene deletion syndromes represent a challenge in providing counseling and anticipatory guidance regarding microarray findings, especially when genes responsible can have variable clinical phenotype, and are responsible for DNA repair.

2649M

A case with mild phenotype of holoprosencephaly is caused by de novo hemizygosity for chromosome 2q14.1-q14.3 involving GLI2 gene. *E. Kirtas[1], E. Kirat[1], A. Koparir[1], E. Guzel[1], E. Fenercioglu[1], M. Seven[1], H. Ulucan[1], M. Ozen[1,2], G. Guven[1].* 1) Istanbul University, Medical School of Cerrahpasa, Department of Medical Genetics, Istanbul, Turkey; 2) Department of Pathology & Immunology Baylor College of Medicine, Houston, TX, 77030, USA.

GLI2 is mediated as an activator by central transcriptional factor on SHH signaling although its precise role on SHH signaling remains unclear. Defects in this gene are associated with holoprosencephaly (HPE) with extremely variable phenotypic penetrance or HPE-like phenotype, abnormal pituitary gland formation and/or function, and polydactyly. Here we present a case with HPE-like phenotype having a 2q14.1-q14.3 deletion. The case was a female, born to healthy and 1.5 degree consanguineous parents, 28-year-old mother and 42-year-old father. She was delivered at term with a birth weight of 3040 g (25-50p) and birth length of 47 cm (10-25 p). She was referred to our department at the age of 2.5 years for mild neurodevelopment delay. Bilateral postaxial polydactyly, grade 3 vesicoureteral reflux, and recurrent infections were treated short after the birth. In physical examination, her weight was 13 kg (%50p) and her height was 90 cm (%50p) while head circumference was 46 cm (<3p). Urinary and sacral USG were within normal ranges while atrophy of parenchyma in left kidney with 99mTc-DMSA SPECT was detected. Cranial CT, MRI and elbow radiography showed no abnormality. Amino acid and metabolic screen were normal except from moderate high levels of lactate and ammonia. Chromosome analysis from the blood lymphocytes revealed 46,XX,ins del(2)(q14.2;q21)dn,inv(9)(p11q13)mat karyotype. Her mother's and father's karyotype were 46,XX,inv(9)(p11q13) and 46,XY, respectively, indicating maternal origin. A detailed analysis of the constitutional chromosomal changes in proband was defined by array comparative genomic hybridization (aCGH) revealed a 5.6 mb heterozygous deletion spanning from 2q14.1 to 2q14.3 has been found. This region involves whole GLI2, which is thought to be responsible for this mild form of HPE. Our results on GLI2 deletion in this case confirms phenotypic heterogeneity and mild form of HPE.

2650T

Severe fetal phenotype of a dominant mesomelic dysplasia, associated with a 790 kb microduplication of HOXD gene cluster at 2q31.1. *S. Odent[1, 7], C. Jeanne-Pasquier[2], P. Balouet[3], N. Leporrier[4], S. Jaillard[5], V. Jauffret[5,6], E. Cherot[1], M. Fradin[1], C. Quelin[1], L. Pasquier[1], V. David[6,7], C. Dubourg[6,7].* 1) Genetique Clinique, CHU de Rennes Hosp SUD, Rennes CDX 2, France; 2) Service d'Anatomie Pathologique, CHU de Caen, 14033 CAEN , France; 3) Service Maternite gynecologie, CH de Saint-Lo, 50009 saint-Lo, France; 4) Service de Genetique, CHU de Caen, 14033 CAEN , France; 5) Service de cytogenetique, CHU de Rennes, Hopital Pontchaillou, Rennes, France; 6) Service de genetique moleculaire et genomique, CHU de Rennes, Hopital Pontchaillou, Rennes, France; 7) CNRS UMR 6290, IGDR, Université Rennes1, France.

Mesomelic dysplasias are a very heterogeneous group of skeletal disorders. Among them, the 2q31.1 microduplication syndrome and Mesomelic Kantaputra dysplasia (MIM 156232) have been associated with microduplication of a cluster of HOXD genes. Phenotype of early fetal mesomelic dysplasia was essentially described in Langer mesomelic dysplasia (MIM 249700) caused by homozygous deletion or mutation of the SHOX gene or PAR1 region downstream of SHOX. We report here the very early fetal phenotype of a mesomelic dysplasia inherited from the father, who was followed since childhood for a growth retardation (-2.5 SD) with macrocephaly (+4 SD) , ulnar deviation of hands and club feet, a significant shortening of ulna and fibula, bowed forearms and legs, difficulties with flexion / extension of the fingers. At 11 weeks of gestation, ultrasound showed a cystic hygroma of 4.5 mm, a punctate appearance of the forearm's bones , shortening of the lower limbs, clubfeet, and an unilateral pleural effusion. A TOP was performed at 13 weeks of gestation. Mesomelic dysplasia was confirmed by fetal autopsy, X-rays, and a particular histological appearance (organization of chondrocytes in shortened columns, triangular densification at diaphyseal angulations). Fetal DNA analysis by array-CGH revealed a microduplication of a 790 Kb involving genes HOXD13, HOXD12, HOXD11, HOXD10, HOXD8, HOXD4, HOXD3, MTX2, which was confirmed by QMPSF. This microduplication was also identified in the father. Conclusion : the different phenotypes of mesomelic dysplasia with early prenatal expression are close, sometimes more severe than the phenotype of an affected parent; research of a genomic microrearrangement is indicated since it can reveal notably a deletion of the SHOX region in Xp22.33, or 2q31.1 microduplication encompassing the HOXD cluster.

2651S

Adaptive and Maladaptive Behavior, Profiles and Developmental Trajectories in Children with Subtelomeric Microdeletions. *G.S. Fisch, S. Yang.* Epidemiology & Health Promotion, New York University, New York, NY., USA.

Despite its importance to clinicians and pediatricians, there are relatively few studies currently which examine developmental trajectories or profiles of adaptive and maladaptive behavior in children with genetic disorders that produce intellectual disability (ID) and/or autism (ASD). Recently, we undertook to study children with subtelomeric deletions that produce ID and/or ASD. We recruited 47 children, 26 females, 21 males, diagnosed with Wolf-Hirschhorn Syndrome (WHS), or one of three other subtelomeric deletions (invdupdel8p23, 2q37 or 11q23-25 (Jacobsen syndrome; JBS). Mean age for the sample at T1 was 11.1 years (±4.4). Initially, we assessed their cognitive abilities, adaptive behavior (DQ) and maladaptive behavior using standardized instruments at Time 1 (T1). Two years later, at Time 2 (T2), we were able to retest 31 children. We compared adaptive and maladaptive scores at T1, but also compared adaptive and maladaptive difference scores from T1 to T2 for the entire group, and by genetic disorder, DQ score at T1 or maladaptive score at T1. Results show an inverse correlation between DQ score and maladaptive score, but it was not statistically significant. However, results from ANOVA indicate statistically significant test-retest differences in maladaptive scores among the four syndromes ($F=3.336$; $P=0.034$). Post-hoc analysis showed 2q37 and JBS maladaptive difference scores were statistically significantly different ($P=0.046$). Children with WHS were most severely impacted in cognitive and adaptive behavior, but with relatively lower maladaptive behavior scores which tend to improve as children age. Curiously, children with JBS have the highest mean IQ but the worst maladaptive behavior and adaptive behavior scores. We employed a general linear model to analyze maladaptive behavior and found maladaptive scores were significantly related to both genetic disorder and changes in IQ scores from T1 to T2 ($F=3.88$; $p< 0.01$). Aspects of maladaptive behavior, particularly as they relate to attention deficits and hyperactivity are currently being analyzed and will be discussed.

2652M

Mosaic 15q11-q13 maternal duplication without Autism. *N. Urraca[1], E. Pivnick[2], K. McVicar[2], R. Thibert[3], S. Parisotto[4], H. Pedro[4], L.T. Reiter[1,2].* 1) Neurology, UTHSC, Memphis, TN; 2) Pediatrics, UTHSC, Memphis, TN; 3) Neurology, Mass General Hospital, Boston, MA; 4) Genetics, UMC, Hackensack, NJ.

Most individuals with an interstitial 15q duplication share common deletion breakpoints with Prader-Willi/Angelman Syndrome (PWS/AS) and are the result of the reciprocal non-allelic homologous recombination (NAHR) events that forms the PWS/AS deletions. Because the 15q11-q13 region has a cluster of genes preferentially expressed from one parental allele, there is also a parent of origin effect for the duplication as well as the deletion. Maternally inherited 15q duplications are generally fully penetrant for Autism Spectrum Disorder (ASD) while paternal cases have incomplete penetrance for ASD and other features including sleep disorders. In most cases the duplication is de novo; however, there are few informative familial cases that will help us better understand the genes contributing to the ASD phenotype. The majority of duplications found in this region are maternal in origin, most likely due to the presence of ASD. We report two families with maternal inherited 15q duplications: family 1 with a Class II duplication and family 2 with a Class I duplication. Interestingly, in both families the mothers have a maternally derived duplication with no apparent ASD phenotype as would be expected in maternal duplication cases. However, the offspring with the duplication met criteria for ASD by ADOS/ADI-R testing. In family 1, the mother had learning disabilities and ADHD as a child, while the mother in the second family had school/learning issues as well. The Broad Autism Phenotype Questionnaire (BAPQ) and the Social Responsiveness Scale-Adult Research Version (SRS) did not reveal an ASD phenotype in the mother in family 1 and will be completed in the second mother. Fluorescence In Situ Hybridization in peripheral blood lymphocytes and skin fibroblasts showed mosaic 15q duplication for the first mother. Cases of paternal inherited int dup(15) have been reported with no obvious autism phenotype, but the child who inherits this same duplication maternally has ASD. The two families we will present came to our attention because of their affected offspring. We were surprised to find a maternal duplication in the mothers as well, but the mosaic status of this duplication in blood and skin may explain the absence of ASD. These two families confirmed our previous finding of ASD being fully penetrant in maternal 15q duplication cases and indicates that in any maternal case with no ASD phenotype a mosaic status needs to be ruled out.

