American Society of Human Genetics 64th Annual Meeting
October 18–22, 2014 San Diego, CA

POSTER ABSTRACTS

Session Topic/Title	Abstract/Poster Board Numbers Start #	End #
Epigenetics	407	510
Genome Structure, Variation, and Function	511	678
Pharmacogenetics	679	741
Complex Traits and Polygenic Disorders	742	1119
Psychiatric Genetics, Neurogenetics, and Neurodegeneration	1120	1361
Bioinformatics and Genomic Technology	1362	1721
Statistical Genetics and Genetic Epidemiology	1722	1890
Evolutionary and Population Genetics	1891	2034
Cardiovascular Genetics	2035	2168
Therapy for Genetic Disorders	2169	2213
Metabolic Disorders	2214	2302
Genetics/Genomics Education	2303	2329
Ethical, Legal, Social, and Policy Issues in Genetics	2330	2383
Genetic Counseling	2384	2402
Health Services Research	2403	2419
Clinical Genetic Testing	2420	2599
Clinical Genetics and Dysmorphology	2600	2785
Prenatal, Perinatal, and Reproductive Genetics	2786	2865
Molecular Basis of Mendelian Disorders	2866	3128
Development	3129	3157
Cytogenetics	3158	3223
Cancer Genetics	3224	3509

Posters should remain on the board for all three days (Sunday through Tuesday)

POSTER AUTHOR SCHEDULE

The program and abstract/poster board number next to each listing is followed by an **S** (Sunday), **M** (Monday), or **T** (Tuesday) to indicate the day on which authors must be present at their poster boards. Refer to the schedule below for presentation times and for the poster mounting/removal schedule.

Poster Mounting and Removal

Authors must put up and take down their posters according to the schedule below. Authors must be present at their boards based on their odd or even abstract/program/board number, and must remain at their boards for the duration of their scheduled presentation times. **Posters should remain on the boards for all three days.**

Sunday, October 19

11:00 am–1:00 pm	All poster authors (Sunday, Monday, and Tuesday) place posters on boards
11:00 am–7:00 pm	Posters available for general viewing
4:00 pm–6:00 pm	**Poster Session I (Sunday Authors Present)**
	4:00 pm–5:00 pm (*odd poster board numbers; author must be present*)
	5:00 pm–6:00 pm (*even poster board numbers; author must be present*)

Monday, October 20

10:00 am–4:00 pm	Posters available for general viewing
2:00 pm–4:00 pm	**Poster Session II (Monday Authors Present)**
	2:00 pm–3:00 pm (*odd poster board numbers; author must be present*)
	3:00 pm–4:00 pm (*even poster board numbers; author must be present*)

Tuesday, October 21

10:00 am–4:00 pm	Posters available for general viewing
2:00 pm–4:00 pm	**Poster Session III (Tuesday Authors Present)**
	2:00 pm–3:00 pm (*odd poster board numbers; author must be present*)
	3:00 pm–4:00 pm (*even poster board numbers; author must be present*)
4:00 pm	Posters closed
4:00 pm–4:15 pm	All authors remove posters from boards
4:15 pm	Exhibit Hall closed

407M

5-hydroxymethylcytosine Dysregulation in Neurodegenerative Disorders. *B. Yao[1], L. Lin[1], C. Street[1], S. Yang[1], C. Stoyas[2], F. Ayhan[3], L. Duvick[4], Z. Zalewski[5], A. La Spada[2], L. Ranum[3], H. Orr[4], D. Nelson[5], P. Jin[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Pediatrics and Cellular and Molecular Medicine, University of California San Diego, San Diego, CA; 3) Molecular Genetics & Microbiology, University of Florida, Gainesville, FL; 4) Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 5) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Neurodegenerative disorders are a heterogeneous group of chronic progressive diseases characterized by neuronal dysfunction, progressive degeneration, and progressive neuronal loss. It has been well established that epigenetic plasticity in DNA methylation-related regulatory processes influences activity-dependent gene regulation, learning and memory, and aging in the central nervous system. Recent studies that methylcytosine (mC) can be oxidized to 5-hydroxymethylcytosine (5hmC) present a particularly intriguing epigenetic regulatory paradigm in the mammalian brain. Our previous works suggest 5hmC modification at selective loci is altered in the cerebellum of FXTAS mouse model. In the present study, we systematically characterize the genome-wide 5hmC distributions in several neurodegenerative disorder mouse models with common features of ataxia, including Fragile X ataxia and tremor syndrome (FXTAS), spinocerebellar ataxia (SCA) type 1, 7, 8 and 17, together with their age-matched wildtype littermates. 1113 common loss-of-5hmC regions in all disease mouse models comparing to their wildtype littermates are identified, whereas 2182 common gain-of-5hmC regions are also generated. Gene Ontology analysis on these 5hmC differential regions indicates a strong correlation of neuronal pathways, such as Purkinje neuron differentiation and cerebellum development, with common loss-of-5hmC regions. Motif identification and transcription factor analysis predict several key transcription factors in neurodevelopment and neuronal functions, including RE1-Silencing Transcription factor (REST), Transcription Factor 4 (TCF4) and Foxhead box L1 (FoxL1), which could bind to DNA in a methylation-dependent manner. Altered cytosine modification at these loci thus could change their binding affinity, and affect their normal function in neurodegenerative mouse models. In addition, Approximately 15% of the 5hmC differential regions in these disease overlap with cerebellum enhancer regions, suggesting their potential epigenetic impact on distal regulatory regions. Our study provides the first systematic investigation of 5hmC profiles in various neurodegenerative disease mouse models, and highlights its key role in neuronal functions. The common differential 5hmC regions in various ataxia-related disorders may sever as “hotspots” for early diagnosis and important therapeutic targets.

408T

Modeling DNA methylation dynamics with approaches from phylogenetics. *J. Capra[1,2], D. Kostka[3].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 3) Departments of Developmental Biology and Computational & Systems Biology, University of Pittsburgh, Pittsburgh, PA.

Methylation of CpG dinucleotides is a prevalent epigenetic modification that is required for proper development in vertebrates. Genome-wide DNA methylation assays have become increasingly common, and this has enabled characterization of DNA methylation profiles from distinct stages across differentiating cellular lineages. Changes in CpG methylation are essential to cellular differentiation; however, current methods for modeling methylation dynamics do not account for the dependency structure between precursor and dependent cell types. We developed a continuous-time Markov chain approach, based on the observation that changes in methylation state over tissue differentiation can be modeled similarly to DNA nucleotide changes over evolutionary time. This model explicitly takes precursor to descendant relationships into account and enables inference of CpG methylation dynamics. To illustrate our method, we analyzed a high-resolution methylation map of the differentiation of mouse stem cells into several blood cell types. Our model can successfully infer unobserved CpG methylation states from observations at the same sites in related cell types (90% correct), and this approach more accurately reconstructs missing data than imputation based on neighboring CpGs (84% correct). Additionally, the single CpG resolution of our methylation dynamics estimates enabled us to show that DNA sequence context of CpG sites is informative about methylation dynamics across tissue differentiation. Our approach also enabled identification of genomic regions with clusters of highly dynamic CpGs. We found that enhancers, in addition to promoters and CpG islands, contain many dynamic CpG sites that are likely relevant to shifts in gene expression across the development of this lineage. Finally, we characterized genetic variation in CpG sites with a focus on mutations that disrupt the potential for CpG methylation. Our work establishes a framework for inference and modeling that is well-suited to DNA methylation data, and our success suggests that other approaches used to analyze DNA nucleotide substitutions will also translate to the modeling of epigenetic phenomena.

409M

Genome-wide Methyl-seq analysis reveals changes in hypothalamic DNA methylation patterns in response to the enhanced maternal care paradigm. *D.H. Yasui[1], T.Z. Baram[2], A. Singh[2], K.W. Dunaway[1], J.M. LaSalle[3].* 1) Medical Microbiology, UC Davis School of Medicine, Davis, CA; 2) Anatomy and Neurobiology, UC Irvine School of Medicine, Irvine, CA; 3) Medical Microbiology and Genome Center, UC Davis School of Medicine UC Davis MIND Institute, Davis, CA.

Enhanced maternal nurturing in rat models leads to a long-lasting modulation of subsequent stress responses and altered expression of key stress-controlling genes. In the “augmented maternal care” (AMC) paradigm, enhanced mothering from postnatal days 2–9 (P9) leads to reduced corticotropin releasing hormone (Crh) expression in the hypothalamic paraventricular nucleus (PVN) which persists through life. We hypothesize that AMC epigenetically sets future gene expression levels by altering DNA methylation levels. Gene levels of Crh were assayed in AMC and control PVN by bisulfite pyrosequencing analysis. As expected, Crh methylation levels were significantly higher in AMC vs control PVN, consistent with repression of Crh expression. However, Crh methylation levels were unaffected in thalamus where no differences in gene expression were observed, suggesting that elevated PVN Crh methylation levels are due to AMC and related to Crh repression. To investigate potential additional genes contributing to the stress-resilient phenotype produced by AMC, Methyl-seq analysis was performed on AMC and control PVN to identify other differentially methylated regions (DMRs). We focused on partially methylated (>70% CpG methylation) domains (PMDs), because they comprise up to 40% of the genome in early life and are enriched in repressed genes. Thus, PMDs are likely to contain DMRs responsive to AMC. We employed a hidden Markov model (HMM) trained to detect PMDs to screen for potential DMRs and identified 38 chromosomal loci, covering ~5% of the uniquely aligned rat genome. Computational analyses confirmed lower average methylation levels in 37 of the 38 identified differential PMDs, consistent with differential methylation in these regions. Interestingly, PVN DMRs included Pcdh gene clusters involved in neuronal identity. Methyl-seq analysis also identified a Crh promoter region that has potentially elevated methylation levels in AMC PVN. In summary, current studies identified both marker gene (Crh) and genome-wide methylation changes related to augmented maternal care. Current and future studies will confirm DMRs by pyrosequencing and Methyl-seq analysis and correlate these with PVN gene expression changes identified by RNA-seq. These results will provide insights into normal brain function as well as early-life influences on genome wide epigenetic reprogramming of hypothalamic genes with implications for certain human for stress-related, neuropsychiatric disorders.

410T

Whole blood DNA methylation changes are associated to malignant pleural mesothelioma. *E. Casalone[1], S. Guarrera[1,2], G. Fiorito[1,2], M. Betti[3], D. Ferrante[4], C. Di Gaetano[1,2], F. Rosa[1,2], A. Russo[1,2], S. Tunesi[4], M. Padoan[4], C. Casadio[5], F. Ardissone[6], E. Ruffini[7], P.G. Betta[8], R. Libener[8], R. Guaschino[9], E. Piccolini[10], D. Mirabelli[11,12], C. Magnani[4,12], I. Dianzani[3,12], G. Matullo[1,2].* 1) Laboratory of Genetic Pathology, Department Health Sciences, University of Piemonte Orientale, I-28100, Novara, Italy; 2) Department of Medical Sciences, University of Turin, Turin, Italy; 3) Laboratory of Genetic Pathology, Department Health Sciences, University of Piemonte Orientale, Novara, Italy; 4) 4CPO-Piemonte and Unit of Medical Statistics and Epidemiology, Department Translational Medicine, University of Piemonte Orientale, Novara, Italy; 5) 5Thoracic Surgery Unit, University of Piemonte Orientale, Novara, Italy; 6) Chest Surgery, Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy; 7) Thoracic Surgery Unit, University of Turin, Turin, Italy; 8) Pathology Unit, Azienda Ospedaliera Nazionale SS, Antonio e Biagio e Cesare Arrigo, Alessandria, Italy; 9) Transfusion Centre, Azienda Ospedaliera Nazionale SS, Antonio e Biagio e Cesare Arrigo, I-15121, Alessandria, Italy; 10) Pneumology Unit, Santo Spirito Hospital, Casale Monferrato, Italy; 11) Unit of Cancer Epidemiology, CPO-Piemonte and University of Turin, Turin, Italy; 12) Interdepartmental Center for Studies on Asbestos and other Toxic Particulates "G. Scansetti", University of Turin, Turin, Italy.

Malignant pleural mesothelioma (MPM) is a rare and aggressive tumor strongly associated with asbestos exposure. Its onset is usually 30–40 years after the first exposure, and it is characterized by a poor prognosis with a median survival of 12 months. Alterations in DNA methylation have been reported in several cancers, and are becoming an established hallmark of tumor. MPM is frequently associated with genetic mutations but also epigenetic changes leading to gene expression modifications. The identification of MPM-specific epigenetic markers in peripheral blood might be a useful methodology for defining biomarkers for potential early detection and may define methylation changes due to asbestos exposure. We conducted an epigenome-wide analysis (>450K CpG sites) on DNA from whole blood cells of 129 MPM cases and 127 controls to evaluate differences in methylation profiles. The sample population was randomly split into two sets: training and test set. In the training set 60 differentially methylated regions (DMRs) between cases and controls, adjusting for gender, age, asbestos exposure, and white blood cells percentage were found (FDR adjusted $p<0.01$). Using a cluster algorithm we validated the DMRs prediction performance in the test set (AUC=0.7625). We found significant enrichment for genes involved in leukocyte trans-endothelial migration, natural killer cell mediated cytotoxicity and cell adhesion molecules pathways. Moreover we identified several genes belonging to the inflammation pathways and related to the cancer progression. Our results suggested that methylation status in whole blood DNA might provide a useful biomarker for potential MPM early detection.

411M

UHRF1 as an epigenetic regulator of CDH1 (E-cadherin) in human breast cancer cell invasion and metastasis. *S.Y. Jang[1], H. Kim[1], C.H. Kim[1], A. Kim[1,2], J. Kim[1].* 1) korea university, seoul, South Korea; 2) Korea University Guro Hospital, Seoul, South Korea.

Human UHRF1 (ubiquitin-like PHD and RING-finger-associated domain-containing) is an epigenetic regulator that is involved in DNA methylation and histone modification. Overexpression in several types of human cancer including breast cancer has suggested the UHRF1 as a putative oncogene. However, molecular mechanisms underlying the role of the UHRF1 in the cancer are still unclear. To understand the epigenetic role of the UHRF1 in regulating the progression of human breast cancer, we analyzed changes in cell morphology, migration, and invasion as well as epithelial and mesenchymal marker proteins. We found that the UHRF1 enhanced motility and invasiveness in the human breast cancer cells. Chromatin immunoprecipitations (ChIP) and immunoprecipitation (IP) assays showed that the UHRF1 protein directly bound and repressed the CDH1 though H3K9me2/3 and H3K9Ac. Inhibition of UHRF1 expression by RNA interference restored CDH1 expression in the breast cancer cells and suppressed the cell invasiveness. Taken together, our study suggested the UHRF1 is critical to epithelial-mesenchymal transition (EMT) through epigenetic regulation of CDH1 that is a hallmark of EMT and contributes to the metastatic advantage of human breast cancer.

Analyses and characterization of adjacent CpG sites of TCGA BRCA HM450K methylation data. *M.P. Lee, H. Liu, H.H. Yang.* CCR, National Cancer Institute, Rockville, MD.

DNA methylation plays important roles in maintaining genome stability and regulating gene expression. It is fundamentally important for cell differentiation and dynamically responding to the physiological and pathologic conditions. The Infinium HumanMethylation450 BeadChip has emerged as a powerful platform to investigate DNA methylation across the human genome. That is the platform used by TCGA for the DNA methylation study. The current challenge in TCGA and other genomic initiatives is in the understanding of these high throughput data. DNA methylation analysis is particularly challenging, especially regarding how to combine methylation data from multiple CpG sites per gene. To address this challenge, we investigated methylation measurements as beta-values among adjacent CpG sites. We analyzed TCGA breast cancer methylation data. The latest release has HM450k data for 812 samples. An example of our analyses of these samples is summarized below. After excluding missing beta-value, we have 302559 CpG sites within 23905 genes for analysis. 21754 genes are represented by at least 2 CpG sites, with an average of 13.8 CpG sites. The variation of beta-value among the CpG sites with a gene is substantial, with standard deviation of 0.2438. The mean difference between minimum and maximum beta-value is 0.6345. We then focused on the analysis of methylation difference between the two adjacent CpG sites. As expected, we found that the beta-value difference increases as the distance between the two CpG sites increases. When the two CpG sites are within 1 kb, the difference in beta-values is usually less than 0.1. We also analyzed the beta-value differences in terms of genomic context, including sites in the promoter region, 5'UTR, first exon, gene body, and 3'UTR, CpG island and CpG island shore, transcription levels, and clinical phenotypes. The insights gained from our analyses of relationship among multiple CpG sites of a gene can help determine how to aggregate multiple CpG sites per gene and how to combine DNA methylation data with gene expression data at gene-level and thus can provide an effective strategy to integrate methylation and gene expression and clinical phenotypes.

Sports Related Concussions Induce DNA Methylation Changes in Immune Cell Trafficking and Cell Survival Pathways. *H. Kim[1], J. Gill[1], S. Yun[3], A. Cashion[1], D. Wang[1], K. Merchant-Borna[2], H. Lee[1], J. Bazarian[2].* 1) SML, NINR/NIH, Bethesda, MD; 2) University of Rochester Medical Center, Rochester, NY; 3) Yotta Bioinformatics, Bethesda, MD.

Sports related concussions (SRC) are common among athletes and place them at risk for neurological and psychological dysfunction. There is considerable variation and outcome from SRC; with most athletes recovering within one week, while others may remain symptomatic for more than one year. The purpose of this study was to determine changes in DNA methylation after a SRC in order to characterize the underlying molecular processes that accompanied recovery. Pre-season blood samples were obtained from 253 college athletes. Athletes were followed over the season and 11 sustained a SRC with subsequent blood obtained 7 days following the injury. In the SRC athletes, whole genome scale DNA methylation using Methyl Binding Domain (MBD)-seq method in peripheral blood mononuclear cells (PBMCs) was compared at baseline (pre-injury) and 7 days following the injury (sub-acute). Genomic regions that differed between baseline and the sub-acute period were determined by MACS for peak calling, PAVIS for annotation, and in-house PERL scripts provided a list of genes that significantly differed in methylation between the two time points. Ingenuity Pathway Analysis was used to determine candidate biological pathways and gene networks most related to SRC. Top canonical pathways related to SRC included: the TCA cycle II, glucocorticoid receptor signaling, as well as cellular salvage pathways, which includes xanthine and xanthosine. Cell death and survival were the primary biological function network related to SRCs. Genes with reduced DNA methylation during the sub-acute period included allograft inflammatory factor 1 (AIF1), a gene that mitigates microglial activation following TBI, and is related to inflammatory activity and regulation. The gene baculoviral IAP repeat containing 3 (BIRC3) which functions to reduce apoptosis following TBI, was also reduced in methylation. Reduced methylation was also found in regions of genes related to protein ubiquitination including the gene SNF8. Our findings illustrate that genes related to neurological disease and psychological disorders are significantly affected by SRC, resulting in reduced methylation of genes related to cellular functions that promote recovery including immune cell trafficking and cell survival. These findings provide unique insights into molecular recovery mechanism following SRC.

414T

Genome-wide DNA methylation analyses identify loci influencing recurrent stroke risk in samples from the Vitamin Intervention for Stroke Prevention clinical trial. *K.L. Keene[1,2], W.M. Chen[2], S.D. Turner[2], A.F. Koeppel[2], S.R. Williams[2], M.M. Sale[2], B.B. Worrall[2].* 1) East Carolina University, Greenville, NC; 2) University of Virginia, Charlottesville, VA.

DNA methylation is a widely accepted epigenetic factor that is important in many diseases. The folate one carbon metabolism (FOCM) pathway plays a critical role in DNA methylation through the conversion of homocysteine to methionine, wherein s-adenosyl methionine is the primary donor for de novo methyltransferase reactions. In addition to its role in DNA methylation, elevated homocyteine levels have been associated with several diseases, including cardiovascular disease and stroke. Due to the cross-talk between genes in the FOCM pathway, DNA methylation, and stroke risk, we have performed analyses of genome-wide DNA methylation status using DNA extracted from buffy coats and Illumina HumanMethylation450 BeadChip arrays, to identify regions of hypo- or hypermethylation that may influence recurrent stroke risk in 183 (105 European descent (ED) and 78 African descent (AD)) samples from the Vitamin Intervention for Stroke Prevention (VISP) clinical trial. VISP was a multi-center, double-blind, randomized, controlled clinical trial designed to determine if daily intake of a multivitamin tablet with high dose folic acid, vitamin B6 and vitamin B12 reduced recurrent cerebral infarction, nonfatal myocardial infarction (MI), or mortality. Ethnicity and gender stratified analyses identified two loci with significant ($P < 10^{-8}$) differential DNA methylation in ED males with (n= 18) and without (n= 39) a recurrent stroke, and one locus with differential DNA methylation in ED females with (n= 14) and without (n= 34) a recurrent stroke. The most significant differentially methylated locus in ED males was located near the cysteine/histidine-rich 1 (CYHR1) gene ($P= 4.85 \times 10^{-08}$; Qval= 0.005). In ED females, the most significant locus was near the centlein, centrosomal protein (CNTLN) gene ($P= 1.70 \times 10^{-08}$; Qval= 0.004). No loci showed significant differential methylation in the AD samples. The CNTLN gene is located adjacent to the 9p21 locus, a region with prior genetic associations with ischemic stroke and coronary diseases. The protein encoded by the CYHR1 gene has been identified as a biomarker of good response to erythropoietin (EPO) in hemodialysis patients. Furthermore, recent studies suggest that EPO might have neuroprotective properties in the ischemic brain. Collectively, our findings could provide insight into epigenetic marks that influence recurrent stroke risk and uncover targeted treatments and regimens to alleviate recurrent stroke.

415M

Vitamin B deficiency and gestational programming of genes related to Alzheimer's disease. *V.C. Silva[1], A.L.D.A Agamme[1], L. Fernandes[1], M.T.C Muniz[2], V. D'Almeida[1].* 1) Psychobiology, Universidade Federal de So Paulo, So Paulo, So Paulo, Brazil; 2) Department of Biological Sciences, Universidade de Pernambuco, Recife/PE.

Fetal antecedents have been associated with increased offspring disease risk through maternal environment, placental changes, and epigenetic programming. Epigenetic regulation is crucial in the development of organisms, since it is required to achieve either stable genes expression or repression at various stages of development. As methionine-homocysteine pathway supports methyl groups among other purposes, to DNA and protein methylation and this flow is sensitive to the supply of amino acids and vitamins, we investigated whether maternal Vitamin B deficiency during early development alters the gene expression of *App*, *Ps1* and *Bace*, which are related to Alzheimer's disease. To this end, we submitted female mice to experimental diet one month before and during pregnancy. After 20 days, plasma homocysteine levels from deficient gestational group (DG, n=7) were approximately 50% higher than control group (CT, n=7) (CT= 9.219 μmol/L, DG= 13.606 μmol/L; p=0.0009). The offspring's male mice (n= 6–8, per group) from control and experimental dams (CTO and DGO) were euthanized after birth, the total brain was harvested and mRNA isolated by Ilustra triplePrep® kit (GE HealthCare). Gene expression of *App*, *Bace* and *Ps1* was quantified by real time PCR using *Gapdh* as the housekeeping gene and data were analyzed by 2-ΔΔCT method. T-test was used to compare the results considering the level of significance $p<0.05$. Our results demonstrated a significant decrease in the *App* and *Ps1* gene expression and no significant difference in *Bace* expression in DGO male offspring at postnatal day 0. The decrease in gene expression showed in present study can be due to an imbalance in the one carbon metabolism, since in a previous study of our group a decrease in S-adenosylmethionine (SAM)/S-adenosylhomocysteine (SAH) ratio was observed. Considering that the manipulation occurred in crucial period of development (prenatal), a higher vulnerability to degenerative processes could be expected as a long lasting consequences of this imbalance. Sources of research support: FAPESP, CNPq and AFIP.

416T

Global Methylation of Fracture Risk in a Cohort of Young African Americans with Forearm Fractures. *C. Sprouse[1], B.T. Harmon[1], H. Gordish-Dressman[1], L.M. Ryan[3], L.L. Tosi[1,2], J.M. Devaney[1,2].* 1) Children's national medical center, Washington, DC; 2) The School of Medicine and Health Sciences, George Washington University, Washington DC; 3) Department of Pediatric Emergency Medicine, The Johns Hopkins Hospital, Baltimore MD.

Forearm fractures account for roughly 25% of all pediatric fractures. The estimated direct costs of treating childhood forearm fractures currently exceed $2 billion dollars per year in the United States. Despite an overall trend of declining injury rates in children, multiple studies have shown that the incidence of forearm fractures among children is increasing. The reasons for this increase in pediatric forearm fracture rates remains unclear. The objective of this study was to provide new insights into the influence of methylation on fracture risk in a young African American cohort. Additionally, we hoped to identify novel epigenetic markers and elucidate novel genetic pathways, which contribute to fracture risk. Our cohort included 138 African American children ages 5 to 9 who were recruited as part of a forearm fracture study. The DNA was extracted from whole blood and analyzed for methylation changes using the Illumina HumanMethylation450 BeadChip (485,577 CpG sites). Statistical analysis was completed on 395,899 CpG sites (Partek Genomics Suite) comparing participants with forearm fractures (n=69) and age-matched controls (n=69). Associations between methylation and fracture status were examined using ANCOVA models with gender and age as covariates. After scrubbing the data and adjusting for multiple testing, 490 CpG sites were significantly different between children with forearm fractures and control participants. The top ranked CpG site by p-value (p= 1.1 X 10-08; cg23369647) was located on a CPG island of the gene SCML4, a novel gene for fracture risk. This gene demonstrated a 58% higher beta value in children with forearm fracture compared with age matched control participants.

Whole-blood DNA methylation patterns and glycemic traits in the KORA F4 study. *J. Kriebel[1,2,3], S. Wahl[1,2,3], S. Zeilinger[1,2], K. Schramm[4,5], W. Rathmann[6], M. Roden[7,8,9], A. Peters[1,2], T. Illig[1,10], M. Waldenberger[1,2], H. Prokisch[4,5], H. Grallert[1,2,3], C. Herder[7,9].* 1) Research Unit of Molecular Epidemiology, Helmholtz Zentrum Mnchen, German Research Center for Environmental Health, Neuherberg, Germany; 2) Institute of Epidemiology II, Helmholtz Zentrum Mnchen, German Research Center for Environmental Health, Neuherberg, Germany; 3) German Center for Diabetes Research (DZD), Neuherberg, Germany; 4) Institute of Human Genetics, Helmholtz Zentrum Mnchen, German Research Center for Environmental Health, Neuherberg, Germany; 5) Institute of Human Genetics, Technische Universitt Mnchen, Munich, Germany; 6) Institute for Biometrics and Epidemiology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University Dsseldorf, Dsseldorf, Germany; 7) Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich Heine University Dsseldorf, Dsseldorf, Germany; 8) Department of Endocrinology and Diabetology, University Hospital Dsseldorf, Dsseldorf, Germany; 9) German Center for Diabetes Research (DZD), Dsseldorf, Germany; 10) Hannover Unified Biobank, Hannover Medical School, Hannover, Germany.

Recent publications indicate an involvement of DNA methylation in the development of type 2 diabetes (T2D). Thus, it is important to study the associations between genome-wide DNA methylation and blood glucose and insulin levels. The aim of the present study was to investigate the role of DNA methylation in whole blood in the development of T2D. Therefore, we performed a methylome-wide association study of glycemic traits (fasting insulin, fasting and 2h glucose) in 1448 whole blood samples of the population-based KORA F4 study using the HumanMethylation 450k BeadChip. Data were BMIQ normalized (beta mixed quantile normalized) and analyzed using linear mixed effect models. We identified four CpG sites that were significantly associated with glycemic traits after correction for multiple testing (Benjamini-Hochberg procedure). In detail, DNA methylation at cg11024682 (located in the *SREBF1* gene locus) was associated with fasting glucose (B-H-adjusted $p = 1.7\times10^{-3}$), cg09613192 and cg22065733 (both unannotated) were associated with fasting insulin (B-H-adjusted $p = 1.8\times10^{-2}$ and 4.2×10^{-2}, respectively), and cg06500161 (located in the *ABCG1* gene locus) was associated with fasting glucose, 2h glucose, and fasting insulin (B-H adjusted $p = 3.0\times10^{-4}$, 1.8×10^{-2}, and 4.3×10^{-3}, respectively) after adjustment for age and sex. After adjustment for body mass index (BMI) or estimated white blood cell counts, we did not detect any genome-wide significant signals. We additionally tested associations between DNA methylation and gene expression in a subset of 538 participants with available gene expression data using linear model and Benjamini-Hochberg correction for multiples testing including an area of ± 500kb around significant CpG sites. The CpG site cg06500161 (*ABCG1*) showed an association with *ABCG1* gene expression level (B-H adjusted $p = 3.0\times10^{-10}$). Our findings support previous evidence of a role of the ABCG1 gene in the regulation of glucose metabolism and suggest that the association might be modulated by epigenetic processes. Our study points towards an association between DNA methylation and T2D related traits. Analyses in insulin-responsive tissues such as adipose tissue, muscle or liver might help to elucidate the underlying mechanisms.