2653T

Prevalence of "Y" chromosome microdeletions in infertile males of Gujarat Population, India. *T.A. Patel[1], H. Pandya[1], H. Bavishi[2], M.V. Rao[1].* 1) Gujarat Genetic Diagnostic Center (GenDiCe), Department of Zoology, University School of Sciences, Gujarat University, Ahmedabad-09, Gujarat, India; 2) Bavishi Fertility Institute, Near Adani CNG Station, Opp Municipal Garden, Ahmedabad-07, Gujarat, India.

"Y" chromosome microdeletions are the leading genetic cause of male infertility. Hence, the purpose of present study is to screen various "Y" chromosomal STS markers in infertile male patients. The blood samples were collected from infertile male patients (n=41). DNA was isolated by standard protocol and various Y chromosomal STS markers were analyzed. In our study 41 cases, attending the clinic, considered to have infertility were analyzed for semen, hormonal and microdeletion profiles along with other socioeconomic factors including previous history. These data showed 3 out of 41 (8%) showed deletions at Y chromosome level (AZF regions) leading to infertility in relation to other factors. In the remaining patients (38) in our study the causes for infertility depend on other factors like hormonal imbalance etc. The data revealed that microdeletion is also one of the causes for inducing sterility in the male in addition to others. Thus, 8% in this western population, it may be contributory for infertility, although such infertility caused ranges 10-15% in other regions of India. In conclusion, Y chromosomal microdeletions play an important role in male infertility, where our region constitutes 8% within our samples analyzed.

2654S

A microdeletion encompassing only three genes within the Potocki-Shaffer syndrome interval at 11p11.2 associated with intellectual disability and craniofacial anomalies. *J.D.J LABONNE[1], J. Vogt[2], L.C Layman[1], HG. Kim[1].* 1) Department of Obstetrics & Gynecology, Institute of Molecular Medicine and Genetics, Georgia Regents University, Augusta, GA 30912, USA; 2) West Midlands Regional Clinical Genetics Service, Birmingham Women's Hospital, Birmingham, UK, B15 2TG.

Potocki-Shaffer syndrome (PSS) characterized by intellectual disability (ID), craniofacial anomalies (CFA), biparietal foramina, and multiple exostoses is a rare contiguous gene disorder caused by a minimal 2.1 Mb deletion at 11p11.2. EXT2 and ALX4 have been shown to be causative for multiple exostoses and parietal foramina, respectively. Haploinsufficiency of PHF21A was the underlying mechanism of ID and CFA in PSS since affected individuals with balanced translocations and deletions showed a reduction of PHF21A protein level. Furthermore, knock-down of PHF21A in zebrafish resulted in CFA and neuronal apoptosis. The death of neurons is a likely cause of ID in patients. We report a 5-year old boy with ID and CFA with a deletion including PHF21A, providing corroborating evidence for a role of PHF21A in these specific phenotypes. BlueGnome 8x60K ISCA design oligonucleotide microarray revealed a heterozygous deletion of at least 173 kb (chr11:45,936,954-46,110,572 / hg19) at 11p11.2 in this patient. This deletion region encompassing only three genes (PEX16, GYLTL1B and PHF21A) is likely to be the smallest with the phenotypes of ID and CFA, when confirmed. The proximal breakpoint of this deletion lies within intron 2 upstream of the last 5'-UTR segment of PHF21A based on the coordinates of the minimal deletion. This suggests that no truncated PHF21A protein can be produced by the heterozygous microdeletion, although the exact boundary of the deletion will be defined by quantitative PCR (qPCR). The affected individual displays CFA including a broad forehead with a slightly prominent ridge in the centre, mild underdeveloped cheekbones, a flat nasal bridge, a small mouth with a thin upper lip, and glued large ears rotated backwards. He also possesses tapering fingers with clinodactyly and his feet display webbing between the second and third toes. He has a small penis with some surrounding dark hairs and palpable testes. He also has difficulties interacting with other children, and prefers adult company. Because of his ID and clinical features, he has been enrolled in a special needs school. qPCR confirmed the microarray result. RT-qPCR and western blot with the anti-PHF21A antibody displayed that PHF21A transcript and protein levels are reduced approximately by one half in this deletion patient. Reduced expression levels of PHF21A indicates that this gene is responsible for the phenotypes of ID and CFA seen in this deletion patient.

2655M

Recurrent microdeletion 12p13 in maternal half-siblings suggestive of gonadal mosaicism. *A.F. Elias, C. Hudson, K. Berry, C. Schwanke, T. Schwalbe, S. Philips, D. Xu.* Medical Genetics, Shodair Children's Hospital, Helena, MT., Select a Country.

Microdeletion 12p13 involving the terminal deletion of variable segments of the short arm of chromosome 12 represents one of the least common subtelomeric rearrangements resulting in a very rare, yet increasingly recognized cause for cognitive impairment. The condition is associated with a variable phenotype including language delay, a specific speech impairment described as childhood apraxia of speech (CAS), developmental delay and intellectual disability (ID) as well as neurobehavioral problems. Other features observed in 12p13 deletions include microcephaly, mild craniofacial dysmorphism, generalized muscular hypotonia, and joint laxity. To our knowledge, germline mosaicism has not been reported for this microdeletion syndrome. Here, we report the presence of a microdeletion 12p13.33p13.32 in two half-siblings who have the same mother and different fathers. Both probands have neurodevelopmental and neurobehavioral manifestations. The 8 year-old girl presents with global developmental delay, CAS, microcephaly and mild dysmorphism, as well as pectus carinatum. Her 18-year-old maternal half-brother was diagnosed with autism at age 5 and has a pectus excavatum deformity. Chromosomal microarray in both probands revealed a 3.9 Mb terminal deletion of the short arm of chromosome 12 (12p13.33p13.32), confirmed by Fluorescent in situ hybridization (FISH) analysis in both cases. Their mother, who is asymptomatic, would be predicted to be an obligate carrier of this deletion. However, FISH analysis of maternal blood lymphocytes and skin fibroblasts did not reveal a deletion or any other rearrangement. Extended analysis of additional interphase nuclei from maternal lymphocytes also was not supportive of possible mosaic deletion in the mother's blood lymphocytes. These results are suggestive of maternal gonadal mosaicism for the familial 12p13 deletion. To our knowledge this observation is the first documentation of germline mosaicism for terminal 12p deletion syndrome. Additional studies in maternal buccal cells as well as studies in blood lymphocytes from other sibs are under way. The implications for estimating recurrence risk and genetic counseling are discussed.

2656T

Chromosome microarray analysis in patients with cleft lip/ cleft palate. *P. Eydoux[1], F. Kozak[2], L. Ogilvie[2], J. Pauwels[2], B. Tsang[1], L. Brown[1].* 1) Dept Pathology, Children's & Women's Hosp, Vancouver, BC, Canada; 2) Dept Pediatrics Children's & Women's Hosp, Vancouver, BC, Canada.

Orofacial clefts are one of the most common malformations among newborns, affecting approximately one in 500 to one in 1000 births. Due to their detrimental effects on physical and psychological well being, a comprehensive approach is required for the management of these children. Both genetic and environmental factors have been associated with the occurrence of cleft lip with or without cleft palate (CLP), occurring in 1-2 in 1000 births. Its highest incidence is found in Asian and First Nations Peoples followed by those of European and African descent, showing involvement of genetic factors. Although little is known about the molecular mechanisms resulting in CLP, copy number variants (CNVs) have long been recognized as associated with CLP in visible chromosome abnormalities or infra-microscopic CNVs. To characterize the etiology of CLP, we conducted a study on 35 consented patients with CLP, considered to be non-syndromic. Patients under two year of age (16 females and 18 males) were tested with chromosome microarray analysis (CMA) using a high-density microarray (Cytoscan HD, Affymetrix). The data was analysed using the Affymetrix software ChAS; interpretation was conducted visually and using software allowing bioinformatics search of the RefSeq, UCSC and OMIM databases. A search was conducted in RefSeq and OMIM with the key-words "cleft lip" or "cleft palate"; in addition, the UCSC database table gwasCatalog was searched with the same key words. We identified pathogenic CNVs in two patients, within regions related to known syndromes: one patient had a 3.67Mb Smith Magenis Syndrome microdeletion at 17p11.2, and another patient had a 2.3Mb microdeletion at 17p13.3, not encompassing the YWHAE gene. In our patients, we did not identify any copy number containing genes or GWAS regions related to CLP in the OMIM, RefSeq and UCSC databases. In addition, regions of homozygosity were unremarkable. Our data does not support involvement of small CNVs in the causation of CLP. In young children with CLP, CMA should be performed to rule out a microrearrangement which may indicate a more complex developmental disorder.

2657S

Xq27.3-q28 duplication syndrome: a new consideration in the differential diagnosis of Prader-Willi syndrome. *M.R. Garcia, M.J.H. Willis.* Pediatrics, Naval Medical Center San Diego, San Diego, CA.

The purpose of this abstract is to present a family with Xq27.3-q28 duplication syndrome, compare their findings to those of previously reported cases, and provide further delineation of this syndrome that has strong phenotypic overlap with Prader-Willi syndrome. Patient 1, is a 7 year-old male who was born at term after an uncomplicated pregnancy. Development first became a concern to the family when he was not able to sit independently at 1 year of age. He continued to have delays in motor and language milestones. At 3 years of age etiologic evaluation were initiated. Chromosomal micro-array identified duplication of Xq27.3-q28. Diagnosis at presentation to our clinic comprised; mild cognitive disability, strabismus, excessive hunger, obstructive sleep apnea, and hypogonadism. His physical exam is significant for short stature, truncal obesity, synophrys, bulbous nasal tip, small scrotum, cryptorchidism, and hypotonia. Patient 2, maternal cousin of Patient 1, is an 11 year old male identified independently to have the same duplication. His medical problems and exam findings are congruent with Patient 1's with the addition of fatty liver and Chiari malformation. In addition to microarray he has had a muscle biopsy and urine glycosaminoglycans which were normal. The mothers of both patients, as well as a third sister, all carry the dupXq27.3-q28. This is the third family reported with Xq27.3-q28 interstitial duplication. The patients described here show significant phenotypic overlap with cases of dupXq27.3-28 described in the literature with keys features of hypotonia, gross motor delay, mild intellectual disability, hypogonadism, short stature and obesity. Deficiency of a number of genes in the duplicated region is associated with human disease; FMR1, IDS, MAMLD1, MTM1 and VMA21. FMR1 duplications have also been associated with intellectual disability. Other genes in this area are likely also dosage sensitive. Xq27.3-q28 interstitial duplication causes an X-linked recessive syndrome with a remarkably consistent phenotype, has very strong overlap with Prader-Willi syndrome (hypotonia, cognitive disabilities, short stature, obesity/polyphagia) and should be considered in the differential for that syndrome. Any patient with phenotypic findings suggestive of Prader-Willi who has negative methylation testing, or who has family history suggestive of x-linked inheritance, should have testing for copy number variants in this region of chromosome X.

2658M

Behavioral, Biochemical and Anthropometric Characteristics of patients with PWS. *H. El-Bassyouni[1], E. M. Salah[2], S. Kholoussi[3], M. Shehab[4], W. Kandeel[5].* 1) Clinical Genetics Department, National Research Centre, Cairo, Egypt; 2) Child Health Department, National Research Centre, Cairo, Egypt; 3) Immunogenetics Department, National Research Centre, Cairo, Egypt; 4) Cytogenetic Department, National Research Centre, Cairo, Egypt; 5) Biological Anthropology Department, National Research Centre, Cairo, Egypt.

Background: Prader-Willi syndrome (PWS) is a genetic disorder characterized by a recognizable pattern of physical findings with significant cognitive, neurologic, endocrine, and behavioral abnormalities. Objective: To study behavioral, cognitive, hormonal and anthropometric characteristics of children with Prader-Willi syndrome (PWS) compared with an age-and gender-matched control group. Subjects and methods: A case- control study of thirteen children and adolescents with PWS (mean age 7.69±4.44 years), and 14 age-and sex- matched non-PWS controls were enrolled. Measurement of anthropometric parameters and body fat percentage (BF %), screening of children's psychosocial dysfunction, assessment of intellectual function and estimation of plasma adiponectin and leptin levels were carried out in all studied subjects. Specific questionnaire for assessment of the behavioral phenotype of PWS was fulfilled by parents. Results: PWS subjects had significantly higher BF%, adiponectin and leptin levels compared to controls (38.84±9.66 vs. 20.26±3.92, P< 0.01; 38.61±13.43ng/ml vs. 24.32±6.04ng/ml, P<0.01;10.39±7.74ng/ml vs. 4±0.71 ng/ml, P< 0.01 respectively). The majority of PWS subjects (84.6%) (11/13) had mild to moderate mental retardation. The most commonly registered behavior problems in PWS subjects were hyperphagia and cognitive rigidity. Inattention was reported in 76.9% (10/13) of PWS vs. 25% (3/14) of the controls. Conclusion: PWS subjects have substantial behavioral problems which are not associated with the degree of hyperphagia or intellectual disability. The distinct body fat distribution in PWS subjects is associated with significantly higher levels of adiponectin and leptin than their lean controls. The primary focus on management of PWS should be placed on weight control and behavior modification.

2659T

A new chromosomal rearrangement resulting in Axenfeld-Rieger syndrome. *L. El Khattabi[1], I. BenAyed[1], C. Ioos[2], L. Perrin[3], D. Le Tessier[1], JM. Dupont[1], A. Lebbar[1].* 1) Laboratoire de Cytogénétique, APHP, Hôpitaux universitaires Paris Centre site Cochin, Paris, France; 2) Unité fonctionnelle de Médecine Physique et Réadaptation de l'enfant, Hôpitaux Universitaires Paris Ouest site Raymond Poincaré, Garches, France; 3) Unité fonctionnelle de Génétique Clinique, CHU Robert Debré, Paris, France.

Axenfeld-Rieger syndrome (ARS) is a developmental disorder that associates eye abnormalities and multiple congenital malformations. An abnormal migration of neural crest cells results in dysgenesis of the anterior segment of the eye. Other manifestations are mild dysmorphic features, dental, cardiac and umbilical anomalies. ARS is inherited in an autosomal dominant manner with high penetrance of *FOXC1* and *PITX2* mutations. However, over 50% of cases remain of unknown cause. Herein, we report a case of ARS associated with epilepsy in a two year-old boy. Clinical examination found some dysmorphic features and growth delay. Ophthalmologic examination revealed a bilateral corectopia, iris hypoplasia and a bilateral embryotoxon, consistent with ARS eye disorders. Whole genome microarray analysis using Nimblegen 135K array showed a 4.55 Mb *de novo* deletion on 4q25q26 bands (nt 112,009,675 to nt 116,558,399 bp - hg18). The deleted region encompasses 9 OMIM genes and its proximal boundary is located 230 Kb upstream of *PITX2*. *In silico* investigation identified the presence of regulatory sequences of *PITX2* in this region. PCR analysis confirmed the deletion of these sequences. Further studies are carried out to assess the disruption of *PITX2* expression. This report of ARS resulting from deletion of *PITX2* gene cis-regulatory elements sequences suggests that analysis of *PITX2* upstream region could be helpful for ARS patients without *PITX2* or *FOXC2* mutations.

Fetal Skeletal Dysplasias in a Tertiary Care Centre: Radiology, Pathology, and Molecular Analysis of 112 cases. *D. Chitayat[1, 2], E. Barkova[3], U. Mohan[4], S. Keating[5], A. Toi[6], J. Frank[1], R. Frank[1], G. Tomlinson[7], P. Glanc[8].* 1) Mount Sinai Hospital, Department of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, University of Toronto, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Division of Clinical and Metabolic Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Medical Imaging, South Shore Regional Hospital, Bridgewater, NS, Canada; 4) Department of Obstetrics and Gynecology, University of Calgary, Calgary, AB, Canada; 5) Mount Sinai Hospital, Department of Laboratory Medicine and Pathobiology -Perinatal Pathology; 6) Mount Sinai Hospital, Department of Diagnostic Imaging; 7) University of Toronto, Institute of Health Policy, Management & Evaluation; 8) Sunnybrook Health Sciences Centre, Department of Medical Imaging.

Fetal skeletal dysplasias are a heterogeneous group of rare genetic disorders, affecting approximately 2.4-4.5/10,000 births. We performed a retrospective review of the perinatal autopsies conducted between the years 2002-2011. The study population consisted of fetuses diagnosed with skeletal dysplasia with subsequent termination, stillbirth and live-born who died shortly after birth. Of the 2,002 autopsies performed, 112 (5.6%) were diagnosed with skeletal dysplasia. These 112 cases encompassed 17 of the 40 groups of Nosology 2010. The two most common nosology groups were osteogenesis imperfecta [27/112 (24%)] and the FGFR3 chondrodysplasias [27/112 (24%)]. The most common specific diagnoses were thanatophoric dysplasia (TD) type 1 [20(17.9%)], and osteogenesis imperfecta type 2 [20 (17.9%)]. The combined radiology, pathology, and genetics investigations and grouping the cases using Nosology 2010 resulted in a specific diagnosis in 96/112 of the cases.

2661M

Rare case of combination osteogenesis imperfecta and genetic skin disease. *N.M. Marycheva[1], J.Y. Kotalevskaya[2].* 1) Sechenov First Moscow State Medical University, Moscow, Russian Federation; 2) MV Vladimirsky Moscow Regional Research Clinical Institute, Moscow.

Osteogenesis imperfecta (OI) is a clinically and genetically heterogeneous disease characterized by fragility of bones and other short stature. OI XI type is a rare form of this disease, which is inherited in an autosomal recessive manner; mutations are described in the *FKBP10* gene. Epidermolysis bullosa (EB) is a group of inherited diseases of the skin manifested in formation of bubbles on the skin because of mechanical trauma. Mutations of simple type of EB are frequently identified in genes of keratin 5 and 14 (*KRT5*, *KRT14*). Here is a description of the case of the combination of OI type XI and simple type of EB. The proband is a 4 years old girl from the 4th pregnancy (in medical history previously was pregnancy with a girl with inherited EB). Clinical manifestations of EB appeared on the 2nd day and OI was diagnosed at the age of 1 month. She was admitted to the orphanage with a diagnosis of OI (fracture of the left humerus and of the right radius, multiple rib fractures in the medical history), the left hip dysplasia, EB of the simple type. Repeated cases of spontaneous fractures during the observation period happened. Examination: weight -12 kg, height - 99 cm, can't sit by her own, can't walk. Light blue sclera. Swarthy skin, multiple foci of de-and hyperpigmentation, blisters on the skin of the hands, elbow bends were observed. Feet hyperkeratosis. Pigeon breast, thighs saber deformity, scoliosis, flat feet, hypermobility of joints of the hands, limitation of movement in the hip and knee joints, muscular hypotonia. There were no other singularities in other systems. Analysis of the literature showed that there was one case of combination of OI type XI and simple type of EB, where were identified homozygous mutations in *FKBP10* and *KRT14* genes. We conducted the ArrayCGH to confirm the assumption of the similarity of our case with the previously described one and to narrow the candidate genes list for further genetic diagnosis. Results: stretches of homozygosity > 3,000,000 bp were identified in the proband. This value exceeds the population level10 times that may indicate kinship parents. One of the longest stretches of homozygosity located on the long arm of chromosome 17, where the genes *FKBP10* and *KRT14* are located. This result indirectly confirms our hypothesis about the possible mutations in the homozygous state in the genes responsible for the development of OI and BE. Sequencing of these genes in work.