418T

The effect of fertility treatments on differential DNA methylation in autism spectrum disorder. *M.T. Siu[1], D. Grafodatskaya[1], D.T. Butcher[1], S. Choufani[1], Y. Chen[1], A. Pietrobon[1], Y. Lou[1], R. Weksberg[1,2,3].* 1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Paediatrics, The University of Toronto, ON, Canada.

Autism spectrum disorder (ASD) is one of the most common neurodevelopmental disorders, with a prevalence of approximately 1 in 88 in North America. Both genetic and environmental factors likely contribute to ASD risk, and the role of epigenetic dysregulation requires further clarification. One possible environmental exposure that may impact epigenetic regulation is the use of fertility treatments (FT). It has previously been shown that the frequency of DNA methylation (DNAm) alterations are increased following FT in etiologically heterogeneous disorders such as Angelman syndrome. To date, FT, including assisted reproductive technologies (ART) and hormonal stimulation of ovulation, contribute to 6% of live-births in the United States per year. FT is associated with increased risks for multiple births, prematurity and low birth weight. In addition, concerns have been raised about the potential for enhanced risks for birth defects and neurodevelopmental disorders. Whether FT contributes to the risk of ASD has yet to be established due to inconsistent results found in epidemiological studies. Our study aims to investigate the intersection of ASD and FT with respect to epigenetic alterations, as measured by changes in DNAm levels in white blood cells. Further, as the epigenetic effects of FT occur during oocyte maturation and early embryonic development, they are likely to be reflected in multiple tissues of the individual, including clinically accessible samples such as blood. Using the Illumina Infinium 450K platform, which covers over 450, 000 CpG sites, we compared genome-wide DNAm levels in five groups: 19 patients diagnosed with ASD and conceived with FT (ASD-FT), 17 patients with ASD conceived naturally (ASD-NC), their respective sex-matched, unaffected siblings, and 23 unrelated controls. Following correction for multiple comparisons in our preliminary analysis, two CpG sites were found to be significantly hypermethylated in the ASD-FT group compared to controls ($q < 0.05$), whereas no probes were found to be significantly affected in any of the other three groups. Furthermore, when global DNAm was assessed, there was a trend towards hypermethylation in the ASD-FT group only. In summary, our results demonstrate both site specific and global effects on DNAm in the ASD-FT group, suggesting that FT may predispose embryos to epigenetic changes, contributing to ASD risk.

Distinct Patterns of DNA Methylation in Labial Salivary Gland Tissue Based on Sjgren's Syndrome Disease Status. *M.B. Cole[1], X. Shao[2], D. Quach[2], H. Quach[2], A. Baker[2], L.F. Barcellos[2], L.A. Criswell[3].* 1) Department of Physics, University of California, Berkeley, Berkeley, CA; 2) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, Berkeley, CA; 3) Rosalind Russell Medical Research Center for Arthritis, Department of Medicine, University of California, San Francisco, CA.

Sjgren's Syndrome (SS, OMIM #270150) is a chronic, multisystem autoimmune disease characterized by progressive destruction of the exocrine glands, with subsequent mucosal and conjunctival dryness. A growing body of evidence indicates that epigenetic changes, in particular, altered patterns of DNA methylation, contribute to the development of this complex disease, modulating risk and severity. We report on an expanded case-control study of DNA methylation differences within labial salivary gland tissues, using biopsies sampled from 12 primary SS cases and 5 controls in the Sjgren's International Collaborative Clinical Alliance (SICCA; http://sicca.ucsf.edu/; HHSN268201300057C) collection. These subjects are part of a larger, 36-subject study group for which blood, gland tissue, and cell-sorted blood samples have been methylotyped (110 samples total). We generated genome-wide DNA methylation profiles using Illumina HumanMethylation450 BeadChips and further characterized full genome SNP profiles using the Illumina HumanOmni2.5-Quad platform. All methylation results were background subtracted ('noob' method in methylumi Bioconductor package) and normalized via all sample mean normalization (ASMN) and beta-mixture quantile normalization (BMIQ). Multidimensional Scaling (MDS) applied to the 360,546 CpG sites passing strict QC criteria visibly separates cases from controls within the first 2–3 components, and this clustering changes substantially with the inclusion of a separate set of 9 symptomatic SICCA controls without true SS (based on SICCA's extensive clinical and serologic data). We demonstrate significant gene-centered mean hypomethylation across *IL10* and *IRF5* in SS cases (FDR ≤ .05). Mean methylation levels within 15 other putative SS-associated genes were similar between cases and controls. We report median methylation levels in specific *BLK* and *KLHL24* CpGs that are 15–25% hypermethylated in SS cases in addition to other sites in *IRF5* and *BLK* displaying 10–20% hypomethylation. Single-site methylation differences across 7 of the 17 genes show model-dependent significance under multiple-testing correction, with 6 of the 7 genes exhibiting hypomethylation at a majority of sites. Our results emphasize the utility of DNA methylation as a potential biomarker of disease status. Additional research, including studies of pathway-specific gene expression will be required to fully define the role of DNA methylation in SS-affected salivary glands.

420T

Age and aging dependent epigenetic drift in Danish twins. *Q. Tan, K. Christensen, L. Christiansen.* Epidemiology, Biostatistics and Biodemography, University of Southern Denmark, Odense, Denmark.

Aging is a biological process involving genetic and epigenetic regulation in the cross-talk between the organism and environment leading to the plasticity of aging. Revealing the molecular and epigenetic mechanisms underlying aging is a challenging aspect in biomedical research. We performed genome-wide DNA methylation profiling on Danish twins collected using cross-sectional and longitudinal designs to look for age and aging dependent epigenetic modification across the genome. The cross-sectional data include 150 pairs of monozygotic twins aged 30–74 who were extremely discordant for birth-weight and the longitudinal data contain 43 pairs of like-sex twins (28 monozygotic pairs and 25 dizygotic pairs) aged from 73–82 followed up 10 years until age 83–92. Data were analyzed using the mixed effect model with a kinship matrix to account for the genetic relatedness in twin data. Our epigenome-wide association study (EWAS) on cross-sectional twin data identified 1088 CpG sites differentially regulated (p<5e–05) by age with 610 hypo- and 478 hyper-methylated. The CpG showing highest significance (p = 1.08e-20, cg16867657) on chromosome 6 is located in the CpG island for gene ELOVL2. This gene has been recently reported as an epigenetic marker for age. With p<5e-05, only 21 CpGs were identified with 13 hypo- and 8 hyper-methylated. However, our analysis revealed a predominant pattern of age dependent hypomethylation on the X-chromosome in males which was replicated by a sub-sample of the cross-sectional twins aged over 56 suggesting more progressive loss of the DNA methylation status at advanced ages in males than in females. Overall, our results showed aging is accompanied by loss of control over the DNA methylome with more hypo- than hyper-methylations especially on X-chromosome in males.

421M

Differentially co-methylated genes in postmortem prefrontal cortex of individuals with alcohol use disorders. *H. Zhang[1], F. Wang[1], H. Xu[1], H. Zhao[2], J.H. Krystal[1], J. Gelernter[1].* 1) Psychiatry Dept / VAMC, Yale University School of Medicine, West Haven, CT; 2) Biostatistics Dept, Yale University School of Public Health, New Haven, CT.

Alcohol use disorders (AUDs) may be associated with regional DNA methylation changes reflecting the vulnerability to heavy drinking and the resulting impact on the brain. Genome-wide DNA methylation was examined in postmortem prefrontal cortex (PFC) of 46 European Australians (23 AUD cases: 16 men and 7 women; 23 matched controls: 16 men and 7 women) using Illumina's HumanMethylation450 BeadChip assays. Differentially methylated CpGs and CpG clusters were identified by multiple linear regression and co-methylation analyses. 58,581 CpGs showed differential methylation in AUD subjects ($P_{nominal}$=2.510^{-7}-0.05), but the significance did not survive multiple testing correction (q >0.05). Secondary analyses of data from the 16 male cases and 16 male controls identified 93,919 differentially methylated CpGs in male AUD subjects ($P_{nominal}$=3.110^{-8}-0.05), and the findings from 21,902 CpGs withstood multiple testing correction (q≤0.05). The majority (86.1%) of the 1,178 differentially methylated CpGs ($P_{nominal}$ ≤1.010^{-4}, q≤0.05) were hypermethylated in male AUD subjects. These 1,178 CpGs were clustered into two modules of inter-correlated CpGs, and both modules were significantly associated with AUDs (Module 1: 38 CpGs, $P_{nominal}$ = 6.310^{-7}; Module 2: 1,139 CpGs, $P_{nominal}$ =1.710^{-8}). 1,139 CpGs in Module 2 were mapped to 868 unique genes associated with Wnt signaling (PBH-adj=0.01) and synapes (PBH-adj =0.02) pathways. Taken together, this genome-wide analysis revealed large numbers of postmortem PFC DNA methylation alterations associated with AUDs, predominately increases in DNA methylation. These alterations were enriched for genes associated with neuronal function and were more prominent in males.

422T

Applying the Infinium HumanMethylation450 BeadChip assay to archival formalin-fixed paraffin embedded material for large epidemiological studies. *E.M. Wong[1], J.H.E Joo[1], C.A. McLean[2], L. Baglietto[3], D.R. English[4], G. Severi[3], J.L. Hopper[4], R. Milne[3], L.M. FitzGerald[3], G.G. Giles[3], M.C. Southey[1].* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria 3010, Australia; 2) Anatomical Pathology, Alfred Health, The Alfred Hospital, Victoria 3181, Australia; 3) Cancer Epidemiology Centre, Cancer Council Victoria, Victoria 3053, Australia; 4) Centre for Epidemiology and Biostatistics, The University of Melbourne, Victoria 3010, Australia.

For many large epidemiological studies, archival formalin-fixed paraffin-embedded (FFPE) tumour material represents both a precious and technically challenging resource for molecular studies due to low yields of often highly-degraded DNA. Using FFPE tumour-derived DNA resources is particularly challenging for current genome-wide detection assays that typically require large amounts of high quality DNA. We have thus devised an improved and robust experimental workflow which includes two quality control (QC) checkpoints to address the issues of low yield and quality of this sample type prior to application on the Infinium HumanMethylation450 Beadchip (HM450K) assay.

Using resources from the Melbourne Collaborative Cohort Study, tumour-derived DNA was extracted from 475 macrodissected FFPE breast tumours. Four hundred and seventy FFPE tumour-derived samples with detectable amounts of DNA progressed through the experimental workflow to QC checkpoint 2, where 42 (8.93%) samples failed to pass the hurdle. Of the remaining 428 samples assayed on the HM450K platform, only 4 (1%) samples did not have average detection p-values across all probes of p≤0.01 and thus, failed our QC criterion. Moreover, any probe within a sample with a detection p-value of ≥0.01 was considered technical noise and subsequently removed. The remaining samples (n=424) had an average detection P-value across all probes of 4.54×10^{-4} with high correlations between biological replicates (correlation coefficient r>0.983) further confirming the capacity of our protocol to generate reproducible high quality data.

We have devised a protocol suitable for the analysis of macrodissected FFPE material on the Infinium HumanMethylation450K Beadchip assay and have achieved a 99% success rate on the HM450K platform when applied to FFPE tumour-derived DNA. This protocol will have utility in epidemiological studies that wish to apply this assay to large numbers of samples in a standard and controlled manner and is applicable to a wide variety of studies that wish to investigate the role of methylation in the predisposition and progression of disease.

423M

Allele-specific distribution of 5-hydroxymethylcytosine at imprinting control regions. *K. Yamazawa[1,2], A. Ferguson-Smith[2].* 1) Pediatrics, Keio University School of Medicine, Tokyo, Japan; 2) Physiology, Development and Neuroscience, University of Cambridge, Cambridge, UK.

Covalent modification of cytosine methylation at carbon five represents a major epigenetic mark of mammalian genome and plays a pivotal role in various biological processes. Recent studies have indicated that the Ten-eleven translocation (Tet) family proteins can enzymatically convert 5-methylcytosine (5mC) to 5-hydroxymethylcytosine (5hmC). Additional processing steps and subsequent base excision repair mechanism would then result in the removal of the methylated base and its substitution with an unmethylated cytosine. However, very little is known about the distribution and function of 5hmC at differentially methylated regions (DMRs) which regulate the expression of imprinted genes. To clarify the role of 5hmC in the epigenetic landscape of genomic imprinting, we profiled the allele-specific distribution of 5hmC at representative DMRs in brain, liver, placenta and ES cells derived from reciprocal hybrid mice. The hydroxymethylated and methylated DNA immunoprecipitations with specific antibodies to 5hmC and 5mC, respectively, were followed by quantitative PCR and pyrosequencing for SNP genotyping in hybrid crosses. We found that brain contains a substantial amount of 5hmC and that 5mC and 5hmC exist on the same allele at DMRs in principle. Our findings raise the possibility that 5hmC could be generated on conversion of 5mC as an intermediate inactive demethylation process at DMRs. It is also noteworthy that methylation analysis with conventional bisulfite conversion could overestimate methylation levels at DMRs.

Obesity accelerates epigenetic aging of human liver. *J.E. Hampe[1], W. Erhart[4], M. Brosch[1], O. Ammerpohl[5], W. von Schnfels[6], M. Ahrens[6], N. Heits[6], J.T. Bell[7], T.D. Spector[7], P. Deloukas[7,8,9], R. Siebert[5], B. Sipos[10], T. Becker[6], C. Roecken[11], C. Schafmayer[6], S. Horvath[2,3].* 1) Medical Department I, TU Dresden, University Hospital Dresden, Dresden, Saxony, Germany; 2) Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA; 3) Biostatistics, School of Public Health, University of California Los Angeles, Los Angeles, California, USA 90095; 4) Department of Medicine I, University Hospital Schleswig-Holstein, 24015 Kiel, Germany; 5) Department Institute of Human Genetics, Christian-Albrechts-University Kiel & University Hospital Schleswig-Holstein, Campus Kiel, 24015 Kiel, Germany; 6) Department of Visceral and Thoracic Surgery, University Hospital Schleswig-Holstein, 24015 Kiel, Germany; 7) Department of Twin Research and Genetics Epidemiology, Kings College London, London SE1 7EH, UK; 8) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, EC1M 6BQ, UK; 9) Princess Al-Jawhara Al-Brahim Centre of Excellence in Research of Hereditary Disorders (PACER-HD), King Abdulaziz University, Jeddah 21589, Saudi Arabia; 10) Institute of Pathology, University Hospital Tbingen, 72074 Tbingen, Germany; 11) Institute of Pathology, University Hospital Schleswig-Holstein, 24015 Kiel, Germany.

Obesity entails an increased risk of many chronic diseases that are typically associated with older age. While it is plausible that obesity increases the biological age of some cell types, it has been difficult to test this hypothesis due to the lack of appropriate biomarkers of aging due to difficulties in quantification of tissue age across tissues. Here, we utilize a novel biomarker of aging known as epigenetic clock to study the effect of high body mass index (BMI) on the DNA methylation ages of blood, liver, muscle and adipose tissue. Using a two-stage replication design, we show that liver tissue from obese subjects exhibits strong age acceleration effects which are is independent from histological nonalcoholic fatty liver disease. The accelerated aging in liver is not reversible after weight loss induced by bariatric surgery. In summary, obesity increases the epigenetic age of liver tissue which in turn may give rise to liver-related comorbidities of obesity such as insulin resistance and liver cancer.

Epigenome-wide association study to identify new biomarkers for heart failure. *U. Afzal[1,2], M. Loh[1], J.S. Kooner[2,3,4], J.C. Chambers[1,2,4].* 1) Department of Epidemiology and Biostatistics, Imperial College London, London, UK; 2) Ealing Hospital NHS Trust, Middlesex, UK; 3) National Heart and Lung Institute, Imperial College London, London, UK; 4) Imperial College Healthcare NHS Trust, London, UK.

Heart failure is a leading cause of morbidity and mortality. In the USA alone, 5.1 million people live with heart failure, and heart failure contributed to 11% of deaths and 32 biliion US dollars annual costs. New tools for diagnosis, prevention and treatment of heart failure are urgently needed. We carried out an epigenome-wide association study to identify DNA methylation markers associated with heart failure. We investigated 93 patients with heart failure (defined as left ventricular ejection fraction <40%) and 186 healthy controls matched 2:1 based on gender, age and ethnicity. Average age in cases and controls were 68 (SD: 10.6) and 62 (SD: 10.6) years old respectively, with 82% male and 66% Caucasian participants. Aetiology of heart failure was ischaemic heart disease (47%), dilated cardiomyopathy (46%) and other etiology (17%). We measured methylation in genomic DNA from peripheral blood using the Illumina 450K HumanMethylation array. We applied a detection p-value threshold of 1×10^{-16}, and subsequently excluded markers with call rates <95%; this left 457,060 CpG sites for analysis. Associations of DNA methylation with heart failure were tested using logistic regression with adjustment for age, gender, ethnicity, white-blood cell estimates and technical covariates. Our study had 80% power to identify CpG sites with odds-ratio for heart failure of >3 in top vs bottom tertile of methylation at $P<10^{-4}$. We find 146 methylation markers associated with heart failure at $P<10^{-4}$. The markers identify 120 unique genes. Pathway analysis (Ingenuity) identifies enrichment ($P<0.05$) for genes known to be involved with cardiovascular disease, and heart muscle function including *CTNNA2*, *CAZS1*, *SMOC2*, *ECE1*, *KCNJ1*, *CBY1* and *CELSR1* ($P=7.2\times10^{-4}$ to 2.1×10^{-6}). There were no markers reaching epigenome-wide significance ($P<10^{-7}$). Our findings provide preliminary evidence for the potential of epigenome wide association to identify DNA methylation biomarkers of heart function in peripheral blood in biologically relevant genes. Our results provide the justification for larger scale efforts to investigate the relationships between DNA methylation and heart function.

426T

X chromosome dosage may cause epigenetic sex differences in asthma region 17q12-q21. *A. Altuwaijri[1], N. Fotouhi-Ardakani[2], AK. Naumova[1,2,3].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 3) Department of Obstetrics and Gynecology, McGill University, Montreal, Quebec, Canada.

Males and females have different susceptibility to diseases including asthma. This is due in part to differences in gene expression levels, which in turn may result from sexual dimorphisms in transcriptional regulation. In our previous work (Naumova, 2013), we demonstrated sex-specific differences in DNA methylation levels of the zona pellucida binding protein 2 (ZPBP2) promoter that is located within chromosomal region 17q12-q21, one of the best replicated GWAS regions for asthma (Moffat 2007, 2010). The differences in methylation levels between males and females were consistent with the sex-specific bias in genetic association that we found in the asthmatic families collection from Saguenay- Lac-Saint-Jean (Naumova 2013). We next hypothesized that sex-specific differences in DNA methylation levels at the ZPBP2 promoter resulted from the dosage of the sex chromosome complement. Therefore, ZPBP2 DNA methylation was investigated in DNA samples extracted from fibroblast cell lines derived from individuals with different sex phenotypes and sex chromosome dosage: e.g. 46, XY females (sex reversal); 45, X females (Turner syndrome); 46, XY males; 46, XX females; 46, XX males, and a 48, XXXY male. No significant influence of sex phenotype or the presence of the SRY gene was detected. However, significant positive correlation was found between ZPBP2 methylation levels and the number of X-chromosomes. Individuals with one X chromosome had considerably lower methylation levels (n=9, average DNA methylation level 17.5 %) compared to individuals with more than one X chromosome (n=9, average DNA methylation level 29.3 %) ($p = 0.005$, t-test statistics). Thus, our data show that the X chromosome dosage has an effect on DNA methylation and perhaps may contribute to disease susceptibility. Our data are consistent with the effect of X-chromosome dosage on gene expression in mice (Wijchers 2010) and DNA methylation in humans (Grafodatskaya 2013). Currently, our laboratory is working towards identifying the X-linked gene(s) that are responsible for methylation differences at autosomal regions and at the asthma-associated region of chromosome 17q12-q21, in particular.

427M

Epigenome-wide DNA methylation and body mass index in monozygotic twins. *J.T. Bell[1], F. Gao[2], C.G. Bell[1], Y. Xia[2], W. Yuan[1], L. Roos[1], P.-C. Tsai[1], K. Ward[1], P. Deloukas[3,4], J. Wang[2], T.D. Spector[1].* 1) Department of Twin Research, King's College London, London, United Kingdom; 2) BGI-Shenzhen, Shenzhen, China; 3) William Harvey Research Institute, Queen Mary University of London, London, United Kingdom; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Obesity is a major risk factor for multiple common diseases. Genetic, environmental and recently epigenetic factors been shown to associate with obesity, offering potential to help understand and modify disease risk. Here, we focus on identifying the epigenetic signatures of environmentally mediated risk of obesity and its impacts, by studying monozygotic twins. We performed an epigenome-wide association scan of body mass index (BMI) in 1,446 UK monozygotic twins from 723 pairs (mean age = 51.8, mean BMI = 25.9 kg/m^2) from the EpiTwin project (www.epitwin.eu), part of TwinsUK. Whole blood DNA methylation was assayed using methylated DNA immuno-precipitation followed by high-throughput sequencing (MeDIP-seq), allowing for full genome-wide coverage at 10.5 million overlapping bins of size 500bp. Differentially methylated regions related to BMI were identified by comparing DNA methylation discordance to BMI discordance within twin pairs (mean absolute BMI twin-pair discordance = 4.4 kg/m^2, mean relative discordance = 0.2 units). The most associated signals included a region within an intron of the *CDKAL1* gene (P = 3.6e-7), a GWAS obesity and type 2 diabetes susceptibility locus. Functional annotation based on gene structure, Encode data, and chromHMM chromatin states showed strong enrichment of differential methylation in poised promoters. Genome-wide significant effects within poised promoters were observed in genes *SUSD4* (FDR = 0.04, P = 2.0e-6) and *SLC10A4* (FDR = 0.05, P = 4.8e-6), and the *SLC10A4* result validated at an overlapping CpG-site on the Illumina 450k array in whole blood samples from 355 individuals. Replication is currently ongoing in 424 individuals using MeDIP-seq. Our results show epigenetic studies in monozygotic twins are a powerful tool for identifying functional genomic changes in complex traits such as obesity.

428T

DNA-methylation and the Down Syndrome phenotype. *A. Bouman[1], P. Henneman[1], M.M.A.M. Mannens[1], A.N.P.M. Mul[1], E.J. Meijers - Heijboer[1], R.C.M. Hennekam[1,2,3].* 1) Department of Clinical Genetics, Academic Medical Center, Amsterdam, The Netherlands; 2) Department of Pediatrics, Emma Children's Hospital, Amsterdam, The Netherlands; 3) Department of Translational Genetics, Emma Children's Hospital, Amsterdam, The Netherlands.

Down syndrome (DS) is the most frequent genetic cause of intellectual disability known today. DS is explained by the presence of an additional chromosome 21 which serves as the basis of DS-pathogenesis. However, underlying cellular and molecular processes causing the DS-phenotype remain not well understood. Several hypotheses exist regarding the implications and effects of the presence of trisomy 21. In this study we hypothesize that the presence of an extra chromosome 21 might influence the DNA-methylation pattern of (parts of) chromosome 21 and/or other loci throughout the genome. Since DNA-methylation plays an important role regarding gene transcription regulation, differentially methylated loci of specific genes can either cause increased or decreased transcription. This altered transcription may play a major role in causing several of the specific features of the DS-phenotype. White blood cell DNA-methylation patterns of 10 individuals with DS and 10 healthy (age- and sex-matched) controls were obtained using the Illumina 450K Human DNA-methylation Array. DNA was bisulphite converted using the gold standard kit of Zymo ®. Analysis of the data was performed using two freely available "R" packages; minfi and champ. We will discuss the results of our DS methylation-study and zoom in on specific genes which show a distinct methylation patterns in DS vs. controls. Our study serves as an addition in ongoing fundamental DS-research.

429M

Low-input Detection of Whole Genome Hydroxymethylation. *J. Burgess[1], D. Han[2], X. Lu[2], A. Khanna[1], C. He[2], H. Grunenwald[1], R. Vaidyanathan[1].* 1) Epicentre, an Illumina Company, 5602 Research Park Boulevard, Madison, WI, 53719; 2) University of Chicago, Department of Chemistry, Chicago, IL, 60637.

5-hydroxymethylcytosine (5hmC) is a recently discovered nucleotide variant with a multitude of implications in human disease and development, including cancer and neuro-disorders. In addition, 5hmC has been shown to be an intermediate step in demethylation, leading to gene expression, and is typically most concentrated in stem cells and brain tissue. A robust method of 5hmC detection includes Tet-assisted Bisulfite Sequencing (TAB-Seq). Used in conjunction with EpiGnomeTM whole genome bisulfite sequencing, which only requires as little as 50ng input DNA, it is possible to sequence the entire hydroxymethylome. In this study, we leveraged the robustness and low input requirement of EpiGnomeTM to obtain good mapping at 100ng input into TAB-Seq, with measured levels of hydroxymethylation that closely mimic previously published whole genome results obtained from microgram amounts of DNA. Investigations to reduce initial TAB-Seq input even further to 10ng (1000 cells) have retrieved promising proof of concept data. Corroboration of these low-input TAB-Seq/EpiGnome data with prior analyses of these mESCs reveals a high correlation. This study demonstrates robust and efficient combination of TAB-Seq with the WGBS EpiGnomeTM Kit to allow the previously unachievable low input detection of the entire 5-hydroxymethylome.

Full resolution DNA methylome analysis in multiple tissues from twins. *S. Busche[1,2], X. Shao[1,2], M. Caron[2], T. Kwan[2], B. Ge[2], F. Allum[1,2], W. Cheung[1,2], S. Westfall[1], J. Qi[1,2], M.M. Simon[2], J.T. Bell[3], P. Deloukas[4,5], M. Blanchette[6], T.D. Spector[3], G. Bourque[1,2], M. Lathrop[1,2], T. Pastinen[1,2], E. Grundberg[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 4) William Harvey Research Institute, Queen Mary University of London, London, United Kingdom; 5) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 6) School of Computer Science, McGill University, Montreal, Quebec, Canada.

DNA methylation is essentially involved in human trait formation and disease susceptibility. Using whole genome bisulfite sequencing we generated full genome single-base resolution methylomes of 34 adipose and 27 whole blood samples from monozygotic (MZ) and dizygotic twins of the well characterized MuTHER cohort aiming to unravel the impact of environmental, genetic, and stochastic factors underlying methylation variation. We generated 2.3 Tbp data yielding an average coverage of 6.3x and 8.7x detecting 25M and 26M CpG sites in fat and blood, respectively (mean methylation ~80%). Static methylation was detected at 23% and 5% of CpGs in fat and blood, respectively, with hypomethylation strongly enriched and hypermethylation strongly depleted in promoter regions in both tissues. Pairwise comparisons identified a total of 21% and 16% population differentially methylated CpGs (pDMCs; $\Delta \geq 40\%$), including 2.2% and 1.7% extreme pDMCs (<20% vs. ≥80%) in fat and blood, respectively. Confounding sequence variants were identified to underlay more than half extreme pDMCs. Population differentially methylated regions (pDMRs) were defined to cover 10% of CpGs per tissue displaying high variation across individuals and high consistency across sites. pDMCs and pDMRs were depleted in promoter regions in both tissues. Fat pDMRs were subdivided into hypo- (<50%) and hypermethylated (≥50%): hypo-pDMRs were 12-fold enriched in enhancers, and transcription factor (TF) binding site motif analysis identified enrichment of TFs involved in energy metabolism and adipocyte differentiation including ERRA (p=1e-95), RXR (p=1e-65), and EBF1 (p=1e-39). Hyper-pDMRs mapped to genes involved in lipid metabolism (p=1.5e-5). Using the MZ twin structure we identified ~90 environmental DMRs (eDMRs) per tissue and pair with no overlap across tissue and found links to phenotype discordance, e.g. body mass index for fat-specific eDMRs. CpH methylation was rare in both tissues impacting 0.2% of total CpH sites (49% CpA, 33% CpT, 18% CpC methylation). Within the population CpH methylation patterns were mainly bimodal although a subset of normal distributed CpH methylation was detected. Genome feature association of CpH methylation is ongoing. Our study describes the first comprehensive and unbiased analysis of human population level DNA methylation variation to date, highlighting the importance of looking beyond promoter methylation and providing a guideline for designing future methylome studies.

431M

Monoamine oxidase A (MAOA) expression level predicts alcohol consumption in Rhesus macaques. *R.P. Cervera Juanes[1], R. Lee[2], B. Park[3], G. Wand[2], K.A. Grant[1], B. Ferguson[1].* 1) Neurosciences, ONPRC, OHSU, Beaverton, OR; 2) Johns Hopkins University, Baltimore, MD; 3) 3Department of Public Health and Preventive Medicine, Oregon Health & Science University, Portland, OR.