2662T

INCONTINENTIA PIGMENTI: A Case Report Associated With Cleft Lip Palate in a Patient at Smile Operation Foundation, Bogotá - Colombia. *m. montiel, l. briceno, j. Martinez, A. Patino, J. Rincon.* medicine, universidad de la sabana, chia, Colombia.

Introduction Incontinentia pigmenti is a neuroectodermal disease, with an autosomal X-linked transmission, also known as Bloch Sulzberger syndrome (1). Epidemiology The Bloch syndrome is a genetic disease X -linked dominant inheritance, with a reported incidence of 1 case per 50,000 live births (3). Genetics They are two types of the disease: the sporadic and genetic IP. The gene involved in the development of IP1 is located in Xp11 chromosome (4). On the other hand, mutations that occur in the NEMO gene (essential modulator of nuclear factor Kb) located on chromosome Xq28 , is responsible for IP2 , with a dominant X -linked inheritance (4). Histology There are four stages of the disease, which are usually sequential. The inflammatory or vesicular phase. (5). Hypertrophic phase, (4). The third stage is known as hyperpigmentation phase (4). Finally, the atrophic phase has hypopigmetation atrophy or areas that tend to appear from adolescence to adulthood (4). Clinic About 80 % of the population with the disease have extracutaneous features of organs derived from neuroectoderm and neural crest in which the most common are dental, ophthalmological and neurological manifestations (3). There are cases of patients with cleft lip and minor manifestations of the disease. The main cutaneous manifestations reported are alopecia, pigmentary and nail changes (4). Case Report This case is about a 5 years old boy which presents a clinical manifestations of the disease like cleft palate, hypopigmented lesions on the abdomen and thorax associated with strabism, dental abnormalities, and alopecia. The case was diagnosticated at Operation Smile Foundation in 2011. Fig 1. The child presents hypomelanosis of Ito in the back Fig 2. The abdomen has hypomelanosis of Ito Fig 3. Associated cleft palate, dental abnormalities and alopecia. Diagnosis For the diagnosis of incontinentia pigmenti, there are some criteria simplified by Landy et al . (6) , but the management is based on an accurate physical examination which must be addressed to the search for skin disorders which are present in all patients, dental (absence of deciduous or permanent teeth, delayed in the eruption, deformations and conical crowns and hook) teeth, and eye CNS disorders (7). When the physician has the clinical suspicion, the histopathology analysis of the lesions is the method that identifies the type of injury and the stage at which the disease is found (7).

2663S

***MuSK* - a new target for lethal fetal akinesia deformation sequence (FADS).** *M. Wilbe[1], S. Ekvall[1], K. Eurenius[2], K. Ericson[1], A. Ameur[1], G. Annerén[1], M-L. Bondeson[1].* 1) Immunology, Genetics and Pathology, IGP, Uppsala, Uppsala, Sweden; 2) Department of Women's and Children's Health, Uppsala University, Uppsala, Sweden.

Fetal akinesia is clinically and genetically heterogeneous disorders, with the common feature defined as reduced or loss of fetal movement. Several disease genes of fetal akinesia have been described. This includes genes involved in motor neuron development and survival, encoding components of the neuromuscular junction (NMJ), adult skeletal muscle proteins and fetal myostructural proteins. However, the genetic etiology of majority of cases with fetal akinesia is still unknown.

We report on a family with recurrent fetal loss, where the parents had five affected fetuses with fetal akinesia deformation sequence (FADS [MIM 208150]) and one healthy child. The fetuses displayed no fetal movements from the gestational age of 17 weeks, extended knee joints, flexed hips and elbows and clenched hands. There was polyhydramnion and no visible fetal stomach.

Whole exome sequencing (WES) of one affected fetus and the parents were performed. A recessive inheritance model was assumed and data was filtered against dbSNP, ANNOVAR and ~900 exomes in our in-house database. Only one candidate homozygous variant was identified in the fetus, c.40dupA (p.Thr14Asnfs*9), located in the first exon of *MuSK* (muscle, skeletal, receptor tyrosine kinase). The variant was verified using Sanger sequencing. Segregation analysis in the family revealed homozygosity for all affected fetuses, while the variant was not present in the healthy child. The c.40dupA variant leads to a frameshift in MuSK predicting a premature stop codon and likely removal of the resulting mRNA via nonsense-mediated decay pathway, causing the FADS phenotype. Haplotype analysis showed that the mutation most likely represents a founder-mutation.

MuSK is an agrin-dependent receptor tyrosine kinase required for formation of the neuromuscular junction and missense mutations in this gene have previously been described in congenital myasthenic syndrome (CMS). Interestingly, MuSK is located in the same acetylcholine receptor pathway as several other genes reported to cause CMS and/or FADS (*CHRNA1*, *CHRND*, *CHRNG*, *RAPSN*, *DOK7*, *CNTN1* and *SYNE1*). To our knowledge, this is the first time *MuSK* is reported to the spectrum of FADS and we propose that *MuSK* should be included in genetic analysis and prenatal screening for FADS.

DIAGNOSIS, PLANNING AND EDUCATIONAL EVALUATION IN GENETICS AS INTERACTIVE MATERIAL, WITH STUDENTS FROM A MEDICAL ODONTOLOGICAL UNIVERSITY AND MULTIDISCIPLINARY EVALUATION AT A PEDIATRIC HOSPITAL. turner, klinefelter, criduchat, down, Duchenne, Mucopolysacharidossis, Muscular dystrophy. *R. Aparicio[1,2], A. Torres Velandia[2,3].* 1) Medical Estomatology, Benemerita Universidad de Puebla; 2) Centro de Estudios e Investigación para el Desarrollo Docente AC, Guadalajara Jalisco; 3) Pedagogic Adviser, ICE-UAEM, México.

A Genetic Disorder is caused by abnormalities in genes or chromosomes. While some diseases, are caused by environmental factors. A great variety of Genetic and Disorders were studied in the Department of Genetics with Medical Students, such as; Cornelia de Lange, Dextrocardia, Kabuki, Duchenne Muscular Dystrophy, Achondroplasia, Albinismo, Osteogenesis Imperfecta, Neurofibromatosis, Down, Criduchat, Turner, Klinefelter, Marfan, Fetal Alcohol, Moebius, Ectodermic dysplasia, Goldenhar and Epiolia. As an reference, a study was performed in this hospital in a 20 years period of time, 6480 Karyotypes , Iontoforesis and metabolic studies (MS) among others have been done, in order to obtain a diagnosis, for a better treatment where the Medical Students learned in a more directly manner. A total of 2370 metabolic studies were performed and 102 clinical cases were associated to different inborn errors of metabolism (IEM). It was then analyzed both Teacher and students the great responsibility we have by learning that some diseases can be due to metabolic error for a protein or enzyme absence. It was important that the Students understood that ADN mutation exists, in relation to chromosome aberration, since a great variety of mutation in the patients were observed similar as Down, Turner and Klinefelter among others were evaluated to understad its pathogenesis in the Hospital. Medical Education policymakers need to seriously rethink many of the decisions that we are taking to promote educational change by changing some Paradigms, not only in this country but along the world. We believe that the project contributes to a change in university teaching health-related to directly assess patients with genetic or congenital abnormalities involved in this study. The porpoise of these knowledge strategies are to offer a better education for medical students to obtain an ability for earlier multidisciplinary medical evaluation for genetic diagnosis, and provide then better medical and therapeutic treatment. This study is performed as part of the academic program of Postdoctoral 2014 ;Diagnosis, assessment and educational planning; title given by the Centre for studies in research for teacher development (CENID). we considered important that both Teacher and Student have the ability to understand how important is the patient and his family that need us, in order to provide a better quality of life, for the different kind of patients according to their genetic disease.

2665T

Duplication of approximately 320 kb in the chromosomal region 7p15.1 in a girl with Peho-like phenotype, and in her normal father. *M. Giovannucci Uzielli[1, 5], G. Scarselli[2], M. Fichera[3], L. Castiglia[4], S. Baffini[5].* 1) Scienze della Salute, University of Florence, Florence (Italy); 2) Dept. of Paediatric Neurology, University of Florence (Italy); 3) Dept. of Medical Genetics, University of Catania (Italy); 4) Lab. Genetics Diagnosis, OASI Maria SS., Troina (Italy); 5) Genetic Science, Piazza Fra G. Savonarola, 11 Florence (Italy).