Monoamine oxidase A metabolizes the neurotransmitters serotonin, norepinephrine and dopamine, which are key regulators of behavior. Both a repeat polymorphism in the promoter of the MAOA gene (MAOA-LPR) and a history of childhood adversity have been linked to risk for alcohol use and behavioral disorders in humans and rhesus macaques. To investigate the potential genetic and epigenetic mechanisms underlying these risks, we collected blood from twelve unrelated, male rhesus macaques before and after they participated in a 12-month alcohol self-administration study. We determined MAOA-LPR genotypes, promoter CpG methylation levels and MAOA mRNA levels in all samples. We found that mRNA levels were independent of MAOA-LPR genotype. However, there was a robust association between site-specific CpG methylation level and MAOA expression. Of particular interest, our results show a strong association between MAOA mRNA level and the subsequent amount of alcohol consumed during the 12-month self-administration protocol. After 12 months of alcohol use, rhMAOA expression was significantly reduced, and there was a moderate increase in regional and site-specific CpG methylation levels. Thus our results indicate that blood MAOA mRNA level is more tightly associated with promoter methylation than with MAOA-LPR genotype. Moreover, since the level of MAOA expression was predictive of subsequent heavy alcohol use, CpG methylation may provide a molecular link between childhood adversity and sustained risk for alcohol use. Finally, our finding that chronic alcohol consumption further dampens gene expression, suggests that reduced MAOA availability, and its downstream effects on dopamine, serotonin and epinephrine levels, may also contribute to alcohol addiction. This work was supported by NIH grants U01AA020928 and U01AA013510.

Genome-wide DNA methylation study in American Indians identifies five genes associated with intrauterine diabetes exposure. *P. Chen, S. Kobes, V. Ossowski, R. Nelson, J. Weil, W.C. Knowler, P.H. Bennett, C. Bogardus, L.J. Baier, R.L. Hanson.* Phoenix Epidemiology & Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health.

Exposure to a diabetic intrauterine environment is a strong risk factor for the development of type 2 diabetes in the offspring. DNA methylation has an important role in the epigenetic response to the environment. However, the genes which are subject to methylation in response to intrauterine diabetes exposure remain largely unknown. To discover differentially methylated genes and relevant pathways in response to intrauterine diabetes exposure, we selected, from a longitudinal study of Pima Indians, 189 individuals whose mothers had type 2 diabetes during their pregnancy and 201 individuals whose mothers didn't have diabetes during their pregnancy. We assayed the offspring's genome-wide DNA methylation in peripheral blood, collected when the participant was not diabetic, using the Illumina HM450 array. Quality control excluded the probes with a detection P value > 0.01 or having a SNP within 10 base pairs. Following these quality control measures, 395,899 methylation sites remained for association testing. The association between intrauterine diabetes exposure and methylation of CpG sites was tested in a linear model with adjustment for maternal age (at the time of the child's birth), as well as the proportion of American Indian ancestry, age and sex of the child. We calculated the difference in methylation score (d, in SD units) in those exposed to a diabetic intrauterine environment, compared with those unexposed. Exposure to a diabetic intrauterine environment was significantly associated with methylation of CpG islands in 5 genes: *LHX3* (d=0.67, FDR=4.6E-4) and *WNT9B* (d=0.52, FDR=4.8E-2) were hypermethylated in those exposed while *PPP1R3B* (d=-0.66, FDR=9.0E-4), *ATP8B3* (d=-0.56, FDR=6.7E-3) and *LINC00839* (d=-0.55, FDR=4.8E-2) were hypomethylated. The expression level of *LHX3*, a LIM1-homeodomain transcription factor which is under the control of the ISL1 transcriptional regulator, has previously been shown to be controlled by methylation in mice. In the pathway enrichment analysis of the 103 hyper-methylated and 1262 hypo-methylated genes (P<0.005) using DAVID, the sequence-specific DNA binding pathway (P=2.9E-5, Bonferroni=7.0E-3) and the guanyl-nucleotide exchange factor activity pathway (P=1.0E-4, Bonferroni=9.4E-2) were enriched. Our results identified five genes that are differentially methylated with exposure to a diabetic intrauterine environment. Validation of these findings in additional samples is ongoing.

DNA enrichment as a cost effective tool to examine DNA methylation at single nucleotide resolution. *A. Czyz, V. Ruotti, A. Tan, D. Hill, S. Kuersten, R. Vaidyanathan.* R&D Department, Epicentre an Illumina company, Madison, WI., USA.

Epigenetic modifications are punctuation marks on DNA, responsible for modification of transcriptional activities. One of the most characterized epigenetic modifications is DNA methylation. DNA methylation plays a role in a variety of biological processes including embryonic development, cell differentiation, chromosome stability, and chromatin structure. Aberrant DNA methylation has been found to be associated with various intellectual disabilities, including obesity, anemia and numerous types of cancer. In mammalian cells, methylation occurs mostly at cytosines that are contained in the symmetrical dinucleotide CpG, or in an asymmetrical CHH or CHG context. Methylated nucleotides are generally grouped in promoter regions, CpG islands, and CpG shores. EpiGnome Methyl-Seq Kit is a simple, 1-day, post-bisulfite library construction method that requires only 50–100 ng of input gDNA. However, providing enough coverage for whole-genome bisulfite libraries typically requires 60–120 Gb of sequencing, and therefore, is relatively expensive. In contrast, several strategies exist for enrichment of target sequences that are more cost effective, including probes and use of methylation-specific antibodies. The central weakness of these last methods is lack of single nucleotide resolution. But, by combining enrichment methods and DNA bisulfite treatment with the EpiGnome protocol, we circumvent this shortcoming. To demonstrate, we took MeCP2 methyl binding domain and IgG A1 antibodies derived against 5mC, and used it for enrichment of beta-lymphocyte gDNA NA18508, prior to continuing with the EpiGnome library preparation kit. The prepared libraries were sequenced and analyzed by utilization of the commercially available BISMARK and MEDIPS bioinformatic packages. We observed significant enrichment of promoter and CpG islands, comparable to standard EpiGnome libraries without enrichment. With only 8GB (50M reads) sufficient for analysis, and thus possibility of multiplexing enriched libraries on HiSeq 2500 platform, the enrichment method provides a cost effective approach for methylation study.

Genapha/dbASM: web based tools to investigate allele-specific methylation. *D. Daley, B. Chen, K. Ushey, G. Ellis.* Dept Med, Center for Heart and Lung Innovation, Univ British Columbia, Vancouver, BC, Canada.

As interest in studying allele-specific methylation (ASM) and it's association with common complex diseases grows, there is a need for a resource that stores and catalogs SNPs and regions that demonstrate allele specific methylation, analogous to NCBI's dbSNP. Additionally, as ASM is a regulatory mechanism that may be associated with hits from genome-wide association studies (GWAS), researchers need a suite of tools to help them evaluate the relationship between GWAS hits and ASM. To facilitate these investigations, we have created a new web resource called dbASM, hosted on the Genapha web server (www.genapha.ca). The aim of dbASM is twofold: 1. Curate from the literature a publicly-accessible database of known sites of ASM. 2. Provide researchers with a web-based platform of tools for exploring ASM and determining regions of interest. We will present the dbASM resource including details on the underlying database construction and datasets, in addition to the web tools and example workflows. The web tools that are currently available are: GWAS Catalog SNP Search, ASM SNP Search, SNP Counter, Methylation Plots Generation, and Sequence Viewer. GWAS Catalog SNP Search allows browsing through NHGRI's Catalog of Published Genome-Wide Association Studies by phenotype and filtering GWAS SNP's based on their relation to suspected sites of ASM. For example, rs11742570 is associated with inflammatory bowel disease (p=2.0 E-82) and demonstrates ASM. ASM SNP Search supports finding SNP's based on: ASM status or interrogability; location compared to genes, a chromosomal region, or other SNP's; and filtering by population minor allele frequencies and sample size. SNP Counter uses asynchronous JavaScript calls to the database to provide real-time counts of types of SNP's in user-selected regions of chromosome. Methylation Plots Generation is a calculates SNP correlation stratifying by genotype with CpG site methlyation patterns, similar to epigenome wide association studies (but without disease status),using CEPH HapMap samples and genotypes and methylation assays on these same samples completed on the Illumina 27K array. Sequence Viewer displays SNP's in the human reference genome (based currently on GRCh37.p10 and dbSNP build 137) with annotations showing ASM SNP's and regions of interrogability via MSRE cut sites for enzymes: HpyCH4IV, AciI, HhaI, and HpaI. These tools are all freely available for use at: http://genapha.icapture.ubc.ca/asm/.

DNA Methylome Modifications Associated with HPA Axis Differences in Chronic Fatigue Syndrome. *W.C. de Vega[1,2,3], P. Manser[4,5], M. Reimers[4,6], S.D. Vernon[7], P.O. McGowan[1,2,3].* 1) Centre for Environmental Epigenetics and Development, University of Toronto Scarborough, Toronto, ON, Canada; 2) Department of Biological Sciences, University of Toronto Scarborough, Toronto, ON, Canada; 3) Department of Cell and Systems Biology, University of Toronto, Toronto, ON, Canada; 4) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA, USA; 5) Department of Biostatistics, Virginia Commonwealth University, Richmond, VA, USA; 6) Department of Psychiatry, Virginia Commonwealth University, Richmond, VA, USA; 7) CFIDS Association of America, Charlotte, NC, USA.

Chronic Fatigue Syndrome (CFS) is a complex multifactorial disease that is characterized by the presence of fatigue and other particular symptoms that cannot be mitigated by rest. CFS is a multisystem and heterogeneous disease, and the biological basis of CFS is poorly understood. Some of the most consistent differences observed in previous CFS studies are modified immune gene expression and changes in the hypothalamic-pituitary-adrenal (HPA) axis that include mild hypocortisolism and enhanced negative feedback to glucocorticoids. To determine a potential role of epigenetics in CFS, we examined the DNA methylome in peripheral blood mononuclear cells (PBMCs) isolated from female CFS patients (n = 46) and healthy controls (n = 25) using the Illumina HumanMethylation450 BeadChip array. All subjects were non-obese and did not consume medications with known immunological or epigenetic effects. A two-tiered approach (a high-confidence and a medium-confidence cutoff) was applied to examine evidence for differential DNA methylation in CFS. The high-confidence cutoff identified 378 differentially methylated sites and the medium-confidence cutoff identified an additional 13,059 differentially methylated sites. RAND-36 scores, a survey assessing quality of life, revealed that CFS patients had lower scores compared to healthy controls across most categories. The first two principal components of RAND-36 explained 85% of DNA methylation variability among subjects and discriminated between CFS and controls accurately. HPA axis response in PBMCs was explored using an in vitro dexamethasone suppression assay. An increased sensitivity to dexamethasone in CFS was observed with the appearance of two subgroups (responders and non-responders) among the CFS subjects. We identified 18 differentially methylated sites between CFS and controls among the medium confidence group that were associated with the HPA axis. DNA methylation differences also existed between responders and non-responders, which underscores the potential of using DNA methylation differences in determining CFS subtypes. Our work is the first to examine DNA methylome changes in CFS and supports a role for epigenetic modifications in the increased glucocorticoid sensitivity observed in some CFS patients. These epigenomic differences could serve as potential biomarkers for future clinical research and assist in determining the biological basis of CFS.

Smoking Associated DNA Methylation Changes in Peripheral Blood Mononuclear Cells from African American Women and Weighted Protein-Protein Interaction Networks. *M.V. Dogan[1,2], B. Shields[2], C. Cutrona[3], L. Gao[1], F.X. Gibbons[4], R. Simons[5], M. Monick[6], G.H. Brody[7], K. Tan[1,6], S.R.H. Beach[7], R.A. Philibert[1,2].* 1) Department of Biomedical Engineering, University of Iowa, Iowa City, IA; 2) Department of Psychiatry, University of Iowa, Iowa City, IA; 3) Department of Psychology, Iowa State University, Ames, IA; 4) Department of Psychology, University of Connecticut, Storrs, CT; 5) Department of Sociology, University of Georgia, Athens, GA; 6) Department of Internal Medicine, University of Iowa, Iowa City, IA; 7) Center for Family Research, University of Georgia, Athens, GA.

Smoking is the largest yet preventable cause of morbidity and mortality in the United States. Regular smoking has been attributed to the vulnerability and progression of numerous diseases and disabilities including cancer, diabetes and stroke. Understanding mechanism(s) through which smoking increases vulnerability to complex disorders is crucial in delineating both prevention and treatment options. Our study examined DNA methylation of peripheral blood mononuclear cells from 111 African American women. In order to determine smoking associated perturbation of DNA methylation, genome wide methylation obtained from the Illumina HumanMethylation 450k BeadChip was analyzed with respect to smoking status, controlling for slide, plate and mixed cell population. This analysis yielded 910 significant loci after genome wide Benjamini-Hochberg correction. Of these loci, two loci from the AHRR gene (cg05575921, corrected p-value = 6.17E-19 and cg23576855, corrected p-value = 3.37E-12) and one locus from the GPR15 gene (cg19859270, corrected p-value = 1.19E-19) were highly significantly differentially methylated. Due to a mere 0.1 difference in average methylation values between smokers and non-smokers at numerous loci, it was crucial to validate the Illumina array findings. Since cg05575921 is not only sensitive to long-term smoking, but also to early smoking, this locus is a consistent, sensitive smoking biomarker. Hence, a quantitative-PCR primer probe set was used to independently validate the differential methylation at cg05575921. A strong correlation of 0.94 was achieved between the primer probe set and the Illumina methylation values. Since there is growing evidence suggesting that genes function in networks rather than independently, methylation at a single locus was translated into weighted protein-protein interaction networks using network theory to obtain an integrated understanding of the proteome. Critical sub-networks were generated using the miPALM algorithm. This greedy search algorithm mapped smoking associated DNA methylation to 10 significant protein sub-networks ranging from 5 to 25 proteins. BiNGO analysis of these networks demonstrated enrichment for pathways mediating inflammation, immune function and coagulation. Hence, it can be concluded that smoking potentially increases vulnerability to diseases with inflammatory components by perturbing pathways through the alteration of DNA methylation signature of peripheral blood mononuclear cells.

Obesity is a global health problem and a major risk factor for type-2 diabetes and cardiovascular disease. The mechanisms underlying obesity and its complications are incompletely understood. We carried out an epigenome-wide association (EWA) study to investigate the relationship of DNA methylation with body mass index (BMI) to examine the epigenetic perturbations associated with obesity. The EWA study included four studies comprising 5,387 whole-blood samples from European (N=2,707) and South Asian (N=2,680) individuals. DNA methylation was determined by Illumina Infinium 450K Human Methylation array. Associations of DNA methylation with BMI were tested in each cohort using linear regression with adjustment for age, gender, physical activity, smoking, alcohol intake, white-blood cell estimates and technical covariates. Meta-analysis across the studies was done by METAL. Our primary EWA yielded CpG sites at 207 independent genetic loci associated with BMI at $P<1\times10^{-7}$, with little evidence for heterogeneity between the populations. We then carried out replication testing of the 207 sentinel CpG sites amongst 4,998 whole-blood samples from 9 independent cohorts. 187 of the 207 markers reached $P<0.05$ in replication testing and remained $P<1\times10^{-7}$ in combined analysis across all stages. A gene set enrichment analysis of the 187 identified genetic loci revealed enrichment for pathways involved in transmembrane transport and metabolic signalling (lipid metabolism, insulin signalling and PPAR signalling) at the 5% FDR level. Further, the 187 sentinel CpGs were located outside CpG Islands and show a significant enrichment for "open sea" locations ($p=4.4\times10^{-9}$), mostly located within gene bodies ($p=2.6\times10^{-4}$). We overlapped the 187 sentinel CpG sites with ENCODE ChiP data peaks and observed an enrichment for DNase hypersensitivity sites ($p=2.4\times10^{-7}$), enhancers ($p=3.5\times10^{-9}$) and the activating histone mark H3K4me1 ($p=3.85\times10^{-12}$). We identify 187 genetic loci at which DNA methylation is associated with BMI. Our results provide new insight into potential DNA regulatory mechanisms associated with obesity and its complications.

Hypomethylation of Synaptic Genes revealed in Dup15q Autism. *K. Dunaway[1,2,3,4], M.S. Islam[1,2,3,4], D.I. Schroeder[1,2,3,4], I.N. Pessah[3,4,5,6], P. Lott[2], M. Meguro-Horike[7], S. Horike[7], R. Chu[1,2], I. Korf[2], J.M. LaSalle[1,2,3,4].* 1) MMI, UC Davis, Davis, CA; 2) Genome Center, UC Davis, Davis, CA; 3) MIND Institute, Sacramento, CA; 4) Center for Children's Environmental Health, UC Davis, Davis, CA; 5) Environmental Toxicology, UC Davis, Davis, CA; 6) Molecular Biosciences, UC Davis, Davis, CA; 7) 7Advanced Science Research Center, Kanazawa University, 13-1 Takaramachi, Kanazawa 920-0934, Japan.

Chromosome 15q11-13 duplication syndrome (Dup15q) is one of the most common copy number variations observed in autism-spectrum disorders. Surprisingly, a prior analysis of Dup15q human brain samples showed both DNA hypomethylation measured by LINE-1 pyrosequencing and significantly higher levels of the persistent organic pollutant PCB 95 than controls or idiopathic autism cases. In order to take an unbiased view of the whole methylome, including genic, intergenic, and repetitive regions, we performed MethylC-seq and developed novel bioinformatic analyses. Six Dup15q and matched control cortical (BA19) postmortem samples were used to determine methylation patterns in Dup15q through custom hidden Markov models, demonstrating large-scale hypomethylated domains throughout the genome. We also analyzed percent methylation in repetitive regions, which are normally neglected due to the complexity of their analyses. Using a bioinformatics toolkit we created, LINE-1 hypomethylation in Dup15 brain samples compared to controls was confirmed and analysis of additional repetitive elements is underway. To experimentally model the interaction of Dup15q and PCB 95, human SH-SY5Y neuroblastoma cells containing an additional maternal chromosome 15 (SH-15M) were assayed using MethylC-seq. SH-15M cells exhibited a 2–14% increase of hypomethylated domains spanning across every autosome compared to the parental SH-SY5Y cell line, an effect independent of PCB-95 exposure. Genes within the hypomethylated regions specific to SH-15M were enriched for functions at the postsynaptic cell membrane while those genes in hypomethylated regions specific to PCB 95 exposure were enriched for ion channels, neurotransmitter, and synaptic functions. Transcript levels of 48 autism candidate genes found in these hypomethylated regions were compared them across 48 different cell lines, single-cell clones, and postmortem brain samples by quantitative RT-PCR in the Fluidigm Biomark. Aberrant transcript levels were observed for multiple glutamate, serotonin, and GABAA receptor genes, with a significant compounding effect of SH-15M and PCB 95 for GRIA1. In summary, we found large-scale epigenomic changes to the brain methylome in Dup15q syndrome that can be modeled in cell culture and further compounded by PCB 95 exposure, altering synaptic gene transcript levels. These results have implications for understanding and treating complex gene-environment interactions in autism-spectrum disorders.

439M

Genome-wide DNA methylation study identifies genes associated with GDF-15 levels. *W.E. Ek[1], A.K. Hedman[2,4], S. Enroth[1], S. Gustafsson[2,4], E. Ingelsson[2,4], U. Gyllensten[1], L. Lind[3], A. Johansson[1,4].* 1) Department of Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala University, Uppsala, Uppsala, Sweden; 2) epartment of Medical Sciences, Molecular epidemiology, and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Medical Sciences, Cardiovascular Epidemiology, Uppsala University Hospital, Uppsala, Sweden; 4) Uppsala Clinical Research Center, Uppsala University, Uppsala, Sweden.

Introduction. Growth differentiation factor 15 (GDF-15) is a member of the transforming growth factor-β (TGF-β) family. Under physiologic conditions, GDF-15 is expressed in low to moderate levels in most healthy tissues and levels may increase in response to pathological stress associated with inflammation, oxidative stress or tissue damage. Overexpression of GDF-15 has been seen in various cancers and growing evidence indicate that GDF-15 levels in plasma may be a new biomarker for risk stratification and therapeutic decision making in cardiovascular disease.

Methods: We performed a genome-wide DNA methylation study to determine the association between GDF-15 and DNA methylation in 717 individuals from the Northern Sweden Population Health Study (NSHPS). DNA methylation status, in white blood cells, was determined at more than 475,000 sites distributed throughout the genome. Significant findings where replicated in 950 individuals from an independent cohort (PIVUS). We also performed gene ontology (GO) enrichment analysis to identify terms enriched for differently methylated genes in relation to GDF-15 levels.

Results: A total of 31 CpG sites, corresponding to 22 genes, were significantly associated (false discovery rate [FDR] q-values < 0.05) with GDF-15 in NSHPS. Of these, 12 sites replicated in PIVUS ($p < 0.05$). One of the replicating sites is located in the promoter region of MIR21, which encodes one of the most well studied microRNAs that has been associated with cancer and cardiovascular diseases. A total of 125 enriched biological processes were identified (FDR q-value < 0.05), of which 43 (34 %) replicated ($p < 0.05$). Among the enriched biological processes, we found terms involved in developmental, biological and metabolic processes. A total of 13 enriched molecular functions were also identified (FDR q-value < 0.05), of which 5 (38 %) replicated ($p < 0.05$). Among molecular functions, we found terms involved in protein binding and kinase activity.

Conclusion: We have shown that GDF-15 levels are correlated with DNA methylation level at numerous sites in the genome providing new leads for investigating the links between GDF-15 and cardiovascular disease. However, our results suggest that GDF-15 plays an important role in many biological processes, even in the absence of response to pathological stress.

Black-white difference in regional patterns of DNA methylation: the Bogalusa Heart Study. *X. Fu[1], D. Sun[2,3], S. Li[2], C. Fernandez[2], T. Chen[4], Y. Lian[4], Q. Li[4], W. Chen[2].* 1) Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA; 2) Department of Epidemiology, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA; 3) Department of Epidemiology, School of Public Health, Peking University Health Science Center, Beijing, China; 4) Microarray Core Facility, University of Texas Southwestern Medical Center, Dallas, TX, USA.

Although DNA methylation profiles vary by populations, regional patterns of DNA methylation in different populations are largely unknown. The objective of this study is to examine black-white difference in regional patterns of DNA methylation in relation to pathophysiological pathways. This study included 846 adults aged 28–51 years (594 whites and 252 blacks) from the Bogalusa Heart Study. Peripheral leukocyte DNA methylation was measured with Infinium HumanMethylation450 BeadChip. After sample and probe quality analysis and cell-type count estimation, a linear regression model with age, gender, cell-type count included as covariates was fitted to find the significantly differential methylation sites between races. To avoid bias towards high probe density region, a feature-oriented dynamic window method "lasso" was used to capture significantly differential regions. Enrichment analysis in KEGG pathways was performed with selected differential methylation-related gene sets. Besides, correlation patterns of methylation were examined by race groups, followed by a comparison with genetic LD structure. A total of 1,225 regions were captured among 48,241 sites that were found to be significantly, differentially methylated between blacks and whites. Enrichment analysis using genes located in these 1,225 regions identified 15 pathways in the KEGG database which were related to human complex diseases known to have different prevalence rates among populations. In correlation analysis, significant differences in both position and size of clusters were observed in every chromosome, especially in chromosome 2, 4, 10, 13 and 22, between blacks and whites. These correlation patterns were not all caused by genetic LD structures. In conclusion, the findings of the current study on black-white difference in regional patterns of DNA methylation has implications in understanding of potential race-specific epigenetic mechanisms and pathophysiological pathways underlining chronic diseases.

Identification of epigenetic signatures of childhood socioeconomic-related adversity. *S.J. Goodman[1,2], W.T. Boyce[3,4,5], S. Lam[4], J.L. MacIsaac[1], M.J. Jones[1], S.M. Mah[1], A. Zaidman-Zait[4], M.S. Kobor[1,2].* 1) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, Vancouver, British Columbia, Canada; 2) Medical Genetics, University of British Comlubia, Vancouver, British Columbia, Canada; 3) School of Population and Public Health, University of British Comlubia, Vancouver, British Columbia, Canada; 4) Human Early Learning Partnership, University of British Comlubia, Vancouver, British Columbia, Canada; 5) Pediatrics, UCSF School of Medicine, San Francisco, California, USA.

Rationale: Socioeconomic status (SES) is a potent yet enigmatic environmental determinant of human health. Childhood experiences of SES are known to alter development and well-being and cause health disparities later in life, suggesting that they are somehow 'biologically embedded'. Gene Expression Collaborative for Kids Only (GECKO) was established to study the mechanisms of biological embedding in socioeconomically diverse children. An important part of the study is investigating how DNA methylation may interact with both the environment and DNA variants, thereby stably imprinting genetic and environmental information into the epigenome. We hypothesize that socially driven developmental trajectories in children are mediated by the interactions of environment, epigenetics and genetic variants, which ultimately result in phenotypic differences and health disparities later in life. **Methods:** Using the Illumina Human Methylation 450K array platform, we have examined genome-wide DNA methylation of buccal epithelial cells (BECs) in 400 8–10 year old individuals from the GECKO cohort. For a subset of participants, whole blood and newborn dried blood spot (DBS) samples were obtained to compare BEC methylation patterns to those present in peripheral blood mononuclear cells (PBMCs) and neonatal blood from each child. Genetic variants were evaluated by running saliva DNA from each participant on the Illumina PsychArray BeadChip. **Results and implications:** We interrogated epigenomic correlates of childhood experiences and exposures to identify a set of loci showing experience-dependent epigenetic modifications. A differential analysis of methylation by SES, as measured by family income, parent occupation and education, produced a list of candidate loci which may be involved in biological embedding. Replication of this analysis on the DBSs and PBMCs reinforced the tissue-specific nature of DNA methylation. Unsupervised clustering of the paired DBS and PBMC samples showed that the methylation of two unrelated individuals in a single tissue is more alike than the methylation of two tissue types from one individual. Candidate methylation loci will be interrogated for DNA variants to identify potential risk alleles which are more prone to methylation disturbances by SES. Understanding the molecular and epigenetic mechanisms by which early adversity and SES lead to disturbances in health is a fundamental first step in elucidating the origins of health disparities.

442T

Methylation patterns are associated with chronological age in the Khomani San of South Africa. *S. Gopalan[1], O. Carja[2], E. Patin[3], M.S. Kobor[4], H. Fraser[2], M. Feldman[2], A. Froment[5], L. Quintana-Murci[3], B. Henn[1].* 1) Ecology and Evolution, Stony Brook University, Stony Brook, NY, United States; 2) Department of Biology, Stanford University, Stanford, CA, United States; 3) Department of Genomes and Genetics, Human Evolutionary Genetics, Institut Pasteur, Paris, France; 4) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 5) Musum National d'Histoire Naturelle, Paris, France.

Changes in genomic methylation have been found to be associated with advancing age. Increased age is correlated with an overall genome-wide reduction in methylation, but also an increase in methylation of particular regions, such as CpG islands. So far, studies of methylation as it relates to aging in humans are primarily done in populations of European origin. It remains challenging to control for the effects of extrinsic factors, for example diet and smoking, which are known to be substantial.

We set out to identify CpG sites associated with aging in the Khomani San, a population of former hunter-gatherers living in the Kalahari Desert of South Africa. Previous studies have found that the KhoeSan populations are the most genetically diverse in the world and are among the few remaining societies that have not adopted an agriculturalist lifestyle. The Baka Pygmies are another group of African hunter-gatherers who live in the rainforests of Central Africa. Despite sharing similar subsistence strategies, and societal circumstances of poverty and malnutrition, the age structure of their populations differs greatly. It is common for Khomani San individuals to reach to age of 70 or more, while Baka Pygmies rarely reach the age of 50. We investigated the methylation profiles of individuals in both groups and compared them to European methylation profiles. Saliva samples from 56 Khomani San and 36 Baka individuals were methyltyped on the Illumina 450K array. Khomani individuals ranged from 21 to 91 years old (median 62.5) whereas Baka individuals ranged from 5 to 59 years old (median 29.5). We performed an epigenome-wide association study (EWAS) to identify sites that were significantly associated with chronological age in the Khomani San individuals. This resulted in over 100 CpG sites. We replicated the strong signal of hypermethylation in the CpG island of the *ELOVL2* gene, which was recently identified as a biomarker for aging in blood cells (Garagnani et al., 2012). These results demonstrate that some key sites of methylation are associated with aging in diverse human populations. Our results may prove useful for forensic work as well as future epidemiological studies.