The increasing use of molecular tools in the diagnostic work-up of patients with syndromic and non-syndromic intellectual disabilities, is detecting the base of a growing number of birth defects. We report on a patient with a complex abnormal phenotype, characterized by congenital, peripheral, and persistent oedema, multiple anomalies, and profound mental retardation. The clinical data collected at birth and after a 24 years follow-up gave us the opportunity to well observe the specific aspects of her phenotype and natural history, suggesting the diagnosis of Peho syndrome (or better, Peho-like syndrome), a rare progressive infantile encephalopathy. So far, no candidate genes, no gene's location, no specific biochemical test to confirm the clinical diagnosis are reported in the literature for this rare disorder. Array-comparative genomic hybridization, using Human Genome CGH 60k Oligo Microarray kit (AMADID 21924, Agilent Technology) with Median of the spatial resolution 41.5 kb, showed an interstitial duplication of approximately 320 kb, in the chromosomal region 7p15.1 in both our patient and her normal father. This region encompasses the two genes CPVL and CHN2, also known as chimerin 2, a member of the chimerin family. Vitellogenic-like, CPVL is a carboxypeptidase, whose function has not yet been determined. Normal the molecular study in the mother. Conventional karyotype of the patient and both parents was also normal. The pathological meaning of this duplication is not therefore clear. Recently a similar duplication was included in the data base of Troina: unfortunately the description of the clinical phenotype observed in this patient is limited to "global difficulties".

2666S

An interstitial microdeletion of 4q21 in a girl with pituitary insufficiency associated with empty sella, epilepsy, severe growth impairment, and profound intellectual disability. *E. Nishi[1,2], K. Wakui[2], M. Arakawa[1], S. Hirabayashi[3], Y. Fukushima[2], T. Kosho[1,2].* 1) Dept Genetics, Nagano Children's Hosp, Azumino City, Nagano, Japan; 2) Dept Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Dept Pediatric Neurology, Nagano Children's Hospital, Azumino, Japan.

Microdeletion 4q21 syndrome (OMIM#613509) is characterized by severe intellectual disability, lack of speech, hypotonia, significant growth restriction, and distinctive facial features. The deletion sizes varied from 2.0 to 15.1 Mb, and the common features have been associated with a 1.37 Mb minimal critical region including five known genes: *PRKG2, RASGEF1B, HNRNPD, HNRPDL,* and *ENOPH1* [Mitchell et al., 1981; Nowaczyk et al., 1997; Harada et al., 2002; Friedman et al., 2006; Bonnet et al., 2010; Dukes-Rimsky et al., 2011; Lipska BS et al., 2011; Tsang E et al., 2012; Bhoj et al. 2013] . We report a girl with a de novo interstitial microdeletion of 4q21, who showed pituitary insufficiency associated with empty sella, epilepsy, severe growth impairment, and profound intellectual disability. The patient was the first child of a healthy 26 -year-old mother and a healthy 30-year-old non-consanguineous father. She was born by caesarean-section at 38 weeks and 6 days of gestation. Her birth weight was 2206g (-2SD), length was 43.4cm (-2.4 SD), and OFC was 32.8cm (-0.07 SD). She showed hypotonia and severe developmental delay. She raised her head at the age of 9 months, and walked unsupported in a wide gait at the age of 6 years. She also spoke no words, and profound intellectual disability. Brain MRI showed thinning of pituitary gland with empty sella. At the age of 10 years, she had severe growth impairment with the weight as 20.55kg (-1.8SD), the height as 112.3cm (-3.8SD), and the OFC as 49.1 cm (-2SD). She was found to have growth hormone deficiency and hypoplastic pituitary gland with empty sella, and growth hormone replacement therapy was started. G-banded karyotype was 46,XX, inv(12)(p12.3q13.3)mat. Microarray analysis (135K Oligo, Roche) revealed a de novo 2.16 Mb microdeletion at 4q21 [arr[hg18] 4q21.22q21.23(29,297,619-30,447,117)x1 dn]. The deleted segment encompassed 15 OMIM genes (*HNRNPD, HNRPDL, SCD5, SEC31A, THAP9, LIN54, PLAC8, COQ2, HPSE, HELQ, MRPS18C, FAM175A, and AGPAT9*), which shared only two genes (HNRNPD and HNRPDL) with the previously reported minimal critical region of microdeletion 4q21 syndrome. *HNRNPD* and *HNRPDL* might be the most contributing genes for cardinal features of microdeletion 4q21 syndrome comprising severe growth impairment, severe developmental delay with hypotonia, distinctive facial features, and profound intellectual disability with lack of speech.

2667M

The phenotypic variability of split hand and split foot malformation. *T. Yokoi[1,3], C. Hatano[1], T. Saito[2], J. Nagai[2], Y. Enomoto[1], K. Kurosawa[1], H. Ida[3].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Department of Clinical Laboratory, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, The Jikei University School of Medicine, Tokyo, Japan.

Split-hand/foot malformations (SHFM) are a heterogeneous group of malformations, in which the hand and/or foot findings may occur in isolation or with other anomalies. There are five subtypes due to loci of chromosome in SHFM to date. SHFM occurs either sporadically or in families. There are autosomal inheritance and X-linked inheritance. In addition to each subtype's character, each patients has phenotypic variability. Here we report two different types of SHFM cases. Case1 is a-3-year-old-boy who has bilateral split hand showing a deep central cleft and bilateral split foot without any other anomalies and symptoms. His mother is also the patient of SHFM and has the similar features like her son. Case 2 is a-5-year-old-boy who has bilateral split hand showing a deep central cleft and bilateral split foot with developmental delay, sensorineural hearing loss and microtia. He has no families with any anomaly. Micro array analysis showed 430kb duplication of 10q24.21q24.32 including *SHFM3* in case1 and 400kb deletion of 7q21.3 including *DLX6* and *DLX5* in case2. These cases indicate the necessity to treat carefully SHFM patients and their families due to their phenotypic and genetic variability. Array Comparative Genomic Hybridization (array CGH) analysis can be considered as a method of choice for fast and accurate detection of unbalanced structural and numerical chromosomal abnormalities such as SHFM.

Clinical Implementation of Chromosome Microarray Analysis in Singapore. *H. Law[1], M. Brett[2], M. Yong[3], H. Yon[3], R. Roch[1], M. Tan[3], H. Ee[1], E. Tan[2], B. Cham[1], J. Lim[1], E. Tan[1], I. Ng[1], S. Jamuar[1], A. Lai[1].* 1) Paediatric Medicine, KK Women's & Children's Hospital, Singapore; 2) KK Research Centre, KK Women's & Children's Hospital, Singapore; 3) Department of Pathology and Laboratory Medicine, KK Women's and Children's Hospital, Singapore.

Background: Chromosome microarray analysis (CMA) is recommended as the first-tier genetic test for children with intellectual disabilities, development delay, autism spectrum disorder and/or multiple congenital anomalies. Although CMA is routinely available in USA, our lab only recently started offering it as a clinical test. Method: From May 2013 to May 2014, 100 patients were screened using the Agilent 4x180K CGH+SNP array. The indications for testing included developmental delay, intellectual disability, autism spectrum disorder and/or multiple congenital anomalies. Results: Copy number variants (CNVs) ranging in size from 10kb to 36.4 Mb were found in 38 patients (38%). Pathogenic and likely pathogenic CNVs were found in 18 (18%) patients. These included 14 deletions, 3 duplications and a patient with both a deletion and a duplication. Recurrent microdeletion and microduplication syndromes including the 1p36 microdeletion (2), Williams syndrome (2), Cat Eye syndrome, Cri du Chat syndrome, Miller Diecker syndrome, 3q29 microdeletion, 15q24 microdeletion, and 1q43q44 syndrome were detected in our patients. CNVs of uncertain clinical significance were detected in 20 (20%) individuals: 11 were duplications and 9 were deletions. However, as Singapore is a self-payer health care system, parental testing could not be performed in all 20 cases and hence, significance of these variants could not be established conclusively. Conclusion: CMA is a powerful tool in identifying pathogenic chromosomal copy number alterations. However, in countries with self-payer health care systems like Singapore, cost plays an important role in successful implementation of a diagnostic clinical test. In addition, more data relating to the local population needs to be collected to enhance interpretation of the CMA results.

2669S

Natural history and clinical management of patients with ASXL1 mutations and Bohring-Opitz Syndrome, including the first report of Wilms Tumor in two patients. *B. Russell[1], N. Kramer[2], L. Biesecker[3], J. Johnston[3], W. Rhead[4], A. Pickart[4], A. Dobson[5], L. Clarkson[5], J. Graham[2].* 1) Medical Genetics, Cincinnati Children's Hospital and Medical Center, Cincinnati, OH; 2) Medical Genetics Institute, Cedars Sinai Medical Center, Dept of Pediatrics, Harbor-UCLA Medical Center, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) National Human Genome Research Institute, National Institute of Health, Bethesda, MD; 4) Section of Medical Genetics, Children's Hospital of Wisconsin, Milwaukee, WI; 5) Greenwood Genetic Center, Columbia, SC.

Introduction: Bohring-Opitz syndrome is a rare genetic condition (35 reported cases) characterized by distinct facial features (glabellar nevus flammeus, wide spaced eyes, depressed and wide nasal bridge, anteverted nares, palatal anomalies, micrognathia, low-set posteriorly angulated ears), typical posture (elbow flexion with ulnar deviation and flexion of the wrists and metacarpophalangeal joints), variable microcephaly, severe intellectual disability, hypertrichosis, and feeding problems. Nine published patients with Bohring-Opitz syndrome have been identified as having a mutation in *ASXL1*. We report natural history and clinical management of five previously unpublished patients with mutations in *ASXL1*. Natural History: The 5 patients we discuss range from 2-12 years of age with complicated medical histories that included feeding issues, cyclic vomiting, respiratory infections, insomnia and Wilms tumor. Severity of illness improved with age after the first 1-2 years of life. Dysmorphic features such as nevus flammeus also faded with age. Severe myopia was present in all patients. They also had distinctive personalities (interactive, happy, and curious), and excessive hair growth which were features not described in the literature. Clinical Management: Permanent feeding tubes due to gastric dysmotility, silent aspiration, chronic emesis and poor weight gain were required in 4 of the 5 patients. Two patients had cyclic vomiting that was managed with cyproheptadine, lorazapam, ondansetron and acetaminophen. Recurrent respiratory infections with components of reactive airway disease occurred in 3 patients and 1 patient required a tracheostomy. Insomnia was a significant challenge for 4 of the patients, 2 of which improved with treatment of their severe anemia and 3 patients had obstructive sleep apnea that improved with CPAP or mandibular distraction. With the occurrence of bilateral Wilms tumor in one of the patients, screening renal ultrasounds were recommended to the other patients. This led to the identification and treatment of bilateral Wilms tumor in a second patient. Given the known association between *ASXL1* and myeloid malignancies along with the two patients presented here, consideration of Wilms tumor screening in patients with *ASXL1* mutations will be discussed.