Characterizing a genomic map of 5-hydroxymethylcytosine in human brain at single base resolution through next-generation sequencing. *J. Gross, G.G. Chen, A. Diallo, R. Poujol, C. Ernst, G. Turecki.* Douglas Mental Health Univ Inst, Montreal, Quebec, Canada.

The recent discovery that methylated cytosines are converted to hydroxymethylated cytosines (hmC) by the family of ten-eleven translocation enzymes has sparked significant interest in the field of epigenetics. This finding, along with that of Kriaucionis and Heintz who described the presence of hmC in purkinje neurons, stimulated growing interest in research describing the genomic location, the abundance in different tissues, and the putative functions of hydroxymethylation. To date, there is a lack of reference maps of hmC in post-mortem human brain tissue, which makes challenging to understand the functional role of hmC. To characterize hmC in human brain, DNA from post-mortem brain tissue from 24 subjects who died by natural causes was extracted, glucosylated, and digested with AbaSI, an enzyme that specifically recognizes glucosylated cytosines. Subsequently, custom biotinylated adaptors were ligated to the cleaved DNA, which was then further sheared. Standard libraries were prepared using the enriched fraction and were sequenced on Illumina's HiSeq 2000 sequencers. Bowtie 2.0 was used to map raw reads to the reference genome Hg19 and a custom perl script was used to determine the locations of hmC at single base pair resolution. A combination of BEDtools, R packages, and custom scripts were used to determine enriched and depleted regions in the genome, links to regulatory elements, and correlations with available gene expression data. The results present a unique characterization of hmC in human brain and provide an important reference for future research. Understanding the differences in the genomic locations of hmC will shed light on the growing debate as to whether hmC represents a novel epigenetic mark or whether it is simply an intermediate product of active DNA demethylation.

Global DNA hypermethylation is associated with increased myopia risk. *E. Hsi[1,2], K.C. Chen[3], C.W. Huang[4], M.L. Yu[5,6], C.L. Liang[7], S.S. Juo[2,8].* 1) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Department of Biochemistry, College of Medicine, Taipei Medical University, Taipei, Taiwan; 4) Department of Biotechnology, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 7) Bright-Eyes Clinic, Kaohsiung, Taiwan; 8) Department of Genome Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Purpose: DNA methylation is the most extensively studied epigenetic process that modulates gene expression without changing DNA sequence and is known to be altered by environmental factors. We aimed to discover the association between global DNA methylation and high myopia and find the relevant consequences. Methods: The methylated levels of long interspersed nucleotide elements (LINE-1) are regarded as a surrogate marker of global DNA methylation. Three hundred high myopia and 300 sex-age matched control subjects were used to find the association between high myopia and LINE-1 methylation in leukocytes. We analyze the global DNA methylation among leukocytes, retina and sclera tissues in form deprivation myopia (FDM) mice model. Immunochemistry demonstrates the distribution of homocysteine and methionine. We use dopamine to mimic brighter environment to rescue the myopia state. Results: Subjects with high (82.1% - 91.5%) and middle tertile (79.6% - 82.1%) of LINE-1 methylation have 2.10 and 2.08 fold risk to have high myopia, significantly (p=0.002 and 0.001, respectively). Significantly elevated LINE-1 methylated level in blood and both retina and sclera tissues of both eyes in FDM mice. Immunohistochemical staining indicates elevated homocysteine, methionine levels in both FDM and fellow eyes. Finally, the global methylated level is reduced 2% significantly after 24 hours of dopamine stimulation. Conclusions: Our study demonstrates that LINE-1 DNA hypermethylation is associated with high myopia. Global hypermethylation and accumulated homocysteine indicate a constitutional change which is induced by FDM. Reduced global methylated level is observed after treatment of dopamine and is a novel mechanism in treatment of myopia.

Micoarray approach reveals the differentially methylated regions as potential epigenetic markers in preeclampsia. *H.J. KIM[1], S.Y. KIM[1], S.Y. PARK[1], D.J. KIM[1], D.E. LEE[1], J.H. LIM[1], M.Y. KIM[2], J.H. CHUNG[2], H.M. RYU[1, 2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Objective: The development of preeclampsia (PE) seriously affects the health of the mother and the child, but the precise pathogenesis of PE remains elusive. The placenta is considered to play a key role and DNA methylation may be associated with altered placental development and function. There have been few known fetal-specific marker using the differences between maternal and fetal epigenetic characteristics. We analyzed methylation status of maternal blood and fetal placental DNA using microarray to find a differentially methylated region as potential epigenetic markers for PE. **Methods:** We performed a high-resolution tiling array analysis using a methyl-CpG binding domain-based protein (MBD) method with blood samples from normal pregnancies, placenta samples from normal pregnancies, and blood samples from non-pregnancies. To validate the differentially methylated loci identified from a high-resolution tiling array, bisulfite direct sequencing was carried out in four groups: 1) blood from normal pregnancies, 2) placenta from normal pregnancies, 3) blood from pregnancies with PE, and 4) placenta from pregnancies with PE. **Results:** Differentially hypermethylated loci in the placenta were selected by Agilent Genomic Workbench software using an arbitrary differential ratio cut off of normalized log2 ratio > 2. We confirmed the methylation patterns of CpG sites in the 5 associated regions of selected loci using bisulfite direct sequencing. In the normal and PE group, all selected region showed significant hypermethylation in placenta compared with blood, respectively (P=0.004 for SOD1, P<0.00001 for DSCR3, P=0.0004 for C2CD2, P=0.00003 for UMODL1, P=0.00002 for ENST00000450830). Interestingly, the methylation ratio in each DSCR3 CpG site was significantly increased in PE placental samples compared with normal placental samples (P<0.05 for all CpG sites). **Conclusion:** We found 5 fetal-specific hypermethylated regions. Among these genes, DSCR3 showed significantly aberrant DNA methylation in PE, which may serves as a potential candidate to be developed into epigenetic biomarkers in PE.

446T

Quantification of the placental epigenetic signature of the maspin gene in maternal plasma of pregnancies complicated by small for gestational age. *S.Y. Kim[1], H.J. Kim[1], S.Y. Park[1], D.E. Lee[1], J.H. Lim[1], S.Y. Lee[1], K.S. Kim[1], J.Y. Han[2], M.H. Kim[2], D.W. Kwak[2], H.M. Ryu[1,2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Objective: Quantification of cell-free fetal DNA (cffDNA) by methylation-based DNA discrimination has been used in non-invasive monitoring of adverse pregnancy outcomes. The maspin (serpin peptidase inhibitor, clade B (ovalbumin), member 5; SERPINB5) gene is hypomethylated in the placenta and completely methylated in maternal blood cells. The objective of this study was to examine the possible association between women with small for gestational age (SGA) neonate and cffDNA concentration in maternal plasma during first and second trimesters using tissue-specific epigenetic characteristics of the maspin gene. Methods: We performed a real-time quantitative methylation-specific PCR to quantify the concentrations of unmethylated-maspin (U-maspin) and methylated-maspin (M-maspin) in maternal plasma at 11–26 gestational weeks of women with SGA neonates (n = 55) and with appropriate for gestational age (AGA) neonates (n = 106). Results: At 11–14 gestational weeks, median U-maspin and M-maspin concentrations in women with SGA neonates did not differ significantly from those of women with AGA neonates. There were also no significant differences in the concentrations of U-maspin and M-maspin between the two groups at 15–26 weeks of gestation. The ratio {[U-maspin/(M-maspin+U-maspin)]X100} in women with SGA neonates was similar to that of controls. In addition, statistically significant correlations between U-maspin or M-maspin concentration at first and second trimesters and birth weight and gestational age at delivery were not observed. Conclusion: Concentrations of U-maspin and M-maspin in maternal plasma of the first and second trimesters were not associated with pregnant women who delivered SGA neonates. Our findings indicate that quantification of cffDNA in maternal plasma during early pregnancy using tissue-specific methylation changes of the maspin gene promoter is not a useful predictor of SGA pregnancies.

447M

Methylation levels in peripheral blood may reflect central mechanisms mediating GxE associations with cardiovascular outcomes. *L.C. Kwee[1], C.S. Haynes[1], E.A. Grass[1], I.C. Siegler[2,3], B.H. Brummett[2,3], M.A. Babyak[2,3], R. Jiang[2,3], A. Singh[2,3], R.B. Williams[2,3], E.R. Hauser[1], W.E. Kraus[1,4], S.H. Shah[1,4], S.G. Gregory[1].* 1) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 2) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC; 3) Behavioral Medicine Research Center, Duke University Medical Center, Durham, NC; 4) Division of Cardiology, Department of Medicine, Duke University Medical Center, Durham, NC.

Previous studies have established associations between candidate genes, psychosocial factors, and cardiovascular (CV) outcomes. For example, a genetic variant (rs6318) in the serotonin receptor gene *HTR2C* is associated with both hypothalamic-pituitary-adrenal response to a stress recall task and increased risk of CV mortality. Also, SNPs in the *TOMM40/APOE* region are associated with triglyceride levels, and this effect is moderated by chronic stress. One model for how psychosocial factors affect CV outcomes is that epigenetic changes, such as alterations in methylation status, may mediate the relevant effects. However, it is difficult or impossible to assay epigenetic markers in the tissues that may mediate these effects, such as brain and heart. For cardiovascular disease, however, blood borne factors are in contact with vascular tissue and are of considerable interest. Here, we explore whether methylation levels in peripheral blood provide information to dissect the interaction of psychosocial factors, genetics, and CV outcomes. DNA was obtained from 206 subjects selected from the CATHGEN biorepository of patients referred for cardiac catheterization at Duke University. We selected candidate genes previously associated with coronary heart disease endophenotypes and outcomes (*HTR2C, TOMM40/APOE, ADRB2, BDNF*, and *EBF1*) via interactions with psychosocial stress, and assayed methylation at CpG sites in these genes using the Infinium HumanMethylation450 BeadChip. After QC, data from 169 CpGs in these five regions were available for analysis. We used linear mixed models to test for association between methylation at each probe and an endpoint composed of all-cause mortality or incident myocardial infarction. All models were adjusted for age, sex, race, and batch. Ten CpG sites were nominally associated ($p<.05$) with the endpoint: six in *BDNF* (brain-derived neurotrophic factor; min p=9.1×10–4), and four in *EBF1* (early B-cell factor 1; min p=8.5×10–4). (Due to the correlation in methylation across a gene, strict Bonferroni correction is overly conservative.) We observed consistent methylation changes, as all but one of the significant sites were methylated at slightly higher levels in controls vs. cases ($|\Delta\beta|<.03$ for all). These results indicate that it may be useful and relevant to assay peripheral blood biomarkers in the search for genetic mechanisms that mediate the central effect of psychosocial stress factors on cardiovascular events.

The mechanisms linking DNA sequence variation to phenotypic patterns are incompletely understood. Methylation of genomic DNA at CpG sites regulates gene expression and cellular function. We carried out large-scale Genome-wide Association (GWA) studies to investigate whether the relationship between DNA sequence variation and phenotype may be mediated by DNA methylation. Methylation levels were measured at CpG dinucleotides in genomic DNA from peripheral blood of 1,844 individuals using the Illumina Infinium 450K methylation array. We excluded cross-hybridising markers and markers containing known SNPs within their probe-sequence, resulting in 370,394 CpG sites. Methylation levels were quantile normalised and adjusted for technical biases, gender, age and white-blood cell subpopulations. We generated high density genotype data for the same individuals, including imputation based on 1000 Genomes reference panels. We excluded SNPs with low call rate (<98%), minor-allele-frequency (<1%), Hardy-Weinberg Equilibrium $P<10^{-6}$ and imputation quality (info-score<0.5). This left 7,859,898 SNPs for analysis. Using a highly-parallelized approach we then tested the 7,859,898 SNPs for association with the 370,394 DNA methylation markers, resulting in $\sim 2.9\times10^{12}$ statistical tests. We find 9,883,723 SNP-CpG pairs with evidence for association at $P<10^{-14}$ (corresponding to $P<0.05$ after Bonferroni correction for the $\sim 2.9\times10^{12}$ tests performed). For 9,027,340 associations the SNPs are located in *cis* (within 1mb of the CpG site), while for 856,382 association the SNPs are located in *trans* (SNP-CpG distance >1mb). SNPs associated with CpGs are highly enriched for variants associated with Height, Lipid Levels, Inflammatory Bowel Disease, Multiple Sclerosis and other traits identified by GWA studies. Furthermore, CpGs influenced by genetic variants are enriched for regulatory features such as enhancers and DNase hypersensitive sites. The trans-associations identify multiple SNPs that have a widespread impact on DNA-methylation across multiple regions of the genome, including variants in well-known regulatory genes such as *CTCF*, *NFKB* and the *MHC* region. In conclusion, we report over 9.8 million associations between common genetic variants and methylation of genomic DNA, with evidence for functional enrichment. Our data provides new insight into molecular pathways by linking DNA sequence variation to human phenotype and disease.

449M

Birth weight and DNA methylation. *S. Li[1], D. Sun[1,2], X. Fu[3], C. Fernandez[1], T. Chen[4], Y. Lian[4], Q. Li[4], W. Chen[1].* 1) Epidemiology, Tulane School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Epidemiology and Biostatistics, School of Public Health, Peking University Health Science Center, Beijing, China; 3) Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA; 4) Microarray Core Facility, University of Texas Southwestern Medical Center, Dallas, TX.

Low birth weight for gestational age is a risk factor for adult cardiometabolic diseases. It has been hypothesized that intrauterine growth retardation may result in changes in DNA methylation, by which low birth weight leads to increased risk of cardiometabolic diseases. However, it is not known what specific DNA methylation changes occur as a result of intrauterine growth retardation as indicated by low birth weight. We aimed to examine the association between birth weight and DNA methylation profiles in adults. The study included 679 white and 289 black adult participants aged 28–51 years of the Bogalusa Heart Study who had birth weight data and DNA methylation data (the Infinium HumanMethylation450 BeadChip). After quality control, beta values from 420200 CpG sites were used as outcome variables and birth weight as an independent variable in linear regression models, adjusted for age, sex, cigarette smoking, and body mass index, separately in whites and in blacks. In whites, beta values of ten CpG sites were significantly (false discovery rate <0.05) associated with birth weight, of which three were significant after Bonferroni correction ($P<10^{-7}$). These significant sites are in or near genes EBF4, RAMP2, ARL4C, TBCD, PRRT1, and BAI1, representing cellular component organization or biogenesis, developmental process, immune system process, localization, metabolic process, multicellular organismal process, reproduction, and response to stimulus, in PANTHER analysis. In blacks, only one CpG site was significant ($P<10^{-7}$), with no clear functional implications. We are seeking replications in independent samples and will present updated results in the meeting. In conclusion, we have identified CpG sites whose methylation is associated with birth weight, indicating that prenatal growth environment affects DNA methylation profiles.

450T

Maternal age-related changes in DNA methylation in newborns and adults. *C.A. Markunas[1], A.J. Wilcox[1], Z. Xu[1], B.R. Joubert[1], S. Harlid[2], S.E. Hberg[3], W. Nystad[3], S.J. London[1], D.P. Sandler[1], P.A. Wade[2], R.T. Lie[4,5], J.A. Taylor[1,2].* 1) Epidemiology Branch, National Institute of Environmental Health Sciences, NIH, RTP, NC, USA; 2) Laboratory of Molecular Carcinogenesis, National Institute of Environmental Health Sciences, NIH, RTP, NC, USA; 3) Norwegian Institute of Public Health, Oslo, Norway; 4) Department of Global Public Health and Primary Care, University of Bergen, Norway; 5) Medical Birth Registry of Norway, Norwegian Institute of Public Health, Bergen, Norway.

Older maternal age during pregnancy has been associated with adverse birth outcomes, childhood cancer, type 1 diabetes, and neurodevelopmental disorders in offspring. For many of these conditions the underlying biologic mechanism is unknown. One mechanism by which maternal age may affect the health of the offspring is through epigenetic modifications such as DNA methylation. Using the Norway Facial Clefts Study, a national population-based case-control study of cleft lip and cleft palate, we conducted the largest epigenome-wide association study to date investigating alterations in DNA methylation in newborns related to maternal age at delivery. The Illumina HumanMethylation450 BeadChip was used to assess whole blood DNA methylation in samples collected 2–3 days after delivery from 890 newborns. After data pre-processing, robust linear regression was used to identify CpG sites related to maternal age, adjusting for facial cleft status, birth weight, maternal alcohol use, maternal smoking, maternal education, parity, sex, and technical factors (batch, bisulfite conversion efficiency, and birth year). Additional adjustment for five blood cell subtypes following the method developed by Houseman and colleagues was performed as a sensitivity analysis. Replication of select findings is underway in an independent pregnancy cohort, the Norwegian Mother and Child Cohort Study, using Illumina HumanMethylation450K data from 1068 umbilical cord blood samples. In addition, using data from the Sister Study, a nationwide prospective US cohort of women with a sister with breast cancer, we are exploring whether maternal age-related methylation changes persist into adulthood. The adult analysis includes 1006 women with Illumina HumanMethylation27K data and 181 women with Illumina HumanMethylation450K data generated from whole blood. Identification of the same maternal-age related DNA methylation changes in adults would suggest that these altered methylation states persist for an extended period of time, which may have implications for later health outcomes.

Genetic control of the human blood methylome. *J.L. McClay[1], A.A. Shabalin[1], D.E. Adkins[1], G. Kumar[1], S. Nerella[1], S.L. Clark[1], S.E. Bergen[2], C.M. Hultman[2], P.K.E. Magnusson[2], P.F. Sullivan[3], K.A. Aberg[1], E.J. van den Oord[1], Swedish Schizophrenia Consortium.* 1) Center for Biomarker Research and Personalized Medicine, Virginia Commonwealth Univ, Richmond, VA; 2) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 3) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC.

Comprehensive understanding of genetic influence on the epigenome could shed new light on human genotype-phenotype relationships. In this study, we precision map genome-wide methylation quantitative trait loci (meQTLs) in 697 Swedish subjects. Using SOLiD next-generation sequencing (Life Technologies), we generated an average of 67.3 million methylation-enriched reads per subject to assay whole blood DNA methylation levels at ~27 million autosomal CpGs. We then correlated the resulting methylation measures with 4.5 million SNPs, genotyped on Affymetrix 5.0/6.0 or Illumina Omni quad arrays, with imputation using 1000 Genomes panels. Testing used Matrix eQTL to run all >20 trillion tests in 1.5 days on 50 nodes of a computing cluster. Using stringent (1%) false discovery rate control, 15% of methylation sites showed genetic influence, while 98% of SNPs were associated with methylation at one or more sites. The high proportion of SNP effects was due to linkage disequilibrium (LD), whereby many SNPs tagged each meQTL, whereas long-range correlation between methylation sites was much less extensive. Local meQTL effects (≤ 1Mb between SNP and methylation site) were 189,000-fold more common than distant effects. Most local effects could be explained by CpG-SNPs (SNPs altering CpG sequence), with 75% of methylation sites under local genetic influence having a CpG-SNP (MAF > 0.05) within 250bp, compared to 33% of all sites genome-wide. Local meQTL effects typically occurred outside known genes and were not enriched for several classes of genomic annotations (e.g. CpG islands, DNase clusters). However, these sites were strongly enriched (odds ratio=3) for reported disease-associated loci from the NHGRI GWAS catalog (www.genome.gov/gwastudies). Of the 393 methylation sites under local genetic control that overlapped the GWAS catalog, 366 encompassed a CpG-SNP. Our study confirms that genetic influence on DNA methylation is pervasive, but effects are highly localized. Most meQTLs appear unlikely to affect disease susceptibility, because they typically occur outside of known functional regions. However, mutation of CpGs at critical regulatory loci may be an important etiological mechanism for complex diseases. Our study provides a detailed map of genetic influence on the human blood methylome. Integration of meQTL and functional annotation data into gene mapping efforts could help pinpoint potentially causative mutations in large genomic regions.

DNA methylation profiles of ten patients with Attention deficit hyperactivity disorder: a proof-of-principle study. *C. Milani[1], T.V.M.M. Costa[1], M.M. Montenegro[1,2], G.M. Novo-Filho[2], E.A. Zanardo[2], R.L. Dutra[2], A.T. Dias[1], F.B. Piazzon[1], A.M. Nascimento[2], V. Schuch[3], C.B. Mello[3], M. Muszkat[3], C.A. Kim[1,2], L.D. Kulikowski[1,2].* 1) Departamento de Patologia, Laboratrio de Citogenmica, FMUSP, Sao Paulo, Brazil; 2) Unidade de Gentica, Departamento de Pediatria, Instituto da Criana, FMUSP, Sao Paulo, Brazil; 3) Departamento de Psicobiologia, Universidade Federal de So Paulo, Sao Paulo SP, Brazil.

Introduction: Attention deficit hyperactivity disorder (ADHD) is one of the most common childhood brain disorders and affects approximately 5.3% of children worldwide. Despite the high heritability of the disorder (estimated at 76%), no genetic marker has been consistently identified and the effects on the variability of the ADHD phenotype calls for improvements in research strategies. We performed the proof of principle study in order to characterize DNA methylation profile in peripheral blood leukocytes of individuals with ADHD, providing the first epigenome view study in this disorder. Methods: Genome-wide methylation profile was assessed using DNA extracted from blood lymphocytes of 10 patients with ADHD. We used the Illumina Infinium HumanMethylation450 BeadChip array, which allows the annotation of approximately 480,000 CpG sites per sample at single-nucleotide resolution. Results: The results of all patients showed similar methylation profile and biostatistical tools identified sites with an elevated probability to be consistently hypermethylated in chromosome 13 and 16 and hemimethylated in chromosome 18, 19 and 20. However, some patients revealed slight different methylation profiles involved *BRI3BP*, *RPH3AL*, *ZNF516* and *TP53TG5* genes suggesting an involvement in process as apoptosis mediated by *TNF*, regulation of calcium ions, cell proliferation, differentiation and tumor suppression. In addition, some hypomethylated relevant genes were found in our samples (*NRD1*, *AK3L1*, *RFX5*, *LDLRAP1*, *FBLIM1*, *SYT2*, *BTBD8*, *ZBTB17*, *FITM2*, *TMEM184B*, *CPNE1*, *SPTBN4*). Others were hypermethylated (*ZBTB46*, *OPRL1*, *ZNF8*, *NDUFS7*, *CTDP1*, *TBCD*, *MED24*, *ANK53*, *SPG7*, *ITPK1*, *TPCN2*). In a early conclusion, this proof of principle study showed the DNA methylation status of 96% of CpG islands located in the genome in promoter regions and non-promoter regions of genes. Profile the tissue-specific DNA methylation patterns will provide novel insights into pathogenic mechanisms, as well as help in future epigenetic therapies.

Age-related DNA methylation profiling in CD4 and CD8 T-cells reveals changes in infection-associated and lineage regulator genes. *L. Milani[1], L. Tserel[2], R. Kolde[3], M. Limbach[2], K. Tretyakov[3], S. Kasela[1,4], K. Kisand[2], M. Saare[2], J. Vilo[3], A. Metspalu[1,4], P. Peterson[2].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Molecular Pathology, Institute of Biomedical and Translational Medicine, University of Tartu, Tartu, Estonia; 3) Institute of Computer Science, University of Tartu, Tartu, Estonia; 4) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Ageing is associated with gradual deterioration of immune response, for example, elderly people have lower responses to vaccination and higher risks for infections, autoimmune diseases and tumorigenesis. Although many blood cell types are involved, the most affected cells in this process are T-cells. The reshaping of T-cells during ageing is considered to be most important feature of immunosenescence and causes an immune risk profile associated with higher morbidity and mortality among elderly individuals.

We analyzed the DNA methylation profiles of CD4 and CD8 T-cells and peripheral blood samples from 50 young and 50 elderly individuals to identify the epigenetic basis of these changes and to investigate their association with corresponding gene expression levels.

In DNA methylation analysis of CD4 and CD8 T-cells, we found more differentially methylated CpG sites and larger variability among CD8 T-cells, whereas a relatively low number of changes were detectable in peripheral blood samples after correction for cell subtype proportions. Age-related hypermethylation occurred primarily in the CpG islands of gene promoters with silenced transcriptional activity and was associated with the repressive histone H3K27me3 modification based on ENCODE data. More specifically, we identified a subset of functionally important genes in T-cells, with strong inverse correlation between methylation and expression levels. Among this subset, we found hypomethylation and higher expression of effector T-cell and infection-associated genes as well as hypermethylation of T-cell lineage-specific transcription factor genes in elderly individuals.

Our results argue that although many age-associated DNA methylation changes are shared among blood cells, they do not comprise all the changes that occur in specific blood-cell subsets, such as the T-cells described here. Our findings demonstrate links between age-related epigenetic changes and gene expression in CD4 and CD8 T-cells, and these changes are relevant to the response to infections and to potential harmful consequences leading to immunosenescence.

Influence of maternal nutrition on ancestry-dependent gene methylation in newborns. *K. Mozhui[1], A.K. Smith[2], F.A. Tylavsky[1].* 1) Preventive Medicine, University of Tennessee Health Science Center, Memphis, TN; 2) Department of Psychiatry and Behavioral Science, Emory University, Atlanta, GA.

The epigenome sits at the interface between the external environment and the underlying genetics. There is extensive individual variation in the epigenome that can be shaped by a combination of genetic and non-genetic influences. Here we compare DNA methylation between African and European ancestral groups in two different study cohorts: (1) the CANDLE (Conditions Affecting Neurocognitive Development and Learning in Early Childhood) study, which provides genome-wide methylation (HumanMethylation27) and expression (Illumina WG-6 BeadChip) measures in newborn umbilical cord blood from African Americans (N = 67) and European Americans (N = 45) in the Memphis area, and (2) methylation measures in lymphoblastoid cell lines from Yoruba African (YRI) and CEPH European (CEU) panels of HapMap. We also evaluate the influence of maternal nutrition—specifically, plasma levels of vitamin D and folate during pregnancy—on child methylation. We define ancestry-dependent differences in methylation at ~2,300 genes (over 11% of the CpG sites we surveyed) at an FDR of 5%. About 35% of these differentially methylated sites in CANDLE is replicable in HapMap and include genes involved in tumor suppression (e.g., *APC*, *BRCA1*, *MCC*). Overall, there is lower methylation of CpG islands in African ancestral groups. While maternal nutritional factors have only modest influence on DNA methylation in newborns, we note that the methylation of the immune antigen gene, *CD33* (cg11122968), in influenced by genetic ancestry and maternal vitamin D (unadjusted p = 0.00007). Our results show that ancestry-dependent DNA methylation patterns are remarkably stable and are likely influenced by a combination of genetic and non-genetic factors, including maternal nutrition.

455M

Self-report is a valid measure of maternal smoking during pregnancy and its epigenetic effects are modified by local (cis) genomic ancestry. *S.S. Oh[1], D. Hu[1], J.M. Galanter[1], C.R. Gignoux[2], C. Eng[1], S. Huntsman[1], E.G. Burchard[1], The GALA II Investigators.* 1) UC San Francisco, San Francisco, CA; 2) Stanford University, Palo Alto, CA.

BACKGROUND Maternal smoking during pregnancy (MSP) has been associated with methylation at 26 specific genomic regions (CpG loci) in a birth cohort of newborns. The Norwegian Mother and Child Cohort Study (MoBa) prospectively determined MSP using mid-pregnancy maternal cotinine and used newborn cord blood to assess methylation. We assessed the validity of retrospective self-reported MSP on differential methylation in our own cohort of Latino children by replicating the MoBa results. We further investigated whether MSP-related methylation marks were modified by locus-specific genetic ancestry at that locus. **METHODS** Methylation status for the same 26 MoBa CpGs was assessed with the Infinium 450K Methylation BeadChip using whole blood from 573 Latino children in the GALA II Study, a nationwide asthma case-control study of Latinos. We used robust linear regression to test the association between MSP exposure and methylation at each CpG locus, adjusting for child's sex, age, and ethnicity. Additional covariates included mother's age, parity, and education; child's asthma status, postnatal exposure to tobacco smoke, and proportions of Native American and African ancestry; and technical factors (estimated blood cell counts, batch, chip, position, and the first 10 principal components). We assessed the effect of local European ancestry on methylation by estimating the number of European alleles at each of the 26 loci. The same regression was then repeated after including local European ancestry as a covariate under an additive model. Genetic ancestry was estimated with the program ADMIXTURE using a 3-population model. Local ancestry for the 26 loci was estimated using LAMPLD, assuming 3 ancestral populations. **RESULTS** Remarkably, the relative methylation difference among GALA II subjects was in the same direction as MoBa subjects for 25 out of 26 CpGs. The probability of matching differences in methylation for 25 out of 26 loci occurring by chance is extremely low ($p = 3.9\times10^{-7}$). Thirteen of these CpG loci showed evidence of modification by local European ancestry. For the most significant CpG (cg11715943, mapping to *HLA-DPB2*), each additional European allele at that locus decreased methylation by 2.1% ($p = 9.9\times10^{-11}$). **CONCLUSIONS** We demonstrate in our study that self-report of MSP is comparable to prospectively ascertained, biomarker-validated MSP status. Furthermore, MSP-related methylation is influenced by local genetic ancestry.

Schizophrenia EWAS Supports Findings of GWAS. *A.P.S. Ori[1], J. Listgarten[2], J.Y. Zou[3], L.M. Olde Loohuis[1], M.P. Boks[4], R.S. Kahn[4], J. Ernst[5], R.A. Ophoff[1,6].* 1) Center for Neurobehavioral Genetics, University of California, Los Angeles, Los Angeles, CA; 2) eScience Research Group, Microsoft Research, Los Angeles, California, USA; 3) The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Centre Utrecht, The Netherlands; 5) Department of Biological Chemistry, David Geffen School of Medicine, University of California, Los Angeles, California, USA; 6) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California, USA.

Schizophrenia is a highly heritable and polygenic psychiatric disorder with largely unknown etiology. DNA methylation is an epigenetic mark that has been shown to be both heritable and influenced by environmental factors. Differential DNA methylation at specific promoter regions of schizophrenia candidate genes has previously been linked to the disease. In this study we aim to identify variation in the epigenome that is associated to schizophrenia by interrogating DNA methylation sites across the genome. We matched 450 individuals with schizophrenia and 450 healthy controls for age and gender from a relatively homogeneous Dutch population. Blood-derived whole genome DNA methylation was collected using Illumina's Human Methylation assay. We applied FaST-LMM-EWASher (a linear mixed model with principal components) to identify sites associated to our phenotype of interest while accounting for potential spurious association arising from technical artifacts and cell-type heterogeneity. In addition, we modeled top sites shown to be associated to schizophrenia for presence or absence of chromatin marks using ChromHMM and chromatin state calls derived from ENCODE and Epigenomics Roadmap data. We identify multiple CpG loci with DNA methylation profiles associated with schizophrenia disease status (q-value < 0.05). Among these sites are regions of genes important for neuronal functioning, such as vacuolar protein sorting 52 homolog (VPS52). This gene is involved in vesicle trafficking and fusion to target membranes and is located at the classical MHC locus, a region frequently associated to schizophrenia. In addition, regions close to DNA methylation sites most associated to clinical diagnosis are significantly enriched for common variants associated to schizophrenia based on recent GWAS findings. Finally, we show that DNA methylation at promoter regions associated to the disorder overlap with chromatin marks enriched for fetal brain and cell types involved in immune response. To summarize, we performed an epigenome-wide association study of schizophrenia in a homogeneous sample using whole blood. We observed significant association between DNA methylation and disease status that overall highlights genes implicated in neuronal functioning. These results are also in line with findings of recent genetic schizophrenia studies. Our findings support the potential of using whole blood for studying biological mechanisms underlying psychiatric disorders.

Background: Epigenetic mechanisms might be involved in the regulation of interindividual lipid level variability and thus may contribute to the cardiovascular risk profile. Aim of this study was to systematically investigate the association between genome-wide DNA methylation in whole blood and serum lipid levels of HDL-C, LDL-C, triglycerides (TG) and total cholesterol (TC).

Results: Genome-wide DNA methylation patterns were determined in blood samples of 1776 subjects of the KORA F4 cohort using the Infinium HumanMethylation450 BeadChip (Illumina). Associations between DNA methylation and lipid levels were analyzed using linear mixed-effects models with lipid levels as response. To correct for multiple comparisons, a genome-wide significance level of 1.1E-07 was used according to the Bonferroni procedure. We identified eleven lipid-related CpGs annotated to several genes including *ABCG1*. One CpG site located in *ABCG1* was associated in opposite directions with both HDL-C (β coefficient=0.049, p=8.26E-17) and TG levels (β=0.070, p=1.21E-27). Nine of the associations were confirmed by replication in KORA F3 (N=499) and InCHIANTI (N=472). Associations between TG levels and CpGs of two genes were also found in adipose but not in skin tissue of the MuTHER cohort, indicating tissue specificity. Expression analysis revealed that the association between *ABCG1* methylation and lipid levels is partly mediated by the expression of *ABCG1*. The identified association between *ABCG1* methylation and *ABCG1* mRNA levels is possibly based on methylation-dependent transcription factor binding as observed in electrophoretic mobility shift assays. DNA methylation of *ABCG1* was also associated with previous myocardial infarction in KORA F4 (odds ratio 1.15, 95%CI=1.06-1.25).

Conclusion: We found associations between DNA methylation and lipid levels for genes contributing to the modulation of cholesterol and fatty acid metabolism. The results indicate an epigenetic impact on metabolic regulation in humans and give new insights into the complex picture of lipid-related complex diseases.

The Genome Wide DNA Methylation Signature of Subjects as They Enter and Exit Short Term Alcohol Treatment. *R. Philibert[1, 2], B. Penaluna[1], T. White[1], S. Shires[1], T. Gunter[3], J. Liesveld[1], C. Erwin[4], N. Hollenbeck[1], T. Osborn[2].* 1) Dept Psychiatry, Univ Iowa, Iowa City, IA; 2) Behavioral Diagnostics Iowa City, IA 52240; 3) Indiana Univ. Indianopolis, IN; 4) Texas Tech University Health Sciences Lubbock, TX.

Alcoholism has a profound socio-economic and personal impact on tens of millions of individuals throughout the world. Unfortunately, our ability to quantify the chronicity and quantity of alcohol intake is often hindered by reliance on self-report while our ability to monitor treatment response is challenged by the absence of robust and reliable biomarkers. Recently, in work replicated in over 12 independent genome wide analyses, our consortium has shown that quantitative DNA methylation assessments, particularly at AHRR locus cg05575921, can sensitively and specifically quantify tobacco smoking exposure. Now, in an extension of prior work with lymphoblasts, we examine lymphocyte DNA prepared from heavy, recently intoxicated subjects as they both begin and finish standard 28 day alcohol treatment using standard genome wide methylation techniques and the Infinium 450K HumanMethylationBeadChip. We show that as compared to abstinent controls, heavy alcohol intake is associated with profound widespread changes in DNA methylation with over 800 distinct loci reaching genome wide significance. In marked contrast to prior work with tobacco, there do not seem to be highly sensitive sentinel loci with the overall pattern of changes being consistent with the hypothesis that alcohol affects cellular functions by nonspecific general solvent effects (i.e. changes in cytoplasmic dialect constant). Significantly, there is a marked bias for alcohol induced changes to revert as a function of abstinence. Pathway analysis of the alcohol induced changes demonstrates a mapping of these changes to gene networks involved in apoptosis. Comparison of the methylation signatures for alcohol and tobacco smoke consumption does not demonstrate significant overlap. We conclude that DNA methylation may be useful clinically in the assessment of alcohol use status and monitor alcohol treatment response.

genome wide analysis to find epigenetically inactivated regions associated with Thyroid hormones - A population based crosssectional study. *R. Rawal[1,2], A.M. Nazeer-batcha[3], M. Waldenberger[1], S. Zeilinger[1], C. Gieger[1,2], C. Meisinger[2].* 1) Department of Molecular Epidemiology, Institute of Epidemiology II, Munich, Neuherberg-Munich, Germany; 2) Institute of Genetic Epidemiology, Helmholtz Zentrum Mnchen, Neuherberg, Germany; 3) Department of Medical Informatics, Biometry and Epidemiology, Ludwig-Maximilians- Universitt Mnchen, Germany.

Thyroid gland and thyroid hormones play a significant role in regulating several bodily functions such as cell growth, development and metabolism. Though, several genome-wide association studies (GWAS) have reported a number of genes to be associated with thyroid related phenotypes, some unexplained heritability prevail in human population. Thus, an Epi-genome wide association study (EWAS) was conducted with linear model for phenotype concentrations and logistic model for binary phenotypes in a population based cohort (n = 1,799) using the Illumina 450K Methylation BeadChip to find any association between thyroid related phenotypes and DNA methylation. We report nine distinct CpG sites: four were associated with Tri-iodothyronine (T3) in the gene regions of KLF9, DENND2D, PPP2R5C and one locus in 2p24 region one CpG site in HS3ST3B1 gene was associated with Tetra-iodothyronine (T4), four CpG sites in TSPAN14, CLU, TTLL3, VAT1 genes were associated with T3 to T4 ratio, All reported CpGs showed negative association except two. Smoking adjusted analyses did not provide any information about its influence on the association. These results show the effect of DNA methylation on thyroid hormones and provide additional knowledge on the possibility of methylation, associated with thyroid phenotypes, for future research.

DNA methylation profiles that distinguish rheumatoid arthritis (RA) from osteoarthritis in fibroblast-like synoviocytes can be detected in immune cells from peripheral blood. *B. Rhead[1], C. Holingue[1], M. Cole[1], X. Shao[1], H. Quach[1], D. Quach[1], L.F. Barcellos[1], L. Criswell[2].* 1) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Rosalind Russell Medical Research Center for Arthritis, Department of Medicine, University of California, San Francisco, San Francisco, CA.

RA [MIM 180300] is a chronic inflammatory disease with potential to cause substantial disability, primarily due to the erosive and deforming process in joints. RA etiology is complex, with contributions from genetic and non-genetic factors. Epigenetic changes, such as altered patterns of DNA methylation, are also present in RA. Recent work by Firestein and colleagues (Nakano, 2013) compared genome-wide DNA methylation profiles in synovium-derived fibroblast-like synoviocytes (FLS) from RA patients and osteoarthritis controls and identified a set of differentially methylated genes that appear to distinguish these two forms of arthritis. Given the greater accessibility of peripheral blood compared to synovium-derived FLS, we set out to determine whether similar methylome signatures were present in immune cell subsets in peripheral blood. We generated over 400 genome-wide DNA methylation profiles for 101 women (70 cases from the UCSF RA cohort and 31 controls) using Illumina HumanMethylation450 BeadChips. Four FACS-sorted immune cell types were assayed for each individual: CD14+ monocytes, CD19+ B cells, CD4+ memory T cells, and CD4+ nave T cells. All samples were background subtracted using the lumi Bioconductor package and normalized using all sample mean normalization (ASMN) followed by beta-mixture quantile normalization (BMIQ). All study individuals were fully characterized for whole genome SNP profiles using the Illumina OmniExpress BeadChip. We excluded CpG sites near SNPs known to be common (>1%) from analysis, as well as sites with a low detection p-value, leaving 442,797 sites for analysis. We examined the top differentially hypo- and hypermethylated (n = 17 and 18, respectively) loci from the Firestein study in each immune cell type and found strong evidence for overlapping RA methylome signatures between FLS and immune cells. The most significantly differentially methylated genes in cases vs. controls include *MGMT, ADAMTS2, CABLES1, COL4A1, COL4A2, CYFIP1, EGF, FOXO1, MAP3K1, PHLPP1, PTPN14, RXRA,* and *TGFBR2. MGMT* encodes a DNA repair enzyme and showed the strongest evidence of hypomethylation. The strongest hypermethylation was seen in *MAP3K1*, a serine/threonine kinase involved in some signal transduction cascades. Our investigation of DNA methylation in RA cases and controls underscores the importance of epigenetic mechanisms in RA pathogenesis and represents the largest study, to date, of methylome profiles derived from immune cells.

461M

Epigenome-wide analysis identified highly significant age-related DNA methylation changes. *A. Russo[1,2], S. Guarrera[1,2], G. Fiorito[1,2], C. Di Gaetano[1,2], F. Rosa[1,2], A. Allione[1,2], F. Modica[1], L. Iacoviello[3], M.C. Giurdanella[4], R. Tumino[4], S. Grioni[5], V. Krogh[5], A. Mattiello[6], S. Panico[6], P. Vineis[1,7], C. Sacerdote[1,8], G. Matullo[1,2].* 1) Human Genetics Foundation, Turin, Turin, Italy; 2) Medical Sciences Department, University of Torino, Torino, Italy; 3) Fondazione di Ricerca e Cura “Giovanni Paolo II”, Catholic University, Campobasso, Italy; 4) Cancer Registry and Histopathology Unit, “Civile-M.P. Aging is associated with an increased risk for many complex diseases. DNA methylation represents one of the most promising biomarkers of aging. To evaluate the effect of age on DNA methylation, we examined the methylation levels of more than 450K CpG sites in 206 cases and 206 matched controls belonging to the Italian section of the EPIC cohort. EPIC healthy volunteers were recruited between 1994–98 and followed up for myocardial infarction and other diseases. For the CpG methylation level assessment on blood DNA we used the Illumina HumanMethylation450 BeadChip. Data were analyzed according to standard procedures (MethyLumi, Bioconductor). All analyses were corrected for sex, BMI, season, center of recruitment, cellular subtypes and batch effect. Linear regression analysis showed that 10,000 CpG sites were significantly associated with age after Bonferroni correction ($p<10^{-7}$). Positive correlation with age was found for 5,687 CpG sites (57%), whereas 4,313 CpG sites (43%) were negatively correlated with age. The top four significant loci ($p<10^{-28}$) were located in the CpG islands of *ELOVL2* and *FHL2* genes. Methylation levels of the 4 CpG sites were positively correlated with increasing age, according to previously published results. Gene enrichment analysis highlighted that significantly age-associated genes were involved in transcriptional regulation and alternative splicing. These results confirm that DNA methylation alterations occur during aging and that *ELOVL2* and *FHL2* genes could be used as biomarker of aging. Moreover, the methylation differences associated with age could help in understanding molecular mechanisms that underlie the development of age-related diseases.

Characterizing Functional Methylomes in Human Populations Using Novel Next-Generation Capture Sequencing Approach. *X. Shao[1], F. Allum[1], F. Gunard[2], M-M. Simon[1], S. Busche[1], M. Caron[1], T. Kwan[1], S. Marceau[3], M. Lathrop[1], A. Tchernof[3,4], M-C. Vohl[2,4], T. Pastinen[1], E. Grundberg[1].* 1) Department of Human Genetics, McGill University and Genome Quebec Innovation Centre, Montreal, QC H3A 1A5, Canada; 2) Institute of Nutrition and Functional Foods (INAF), Laval University, Quebec, QC G1V 0A6, Canada; 3) Endocrinology and Nephrology, CHU de Quebec Research Center, Quebec, QC, G1V 4G2, Canada; 4) Quebec Heart and Lung Institute, Quebec, QC, G1V 4G5, Canada.

Whole genome bisulfite sequencing (WGBS) has been widely used to detect DNA methylation at single CpG resolution. However, as only ~20% of CpG sites are variable across individuals or across human tissues, WGBS is inefficient and costly and thus not optimal for population studies of methylation variation and the impact on disease susceptibility. Meanwhile, targeted approaches such as Illumina Human Methylation 450K BeadArray or the reduced representation bisulfite sequencing are biased to gene promoter and cover only a minor proportion of variable CpGs. Here we introduce MethylC-Capture Sequencing (MCC-seq), a novel cost-efficient sequencing approach targeting the most informative fraction of CpGs within disease-relevant tissues. Using adipose tissue and whole blood we have designed capture panels focusing on metabolic and autoimmune diseases that target ~160Mb or ~5M dynamic CpGs/tissue mapping to regulatory elements, hypomethylated footprints or an Illumina450K site. The panels also include all SNPs and their proxies ($r^2 > 0.8$) linked to metabolic or autoimmune diseases (GWAS catalogue 9/2013). The approach is based on bisulfite-converted DNA libraries that are selectively enriched using the custom capture panels (Roche/Nimblegen) and sequenced on the IlluminaHiSeq2000 systems. With multiplexing up to 6-fold/lane we note on average ~62% on-target rate/sample corresponding to ~26X mean genome coverage/sample. We also find a high concordance of within samples CpG methylation on different runs (ρ=0.9). Methylation calls between MCC-seq and WGBS are found to be highly concordant (ρ=0.85), whereas lower concordance of MCC-seq and 450K (ρ=0.80) is observed. Moreover, our results indicate that MCC-seq is capable of simultaneous genotyping where 97% of on-target SNPs could be detected with an average concordance of 99% with genotypes from the Illumina 2.5M array. Finally, we integrated phased genotypes and the MCC-seq data to detect allele-specific methylation (ASM). Preliminary data show ~2.4% of all heterozygous SNP associated CpGs are demonstrating ASM where there is an ~2-fold enrichment in enhancer regions, most likely representing sequence-dependent effects. In addition, while imprinted loci are enriched among ASM they only account for 0.84% of detected sites. Overall, the MCC-seq is cost-efficient and provides single-base resolution of functional DNA methylome and genotype profiles suitable for large-scale disease-association studies.

463M

Facioscapulohumeral muscular dystrophy 2 (FSHD2) testing - a UK pilot study and a clinical diagnostic service. *D.J. Smith[1], JA. Whitfield[1], S. O'Shea[1], R. Whittington[1], L. Yarram-Smith[1], PW. Lunt[2], M. Williams[1].* 1) Bristol Genetics Laboratory, North Bristol NHS Trust, Southmead Hospital, Bristol, UK; 2) National Genetics & Genomics Education Centre, National School for Healthcare Science, Birmingham, UK.

FSHD (affecting ~1 in 20,000 individuals) is an autosomal dominant but epigenetically regulated disorder, with a characteristic pattern of progressive muscle involvement commencing in the face and shoulder-girdle. Two clinically indistinguishable forms (FSHD1 & FSHD2) differ by the molecular basis of epigenetic regulation, but are underpinned by hypomethylation of 4q35, leading to aberrant expression of DUX4 (a toxic transcription factor). FSHD1 (OMIM 158900) (95% cases) is caused by contraction of D4Z4 repeats, resulting in allele specific hypomethylation. FSHD2 (OMIM 158901) (~3% of cases) is contraction independent, caused by mutations in the SMCHD1 gene encoding a chromatin modulating enzyme, resulting in definitive hypomethylation and chromatin relaxation of D4Z4 array on both 4q35 alleles. A permissive haplotype at 4q35 is required for clinical expression of both FSHD1 and 2, necessitating digenic inheritance for FSHD2.

Bristol Genetics Laboratory has provided a FSHD specialist diagnostic service since 1992, and processes over 400 referrals annually. Patients negative for standard and extended deletion analysis but clinically typical for FSHD are candidates for FSHD2 testing (4.8% diagnostic referrals.)

Lemmers et al (2012) identified mutations in SMCHD1 (18p21.31) causing global hypomethylation of D4Z4. Hartweck et al (2013) identified a region showing intense hypomethylation in FSHD2 (DR1). BGL has developed a novel pyrosequencing assay for quantification of methylation using 10 statistically evaluated sites within DR1. A pilot UK cohort of 15 clinically typical FSHD1 negative patients, (assessed by clinical proforma) were assessed for hypomethylation, followed by SMCHD1 sequencing. Our results indicate that 9/15 patients showed hypomethylation (DR1) below a threshold level, with novel candidate SMCHD1 mutations found in all 9; (3 missense, 1 non-sense, 1 duplication, 2 deletion, 2 potential splice site). FSHD2 is an example of digenic inheritance, and this increases the complexity of genetic counselling, as the risk to offspring is between 25 and 50%, depending on the haplotypes of the wider family. We present a service overview, the results of this study and interesting cases highlighting the clinical utility of genetic testing, and family risks associated with this digenic disease.

464T

Sex specific epigenetic and transcriptional responses of peripheral blood leukocytes (PBLs) to lipopolysaccharide (LPS). *M. Stein[1], C. Hrusch[2], J. Nicodemus-Johnson[1], A. Sperling[2], C. Ober[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

Many immune mediated diseases show striking sex differences in prevalence, yet the genetic and epigenetic factors contributing to these differences are poorly characterized. We undertook this study to identify sex-specific differences in methylation and transcriptional responses to LPS, an important activator of the innate immune response, in PBLs collected from 153 members (55% female; range 6–76 years) of a large Hutterite pedigree who previously participated in our studies of asthma. Cells were incubated with LPS+media and with media alone (control) in a closed system (TruCulture®, Myriad RBM, Austin). After 30 hours, DNA and RNA were extracted. In a pilot study of 28 school children (12 girls, 16 boys; 6–14 years old), we used the Illumina Methylation450 Beadchip for methylation and the HumanHt-12v4 for expression studies. Studies in the larger sample are underway. We defined sex-specific differentially methylated regions (DMRs) in response to LPS as CpG sites with methylation response (q-value <0.05) in one sex, but not in the other (q-value >0.2). We observed 39 sex-specific DMRs in response to LPS in girls only and 85 in boys only. 48% of sex-specific DMRs were near a gene that was detected as expressed in the arrays. Expression levels of five (8.5% of expressed genes near a DMR) were correlated with methylation levels. These genes include intriguing candidates that have previously been associated with asthma. For example, methylation levels at a CpG site in the *ANXA2* gene were lower in LPS-treated samples compared to control samples in boys ($P=2.15\times10^{-5}$) but remained unchanged in girls (P=0.48); *ANXA2* expression was higher in LPS-treated samples compared to control samples in boys ($P=1.97\times10^{-4}$) but not in girls (P=0.16). Increased expression of *ANXA2* was previously associated with asthma exacerbations (PMID 10430734). Methylation levels at a CpG site in *ATP2C1* were significantly higher in LPS-treated samples in boys ($P=1.97\times10^{-4}$) but remained unchanged in girls (P=0.95); gene expression was also higher in LPS-treated samples in boys ($P=4.91\times10^{-4}$) but not in girls (P=0.92). Methylation levels in this gene were previously associated with a parent-of-origin effect in children with asthma (PMID 24166889). Overall, these data show that methylation and transcriptional responses to an important environment stimulus (LPS) can be sex-specific, potentially providing a mechanism for the sex disparities in occurrence and course of immune mediated diseases.

465M

CpG Methylation and G-quadruplex structure influence genotyping of the imprinted MEST gene promoter. *A.J. Stevens[1], S. Stuffrein-Roberts[1], A. Gibb[1], K. Doudney[1], A.L Miller[1], A. Aitchison[1], S. Macmill[1], M.R Eccels[2], V.V Filichev[3], P.R Joyce[4], M.A Kennedy[1].* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of Pathology, University of Otago, Dunedin School of Medicine, Dunedin, New Zealand; 3) Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand; 4) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand.

While exploring genetic variability in the maternally imprinted human gene MEST, which plays a role in development and maternal behaviour(1–3), we discovered three SNPs in a CpG island located at the 5' end of the gene(4). These SNPs are in total linkage disequilibrium, such that there are two haplotypes in the human population. When these SNPs were typed in many subjects we observed a non-Mendelian pattern whereby only one haplotype was detectable in each subject, never both, despite the use of multiple genotyping methods. Experiments in which genomic DNA from different subjects was mixed prove that the assays were capable of detecting both haplotypes simultaneously(4). The absence of observed heterozygotes was most likely due to allelic dropout of one allele. Competitive PCR performed on differentially methylated templates of opposite haplotypes showed that the methylated allele consistently fails to genotype. Using circular dichroism spectroscopy (CD), polyacrylamide gel electrophoresis, and fluorescent dimethyl sulfate footprinting we investigated the propensity for sequence motifs from the human MEST promoter region to adopt G4 structure, in vitro. Use of fluorescently labelled primers during PCR showed that these MEST G4 motifs inhibit the amplification of methylated templates for five cycles longer than unmethylated templates. We demonstrated that the combination of G-quadruplex formation and DNA methylation are both required for allelic dropout and neither factor in isolation can explain the observed phenomenon. By investigating the annealing rates of G4 motifs we found methylated oligonucleotides showed faster re-annealing into G-quadruplex structures after heating and it is possible this phenomenon could impact the efficiency of amplification during PCR and account for the observed dropout of the methylated (imprinted) maternal MEST allele. This parent-of-origin specific allelic drop-out of an imprinted locus has important implications for the diagnostic clinical laboratory, and the interaction of G-quadruplexes and methylation in the promoter of an imprinted gene raises the broader question of a potential role for these structures in genomic imprinting or regulation. 1.Lefebvre et al. Dose-dependent changes in DNA methylation identified in Williams syndrome and the reciprocal 7q11.23 duplication syndrome. *E. Strong[1], D. Butcher[2], C.B. Mervis[3], C.A. Morris[4], R. Weksberg[2], L.R. Osborne[1,5].* 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, SickKids Research Institute, Toronto, Ontario, Canada; 3) Department of Psychological and Brain Sciences, University of Louisville, Louisville, KY, US; 4) Department of Pediatrics, University of Nevada School of Medicine, Las Vegas, NV, US; 5) Department of Medicine, University of Toronto, Toronto, Ontario, Canada.

Williams syndrome (WS) is a multisystem developmental disorder caused by hemizygous deletion of 1.5 Mb spanning 26 genes on chromosome 7q11.23. The reciprocal duplication leads to a distinct disorder, 7q11.23 duplication syndrome (Dup7). Both syndromes are associated with developmental delay or intellectual disability, attention deficit hyperactivity disorder, and contrasting cognitive and behavioral phenotypes including different patterns of anxiety disorder. Little is known about the underlying molecular mechanisms. Five genes at 7q11.23 have been implicated in epigenetic regulation, therefore we hypothesized that deletion or duplication of this region would disrupt the epigenetic profile of individuals with WS or Dup7, possibly impacting their phenotypic presentation.

To determine if epigenetic regulation was perturbed in the 7q11.23 disorders, we measured DNA methylation in whole blood from 20 children with WS, 10 with Dup7 and 15 age-matched typically developing controls using the Illumina Infinium HumanMethylation450 array. Differential methylation was assessed using a cutoff of 17% gain or loss of methylation (FDR $p \leq .05$). We identified >1,000 differentially methylated (DM) probes across the WS and Dup7 cohorts that correspond to ~500 unique genes. Hierarchical clustering of the top DM probes resulted in three distinct clusters, corresponding to WS, control and Dup7. WS and Dup7 showed both distinct and dose-dependent changes in DNA methylation, with the WS group showing predominantly hypermethylation and the Dup7 group predominantly hypomethylation. Many of the DM probes spanned genes involved in brain development and function. For the few DM genes where we could assess expression in blood (*RGS2*, *HDAC4*, *DNMT3A*), we show corresponding changes in expression level. We validated the methylation changes in probes from three genes using pyrosequencing and found good correlation with the microarray data ($r^2 > .9$).

The aberrant DNA methylation profiles that we identified in WS and Dup7 suggest methylation differences may contribute to the phenotypic expression of these disorders. Our results suggest that one or more genes within the commonly deleted/duplicated region is important for proper DNA methylation at specific sites within the genome and acts in a dose-dependent manner.

Race-specific association between DNA methylation and body mass index: the Bogalusa Heart Study. *D. Sun[1,2], X. Fu[3], S. Li[1], Q. Li[4], T. Chen[4], Y. Lian[4], C. Fernandez[1], W. Chen[1].* 1) Department of Epidemiology, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA; 2) Department of Epidemiology, School of Public Health, Peking University Health Science Center, Beijing, China; 3) Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA; 4) Microarray Core Facility, University of Texas Southwestern Medical Center, Dallas, TX, USA.

This study test the hypothesis that genome-wide DNA methylation is associated with adiposity measured as body mass index (BMI). As part of the Bogalusa Heart Study, 968 adults aged 28–51 years were recruited between 2006 and 2010. Of these individuals, 830 participants (584 whites, 246 blacks) were examined only once and used as the discovery cohort; 138 participants (95 whites, 43 blacks) were examined twice 3.2 years apart and used as the replication cohort. The discovery findings were replicated by the baseline and follow-up sample. Genome-wide methylation of peripheral leukocyte DNA samples was measured by HumanMethylation450 BeadChip and sample and probe quality analysis was performed. In the association analyses by race, adjusting for age, gender and smoking, DNA methylation levels at 17 sites in whites and at 4 sites in blacks were found to be significantly associated with BMI in discovery cohort. As shown in the table below, 2 (cg06500161 and cg00574958) of the 17 sites in whites and 1 (cg26403843) of 4 sites in blacks were significant in both baseline and follow-up replication cohorts. In conclusion, DNA methylation changes in lipid metabolism-related genes are associated with BMI values, which provides potential race-specific epigenetic mechanisms underlying the development of obesity in whites and blacks.

Effect sizes and Bonferroni-adjusted P values

CpG	Gene	Discovery cohort		Baseline replication		Follow-up replication	
β		P		β	P		
cg06500161	ABCG1	1.4×10^{-3}	2.2×10^{-9}	1.4×10^{-3}	2.0×10^{-3}	1.6×10^{-3}	5.2×10^{-3}
cg00574958	CPT1A	-9.8×10^{-4}	1.1×10^{-9}	-8.8×10^{-4}	1.8×10^{-2}	-7.9×10^{-4}	3.3×10^{-2}
cg26403843	RNF145	2.6×10^{-3}	4.0×10^{-3}	3.0×10^{-3}	4.6×10^{-2}	3.3×10^{-3}	4.1×10^{-2}

Genome-wide association scans identify differentially methylated and expressed regions related to smoking in adipose tissue. *P-C. Tsai[1], C. Glastonbury[1], A. Viuela[1], I. Erte[1], W. Yuan[1], E. Dermitzakis[2], P. Deloukas[3], K. Small[1], T.D. Spector[1], J.T. Bell[1].* 1) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 2) Department of Genetic Medicine and Development, Universit de Genve, Genve, Switzerland; 3) William Harvey Research Institute, Queen Mary University of London, London, United Kingdom.