2670M

Clinical and epidemiological study of orofacial clefts. *S. RASKIN, J. SOUZA.* Group for Advanced Molecular Investigation (NIMA), Graduate Program in Health Sciences, School of Medicine, Pontifícia Universidade Católica do Paraná (PUCPR), Curitiba, Paraná, Brazil.

Cleft lip with or without cleft palate (CL±P) or cleft palate (CP) are groups of malformations named orofacial clefts (OC), which are the second leading cause of birth defects. This study aimed to analyze clinical and epidemiological features of Brazilian patients with OC, studying cases treated in the reference center of the state of Paraná (PR). Methods 2,356 charts were reviewed and 1,838 were evaluated by the same clinical geneticist. Data were collected in the reference center, and compared with those of the Health Department of the state of Paraná. Clinical characteristics, presence of other anomalies, and birth prevalence were evaluated. 389 (21.2%) patients had CP, 437 (23.8%) had cleft lip (CL), and 1,012 (55%) had cleft lip and palate (CLP). Syndromic OC were identified in 15.3% of patients, 10.4% of patients with CL±P, and 33.9% of patients with CP. Common additional anomalies were: central nervous system, limbs, cardiovascular, and musculoskeletal defects. The number of syndromic cases was lower when clinical evaluation was performed by other medical specialists when compared to that of the clinical geneticist. Birth prevalence was 1/1,010 live births. Lack of notification with the national birth registry was observed in 49.9% of CL±P. The present data suggests a decrease of 18.52% in the prevalence of non-syndromic OC after folic acid fortification in Brazil. Conclusion Better understanding of clinical and epidemiological aspects of OC is crucial to improve the understanding of pathogenesis, promote preventive strategies, and guide clinical care, including the presence of clinical geneticists in the multidisciplinary team for OC treatment.

2671T

Lateral Meningocele (Lehman) Syndrome: A Rare Connective Tissue Disorder Craniofacial Dysmorphism. *M. Carter[1], S. Blaser[2].* 1) Pediatrics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Diagnostic Imaging, The Hospital for Sick Children, Toronto, ON, Canada.

Multiple lateral meningoceles are a rare anomaly. Lehman et al. (1977) first described a mother and daughter with similar craniofacial dysmorphisms, skeletal sclerosis, and multiple meningoceles. Subsequently, eight more cases have been described (Philip et al., 1995; Gripp et al., 1997; Chen et al., 2005 and Correia-Sa et al., 2013). The causative gene for Lehman syndrome is not yet known. The patient described in this abstract is a two-year-old boy with Lehman syndrome, born to a non-consanguineous Caucasian couple. Prenatally, a complex cardiac malformation was diagnosed (tubular hypoplasia of the aortic arch with coarctation, large ventricular septal defect, hypoplastic aortic valve, and bilateral superior vena cavae). MRI of brain showed middle cranial fossa encephaloceles and Chiari I malformation, with cerebellar tonsils extending to the posterior arch of C2. After discharge at 2 months of age, parents noted bilateral flank swelling. An ultrasound of the abdomen showed lateral lumbar meningoceles displacing the kidneys and causing the "swelling" due to deficient posterior wall musculature. Spine MRI showed enlarged spinal canal, and bilateral extensive lateral neural foramina meningoceles. The baby was discharged with NG tube in situ for feeding, and eventually required gastrostomy due to dysphagia. He was diagnosed with moderate bilateral conductive hearing impairment; hearing aids were prescribed. He has left amblyopia. Cardiac status has been stable. Dysmorphic features include left posterior plagiocephaly and tall cranial vault, sparse hair, hypoplastic supraorbital ridges, epicanthus, hypertelorism, ptosis, downslanted palpebral fissures, midface hypoplasia, small nares, long philtrum and thin upper vermillion, highly arched palate, bifid uvula, short upper lingual frenulum, asymmetric low set ears with short canals, significant microretrognathia, and bilateral single palmar creases. Neurological exam is significant for paucity of facial movement and diffuse hypotonia and joint hypermobility. Development at 13 months of age was significantly delayed. We present a child with Lehman syndrome, and review the cases reported to date. International collaboration will be useful for discovery of the gene(s) responsible for this complex condition.

2672S

A CHARGE syndrome-like phenotype in a patient with *EP300* splicing mutation. *S. Mizuno[1], Y. Tsurusaki[4], Y. Muramatsu[1], K. Maruyama[2], N. Niimi[3], K. Iio[3], N. Matsumoto[4].* 1) Dept Clinical Genetics, Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Dept Pediatric Neurology, Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 3) Dept Pediatric Surgery, Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 4) Department of Human Genetics, Yokohama City Graduate School of Medicine.

We report here the case of a female child with multiple congenital abnormalities and intellectual disabilities(MCA/ID) and growth retardation whose dysmorphic features and anomalies overlap those observed in CHARGE syndrome. In this patient we identified a de novo EP300 splice mutation by whole exome sequencing. The patient was the firstborn of nonconsanguineous parents(37-year-old father and 32 year-old mother). She was born at 37 weeks gestation by caesarian section because of polyhydramnios. Her birth weight and length were 2,350 g (- 1.4 SD) and 41 cm (-3.5 SD), and her occipitofrontal circumference was 32.5 cm (-0.5 SD). She was noted to have a congenital heart disease, esophageal hiatal hernia, small cleft palate, choanal stenosis, deformed earlobes, and congenital hydronephrosis at birth. She underwent several surgical procedures for correction of a large ventricle septal defect and third degree vesicoureteral reflex. At three years of age, she showed severe growth retardation, complete deafness, swallowing problems which required gastrostomy, strabismus, and scoliosis. Her facial features included a square outline, sparse hair, long eyelashes and severely malformed earlobe. She had moderate to severe intellectual impairment with developmental quotient score of 35 at 3 years of age. Although she showed hyperactive behavior, she enjoyed communicating with others. Because the combination of her malformations fulfilled the criteria of CHARGE syndrome, *CHD7* sequencing was performed. However no mutation was detected. Furthermore, microarray analysis did not reveal any pathogenic copy number variation either. By whole exome sequencing, we identified a de novo *EP300* splice mutation c.3671+5G>C in intron 20, which led to exon skipping. This mutation is considered to be responsible for the phenotype observed in this patient. *EP300* is known as the second gene to cause Rubinstein-Taybi Syndrome(RTS), but previous reports showed that only three percent of patients with RTS were found to have an EP300 mutation. The full phenotypic effects of *EP300* mutation remain unclear. Our patient displayed a number of complex anomalies, as well as growth and developmental retardation, which meet the CHARGE syndrome criteria. The only RTS associated phenotypes were curry eyelashes and marginally flat thumb tip. This suggests that , as well as RTS, mutation in *EP300* can lead to MCA/ID with diverse and broader phenotypic effects.

2673M

Detection of *GPC3* gene deletion by chromosomal microarray analysis in a patient with uncharacteristic Simpson- Golabi- Behmel syndrome. *A. Pietrzyk[1], K. Piotrowski[1], H. Chojnacka[2], M. Dera[1], M.B. Czeszynska[3], S. Zajaczek[1].* 1) Cytogenetic Unit, Department of Pathology, Pomeranian Medical University, Szczecin, zachodniopomorskie, Poland; 2) Department of Pediatric Surgery, Pomeranian Medical University, Szczecin, zachodniopomorskie, Poland; 3) Department of Neonatology, Pomeranian Medical University, Szczecin, zachodniopomorskie, Poland.

Introduction: Simpson- Golabi- Behmel syndrome (SGBS, OMIM 312870) is a rare X-linked overgrowth syndrome caused by loss-of function mutations or deletions in glypican- 3 gene *(GPC 3)*. Mapped at Xq26 it encodes a cell-surface heparan sulphate proteoglycan which has been indicated as a major factor in morphogenesis and modulator of cellular response to growth factors. The main clinical findings include: overgrowth, organomegaly, macroglossia, distinctive dysmorphic features, cardiac defects, renal and skeletal abnormalities as well as increased risk of embryonal cancers.

Case report: A four-year-old boy presented for genetic evaluation of dysmorphic features, development delay, and complex heart defect. Prematurity (with its complications), epilepsy, hypothyroidism were remarkable in his medical history. Neonatal cranial ultrasound revealed abnormal image of anterior horns of lateral ventricles. He required regular care of pediatric cardiologist due to pulmonary stenosis and ventricular septal defect. Upon clinical evaluation: trigonocephaly, “coarse” face, hypertelorism, macroglossia, supernumerary nipples, hypotonia, hepatomegaly, hypospadias and cryptorchidism were noted, which belong to SGBS spectrum. Neither prenor post-natal macrosomia as well as neoplasias were observed. Additionally, our patient suffered from mild optic atrophia since neonatal period and developed severe hyperopia. Parents: 25-year-old mother and 29-year-old father were healthy and family history was negative for congenital disorders.

Patient’s karyotype was determined as: 46, XY, inv (Y)(q11qter). Microarray analysis detected interstitial deletion of chromosome Xq.26.2 (395.74-444.63 kb, coordinates according to HG19: 132570975-132966712) containing critical region for SGBS and *GPC3* gene. Further tests showed that mother of our patient was a carrier of aforementioned microaberration.