Smoking is an important environmental risk factor in the development of chronic disease and cancer. Multiple epigenome-wide association scans (EWASs) for smoking have identified and replicated differentially methylated regions in blood. To explore these effects across tissues, we analysed DNA methylation profiles from the Illumina 450k array in adipose tissue samples from 349 healthy female twins, including 35 current smokers, 128 ex-smokers, and 186 non-smokers. We identified 39 CpG sites in or near 25 genes that were significantly associated with smoking at a false discovery rate of 5%. Several of the smoking-associated methylated sites, such as those in the *AHRR*, *F2RL3*, and *CYP1A1* gene, were previously identified to be associated with smoking in blood and lung tissues. Furthermore, smoking-related regions were predominately hypo-methylated in adipose tissue, consistent with previous results. We next performed a genome-wide scan of RNA-sequencing gene expression profiles in the same 349 adipose tissue samples to identify differentially expressed exons associated with smoking. In total, 48 exons in 35 genes were associated with smoking status at a false discovery rate of 5%. Of the 35 genes, 4 genes (*CYTL1*, *AHRR*, *F2RL3*, and *CYP1B1*) overlapped with the top methylation results. Inter-individual correlation showed strong associations between DNA methylation and exon expression levels at a number of genes, including several of the smoking-associated loci. To our knowledge, this is the first smoking-EWAS in adipose tissue. We identified both adipose-specific and tissue-shared DNA methylation changes related to smoking, with corresponding gene expression associations with smoking status. We conclude that smoking exerts a strong effect on DNA methylation and gene expression levels across multiple tissues, and suggest that smoking should be incorporated as a covariate in future EWAS.

Studying body mass-related DNA methylation signatures is promising from two perspectives. First, epigenetic mechanisms might be involved in the development of obesity, and second, epigenetic regulation may partially be underlying obesity-related pathogenic processes including disturbed lipid and glucose metabolism. In an epigenome-wide approach based on the Illumina Infinium 450k assay, we have identified 187 methylation sites stably associated with body mass index (BMI) in more than 10,000 individuals of European and South Asian ancestry. In subsamples of 3961 and 703 subjects, the identified methylation sites were integrated with single nucleotide polymorphism and gene expression data. In addition, directionality of the observed BMI-methylation associations was explored by means of Mendelian randomization experiments using SNPs associated with BMI in published genome-wide association studies, and SNPs associated with methylation in our study as instrumental variables. Furthermore, we tested association of the identified methylation sites with incident type 2 diabetes (T2D) during a follow-up of 7.6 years on average (n = 3064), as well as with clinical traits reflecting glucose and lipid metabolism and inflammation (n = 4176). Methylation at 125 CpG sites showed strong genetic regulation ($p = 4.610^{-8}$ to 1.010^{-350}). 13 CpG sites were significantly associated with expression of genes located in *cis* ($p = 5.510^{-6}$ to 6.110^{-35}). Mendelian randomization experiments suggest that methylation at the majority of CpG sites might be consequential to changes in BMI. 92 methylation sites showed significant association with future risk of T2D ($p = 7.110^{-12}$ with *ABCG1*) or clinical traits independent of BMI, most prominently with triglycerides ($p = 5.610^{-65}$ with *ABCG1*), HDL cholesterol ($p = 3.810^{-45}$ with *ABCG1*), C-reactive protein ($p = 6.510^{-36}$ with *CRELD2*) and HbA1c ($p = 1.610^{-12}$ with *ABCG1*). Adjustment for methylation levels at the identified CpG sites resulted in a reduction of up to 68% in the association of these traits with BMI ($p = 1.210^{-4}$ to 3.810^{-19}). Ongoing analyses will determine the extent to which some of this reduction is due to mediation through methylation. The presented work provides a close examination of the CpG sites discovered in the first large meta-analysis of genome-wide DNA methylation in relation to BMI. Our findings provide new evidence for biological pathways underlying obesity and related metabolic disturbances.

Asthma and allergic diseases are caused by a combination of genetic and environmental factors. Although a large number of genetic variants are associated with asthma and allergic risk, many of the risk factors remain unexplained. We hypothesize that epigenetic mechanisms are partly responsible for the missing heritability and tested our hypothesis using an epigenome-wide association approach. We examined DNA methylation in asthma and allergy in 1748 blood samples collected at birth, 4 and 8 years old using a case-cohort design. Cases of asthma and allergic disease (asthma, eczema or allergic rhinitis) were selected from 4 European birth cohorts (PIAMA, BAMSE, INMA and EDEN), participating in the Mechanism of the Development of Allergy (MeDALL) consortium. DNA methylation profiling was performed using the Illumina Infinium Human Methylation 450k chip that measures 485,512 different CpG sites covering 96% of RefSeq genes. CpG sites related to asthma and allergic diseases were identified using robust linear regression. DNA methylation profiles differ strongly with childhood age, but not so much with the country of origin. We identified 7 CpG sites that are differentially methylated between individuals with and without asthma/allergy at genome wide significant level ($<1.0310^{-7}$), annotated to genes *ETV6*, *LMAN2*, *TNK2*, *RPUSD2*, and *THRA*. These top target CpG sites are currently being validated and replicated in around 6000 DNA samples from 10 European cohorts. To our best knowledge, this is the first study of differential methylation across the genome in relation to asthma and allergic diseases in childhood. Our findings will help to explore the mechanisms of initiation of asthma and allergy.

Epigenome-wide DNA methylation changes in blood from infants with facial clefts in the Norway Facial Clefts Study. *Z. Xu[1], A.J. Wilcox[1], R.T. Lie[3,4,5], J.A. Taylor[1,2].* 1) Epidemiology Branch, National Institute of Environmental Health Sciences of NIH, RTP, NC, USA; 2) Laboratory of Molecular Carcinogenesis, National Institute of Environmental Health Sciences of NIH, RTP, NC, USA; 3) Norwegian Institute of Public Health, Oslo, Norway; 4) Department of Global Public Health and Primary Care, University of Bergen, Norway; 5) Medical Birth Registry of Norway, Norwegian Institute of Public Health, Bergen, Norway.

Isolated orofacial clefts are among the most common congenital birth defects. Recent studies have shown that both genetic and environmental factors can increase risks for these defects, however the underlying biological mechanisms are unknown. Using the Illumina HumanMethylation450 BeadChips we conducted an epigenome-wide DNA methylation study in blood from 2–3 day old infants collected in the nationwide population-based Norway Facial Clefts Study. Our study included 453 healthy controls and 312 infants with isolated clefts (94 cleft lip only; 86 cleft palate only; 132 cleft lip & palate). We did not find significant evidence of association between methylation and cleft lip only; and for cleft lip & palate found only 1 significant CpG at a false discovery rate threshold (FDR) q<0.01. However, for cleft palate only cases we found evidence of association with methylation for 556 differentially methylated CpGs (dmCpG) at FDR q < 0.01. There were similar numbers of increasingly methylated dmCpGs (incCpG, 277) and decreasingly methylated CpGs (decCpG, 279). The incCpGs were enriched in genomic regions with lower CpG density and depleted for active histone marks while decCpGs were enriched in higher CpG density regions and enriched for active histone marks. Although the differences in methylation for the other two case groups were not significantly different from controls, > 90% of the dmCpGs identified for cleft palate only had concordant direction of methylation change relative to controls in both the cleft lip only and cleft lip & palate cases. We suggest that this surprising concordance among the three case groups for these epigenetic changes may reflect their common etiologic pathways.

472T

Multiplexed and Quantitative DNA Methylation Analysis Using Long-Read Single-Molecule Real-Time (SMRT) Bisulfite Sequencing. *Y. Yang[1], R. Sebra[1], I. Peter[1], R.J. Desnick[1], C.R. Geyer[2], J.F. DeCoteau[2], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Cancer Stem Cell Research Group, University of Saskatchewan, Saskatoon, SK, Canada, S7N 4H4.

DNA methylation has important roles in transcriptional regulation, imprinting, X chromosome inactivation and other cellular processes, and aberrant CpG methylation is directly involved in the pathogenesis of human imprinting disorders and many cancers. Targeted analysis of CpG methylation typically is accomplished by pyrosequencing or laborious bisulfite amplicon cloning and sequencing. Although high-throughput targeted methods have been developed to enhance sequencing depth and CpG methylation quantitation, these techniques are limited by amplicon size and short read length. To enable targeted CpG methylation analyses across entire CpG islands and other genomic regions, we developed a quantitative method that is capable of a high degree of multiplexing using long-read single-molecule real-time (SMRT) bisulfite sequencing (Pacific Biosciences). This method was tested using three healthy peripheral blood DNA samples and analyzing the methylation levels of 13 amplicons (609 bp to 1491 bp) encompassing 10 CpG islands. Sequencing read depth ranged from 175X to 1263X per amplicon and the average depth at each CpG site (n=618) was 559X, which resulted in highly quantitative measurements of amplicon CpG methylation ranging from 0.032 to 0.558. In addition, six amplicons (702 bp to 969 bp) encompassing five CpG islands and 473 CpG sites in 30 hematological malignancy cell lines were subjected to SMRT bisulfite sequencing, achieving up to 494X coverage and identifying amplicon CpG methylation ranging from 0.017 to 0.988. Notably, statistical modeling indicated that minimum sequencing depths of 19X and 97X are necessary to accurately quantify methylation levels of 0.050/0.950 and 0.500, respectively, with a margin of error ≤ 0.1 and 95% confidence level. Reproducibility was assessed by SMRT bisulfite sequencing four amplicons of the *TUBGCP3* CpG island, which resulted in highly consistent methylation quantitation (s.d.=0.023). SMRT bisulfite sequencing was validated by comparing CpG methylation levels to both 450K-array (Illumina; 68 CpG sites, r=0.903±0.009) and SureSelect Methyl-Seq (Agilent; 226±79 CpG sites, r=0.927±0.016) data. Coupled with an optimized long-range bisulfite amplification protocol, multiplexed SMRT bisulfite sequencing is an accurate and cost-effective method for targeted CpG methylation analysis that is capable of interrogating ~1.5 kb regions in a single sequencing read, which theoretically covers ~90.5% of CpG islands in the human genome.

473M

DNA methylation in preeclamptic versus normotensive placentas. *K.R. Yeung[1], C.L. Chiu[1], R. Pidsley[2], A. Makris[1,3], A. Hennessy[1], J.M. Lind[1].* 1) University of Western Sydney, Campbelltown, Australia; 2) Garvan Institute of Medical Research, Sydney, Australia; 3) Liverpool Hospital, Liverpool, Australia.

Preeclampsia (PE) is a hypertensive disorder that affects approximately 5% of pregnancies and is a leading cause of maternal and fetal morbidity and mortality worldwide. While the underlying causes of PE are heterogeneous, it is widely accepted that clinical symptoms originate from aberrant placentation early in pregnancy leading to gene expression and physiological changes. There is evidence to suggest that epigenetic mechanisms, such as DNA methylation play a role in placental morphology, development and function. While multiple studies have investigated gene expression changes in preeclampsia, few have looked at epigenetic changes. The aim of this study was to compare DNA methylation profiles in preeclamptic and normotensive placentas. Genomic DNA was extracted from placental samples of PE (n=8), and normotensive pregnancies (n=16). The Illumina Infinium HumanMethylation450K BeadChip was used to assess DNA methylation at > 480 000 CpG sites. All analyses were conducted using publically available Bioconductor packages in R. Following standard quality control and processing steps, linear regression models were used to assess the association between methylation and case-control status at each CpG site. The DMRcate package was used to identify regions of differential methylation. A total of 63 CpG sites across 47 genomic regions were identified as having significantly different DNA methylation in PE placentas compared with controls (absolute beta difference > 5% and FDR value < 0.05). Of these, a number have been identified as having potential involvement in the placental dysregulation observed in PE. Selected gene regions with significantly different methylation profiles in cases versus controls include *SPESP1, NOX5, MIR548H4* (B= 0.28, P = 0.03), *AJAP1* (B= −0.20, P = 0.04), *PARD3* (B= −0.13, P =0.03), *ERRFI1* (B= −0.13, P = 0.03), *PDLIM2* (B= −0.07, P = 0.04), *CSNK1D* (B= −0.08, P = 0.04), and *ITLN1* (B= −0.12, P = 0.04). This study identified genome-wide changes to DNA methylation profiles in placentas from women with PE that may be associated with changes in placental development and function. Functional characterisation of genes identified to be differentially methylated in diseased placentas is required. This research may lead to improved understanding of the pathophysiological disease process.

Analysis of DNA methylation by 450K BeadChip to characterize effects of early life exposures in children. *P. Yousefi, K. Huen, G. Motwani, H. Quach, V. Dav, L. Barcellos, B. Eskenazi, N. Holland.* CERCH, SPH, University of California, Berkeley, Berkeley, CA, United States.

Epigenetic mechanisms, particularly DNA methylation, are a possible link between genetic and environmental determinants of health. As the methylome undergoes rearrangement *in utero* and is susceptible to environmental insults, it may be a mechanism explaining the developmental origins of human disease. Polybrominated diphenyl ethers (PBDEs) are flame retardant chemicals that have been widely used in consumer products over the last 40 years. In the CHAMACOS longitudinal birth cohort, which follows participants from low-income Mexican-American farmworker families in California, we have previously found that prenatal and early-life exposure to PBDEs is associated with a variety of adverse health effects, including decreased fertility, abnormal mental development, and altered thyroid function in children. Further, we have demonstrated that exposure to PBDEs is also associated with altered DNA methylation in LINE-1 repetitive elements in newborn children. Here, we report results of the analysis of site-specific DNA methylation by Illumina Infinium HumanMethylation450K BeadChips assessed in cord blood from CHAMACOS newborns and from the same children at 9 years of age. The Illumina assay simultaneously interrogates methylation at 485,512 CpG sites, in 99%; of all RefSeq Genes and 96%; of CpG Islands. Multivariate linear regression and generalized estimating equation analysis identified 8 differentially methylated positions (DMPs) associated with prenatal PBDE exposure (FDR < 0.05). These DMPs were located in 4 different genes: *AMN, EPHA6, FAM150A,* and *SMAD5.* We additionally identified clusters of CpG sites associated with prenatal PBDE exposure by the bumphunter and ChAMP lasso algorithms. Differential cell counts were used to evaluate how white blood cell type composition modified the relationship between exposures and DNA methylation profiles at birth. New data will be presented on the potential role of altered DNA methylation in mediating the effects of environmental exposures on children's health.

Comparing Statistical Methods for Differential Methylation Identification Using Bisulfite Sequencing Data. *X. Yu[1], S. Sun[2].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Mathematics, Texas State University, San Marcos, TX.

DNA methylation is an epigenetic modification involved in organism development and cellular differentiation. Identifying differential methylations can help to study genomic regions associated with diseases. Differential methylation studies on single-base-resolution has become possible with bisulfite sequencing (BS) technologies. Several methods have been developed to identify differentially methylated regions (DMRs) in BS data. In this poster, we provide a comprehensive comparison analysis of five DMR identification methods: methylKit, BSmooth, BiSeq, HMM-DM, and HMM-Fisher. We summarize the features of these methods from several analytical aspects, and compare their performances using both simulated and real BS datasets. Based on the simulated analysis results, our discoveries are summarized below. First, parameter settings may largely affect the accuracy of DMR identification. Different from the default settings, the modified parameter settings yield higher sensitivities and/or lower false positive rates. Second, all five methods show higher accuracy in the identification of simulated DMRs that are long and have small within group variations. Third, HMM-DM and HMM-Fisher yield relatively higher sensitivities and lower false positive rates than others, especially in DMRs with large variations. Moreover, in the real data analysis, five methods show low concordance, probably due to the different approaches they have used when addressing the issues in DMR identifications. In addition, we find that among the three methods (methylKit, BSmooth, and BiSeq) that involve methylation estimation, BiSeq can best present the raw methylation signals. Therefore, based on these results, we suggest that users select DMR identification methods based on the characteristics of their data and the advantages of each method. To guarantee a higher accuracy in validation and further analysis, users may choose the identified DMRs that are relatively long and have small within group variations as a priority.

Potential susceptibility factors of congenital heart disease identified by epigenome-wide association study of placenta. *C. Zeng[1], W. Wei[1], J. Zhu[2], Z. Liu[2].* 1) Laboratory of Genome Variations and Precision Biomedicine, Beijing Institute of Genomics, Chinese Academy of Sciences; 2) National office for Maternal and Child Health Surveillance, West China Second University Hospital, Sichuan University.

Congenital heart disease (CHD) is the most common birth defect and genetic, epigenetic, and environmental factors all have contributions to its occurrence. As a nutrition-exchanging organ in embryo development, placenta provides a connection between fetal and environmental factors. Epidemiology studies show that the placentas of CHD fetuses are smaller than that of the healthy ones. To find epigenetic changes in the placenta which may bear the sign of the CHD statues or link the disease with the causative environmental exposure, we performed epigenome-wide association study (EWAS) in 26 placentas of CHD fetuses and 15 placentas of the healthy ones. Considering the anatomy of placenta, each sample was divided into the maternal side and the fetal side for analysis. DNA methylation profiling was performed using Illumina Methylation 450K chip, and loci around SNP sites were ignored. To remove possible contaminations from the blood, we did principle component analysis (PCA) in placenta and blood samples. Two CHD and one control were then excluded due to their closeness to blood samples in PC2.

The DNA methylation of fetal side tissues differed significantly from the maternal side in PC4, which was set to be the covariant in EWAS. In association analysis using linear regression model, 44 loci of significantly differential methylation were observed ($p<10^{-4}$) between cases and controls in maternal side, and their corresponding genes were enriched in alcohol metabolism process, including ST3GAL6, ALDH2, PGD, and SQLE genes, as revealed by ingenuity pathway analysis. Furthermore, 12 of these 44 genes were conserved between placenta and fetal heart, suggesting these genes may harbor important methylation changes in CHD. In fetal side, however, there were only 9 loci, including CASQ2 gene relating to ventricular tachycardia. For the regulation elements, 65 genes showed significant difference ($p<10^{-3}$) on their promoters, TSSs or gene bodies in maternal side. These genes were enriched in small molecular metabolism including nicotine and pathways involved in neuron system development. Our results suggest that environmental exposure such as nicotine and alcohol are related to CHD possibly affecting the methylation of placenta. Methylation changes in certain genes may provide clues for the occurrence of CHD.

An epigenetic map of age-associated autosomal loci in Northern European families at high risk for the Metabolic Syndrome. *Y. Zhang[1], D. Cerjak[1], J. Kent Jr.[2], R. James[1], J. Blangero[2], M. Carless[2], O. Ali[3].* 1) Medicine, Medical College of Wisconsin, Milwaukee, WI; 2) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Purpose: Prevalence of chronic diseases such as cancer, type 2 diabetes, metabolic syndrome (MetS) and cardiovascular disease increases with age in all populations. Epigenetic features, including DNA methylation, change with age and are hypothesized to play important roles in the pathophysiology of age-associated diseases. We searched for age-associated methylation signatures in individuals at high risk for MetS. Methods: Genome-wide DNA methylation was profiled in 192 individuals of Northern European ancestry using the Illumina HumanMethylation450 array. Subjects (aged 6–85 yrs) belonged to 7 extended families and 73% of adults and 32% of children were overweight or obese. A strict marker filtering system was applied and CpG sites that passed quality control were subjected to quantitative assessment against age using the computer package Sequential Oligogenic Linkage Analysis Routines(SOLAR). We then applied a positional density-based clustering algorithm to generate a map of epigenetic "hot-spots" of age-associated genomic segments. Gene/pathway enrichment analyses were performed on these clusters using the KEGG and GO databases. Results: We identified 21,432 age-associated autosomal CpG sites that surpassed the genome-wide significance threshold ($p<3.65\times10^{-7}$ after correction for multiple testing) of which 12,511 are positively associated with age and 8,922 are negatively associated. We identified 246 age-associated differentially methylated CpG clusters (aDMCs); in 185 of these clusters, all the CpG sites within are positively associated with age, in 7 all are negatively associated, and in 54, sites with both directions were observed. Within the 185 positive aDMCs reside 199 genes that are enriched in specific KEGG pathways and GO terms. The three most significantly enriched pathways are the hedgehog signaling pathway (adjusted $p=3.87\times10^{-05}$), maturity onset diabetes of the young (MODY) (adjusted $p=2.58\times10^{-03}$) and basal cell carcinoma (adjusted $p=3.30\times10^{-03}$). Significant GO terms include those related to embryonic development, stem cell development, regulation of cell differentiation and proliferation, insulin secretion, metabolism homeostasis and aging. Conclusion: In a family cohort at high risk for MetS, we identified 185 positively associated aDMCs enriched in several important biological pathways. These findings will guide further studies to determine the mechanisms whereby genomic CpG methylation is involved in aging and aging-related diseases.

478T

A microRNA self-regulatory network in testicular germ cell tumor. *W. Chan[1], Y. Suen[1], S. Gu[1], L. Li[1], B. Chen[1,2].* 1) CUHK-Shandong University Joint Laboratory on Reproductive Genetics, School of Biomedical Sciences, Chinese University of Hong Kong, Shatin, Hong Kong SAR; 2) Department of Biological Science and Biotechnology, School of Science, Wuhan University of Technology, Wuhan, Hubei, China.

It was previously demonstrated that microRNA-199a (miR-199a) was down-regulated in testicular germ cell tumor (TGCT) partially caused by hypermethylation of its promoter. miR-199a is encoded by two loci in the human genome, namely, miR-199a-1 on chromosome (Chr) 19 and miR-199a-2 on Chr 1. Both loci encode the same miR-199a. Another microRNA, miR-214, also locates on Chr 1 and in close vicinity of miR-199a. Previous study revealed that it is co-transcribed with miR-199a-2. However, the biological significance of the co-transcription of miR-199a and miR-214 remains largely unknown. In this study, we showed that miR-199a and miR-214 were concordantly expressed in a TGCT cell line NT2 and in TGCT patient tissues. After 5-aza treatment, miR-199a and miR-214 expression was significantly increased in NT2. Silencing of DNMT1 [DNA (cytosine-5)-methyltransferases 1] with siRNA restored the expression of miR-199a and miR-214, accompanied by de-methylation of the promoters of miR-199a-1/2. Tumor protein p53 (TP53) down-regulated the expression of DNMT1 in NT2 cells and overexpression of TP53 restored the expression of miR-199a and miR-214. In addition, silencing of PSMD10 up-regulated the expression of TP53, while miR-214 over-expression resulted in PSMD10 down-regulation and TP53 up-regulation. Collectively, our findings highlighted a miR-199a/miR-214/TP53/DNMT1 self-regulatory network, which caused the down-regulation of miR-199a, miR-214, and TP53, respectively, as well as the up-regulation of DNMT1 in TGCT. These observations partially explain the mechanism of promoter DNA hypermethylation of miR-199a in TGCT. They also suggest a potential therapeutic approach by targeting the miR-199a/miR-214/TP53/DNMT1 regulatory network in the treatment of TGCT.

479M

Genetic and epigenetic control of regulation of miR-9 expression by alcohol. *A. Pietrzykowski[1, 2], Y. Wang[1], E. Mead[1], A. Thekkumthala[1], L. Tejeda[1], D. Pham[1].* 1) Department of Animal Sciences, Rutgers University, New Brunswick, NJ; 2) Department of Genetics, Rutgers University, New Brunswick, NJ.

Alcohol Dependence (AD) is a complex, chronic disease with high morbidity in humans. Some individuals are genetically predisposed to the development of AD. AD progresses due to frequent alcohol exposures and withdrawals, which cause permanent changes in complex gene expression networks in the brain. However, the molecular mechanisms of these changes and their connection to predisposition are largely unknown. microRNAs are master regulators of gene expression networks. To better understand the role of microRNAs in AD we are using a multiplex, genetic and epigenetic approach focused on a specific microRNA called miR-9. miR-9 is one of the most important brain microRNAs and a regulator of neuronal function. Our and others work showed previously that alcohol affects miR-9, and that it plays a key role in the development of molecular tolerance to the drug. Using mouse striatal cultures we observed that the expression levels of miR-9 depend highly on the interplay between alcohol exposure and withdrawal. Additionally, using human DNA samples (COGA - the Collaborative Studies on Genetics of Alcoholism) we determined that there are specific SNPs in miR-9 regulatory regions (promoters), which are highly associated with AD. Interestingly, presence of minor alleles could change binding of transcription factors as well as affect DNA methylation, which could lead to altered expression of miR-9. Indeed, the levels of miR-9 in the postmortem prefrontal cortex of individuals who suffered from AD are decreased. These results can enhance our insight into the molecular differences between binge drinking and chronic consumption associated with AD and shed some light on genetic predisposition to AD. Together, we observed that microRNAs are intermediaries of alcohol actions in the brain, thus could be considered as attractive, novel therapeutic targets of AD.

480T

DNA methylation patterns of specific L1 loci on the short arm of chromosome 21. *S. Tincher, C.A. Ruggeri, A. Khan, J.L. Doering.* Biology, Loyola University Chicago, Chicago, IL.

While 10–15% of the human genome is composed of heterochromatic DNA, these regions are not included in the completed genome sequence. We are using the short arm of chromosome 21 (HC21p) as a model for understanding the structure and function of heterochromatin. While L1 retrotransposons are underrepresented in heterochromatin, including HC21p, there is a disproportionate number of full length L1s on HC21p. L1 elements are also overrepresented on the X chromosome, and it has been proposed that these L1s are involved in the assembly of heterochromatic nuclear compartments during X chromosome inactivation. The L1 internal promoter is highly conserved and includes a CpG island involved in the DNA methylation silencing mechanism. The activity of full-length L1s is usually suppressed in normal tissues by DNA methylation, but L1 promoters on the inactive X are hypomethylated. The L1s on HC21p may be similarly involved in organizing the heterochromatin in that genomic region, possibly through epigenetic modifications. L1 structure and function, including promoter methylation levels, have not previously been studied in heterochromatic regions of the genome like HC21p. Our goal is to examine the promoter methylation status of specific L1s on HC21p to determine if there is hypomethylation like that on the inactive X. Using bisulfite sequencing PCR on both chromosome-specific hybrid cell lines and leukocytes, we determined the DNA methylation patterns in the promoter regions of six specific full length L1s on HC21p, three of which are located within alphoid sequences. We also included in our analysis two control L1s from the euchromatic HC21q, as well as LRE3, a highly active L1 on HC2. The promoters in these control loci have 93–99% overall methylation levels, while the promoters of evolutionarily older L1 elements on HC21p have lower methylation levels, ranging from 35–57% in both cell types. Interestingly, the one HC21p L1 locus that is of the same recently evolved L1PA2 family as the control loci is less methylated than the controls in both the hybrid cell line and leukocytes, with values of 80% and 73%, respectively. Four CpG sites in the L1 promoter have been specifically implicated in the suppression of L1s. In most of the HC21p L1 promoters these sites are either absent or hypomethylated compared to the same sites in the control loci. Thus, the promoters of the L1s on HC21p are hypomethylated and may be contributing to this region's heterochromatic state.

Inter-individual Variation in Epigenetic Susceptibility to D4Z4 Chromatin Relaxation Explains Clinical Variability in FSHD1 and FSHD2. *R.J.L.F. Lemmers[1], J.J. Goeman[2], P.J. van der Vliet[1], M.P. van Nieuwenhuizen[3], J. Balog[1], G.W. Padberg[4], S. Sacconi[5], R. Tawil[6], S. Tapscott[7], E. Bakker[3], S.M. van der Maarel[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Department of Biostatistics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Neurology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) Centre de rfrence des Maladies neuromusculaires and CNRS UMR6543, Nice University Hospital, Nice, France; 6) Department of Neurology, University of Rochester Medical Center, Rochester, NY, USA; 7) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Facioscapulohumeral muscular dystrophy (FSHD) is a common myopathy that progressively affects the facial and upper extremity muscles with marked clinical variability, within and between families. FSHD is caused by contractions of the D4Z4 repeat array on chromosome 4 to 1–10 units (FSHD1), or by mutations in the chromatin modifier *SMCHD1* on chromosome 18 (FSHD2). In somatic cells, SMCHD1 binds to the D4Z4 repeat array to maintain a repressed D4Z4 chromatin structure. Both FSHD situations lead to a partial failure in repeat mediated epigenetic repression of the D4Z4 repeat array and transcriptional derepression of D4Z4-encoded DUX4 that is toxic to muscle cells. We demonstrate that the level of CpG methylation at D4Z4, as a measure of epigenetic repression, linearly correlates with the size of the D4Z4 repeat array. More importantly, we show that the variability in clinical severity in FSHD1 and FSHD2 individuals is caused by individual differences in the degree of CpG hypomethylation at D4Z4. In FSHD2 the epigenetic susceptibility depends on both the D4Z4 repeat array size and the nature of the *SMCHD1* mutation: SMCHD1 open reading frame-preserving mutations being more deleterious for the maintenance of a repressive D4Z4 chromatin state than open reading frame-disrupting mutations. In FSHD1 families, the clinical severity not only depends on the size of the D4Z4 repeat array, but also on the degree of hypomethylation. We show that affected FSHD1 individuals have a greater degree of D4Z4 chromatin relaxation than expected based on their pathogenic D4Z4 repeat array size. In contrast, non-penetrant gene carriers of the same pathogenic array are protected from disease having normal levels of D4Z4 methylation. This study suggests that natural variation in chromatin repressor activity affects D4Z4 methylation providing an epigenetic basis for the striking variability in onset and disease progression, a mechanism that may well translate to common diseases.

Identification of tumor supressor genes modulated by histone acetylation in gastric cancer. *F. Wisnieski[1], D.Q. Calcagno[2], M.F. Leal[1,3], L.C. Santos[1], C.O. Gigek[1], E.S. Chen[1], T.B. Pontes[1], S. Demachki[2], R. Artigiani[4], P.P. Assumpo[2], L.G. Loureno[5], R.R. Burbano[6], M.C. Smith[1]*. 1) Genetics Division, Department of Morphology and Genetic, Federal University of So Paulo, So Paulo, Brazil; 2) Nucleu of Research in Oncology, Joo de Barros Barreto University Hospital, Federal University of Par, Belm, Brazil; 3) Department of Orthopaedics and Traumatology, Federal University of So Paulo, So Paulo, Brazil; 4) Department of Pathology, Federal University of So Paulo, So Paulo, Brazil; 5) Department of Surgical Gastroenterology, Federal University of So Paulo, So Paulo, Brazil; 6) Human Cytogenetics Laboratory, Institute of Biological Sciences, Federal University of Par, Belm, Brazil.

Despite the fact that overall rates of gastric cancer (GC) continue to decline worldwide, the majority of patients are still diagnosed with advanced disease in Western countries. In these cases, surgical resection of the primary tumor offers limited value for a cure and has high morbidity rates. New strategies for early diagnosis and new therapeutic methods in GC continue to be explored. Epigenetic control using histone deacetylase inhibitors, such as trichostatin A (TSA), is a promising cancer therapy. This study aimed to identify genes modulated by TSA in gastric cell lines, and to evaluate the expression of selected genes in gastric resection specimens. ACP02 and ACP03 GC cell lines were treated in triplicate with 250 nM TSA for 24 hours. Differentially expressed genes (DEGs) in treated cell lines compared to controls were identified using microarray assay. The validation of selected DEGs and the assessment of their expression in 46 pairs of primary gastric adenocarcinoma and adjacent non-tumor tissues were performed using qRT-PCR. Possible associations between the expression level of these genes and clinicopathological features were also evaluated. Microarray analysis revealed 42 DEGs (20 upregulated and 22 downregulated genes). Ten relevant functions were observed in which 2 were enriched with a significant number of genes: a) connective tissue, immune, and inflammatory diseases; b) cell cycle, drug, and lipid metabolism. The upregulated DEGs *BMP8B*, *BAMBI*, and *LRRC37A2* were validated and initially selected for gastric tissue analysis. Reduced transcript levels of *BMP8B* were found in diffuse-type and poorly differentiated gastric tumors compared with adjacent non-tumor tissues (p=0.0001 and p=0.006, respectively). In addition, reduced expression of *LRRC37A2* was observed in early staging gastric tumors compared with adjacent non-tumor tissues (p=0.001). On the other hand, the level of expression of *BAMBI* did not differ between gastric tumor and non-tumor samples. Our results demonstrated, for the first time, *BMP8B* and *LRRC37A2* are possible tumor suppressor genes in gastric cancinogenesis and constitute potential targets for epigenetic therapy through histone deacetylase inhibitors.

***KDM5C* SINEUP activates an epigenetic path damaged in XLID/Epilepsy diseases.** *L. Poeta[1], S. Zucchelli[2], A. Padula[1], A. Ranieri[1], S. Filosa[3, 4], P. Collombat[5], M.B. Lioi[6], M.V. Ursini[1], S. Gustincich[2], M.G. Miano[1]*. 1) Institute of Genetics and Biophysics "Adriano Buzzati Traverso", CNR, Naples, Italy; 2) SISSA, Area of Neuroscience, Trieste, Italy; 3) Institute of Biosciences and Bioresources, CNR, Naples, Italy; 4) Istituto Di Ricovero e Cura a Carattere Scientifico, Neuromed, Pozzilli, Italy; 5) Inserm U1091 Diabetes Genetics Team, Nice, France; 6) University of Basilicata, Potenza, Italy.

Mis-steps in histone methylation-demethylation rounds have been directly involved in several forms of Intellectual Disability (ID) with Epilepsy. Lysine-specific demethylase 5C (*KDM5C*) is an X-linked gene which encodes a chromatin JmjC eraser with H3K4me2/3 demethylase activity. *KDM5C* is frequently mutated in a spectrum of XLID and/or malignant Epilepsy. It functions as a transcriptional repressor and interacts with REST/NSRF, a master epigenetic hub that is critical for transition of neural progenitors to neurons. Noteworthy, a defective KDM5C-H3K4me3 path has been found in association with a mis-regulation of XLID/Epilepsy effector genes. We report here the application of SINEB2 long non coding RNAs (SINEUPs) technology to target KDM5C-H3K4me3 axis. SINEUPs are a new functional class of antisense lncRNAs with embedded repetitive elements that activate the production of target proteins to physiological levels. We generated synthetic lncRNAs antisense to *KDM5C*. In transfected cell lines, HEK293T and P19, we obtained increased levels of endogenous KDM5C protein by using both human and murine SINEUPs. As expected, increasing doses of transfected antisense *KDM5C/Kdm5C* SINEUPs titrated KDM5C protein, in both cell lines. When increasing amounts of the SINEUP were co-transfected with human KDM5C into HEK293T cells, dose-dependent KDM5C protein upregulation was observed in the absence of change in the quantity of exogenous *KDM5C* mRNA. Given the H3K4 demethylase activity of KDM5C, we therefore tested the level of H3K4me3 and verified that the increase amount of KDM5C inversely correlates with a decrease in H3K4me3 signal. However, the snapshot of this captivating stratagem may become more well-defined once we will decipher the effect of KDM5C knock-up in *Arx* KO/*Kdm5C*-depleted ES cell line. Noteworthy, SINEUPs are a new class of RNA therapeutics that allows to design gene-specific approaches to treat ID, malignant epilepsy diseases and many other neuropathologies with seizure linked to insufficient activity of chromatin and/or transcriptional regulators. *Italic Text*.

The impact of antisense transcription on epigenetic signals. *C. Wadelius[1], S. Bornelöv[2], J. Komorowski[2,3]*. 1) Dpt of Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Dpt of Cell and Molecular Biology, Uppsala University, Uppsala, Sweden; 3) Polish Academy of Sciences, Warszawa, Poland.

Several histone post-translational modifications are preferentially located in the promoter region of genes and are associated to the promoter activity. It is debated whether the histone modifications regulate the gene expression i.e., the histone code hypothesis or if they are put there as a consequence of transcription. In an earlier study we observed that the histone 3 acetylation signal upstream of the transcriptional start site (TSS) was lower in unidirectional compared to bidirectional genes. Following this observation, we hypothesized that the transcribed region is modified during transcription and that the observed upstream signal is caused by transcription in the opposite direction from the TSS. Promoters directing transcription in both directions are frequent in the genome, which would explain the common occurrence of upstream signals. Here we identified bidirectional or unidirectional genes based on TSS identified from cap analysis of gene expression and database searches. We compared histone modification signals between these two classes of genes across several cell types. We have found significant differences for well-known histone modifications, e.g. H3K4me3, H3K9ac and H3K27ac for which the upstream signal is higher in the bidirectional genes. Furthermore, we have compared transcription factor bindings between bidirectional and unidirectional genes and found examples of differences in their prevalence and position relative to the TSS. In conclusion, our results support the model of histone modifications occurring in transcribed regions and thus being a consequence of transcription. In addition, we have identified transcription factors which may be involved in the direction of transcription initiation.

Methylation analysis and diagnostics of Beckwith-Wiedemann syndrome in 1000 subjects. *A. Ibrahim[1,2], G. Kirby[3], C. Hardy[4], R. Dias[3], L. Tee[3], D. Lim[3,4], J.N. Berg[2], F. MacDonald[4], P. Nightingale[5], E.R. Maher[1,3].* 1) Department of Medical Genetics, University of Cambridge and NIHR Cambridge Biomedical Research Centre, Cambridge, United Kingdom; 2) Department of Clinical Genetics, University of Dundee, Dundee, United Kingdom; 3) Centre for Rare Diseases and Personalised Medicine, School of Clinical and Experimental Medicine, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom; 4) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Birmingham, United Kingdom; 5) Wellcome Trust Clinical Research Facility, University Hospitals Birmingham NHS Foundation Trust, Queen Elizabeth Hospital, Birmingham, United Kingdom.

Background - Beckwith-Wiedemann syndrome (BWS), a congenital overgrowth disorder with variable expressivity and a predisposition to tumorigenesis, results from disordered expression and/or function of imprinted genes at chromosome 11p15.5. There are no generally agreed clinical diagnostic criteria, with molecular studies commonly performed to confirm diagnosis. In particular, methylation status analysis at two 11p15.5 imprinting control centres (IC1 and IC2) detects up to 80% of BWS cases (though low-level mosaicism may not be detected). In order to evaluate the relationship between the clinical presentation of suspected BWS and IC1/2 methylation abnormalities we reviewed the results of >1000 referrals for molecular diagnostic testing.

Methods and Results - 507/1091 (46.5%) referrals had a positive diagnostic test for BWS. The frequency of tumours was 3.4% in those with a molecular diagnosis of BWS. Previously reported genotype-phenotype associations with paternal uniparental disomy, IC1, and IC2 epimutation groups were confirmed and potential novel associations detected. Predictive values of previously described clinical diagnostic criteria were compared, and although there were differences in their sensitivity and specificity, receiver operating characteristic (ROC) analysis demonstrated that these were not optimal in predicting 11p15.5 methylation abnormalities. Using logistic regression, we identified clinical features with the best predictive value for a positive methylation abnormality. Furthermore, we developed a weighted scoring system (sensitivity - 75.9% and specificity - 81.8%) to prioritise patients presenting with the most common features of BWS, and ROC analysis demonstrated superior performance (area under the curve - 0.85; 95% CI: 0.83–0.87) compared to previous criteria.

Conclusion - We suggest that this novel tool will facilitate selection of patients with suspected BWS for routine diagnostic testing and so improve the diagnosis of the disorder.

Pastinen[9], M. Lathrop[9], F. Demenais[1,2], E. Bouzigon[1,2].* 1) U946, INSERM, PARIS, France; 2) Universit Paris Diderot, Sorbonne Paris Cit, Institut Universitaire d'Hmatologie, France; 3) Universit du Qubec Chicoutimi, Canada; 4) National Heart Lung Institute, Imperial College, UK; 5) Section of Biology and Genetics, Department of Life and Reproduction Sciences, University of Verona, Italy; 6) U1163, INSERM, PARIS, France; 7) Max-Delbrck-Center for Molecular Medicine (MDC), Berlin, Germany; 8) Department of Epidemiology, Harvard School of Public Health, Boston, USA; 9) McGill University, Montreal, Canada.

Several lines of evidence support the role for epigenetic mechanisms such as imprinting in asthma and allergic diseases. We conducted a genome-wide linkage scan for the combined asthma-plus-rhinitis phenotype (AST+AR) in 615 families from European ancestry (French (Epidemiological study on the Genetics & Environment of Asthma, EGEA), British (Medical Research Council Asthma, MRCA) and Italian (Verona)) and detected a linkage signal in the 4q35 region with increased evidence when accounting for maternal imprinting ($p=7\times10^{-5}$). We then investigated further this region using a panel of 1,300 SNPs (spanning 6 Mb) genotyped in 162 families from the EGEA study (207 offspring). We tested the association between these SNPs and AST+AR using the Parent-of-Origin-Likelihood Ratio Test (PO-LRT) which allows detecting parent-of-origin and/or maternal genotype effects. We identified 18 SNPs associated with AST+AR at $p<0.005$ that were investigated for replication in 152 asthmatic French Canadian families from the Saguenay-Lac-Saint-Jean study (SLSJ). Combination of EGEA and SLSJ results under a maternal imprinting best-fitting model showed evidence for association for one SNP ($p_{meta}=4\times10^{-5}$), lying at 1.6 Mb from the linkage peak, that accounted for most of the 4q35 linkage signal. Many cis-regulatory elements (enhancers, silencers, insulators) are described in a 50 kb surrounding region of the replicated SNP. Using the Quantitative Transmission Disequilibrium Test (QTDT), we tested for association between the replicated SNP and 26 DNA methylation probes of that region, measured in white blood cells of 159 individuals (40 SLSJ families), while accounting for parent-of-origin effect and adjusting for AST+AR. Maternally inherited risk allele of the replicated SNP was associated with increased methylation of the top-ranked probe ($p<10^{-5}$ after permutations). This probe was located at 529 bp from the SNP and lies within regulatory elements that include a predicted active promoter in lung fibroblasts, DNase I hypersensitive clusters, and binding sites of two transcription factors involved in inflammatory response initiation (RelA and NF-κB). This study identified a maternally imprinted SNP that affects AST+AR through an epigenetic mechanism. Prediction of imprinted genes based on the genome-wide methylation analysis. *N. Ternikova[1,2,4], N. Tnisson[1], K. Lokk[1], A. Salumets[3,5,6], A. Metspalu[1,2], R. Mgi[2].* 1) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 2) Estonian Genome Center, University of Tartu, Tartu, Estonia; 3) Competence Centre on Reproductive Medicine and Biology, Tartu, Estonia; 4) Quantitative Genetics Group, Public Health Genomics Unit, Institute for Molecular Medicine, Helsinki, Finland;; 5) Institute of Biomedicine, University of Tartu, Tartu, Estonia; 6) Department of Obstetrics and Gynecology, University of Tartu, Tartu, Estonia.

Genomic imprinting is an epigenetic gene-marking phenomenon that is established in germline. The importance of genomic imprinting is to regulate gene expression in parental-specific manner. One of the new findings has shown that imprinting does not always occur similarly across all tissues. Recent studies suggest a more complicated scheme of tissue-specific promoters and epigenetic marks. We test the hypothesis that imprinted genes can be predicted by the methylation level. In case of genomic imprinting one of the parental copies is usually silenced through DNA methylation. Based on this knowledge we expect semi-methylation in imprinted genes. In order to prove this hypothesis we analysed the DNA methylation in well-known imprinted genes across the tissue panel from the same individuals. All 17 tissues from every 4 individuals were collected during the autopsy. DNA methylation analysis of the total 72 tissue samples and controls was performed with the Illumina Infinium HumanMethylation450 BeadChip in Estonian Genome Centre. We used Levene's test for comparison of known imprinted genes with the rest of the genes captured by 450K methylation array. As a result, all imprinted genes (n=92) demonstrated less variability in the methylation level ($p < 0.01$) across all 17 tissues when compared to non-imprinted genes. We also visualized the CpG patterns of known imprinted genes across all tissues. Each CpG was annotated to its exact location in the genome in exon, gene body or UTR region. Visualized CpG patterns also confirmed tissue-specific nature of imprinted genes. For example, gallbladder shows medium methylation of KCNQ1DN gene as CpG sites are only partially methylated, while in isciatic nerve the CpG sites are not methylated. Using this mapping method, we have narrowed down the list of potential candidate genes to 3 000. We found that some genes meet the criteria for candidate imprinted genes in all somatic tissues, while other genes meet those criteria only in some of the tissues. As the next step we are using the RNAseq data to further narrow down the list of candidate genes. Our method can be regarded as a tool to identify the tissue specificity of the already established imprinted genes as well as to discover new imprinted genes across the whole human genome. Our method will give a better understanding of the nature of the imprinted genes.

Characterizing the processing, localization, and function of *Snord116* noncoding RNAs at the Prader-Willi locus. *R. Coulson, W. Powell, D. Yasui, J. Aflatooni, S. Wong, J. LaSalle.* Medical Microbiology and Immunology, Genome Center, M.I.N.D Institute, University of California Davis, Davis, CA.

Prader-Willi syndrome (PWS) is a neurodevelopmental disorder caused by paternal deficiency of the imprinted 15q11-13 noncoding RNA cluster SNORD116. This repeat cluster is GC-skewed, resulting in R-loop formation, histone displacement, and chromatin decondensation specifically of the paternal allele upon neuronal transcription. SNORD116 produces two noncoding RNAs: SNORD116 snoRNAs, which localize to the nucleolus of maturing neurons, and 116 host gene (116HG), which forms an RNA cloud at its paternally decondensed site of transcription. To understand the processing, localization, and functional relevance of each component of SNORD116, we engineered novel transgenic mice to test complementation of the PWS mouse model, Snord116del. Complete transgene wild-type (Ctg/WT) mice containing 27 copies of the transgenic Snord116 repeat were generated and bred to Snord116del males to produce offspring lacking paternal Snord116 but expressing the transgene (Ctg/Snord116del). RNA fluorescence in situ hybridization (FISH) analysis of brain showed that spliced 116HG localized in a distinct cloud at its decondensed transcription site and mature snoRNAs localized to the nucleolus in wild-type (WT) but not Snord116del neurons, as previously described. In Ctg/WT neurons, a single 116HG RNA cloud was detected that was significantly larger than that observed in WT neurons, suggesting that the Ctg-derived 116HG colocalizes with the endogenous 116HG RNA cloud at the paternal Snord116 locus. In addition, snoRNAs were detected in the nucleolus at a significantly higher level in Ctg/WT than in WT neurons. In non-neuronal Ctg/WT tissues and all Ctg/Snord116del tissues, no RNA cloud or snoRNAs were detected. qRT-PCR analysis demonstrated that splicing of Snord116 was largely restricted to neuronal tissues of both Ctg/WT and Ctg/Snord116del mice, despite expression of the transgene in many tissues. These combined results suggest that processing of the Snord116 transcript is dependent on neuronal factors and/or chromatin states, including the decondensed Snord116 paternal allele. Analyses of a spliced 116HG/Snord116del transgenic mouse is underway to further test the hypothesis that localization of the 116HG RNA cloud requires the decondensation of paternal Snord116 in neurons. Understanding how DNA-RNA interactions mediate the processing and localization required for Snord116 function and phenotypic rescue is critical for the development of effective PWS therapies in the future.

Evolutionarily-conserved Imprinting Between Mouse and Human Orthologs Identified 17 Novel Candidate Genes for Human Imprinting Disorders. *E.J. Bhoj[1], F. Rajabi[2], E.H. Zackai[1], W.H. Tan[2].* 1) Department of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Boston Children's Hospital, Boston, MA.

There are about a dozen human imprinted disorders that cause a wide range of dysmorphic and neurocognitive phenotypes. Some are only recently being appreciated as they present with a subtle phenotype, such as maternal uniparental disomy (UPD) of chromosome 20, which results in failure to thrive in infancy. We hypothesize that there are additional human imprinted disorders with subtle or late-onset effects that have not been previously recognized. To identify these novel imprinting disorders we have searched the literature for every human imprinted gene, identified each mouse ortholog, determined its imprinting status in the mouse, and collected information about the function of each mouse gene. We anticipate that by focusing on those genes that through evolutionary conservation are imprinted in both the mouse and human, we can derive information about their potential pathology in humans. Using this method we were able to discover 17 human genes that are imprinted in both humans and mice, and have functional data in mice to suggest that disturbed expression would lead to an abnormal phenotype in humans. These genes are: DIRAS3, TP73, SLC22A3, DDC, GRB10, MAGI2, PEG10, PPP1R9A, CALCR, DLGAP2, GLIS3, INPP5F, ANO1, SLC38A4, GATM, PEG3, and NLRP2. Many of these genes have mouse models that demonstrate abnormal phenotypes as varied as profound tracheomalacia, hydrocephalus, dysregulated fetal growth, neurologic disorders, impaired lactation, chronic inflammation and infection, abnormal social functioning, calcium metabolism derangement, and a range of congenital dysmorphisms. If there are additional patients with deleterious mutations in these genes they would likely not be identified through whole exome sequencing as the mutation could be inherited from a normal parent, and therefore discarded in the variant analysis. In addition, patients with UPD may lead to an abnormal phenotype. If there is a large region of isodisomy it may be identified by single nucleotide polymorphism (SNP) array, but smaller regions of isodisomy or any heterodisomy will be missed by conventional SNP array. Therefore, evolutionary conservation is a powerful tool to identify novel genes involved in human imprinting disorders with subtle or late-onset effects.

Random monoallelic expression in neural stem cells, induced pluripotent stem cells and neural committed cells. *A.R. Jeffries[1,2], D.A. Uwanogho[2], G. Cocks[2], L.W. Perfect[2], E.L. Dempster[1], J. Mill[1], J. Price[2].* 1) University of Exeter Medical School, Medical Research, RILD level 4, Royal Devon & Exeter Hospital, Barrack Road, Exeter. EX2 5DW. United Kingdom; 2) King's College London, Centre for the Cellular Basis of Behaviour, The James Black Centre, 125 Coldharbour Lane, London. SE5 9NU. United Kingdom.

Random monoallelic expression is where the choice of which alleles to express is made at random early in development and maintained in subsequent clonal progeny. This results in cellular level heterogeneity of allele specific gene expression together with any resulting phenotypic effects. Up to 10% of autosomal genes can show random monoallelic expression yet little is known on the precise mechanisms behind the allelic choice made early in development.

We use epigenetic reprogramming to investigate the effects on previously characterized random monoallelic expressed genes. We also neuralize the resulting induced pluripotent stem cells (iPSCs) to a more committed state to further examine allelic choice.

Results: Genes which previously showed random monoallelic expression in neural stem cells reverted to biallelic expression after epigenetic reprogramming into iPSCs. Lineage commitment into neural stem cells followed by clonal isolation revealed a number of genes showing random monoallelic expression choice, many of which represented new gene loci. Global DNA methylation analysis was also performed using the Illumina 450k methylation beadchip. Clones undergoing monoallelic expression showed increased DNA methylation at gene promoters compared to sister clones which showed biallelic expression.

In summary, random monoallelic expression is lost during epigenetic reprogramming but re-established in a stochastic fashion when cells are committed towards a neural lineage. Clonal differences in allelic expression status show associated promoter level DNA methylation differences.

Somatic and genetic variations in regulatory regions revealing discordance between monozygotic twins. *K. Kim[1], HJ. Ban[2,3], J. Seo[4], K. Lee[1], M. Yavartanoo[1], SC. Kim[5], K. Park[2], SB. Cho[2], JK. Choi[2].* 1) Department of Bio and Brain Engineering, KAIST, Daejeon 305–701, Republic of Korea; 2) Department of Biomedical Informatics, Center for Genome Science, National Institute of Health, KCDC, Choongchung-Buk-do 363–951, Republic of Korea; 3) Division of Molecular and Life Sciences, Hanyang University, Ansan, Gyeonggi-do 425–791, Republic of Korea; 4) Research Institute of Bioinformatics, Omicsis, Inc. Daejeon 305–333, Republic of Korea; 5) Samsung Genome Institute, Samsung Medical Center, Seoul 135–710, Republic of Korea.

Open chromatin has important role as regulatory region in transcriptional process, and genetic variations in open chromatin have been known to contribute to discordance of gene expression and phenotype. However, the effect of somatic variation on regulatory region still remains to be elucidated. In this study, we performed FAIRE sequencing (~72X) to analyze open chromatin, array-based genotyping across 72 monozygotic (MZ) twins to identify genetic and somatic variations that can explain twin discordance in chromatin accessibility. First, we focused on the spectrum of somatic and genetic sequence variations underlying discordant open chromatin mainly via the disruption of transcription factor binding sites (TFBSs). The change of chromatin accessibility due to C:G > A:T transversions seemed to be subject to purifying selection, because of their strong impact on chemical bonding, as indicated by a lower frequency of polymorphisms than somatic mutations. Of note, CpG located in TFBSs were found to be mutated or polymorphic only 1/5 as often as expected. In particular, those CpGs whose methylation is specifically regulated during cellular differentiation appeared to be protected from the high mutation rates associated with 5'-methylcytosines, thereby implying that the spectrum of CpG variations may be shaped at developmental level but not through natural selection. Next, we used genetic association mapping of within-pair chromatin differences to search for cases in which twin siblings with a particular genotype associated with chromatin discordance at the relevant locus. At an FDR of 0.01 for local associations, ~1000 chromatin sites were found to be differentially accessible depending on the genotype of a nearby locus. This demonstrates that epigenetic differences can bring about regulatory variations through interactions with genetic factors. Remarkably, poised promoters present high levels of chromatin discordance in association with either somatic mutations or genetic interactions and therefore most likely induce differential regulatory responses to environmental stimuli. Our observations illustrate how somatic mutations and genetic polymorphisms may contribute to regulatory discordance.

492T

Deciphering the role of DNA methylation in osteoporosis using MeDIP-seq: A twin-based study design. *J.A. Morris[1,2], F. Gao[3], V. Forgetta[2], Y. Xia[3], P.C. Tsai[4], W. Yuan[4], C.M. Greenwood[1,2,5,6], E. Grundberg[1], T.D. Spector[4], J. Wang[3], J.T. Bell[4], J.B. Richards[1,2,6].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, Canada; 3) BGI-Shenzhen, Shenzhen, China; 4) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 5) Department of Oncology, McGill University, Montreal, Canada; 6) Department of Epidemiology, Biostatistics, & Occupational Health, McGill University, Montreal, Canada.

Osteoporosis is a common disease that leads to an increased risk of fracture through decreased bone mineral density (BMD) and defects in bone. Osteoporotic fractures are a socio-economic burden and are increasing in incidence with the ageing of industrial societies. Since 2007, numerous genome-wide association studies (GWAS) for osteoporosis and related traits have identified multiple common genetic variants associated with BMD, however little is known concerning the role of epigenetic changes influencing BMD. The aim of this study is to investigate the association between epigenetic changes and BMD phenotypes by undertaking an epigenome-wide association study of monozygotic (MZ) and dizygotic (DZ) individual twins from EpiTwin (http://www.epitwin.eu/), a TwinsUK project (http://www.twinsuk.ac.uk/).

We have completed whole genome methylated DNA immunoprecipitation sequencing (MeDIP-seq) for 1,248 MZ twins and 320 DZ twins to quantify genome-wide methylation levels. Methylation levels for each 500 bp region (250 bp overlap) of the genome will be compared with BMD for all twins using a linear mixed effects model to account for the twin relationships. Additional effects will include age, gender, and batch. Significant regions will be differentially methylated regions (DMRs), identified to be associated with BMD through variation in methylation levels. Analysis is currently ongoing. Each twin has three measurements for BMD at total forearm, total hip, and total spine.

Identified DMRs suggest that region-specific variation of methylation levels is associated with osteoporotic phenotypes. Significant findings will be qualitatively compared to regions already identified by GWAS to influence BMD, where any overlaps would suggest an additional mechanism of influence for the region on BMD. DMRs could also identify novel drug targets to treat osteoporosis, as the majority of osteoporosis drug targets have been identified through studying the determinants of BMD.

493M

Epigenome-wide association study of sexual orientation in monozygotic twins. *T.C. Ngun[1], W. Guo[2], N.M. Ghahramani[3], K. Purkayastha[1], F.J. Sanchez[4], S. Bocklandt[1], M. Zhang[2, 5], M. Pellegrini[6], E. Vilain[1].* 1) Department of Human Genetics, David Geffen School of Medicine at University of California Los Angeles (UCLA), Los Angeles, CA, USALos Angeles, CA; 2) Bioinformatics Division and Center for Synthetic & Systems Biology, TNLIST, Tsinghua University, Beijing 100084, China; 3) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 4) Department of Counseling Psychology, The University of Wisconsin-Madison, WI, USA; 5) Department of Molecular and Cell Biology, Center for Systems Biology, The University of Texas at Dallas, Richardson, TX 75080, USA; 6) Department of Molecular, Cellular, and Developmental Biology, UCLA, Los Angeles, CA, USA.