Conclusion: Clinical manifestation of our patient closely resembles SGBS phenotype but some typical features were not present. Also, other symptoms that we observed couldn’t be found in the available data of similar cases. Confirmed genetic diagnosis has a great significance when a preventive therapeutic measures are possible as well as for a relevant genetic counselling in X-linked disorders considering its implications for reproduction.

2674T

A further case of ESCOBAR syndrome : Definition of novel mutation in CHRNG gene. *i. tekin[1], t. atik[2], h. onay[1], a. aykut[1], o. cogulu[2], f. ozkinay[2].* 1) Department of Medical Genetics, Faculty of Medicine, University of Ege, Izmir, Turkey; 2) Deparment of Pediatric Genetics, Faculty of Medicine, University of Ege, Izmir, Turkey.

Escobar syndrome (ES) is a rare autosomal recessive disorder which is also defined ‘nonlethal form of multipl ptergium syndromes’. ES is characterized by ptozis, low set ears, multiple ptergia, congenital contractures , arachnodactyly, short stature, scoliosis and cryptorchidism. Nonlethal Escobar variant is caused by homozygous or compound heterozygous mutations in CHRNG gene. Here we present a case who was considered to have Escobar syndrome with clinical features subsequent molecular analysis of her CHRNG gene showed a novel missense mutation. An 8-year old female patient born from a consanguineous marriage was referred to pediatric genetics subdivision because of dysmorphological findings recognised at birth. Her height was 113cm(3-10p), weight 22kg(10-25p), head circumference 50cm(<2p). She had downslanting palpebral fissures, hypertelorism, epicantal folds, high arched palate and multipl pterygia of limbs, flexion contractures and bilateral hypoplastic labia majora. DNA analysis revealed a homozygous novel p.P506S mutation in CHRNG gene. It was found a deteriorating mutation in silico analysis. This is the first Escobar case whose molecular analysis has been performed in Turkey.

De novo heterozygous deletion involving NFIX in a Japanese subject with severe intellectual disability, postnatal growth delay and relative macrocephaly. *D.T. Uehara[1], S. Hayashi[1], S. Mizuno[2], J. Inazawa[1].* 1) Department of Molecular Cytogenetics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 2) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Kasugai, Japan.

Intellectual disability (ID) is a genetically heterogeneous condition affecting 1-3% of the population, often associated with other clinical findings broadly referred to as multiple congenital anomalies (MCA). Among the genetic causes of MCA/ID, submicroscopic copy number variants (CNVs) are estimated to contribute to 15-20% of the cases. However, the etiology remains largely unknown in most cases. In order to identify pathogenic CNVs in Japanese subjects presenting with MCA/ID of unknown etiology, we have screened 646 cases using multiple microarrays for nine years. Here we describe one case, a female patient with a 394 kb de novo deletion at 19p13.2 involving NFIX gene (OMIM *164005), detected by SNP arrays. Clinical features include severe ID, hypotonia, small intestinal atresia, low stature (-3.5 SD) and weight (-2.5 SD) along with a relative macrocephaly (-0.7 SD) at the age of seven years old, although her birth size was normal. NFIX belongs to the nuclear factor one (NFI) family, which encodes four transcription factors essential for normal development. Previous reports have identified NFIX heterozygous deletions and point mutations in a few patients whose common features were ID, overgrowth and macrocephaly. A subset of those reports were described in patients with Sotos-like or Marshall-Smith syndromes, two overgrowth disorders characterized by advanced bone age, and in the latter case, skeletal anomalies. Our patient is the first description of haploinsufficiency of NFIX associated with postnatal growth delay. A possible explanation for that could come from two Nfix mouse models with marked differences in phenotypes: in one model, Nfix deficiency produced brain malformation and severe skeletal defects, while the other one primarily showed defects in brain development. Therefore, this present case might help clarify the actual role of NFIX in development. Nevertheless, the contribution of the other genes (LYL1, TRMT1, NACC1, ST×10, IER2 and CACNA1) encompassed by the rearrangement cannot be discarded, as well as other variants elsewhere.

Facial dysmorphism, skeletal abnormalities and central nervous system abnormalities in two sibs born to a consanguineous couple: A new autosomal recessive condition. *L. Chad[1, 2], M. Thompson[3], I. Miron[1], P. Shannon[3], S. Keating[3], D. Chitayat[1, 2].* 1) Department of Obstetrics and Gynecology, The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 2) Department of Pediatrics, Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada.

We report two female fetuses born to a consanguineous Sri-Lankan couple with facial dysmorphism, central nervous system and skeletal abnormalities. To our best knowledge this is a hitherto new autosomal recessive condition. The fetuses, both female, presented with thickened nuchal folds, echogenic bowel and kidneys, rocker-bottom feet, ventriculomegaly and intrauterine growth restriction. Detailed autopsies following termination of pregnancy at 23.4 and 22.3 weeks gestation respectively revealed short sloped forehead and hypertelorism with webbing of the neck, hydrocephalus with aqueduct stenosis as well as marked narrowing of the spinal canal and platyspondyly with delayed ossification and flattened acetabular roofs, broad hands with brachydactyly and narrow wrists. Microarray analysis was normal on both. These findings likely represent a new genetic syndrome with most probably autosomal recessive mode of inheritance. Whole genome sequencing is being done to try and identify the causative gene.

Paraspinal neurofibromas in LEOPARD syndrome. *E. Conboy[1], R. Dhamija[2], D. Babovic-Vuksanovic[2].* 1) Department of Pediatric and Adolescent Medicine, Mayo Clinic, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN.

LEOPARD Syndrome (LS) is an autosomal dominant disorder characterized by lentigines, EKG abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, growth retardation and deafness. There is significant clinical overlap between LS and other disorders that result from dysregulated Ras/mitogen-activated protein kinase (MAPK) pathway, including Neurofibromatosis type 1 (NF1) Noonan syndrome, Costello syndrome, Legius syndrome and cardio-facio-cutaneous syndrome. Except for NF1, other RASopathies are not known to be associated with development of neurogenic tumors. We describe two unrelated adult patients with clinical diagnosis of LS and massive paraspinal neurofibromas (dumbbell neurofibromas). Both patients were initially evaluated for NF1, but on the clinical exam they had lentigines, ocular hypertelorism, hearing loss, and positive family history lentigines. One of patients was found to have a heterozygous mutation (T468M) in the PTPN11. Dumbbell neurofibromas are an unusual complication of LEOPARD syndrome and may be an under-recognized manifestation of this disorder. We suggest surveillance for internal neurofibromas in patients with LS, since the risk for development of malignant peripheral sheet tumors in these patients may be increased.

Transcriptional hallmarks of Neurofibromatosis type I in whole blood cells. *G. Picco[1,2], F. Natacci[3], E. Trisolini[4], D. Cantarella[1], C. Cesaretti[3], G. Melloni[3], E. Riberi[5], F. Dutto[5], M. Cirillo Silengo[5], S. Vannelli[5], E. Medico[1,2], G.B. Ferrero[5].* 1) Department of Oncology, University of Torino, Torino, Italy; 2) Candiolo Cancer Institute, FPO IRCCS, Candiolo, Italy; 3) Medical Genetics Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milano, Italy; 4) Department of Medical Science, University of Torino, Torino , Italy; 5) Department of Pediatrics, University of Torino, Torino, Italy.

Neurofibromatosis type 1 (NF1), an inherited neurocutaneous disease that has a major impact on the nervous system, eye, skin, and bone, is one the most common congenital non-chromosomal disorders affecting development and growth (1 in 3000 live births). This complex disorder is characterized by an extremely variable clinical presentation and Individuals with NF1 have a predisposition to benign and malignant tumor formation. Aggressive neoplasms as malignant peripheral nerve sheath tumors (MPNST) and juvenile myelomonocytic leukemia (JMML) can be observed in a significant fraction of patients. NF1 is caused by a wide spectrum of mutations affecting the NF1 gene, resulting in loss of function of the gene product neurofibromin, a negative regulator of Ras. These mutations reduce inhibitory activity of the protein, promoting Ras/MAPK pathway signaling, which regulates cell proliferation and differentiation by ultimately controlling gene expression. To investigate the transcriptional consequences of the aberrant activation of the RAS signaling driven by NF1 molecular lesions, we performed Global mRNA Expression Profiling (GEP) in human blood cells, a target tissue of the syndrome. In details, we analyzed 43 samples from molecularly defined NF1 patients and 17 additional samples collected from age- and sex-matched controls. Total RNA extracted from whole blood (PAXgene RNA collection tubes) was processed for expression profiling on Illumina Beadarrays. Subsequently, GEP analysis allowed the identification of a transcriptional signature composed by approximately 100 genes differentially expressed between NF1 cases and control samples. Interestingly, the gene expression patterns highlight a subset of genes subdividing NF1 samples in distinct subgroups. This evidences suggest that the transcriptome of NF1 patients presents clear elements of heterogeneity, possibly reflecting the clinical variability typical of this syndrome. These data establish peripheral blood expression profiling as a powerful tool to appreciate perturbations driven by germline mutations affecting the NF1 gene.

Fibrodysplasia ossificans progressiva (FOP): A case report. *I.M. Salazar-Dávalos[1], M.A. Aceves-Aceves[1], G. Pérez-García[2], M.I. Ornelas-Arana[2], D. García-Cruz[1,3], S.A. Alonso-Barragán[3], N.O. Dávalos[3], M. Salazar-Páramo[4], I.P. Dávalos[1,3].* 1) Instituto de Genética Humana, DGH, CUCS, Universidad de Guadalajara, Guadalajara, México; 2) Hospital Civil de Guadalajara "Fray Antonio Alcalde" Guadalajara, México; 3) Doctorado Genética Humana, CUCS, Universidad de Guadalajara, CIBO-IMSS, Guadalajara, México; 4) Depto. Fisiología, CUCS, Universidad de Guadalajara, Div. Investigación, UMAE, HE, CMNO , IMSS, Guadalajara, México.

Introduction: Fibrodysplasia ossificans progressiva (FOP) (OMIM #135100) is a rare autosomal dominant disease with complete penetrance caused by heterozygous mutation in the ACVR1 gene (102576) on chromosome 2q23. 95% of FOP cases are sporadic. FOP involves progressive ossification of skeletal muscle, fascia, tendons, and ligaments. FOP has a prevalence of approximately 1 in 2 million worldwide. (Petrie et al. 2009). The treatment is mainly preventive including avoidance of trauma, passive physiotherapy and prevention of chest infections. (Dhamangaonkar et al. 2013). Objective: To present a FOP male patient. Case report: The propositus aged 21 year-old presented, at age of 15 years, intense pain on right dorsal and lumbar region, later developed a painful lump on right costal region and limitation movement of right arm. He was diagnosed with FOP. Physical examination at present: weight 64kg, height 1.72 m, sparse eyebrows, cervical movement restriction, in posterior thorax presented three masses (2 x 2cm each), two on right scapula and one on the left scapula, scoliosis, restricted mobility on right arm and shoulder with restriction of pronation and supination, bilateral short great toes deformities with hallux valgus. He had repeated episodes of acute pain and inflammation of soft tissue, principally in scapular and pelvic girdle. The disease has been progressive with functional limitation. Laboratory studies gave normal or negative results. Thorax and abdominal CT reported new bone formation at right pectoral muscle, trapezium and gluteus medius. Conclusions: We present a sporadic FOP in a male patient. FOP is an incapacitating progressive disease the diagnosis is based mainly on clinical and imaging findings. The treatment is multidisciplinary and basically symptomatic, early diagnosis is fundamental to avoid aggravating factors and improve the quality of life.

Quantitative phenotype evaluation and management in osteogenesis imperfecta: Egyptian Experience. *M.S. Aglan[1], G.A. Otaify[1], R. ElHoussini[1], M.S. Abdel-Hamid[2], V.L. Ruiz-Perez[3,4], S. Temtamy[1].* 1) Clinical Genetics Department, Center of Scientific Excellence for Human Genetics, Human Genetics and Genome Research Division, National Research Centre, Cairo, Egypt; 2) Medical Molecular Genetics Department, Center of Scientific Excellence for Human Genetics, Human Genetics and Genome Research Division, Cairo, Egypt; 3) Instituto de Investigaciones Biome'dicas, Consejo Superior de Investigaciones Cienti 'ficas-Universidad Auto'noma de Madrid, Madrid, Spain; 4) Centro de Investigacio'n Biome'dica en Red de Enfermedades Raras (CIBERER), Instituto de Salud Carlos III (ISCIII), Madrid, Spain.

Osteogenesis imperfecta (OI) is a heterogeneous genetic disorder characterized by bone fragility and fractures. Patients with OI have clinical features that may range from mild symptoms to severe bone deformities and neonatal lethality. We studied more than 150 referred patients with OI. Thirty percent of the referred patients were consistent with autosomal recessive (AR) inheritance indicating a higher percentage of recessive types in our community compared to Western countries as a result of a higher consanguinity rate in our population (20-40%). For clinical purposes, we proposed a quantitative scoring system for assessment of severity in OI. The clinical scoring system (CSS) includes five major criteria of clinical and prognostic value; number of fractures per year, motor milestones, long bone deformities, length/height standard deviation score (SDS), and z-score of bone density. Each criterion in the CSS was assigned a score from 1 to 4 according to standard definitions. Each patient is marked on a scale from 1 to 20 according to these five criteria. The CSS was assessed by its application on patients with different Sillence types of OI and proved to be an easy quantitative tool for assessment of disease severity. Molecular studies carried out for autosomal dominant (AD) and AR-OI patients resulted in new gene identifications and novel mutations in known AD and AR genes causing OI. The CSS applied to these patients, denoted that AR patients were significantly more severely affected than AD patients. Thirty three patients with OI were treated with cyclic biphosphonate injections in the form of zoledronate every 6 months with follow up for a period of 24 months. Significant improvement was noted in different parameters including the number of fractures, bone density, pain and motor milestones. Applying the CSS to these patients before and after therapy proved to be a good indicator for response to treatment. Our experience shows that applying the proposed CSS can quantitatively reflect the degree of severity in OI patients and can be used in complement with the Sillence classification and molecular studies. It also proved to be of significance in the assessment of response to treatment in OI patients.

Rare Cases of Congenital Arthrogryposis Multiplex without pterygium due to novel CHRNG Mutations. *J. Seo[1], Y. Yongjin[1], L. Youngha[1], K. Jung Min[2], S. Yong Beom[3].* 1) Biomedical Sciences, Seoul National University , Seoul, South Korea; 2) Department of Pediatrics, Seoul National University Hospital, Seoul, Korea; 3) Department of Rehabilitation Medicine, Pusan National University Hospital, Pusan, Korea.

Two unrelated patients visited outpatient clinic for evaluation of scoliosis and gait disturbance. The examination revealed multiple joint contractures in both upper and lower limbs without pterygium. Karyotyping of the proband was normal. Electrodiagnostic study did not reveal peripheral neuromuscular causes of the symptoms. Whole exome sequencing analysis of the patient genomes led to the discovery of identical missense variant (p.Pro143Arg) and frame-shift deletion (p.Pro251fs) on CHRNG, encoding acetylcholine receptor gamma subunit. They comprise rare cases of congenital arthrogryposis multiplex without pterygium related to the novel recessive CHRNG variants in two Korean subjects without apparent kinship. Further understanding of these mutations could achieve a better treatment and follow up plan.

A case of low frequent somatic and/or germline mosaicism in the ARSE gene detected by deep sequencing using NGS. *T. Kaname[1], K. Kurosawa[2], M. Higa[1], K. Yanagi[1], K. Naritomi[1].* 1) Dept Med Gen, Univ Ryukyus, Nishihara, Okinawa, Japan; 2) Kanagawa Child Medical Center, Kanagawa, Japan.

Chondrodysplasia punctata 1 (CDPX1) is an X-linked recessive disorder characterised by punctate calcifications in radiographs of the feet and other sites, nasomaxillary hypoplasia and brachytelephalangy. It is known that mutations of the arylsulfatase E (ARSE) gene affect the disorder. A male patient clinically diagnosed with CDPX1 was encountered. Examination of the ARSE gene by Sanger sequencing for all exons revealed a missense mutation, c.266G>A (p.S89N) in the patient. The mutation was not found in 250 healthy controls. Prediction of functional effects of the substitution by PolyPhen-2 and SIFT displayed that the mutation affects the protein function. In order to confirm whether his mother is a carrier, a molecular test was done as well. However, the Sanger sequencing could not detect the mutation in the mother, suggesting that the mutation was de novo. Then, we performed deep sequencing of the ARSE gene in the mother using a next generation sequencer, revealed that the mother had a somatic mosaicism of the mutation at 3.2% and 6% of allele frequency in the blood cells and buccal cells, respectively. We concluded that the deep sequencing using NGS could detect low frequent mosaicism, which might be a part of germline mosaicism. In such ‘de novo’ mutation, the deep sequencing should be performed to see whether the parents are mosaic in order to make reliable genetic counselling.

2683T

A further case of Hajdu-Cheney syndrome having a novel mutation in NOTCH2 gene. *A. KAVASOGLU[1], H. ONAY[1], M. ARGIN[2], F. OZKINAY[1].* 1) Department of Medical Genetics, Ege University Faculty of Medicine, Izmir, Turkey; 2) Department of Radiology, Ege University Faculty of Medicine, Izmir, Turkey.

Hajdu-Cheney syndrome is a very rare, autosomal dominant syndrome characterized by skeletal dysplasia, characteristic craniofacial and dental features, acro-osteolysis and proportionate short stature. We describe, here, a 35-year-old male patient with typical clinical and radiological features of Hajdu-Cheney syndrome. His height was 164 cm. He had typical facial features including hypertelorism, bushy eyebrows, micrognathia, dental anomalies, low-set ears, short neck and short fingers. X-ray studies showed wormian bones in the skull, acro-osteolysis of distal phalanges, short bowed long bones. On echocardiography, minimal mitral and aortic regurgitation were observed. Odiological examination revealed a conductive hearing loss. Regarding clinical findings, he was considered to have Hajdu-Cheney syndrome. Molecular analysis showed a heterozygous truncating c.6616 G-T (p.E2206X) mutation in the last exon of NOTCH2 gene. This Hajdu-Cheney case with a novel mutation is the first case whose molecular diagnosis was performed in Turkey and may help to establish phenotype-genotype correlation in the syndrome.

2684S

Expanding the diagnostic spectrum of terminal transverse limb defects: atypical mutations in *ACVR1* result in a phenotype with elements of Adams Oliver syndrome and Fibrodysplasia Ossificans Progresiva. *R. Mendoza-Londono[1], A. Al Maawali[1,2], L. Dupuis[1], F. Hyland[3], C. Scafe[3], T.A. Paton[4], C.R Marshall[4,5].* 1) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children and University of Toronto, Toronto, Canada; 2) Department of Genetics, Sultan Qaboos University Hospital, Sultan Qaboos University, Muscat, Oman; 3) Thermo Fisher Scientific, 200 Oyster Point Boulevard • South San Francisco • CA; 4) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 5) Division of Molecular Genetics, Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada.