Sexual orientation is one of the most pronounced sex differences in the animal kingdom. Although upwards of 95% of the general population is heterosexual, a small but significant proportion of individuals (3–5%) is homosexual. Previous work has consistently shown that sexual orientation has a strong genetic component. Male sexual orientation has been linked to several genomic loci including Xq28, 8p12, and 10q26, which is an imprinted region. As with other complex traits, environmental factors also play an important role. For instance, monozygotic twins show substantial levels of discordance for this trait. Additionally, each biological older brother a man has increases the probability of him being gay by 33%. Taken together, the evidence strongly suggests a role of epigenetic mechanisms in the regulation of sexual orientation. We aim to elucidate the molecular mechanisms underlying sexual orientation by investigating DNA methylation patterns on a genome-wide basis in 34 monozygotic male twin pairs that are discordant for sexual orientation using reduced representation bisulfite sequencing (RRBS). As a control population, we also performed RRBS on 10 monozygotic twin pairs concordant for homosexuality. Subjects were classified as homosexual or heterosexual based on their sexual feelings (as measured by the Kinsey scale). We first consolidated nearby CpG sites into short regions (100–500 bp) to increase the signal to noise ratio in our data. A linear mixed modeling approach was used to identify regions that were significantly associated with sexual orientation (sexual orientation DMRs). At a false discovery rate of 10%, we identified 136 sexual orientation DMRs. One of these regions was in 10q26 but there were no other overlaps between our data and previous linkage findings. This discrepancy was not surprising as prior studies primarily used families with evidence of maternal loading, which was not a criteria for inclusion in our study. Several genes associated with sexual orientation DMRs were involved in the androgen signaling pathway: (1) *AR*, which encodes the androgen receptor; (2) *ZDHHC7*, which regulates the localization of sex steroid receptors; and (3) *SULT1A3*, which is part of the alternative androgen synthesis pathway. Our findings demonstrate that numerous epigenetic changes are associated with sexual orientation in humans and that our approach has the potential to identify novel genes that influence this trait.

494T

Genes that escape from X inactivation vary in mouse tissues. *C. Disteche[1,4], J. Berletch[1], W. Ma[2], F. Yang[3], J. Shendure[2], W. Noble[2], X. Deng[1].* 1) Dept Pathology, Univ Washington, Seattle, WA; 2) Dept Genome Sciences, Univ Washington, Seattle, WA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Dept of Medicine, Univ Washington, Seattle, WA.

X chromosome inactivation (XCI) silences most genes on one X chromosome in female mammals, but some genes escape XCI. Surveys in cultured human/mouse hybrid cells and in cell lines from individuals with skewed XCI have shown that about 8–15% of human genes consistently escape XCI, 10–13% display variable levels of escape, and 10–20% vary between cell lines and individuals. Escape from XCI results in significant sexual dimorphisms in levels of gene expression, and bi-allelic expression of at least some escape genes is important for a normal phenotype in human females. Indeed, the presence of a single X chromosome (45,X) results in Turner syndrome. To identify escape gene in vivo and to explore molecular mechanisms that regulate this process we analyzed the allele-specific expression and chromatin structure of X-linked genes in mouse tissues and cells with skewed XCI and distinguishable alleles based on single nucleotide polymorphisms. Using a new method to estimate allelic expression, we demonstrate a continuum between complete silencing and significant expression from the inactive X (Xi). Few genes (2–3%) escape XCI to a significant level and only a minority differs between mouse tissues, suggesting stringent silencing and escape controls. Allelic profiles of DNase I hypersensitivity and RNA polymerase II occupancy of genes on the Xi correlate with escape from XCI. Allelic binding profiles of the DNA binding protein CCCTC-binding factor (CTCF) in different cell types indicate that CTCF binding at the promoter correlates with escape. Importantly, CTCF binding at the boundary between escape and silenced domains may prevent the spreading of active escape chromatin into silenced domains.

Male Rett syndrome: Clinical profiling and insights into epigenomics. *J. Duis[1], S. Gupta[2], S. Naidu[2].* 1) The McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 2) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

Rett syndrome (RTT [MIM 312750]) is an X-linked disorder caused by mutations in the gene encoding methyl CpG binding protein 2 (MECP2), which is known to be essential in neuronal function. Once thought to be lethal, male Rett is now extensively described. We report 7 cases of male Rett with special attention to the clinical profile including phenotype and genotype correlations. We review what is known in the literature, report novel mutations with insights into inheritance of these mutations, the roles of maternal inheritance gleaned from these cases, and how this facilitates global understanding of the roles epigenetics may play in this disorder.

496T

Examining Escape from X Chromosome Inactivation and Sex-Differential Gene Expression. *P.G. Bronson, T.R. Bhangale, K.T. Cuenco, W. Ortmann, R.R. Graham, T.W. Behrens.* Genentech, Inc., South San Francisco, CA.

Autoimmune disease displays a predilection for females, with a sex ratio of up to 12:1 for systemic lupus erythematosus in women. The cause of this sex imbalance is unknown, but hormones are suspected to play a role. A gene dosage effect for the X chromosome may also be involved. Female embryonic cells undergo X chromosome inactivation (XCI), through CpG hypermethylation and chromatin remodeling initiated by the noncoding RNA XIST, to randomly turn all but one X into a compact, inactive state. Previous studies have established that ~15% of the 1,031 genes on X escape XCI. We analyzed 195 lymphoblastoid cell lines (LCLs) from females with RNA-Seq expression data (Geuvadis RNA Sequencing Project of 1KGP) and DNA sequence genotypes available (1KGP) to identify a subset of "monoclonal" LCLs. We defined a "monoclonal" LCL as one in which the same X was inactivated in ≥95% of the LCLs, as determined by informative (heterozygous variants) in non-escaping genes on X. RNA-Seq reads were mapped to the reference genome using GSNAP, which performed splice-junction-aware split-read alignment. Using known variants in the samples, GSNAP performed SNP-tolerant alignment and removed the reference-bias in read mapping. Gene expression levels were quantified in terms of RPKMs using DEseq. We identified 63 "monoclonal" LCLs of the 195 examined, and observed escape from XCI in 80 genes using informative SNPs; escape was defined as having >=1 heterozygote cell line with skewed XCI (≥90% of RNA reads coming from only one of the two alleles). From the literature we identified an additional 41 escaping X genes for a total of 121 genes that escape XCI. The Kolmogorov-Smirnov test was used to test 13,615 genes for expression differences between females (n=241) and males (n=214). Significant gene expression differences, defined as >1.2 fold difference and $p \leq 1.5 \times 10^{-3}$, were observed in 13.3% of escaped genes. Expression differences were observed for an additional 7 X genes and 16 autosomal genes, including the T-cell activation RhoGTPase activating protein (an autoimmunity locus) and adrenomedullin (previously reported to have higher expression in females). Further work is underway to annotate the genes that escape XCI, and those that show differential expression between females and males. Additional datasets are also being examined. Understanding the mechanisms that control expression of genes on the X chromosome may provide important new insights into autoimmunity.

Placental microRNAs as potential biomarkers for noninvasive detection of trisomy 21. *H.M. Ryu[1,2], J.H. Lim[1], H.J. Kim[1], A.R. Oh[1], S.Y. Kim[1], D.E. Lee[1], S.Y. Park[1], Y.J. Han[2], J.S. Choi[2], K.H. Choi[2].* 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Objectives: The discovery of fetal nucleic acids in the plasma of pregnant women has led to the development of noninvasive prenatal tests (NIPT). The occurrence of placental microRNAs (miRNAs) in maternal blood has been demonstrated and then proposed as a particular class of molecular biomarkers for the NIPT. However, miRNAs for NIPT of fetal trisomy 21 (T21) have yet to be reported. The objective of this study was to discover a panel of placental miRNAs as potential novel biomarkers for NIPT of T21 fetus and to predict biological functions of new biomarkers using bioinformatics tools. Method: Using microarray-based expression profiling, we compared the expression levels of miRNAs in whole blood samples from non-pregnant women, whole blood samples from pregnant women, euploid fetal placenta samples from pregnant women, and T21 fetal placenta samples from pregnant women. We analyzed the differentially expressed miRNAs according to the presence or absence of disease and tissue type (p value < 0.05 and two-fold expression change). Potential target genes of miRNAs were predicted using the miRBase program. To predict their functions, the functional annotation tools provided by the WebGestalt database were used. Results: We identified 299 miRNAs which reasonably separate the whole blood from the placenta. Among identified miRNAs, 150 miRNAs up-regulated in the placenta and 149 miRNAs down-regulated. Most of up-regulated miRNAs in the placenta were members of mir-498, mir-134, and mir-127 clusters as placenta specific miRNA located on chromosome 19 and 14. Among up-regulated miRNAs in the placenta, mir-1973 and mir-3196 were highly expressed in the T21 placenta than in the euploid placenta. The two miRNAs potentially regulated 203 target genes. Interestingly, the genes were significantly associated with T21-related disorder such as congenital abnormalities and mental disorders. The genes were involved in various pathways such as ErbB signaling, calcium signaling, chemokine signaling, focal adhesion, MAPK signaling, endocytosis, and pathways in cancer. Conclusions: In conclusion, our study indicated miRNAs that may be potential biomarkers for NIPT of fetal T21 as well as provided new insights by regulation of miRNAs into the molecular mechanisms in the placenta of T21 fetus.

Detection of *in vivo* G-quadruplex structure of the *ANXA5* promoter that contributes to the recurrent pregnancy loss. *H. Inagaki[1], S. Ota[1], H. Miyamura[1,2], M. Tsutsumi[1], T. Kato[1], H. Nisizawa[2], I. Yanagihara[3], H. Kurahashi[1].* 1) Molecular Genetics, ICMS, Fujita Health University, Toyoake, Aichi, Japan; 2) Obstetrics and Gynecology, Fujita Health University School of Medicine, Toyoake Aichi, Japan; 3) Developmental Medicine, Osaka Medical center and Research Institute for Maternal and Heath, Izumi, Osaka, Japan.

Recent findings have highlighted the possibility that polymorphisms within the annexin A5 gene (*ANXA5*) promoter contribute to the etiology of recurrent pregnancy loss. However, the underlying mechanisms are unknown. An M2 haplotype of the polymorphism confers a high risk of onset for recurrent pregnancy loss. The M2 haplotype shows lower promoter activity and expresses lower level of *ANXA5* mRNA. This promoter region could form guanine-quadruplex (G4) structure, and the M2 allele possesses less potential than the major allele in vitro. In addition, the promoter activity correlated with the *in vitro* G4 propensity estimated by circular dichroism. In our present study, we assessed *in vivo* G4 structure of the *ANXA5* promoter region using bisulfite method. The genomic DNA from the placenta was treated with sodium bisulfite without dissociation of the DNA. Under this condition, the nucleotide Cs could be changed to U only at the single-stranded regions, but not at the double-stranded regions. After the conversion, we amplified this region by PCR, cloned the corresponding region and determined the conversion rate of the Cs. The promoter region showed about 24% conversion of Cs, while other regions resulted in 8%. When the conversion rate was calculated in each strand, the complementary strand of the promoter region showed the higher conversion rate. This phenomenon could be explained that the strand forming G4 structure is resistant about bisulfite attack, while the complementary strand is left to be single-stranded that resulted in higher conversion rate. The lower conversion rate was observed in the DNA with M2 haplotype than that of major haplotype. These results suggest that the G4 structure at the promoter drives expression of *ANXA5*, and the M2 haplotype reduces the G4 propensity and the *ANXA5* expression resulting in hypercoagulation within the placental villi leading to the recurrent pregnancy loss.

An epigenetically regulated expression-variable class of genes depleted in neurodevelopmental CNVs. *A. Gimelbrant[1,2], L.A. Weiss[3,4].* 1) Cancer Biology, Dana-Farber Cancer Institute, Boston, MA., United States; 2) Genetics, Harvard Medical School, Boston, MA, United States; 3) Psychiatry, University of California San Francisco, San Francisco, CA, United States; 4) Institute for Human Genetics, University of California San Francisco, San Francisco, CA, United States.

We recently discovered that >3,000 human autosomal genes can be expressed from a single allele in one cell, and from the other allele -or both- in a neighboring cell. This epigenetic phenomenon is known as variable monoallelic expression (MAE). MAE is a mitotically stable process generating a somatic mosaic of MAE and BAE cells in a given tissue, with mRNA expression levels higher in BAE cells compared with MAE cells for the same gene. Little is known about functional consequences of MAE. We hypothesize that MAE increases expression level variability in the population, with potential impact on phenotypic variation.

In this study, we used a chromatin signature to identify MAE genes in lymphoblastoid cell lines and in human fetal brain tissue. We assessed available data to compare expression variation in MAE genes to BAE genes at three distinct scales. At the trans-species level, we evaluated gene expression differences between humans and non-human primates. In the human population, we used genetic mapping of expression variability data to identify genes with polymorphisms influencing expression variance. Finally, we provide an analysis of pathogenic and non-pathogenic neurodevelopmental copy number variant (CNV) data in humans.

We find that MAE genes show higher interspecies variance in expression level at the mRNA and protein level and are more likely to have acquired differences in expression during evolution compared with constitutive BAE genes ($P_{RNA}<3\times10^{-8}$; $P_{PROTEIN}<4\times10^{-5}$). We show that MAE genes are more likely to have evQTLs (expression variability quantitative trait loci) than BAE genes ($P<10^{-23}$). Finally, we observe that fetal brain MAE genes are specifically depleted in pathogenic neurodevelopmental CNVs but not polymorphic CNVs ($P<2\times10^{-4}$).

Our results suggest that genes undergoing MAE appear to be a special set of epigenetically-regulated genes subject to both more extreme species differences and more extreme individual differences in expression level. Depletion of these genes in pathogenic neurodevelopmental CNVs suggests that neurodevelopmental processes subject to genomic haploinsufficiency are also less tolerant to epigenetically-mediated expression variation by MAE.

Defining the role of CGGBP1 protein in FMR1 gene expression. *M. Goracci, S. Lanni, F. Palumbo, G. Mancano, P. Chiurazzi, E. Tabolacci, G. Neri.* Institute of Medical Genetics, Catholic University, Rome, Italy.

Fragile X syndrome (FXS) is the most common heritable form of cognitive impairment and is caused by the expansion over 200 repeats and subsequent methylation of the CGG triplets at the 5' UTR of the FMR1 gene, leading to gene silencing. The epigenetic and molecular mechanisms responsible for FMR1 gene silencing are still unclear. To outline structure-specific proteins that could recruit components of the silencing machinery we investigated the role of CGGBP1 in FMR1 gene transcription. CGGBP1 is a highly conserved protein which binds specifically unmethylated CGG tracts. The role of CGGBP1 on FMR1 transcription is yet to be defined. Sequencing analysis and expression studies through quantitative PCR of CGGBP1 were performed in cell lines with different allele expansions (wild-type WT, premutation, methylated full mutations FXS and unmethylated full mutation UFM), demonstrating no differences between them. ChIP assays showed that CGGBP1 binds unmethylated CGG triplets of the FMR1 gene proportionally to the length of the repeats. We also observed that CGGBP1 binding to the FMR1 locus was restored after pharmacological demethylation with 5-azadC of FXS alleles, suggesting a possible role for CGGBP1 in FMR1 expression. CGGBP1 silencing with siRNA (reaching ~ 85% of CGGBP1-mRNA depletion) did not affect FMR1 transcription in WT and UFM fibroblasts. Although the strong binding to the CGG tract could suggest a relevant role of CGGBP1 on FMR1 gene expression, our results demonstrate that CGGBP1 is not a direct regulator of FMR1 transcription. Supported by Telethon Onlus, FRAXA Foundation and Italian Association for fragile X syndrome.

Epigenomic Analysis for Single Cells and Small Quantities of Cells. *X. Pan[1], J. Yang[1], L. Han[2], N. Liu[1], H. Zhu[1], Y. Tanaka[1], Y. Li[1], X. Zi[1,2], H. Wu[3], M. Riester[3], J. Xiong[1], J. Wu[1], G. Euskirchen[4], W. Li[1], F. Rong[2], F. Michor[3], M. Snyder[4], S. Weissman[1].* 1) Genetics, Yale School of Medicine, New Haven, CT; 2) Yale School of Engineering & Applied Science, New Haven, CT; 3) Biostatistics and Computational Biology, Dana-Farber Cancer Institute, Harvard University, Boston, MA; 4) Department of Genetics, Stanford University, Stanford, CA.

Functional genomics analysis in single cells provides unique power for the analysis of heterogeneous biological systems and is applicable for the study of mechanism of differentiation, reprogramming and development as well as clinics. In recent years single cell analysis (SCA) has achieved great progresses in the analysis of genomic sequences and transcriptomes, but study of epigenetic marks has lagged. Previously we have established methods for whole DNA pool amplification (WPA) and sequencing(1), full length mRNA-seq (SMA and PMA)(2), robust measurement of the integrate length of the telomeres in single cells (SCT-pqPCR)(3), and analysis of DNA and RNA from the same single cells. Representative results from our lab include unexpected levels of heterogeneity in hematopoietic early precursor cells and complexity in the early response of normal hematopoietic cells to exposure to erythropoietin, the demonstration of increasing telomere heterogeneity in aging cell cultures, and telomere expansion in the first few divisions of fertilized eggs. Recently we have worked out several new and sensitive methods for CpG methylation profiling of a low number of cells or single cells. An ultrasensitive RRBS at consistently reached >50% coverage for single cells comparing to conventional RRBS; two methods for CpG methylation pattern profiling (CpGMp) for single cells gives a much higher coverage of DMRs (differentiatially methylated regions) and CpG islands without bisulfite conversion. In addition, we have also developed a new concept and method for genome-wide extraction of large blocks of highly compacted chromatins (HCC) by sequencing, from as few as 100-cells. This compacted DNA shows positive or negative correlations with histone modifications H3K27me3, H3K27ac, H3K4me2, and H3K9ac, CTCF, and enhancers. Interestingly, HCC are inversely correlated to DHS in general, but a large set of blocks of DNA are neither HCC nor DHS (DNase I hypersensitive sites). Thus, HCC provides a new parameter to sensitively measure chromatin structure. Ref: (1). Pan X, et al. (2008) A procedure for highly specific, hypersensitive and unbiased whole genome amplification. RNA-Seq revealed canonical RNA editing in mouse retina with laser-induced choroidal neovascularization. *J. Chen[1], S. Huang[1], J. Liang[1], Z. Lu[1], C. Pang[2], M. Zhang[1], H. Chen[1].* 1) Joint Shantou International Eye Center, Shantou University/The Chinese University of Hong Kong, Shantou, Guangdong, China; 2) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong Special Administration Region, China.

Purpose: Laser-induced choroidal neovascularization (CNV) in mice is an important animal model to study exudative age-related macular degeneration, but molecular changes in the retina in CNV mice remain largely unclear. In this study RNA-Seq was used to study RNA-editing in the retina of mouse CNV model.

Methods: Laser photocoagulation of Bruch's membrane was used to induce CNV in the right eyes (OD) of three adult C57B/L6 mice. Total RNA was extracted from the whole retina of CNV (OD) and untreated contralateral (OS) eyes on Day 3. RNA-Seq was performed on the Illumina HiSeq 2000 platform with configuration of 20 million 100 bp pair-end reads per sample. Reads were aligned to the mouse full genome (UCSC version mm10) using Bowtie and splice junctions were identified by using TopHat2. Quantification of expression level and analysis of differential expression of RNA-Seq data were done using R language package EdgeR. An FPKM (fragments per kilobase of exon per million fragments mapped) filtering cutoff of 1.0 in at least three of the six samples was used to filter genes with low expression. Canonical RNA editing sites with editing level ≥ 1% were identified using Samtools and VarScan. Analysis of gene ontology (GO) enrichment and KEGG pathway was performed using DAVID bioinformatics resources. Gene network was constructed using GeneMANIA.

Results: In total 33 potential canonical RNA-editing sites were detected only in the retina with CNV but not in the contralateral untreated retina. Among these sites, the highest level of RNA editing was found at the 3'-UTR of Tapbp (19.60 ± 11.43%). Six protein-coding genes with RNA editing including Tapbp were also found to be differentially expressed in the retina with CNV compared to the contralateral retina. GO analysis showed that gene network of the protein coding genes with RNA editing was mainly involved in immune response.

Conclusions: In the current study, RNA-Seq analysis revealed remarkable RNA-editing in the retina of CNV mouse model. RNA editing could play a substantial role in retina inflammation during CNV.

The influence of Microvesicles carrying microRNA on cross talk between FOXP3 and EZH2 in multiple sclerosis. *A. Hossein-nezhad[1,2,3], Z. Maghbooli[3], S.M. Eshaghi[3], S. Emamgholipour[3], MA. Sahraian[3].* 1) University of Miami, Miami, FL; 2) Boston University, Boston, MA; 3) Tehran University of Medical Sciences, Tehran.

Transcription factor FoxP3 is found initially as a key regulator in regulatory T cells. We have previously reported an inverse coloration between FoxP3 and inflammatory cytokine in different subtype of multiple sclerosis (MS) that were involved in the MS severity. Also we showed the effect of microvesicle on changing the specific gene expression profiles. Relatinship between FoxP3 and Ezh2, an enzyme for histone 3 lysine 27 methyl transferase, reported in cancer. In this report, we present evidence showing that circulating microvesicle of healthy subject regulates cross talk between Ezh2 and Foxp3 in peripheral blood mononuclear cells (PBMC) of multiple sclerosis patients, which is critical for MS monitoring and treatment. Fifteen primary progressive subtype of MS patients and 15 healthy age and sex-matched controls were included in the study. All patients gave their informed consent and the study was approved by the local ethics committee. PBMCs were isolated by Ficoll-Isopaque density gradient centrifugation. The gene expression profiling was determined with Real time PCR. The serum levels of TNF-α, IL-1β, and RANKL were measured by ELISA and hs-CRP levels was determined by imunoturbidimetric method. Microvesicles isolated from healthy controls sera underwent an ultracentrifuge. Gene's expression was evaluated before and after microvesicle induction of PBMC. We have also induced PBMC with RNase-treated microvesicles. MS patients had higher levels of TNF-α, IL-1β, CRP, RANKL and EZH2 and lower levels of foxp3 than healthy controls. RANKL and TNF-α showed a reverse significant correlation with FoxP3 relative expression levels. We have also observed the inverse correlation between FoxP3 and Ezh2 in MS patients. The expression of Ezh2 in PBMC of MS patients decreased after induction by microvesicles, which extracted from healthy controls and also expression of FoxP3 increased. RNase-treated microvesicles had no significant effect on gene expression profiles. This study shows an important part for epigenetic changes during cross talk between EZH2 and FoxP3 in MS. It highlights the role of RNA content of microvesicles from healthy controls to suppress Ezh2 in primary progressive multiple sclerosis. This study represents an opportunity for novel therapeutic agents in multiple sclerosis based on microRNA content of microvesicles. In addition, cross talk between Ezh2 and FoxP3 may important in monitoring and targeting therapy in multiple sclerosis.

Analysis of miRNAs in MELAS mutant cells. *R. Li[1,2], D. Wang[3], N. Dasgupta[1].* 1) Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH. Division of Human Genetics, Cincinnati Children's Hospital Medical Center, 3333 Burnet Avenue, Cincinnati, OH 45229; 2) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH 45229; 3) Maxillofacial Pathology and Radiology Department, Ohio State University College of dentistry. 304 W. 12th Avenue, Columbus, OHIO 43210.

MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) is caused by A3243G mutation in mtDNA. The pathogenic mechanism of MELAS is not completely understood. microRNAs (miRNAs) regulate gene expression via the targeting of mRNA for degradation or by suppression of mRNA translation through complementarity to target mRNAs. The A3243G mtDNA mutation increases mitochondrial membrane permeability, may lead to the increased import of miRNAs into mitochondria. We hypothesize that MELAS-associated A3243G mtDNA mutation results in the accumulation of specific miRNAs in mitochondria, targeting on mitochondrial RNAs, causing mitochondrial dysfunction and contributing to the pathogenesis of MELAS. To study whether miRNAs is relevant to MELAS, cell pellets and pure mitochondria were obtained from A3243G homoplasmic mutant 43B cybrids and wild type HSI cybrids as well as normal human fibroblast (HF), mutant fibroblasts hf16 and hf68 with 90% and 30% of A3243G mutation respectively. Pure mitochondria were then treated by RNase A to eliminate cytoplasmic RNAs. Total RNA preparations were obtained from cell pellets of 43B, HSI, HF, hf16 and hf68 and their RNase A treated mitochondrial pellets. Next-gen sequencing of small RNA (15–49 bp) including miRNAs (18–23 bp) were carried out using cellular RNA and RNase A treated mitochondrial RNA samples. The small RNA sequence results demonstrated that some miRNAs were enriched in both 43B and HSI mitochondrial RNA. 40 miRNAs in HSI mitochondria and 7 miRNAs in 43B mitochondria were richer than in their cellular miRNAs. Most important, several miRNAs were enriched in MELAS-associated mitochondria compared with wild type mitochondria. RT-qPCR results confirmed these miRNAs were richer in 43B mitochondria than in HSI mitochondria. These miRNAs were also increased in hf16 fibroblast mitochondria. However, these miRNAs were unchanged in their cellular. These findings suggested the MELAS mutation, mtDNA A3243G, resulted in an increased import miR-181c and miR-423-5p from cytoplasm into mitochondria. We identify 7 miRNAs, particularly miR-181c and miR-423-5p, are enriched in mitochondria of MELAS cybirds and patient fibroblasts with high percentage of mtDNA A3243G mutation. These mitochondrial miRNAs provide attractive candidates for study of the pathophysiology of mitochondrial diseases and potentially establishing a miRNA-based therapeutic strategy for individuals with incurable mitochondrial disease.

Genome-wide microRNA expression profiling in fetal trisomy 21 placenta. *J.H. Lim[1], S.Y. Park[1], J.W. Kim[1], D.E. Lee[1], S.Y. Kim[1], H.J. Kim[1], K.S. Kim[1], H.K. Ahn[2], S.W. Lee[2], H.M. Ryu[1,2].* 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Trisomy 21 (T21) is the most common known aneuploidy, caused by an extra copy of all or part of human chromosome 21 (hsa21). Differential expression of microRNAs (miRNAs) has been identified in many diseases, including T21. However, the changes of the genome-wide microRNA expression in the T21 placenta have yet to be determined. Moreover, the biological functions of the differentially expressed miRNAs in the T21 placenta are still unclear. Thus, we investigated the genome-wide miRNA expression profiling of the T21 placenta using microarray and analyzed the biological functions of the differentially expressed miRNAs in the T21 placenta using bioinformatics tools. Total RNA extracted from placenta samples of T21 and euploid fetus was used for miRNA microarray. To investigate the functions of the differentially expressed miRNAs (fold change >2.0 and P<0.05), the miRWalk database was used to predict their potential targets, which were afterwards submitted to the functional annotation tool provided by the WebGestalt database. The interaction map of potential target genes was generated using STRING 9.1. In total, 34 miRNAs were significantly differentially expressed in the T21 placenta, compared with the euploid placenta (16 up-regulated and 18 down-regulated). Target genes of up-regulated and down-regulated miRNAs were identified 7,434 and 6,071, respectively. Out of total target genes, 76 genes were identified within hsa21 (10 and 34 genes being controlled by the down- and up-regulated miRNAs, respectively, and 32 by both). Target genes of abnormally expressed miRNAs were significantly associated with in T21 as well as T21-related disorder such as mental retardation, chromosome disorders, and so on. Moreover, the genes were involved in various mechanisms such as metabolic pathways, natural killer cell mediated cytotoxicity, toll-like receptor signaling pathway, and so on. Interaction network of target genes showed the regulatory mechanism of hsa21 genes targeted by miRNAs in the T21 placenta. To the best of our knowledge, this is the first genome-wide study to comprehensively survey placental miRNAs of T21 fetuses. Our results provide a new insight into understanding the expression characteristic of microRNAs in the T21 fetal placenta. Additionally, findings of our study indicate that the differentially expressed miRNAs in the T21 placenta may potentially affect various pathways related with pathogenesis of the T21.

Regulation of *COL1A1* by miRNAs in scleral fibroblasts: Implications for myopia control. *R. Metlapally, K.K. Wang, C.F. Wildsoet.* School of Optometry, UC Berkeley, Berkeley, CA.

Purpose: Previous work has implicated scleral (outer white coat of the eye) miRNAs in ocular growth regulation during normal and myopia (near-sightedness) development. Scleral thinning and extracellular matrix (ECM) loss are classic features of high/pathological myopia caused by excessive axial elongation of the eye. miRNAs represent potential therapeutic targets for myopia control by promoting/enhancing ECM deposition in the sclera. Since *COL1A1*, the most prevalent protein in the scleral ECM, undergoes degradation and loss in myopia and miRNAs are known to regulate *COL1A1*, we investigated the potential of altering *COL1A1* gene expression levels via selective manipulation of miRNA activity in scleral fibroblast cultures. **Methods:** Human scleral fibroblasts from donor eyes were grown in culture using standard methods. miRNA inhibitors directed at let-7c, let-7e, miR-98 or miR-103 were introduced into the cells via electroporation. Cells were lysed after 48 hours, followed by RNA extraction and reverse transcription using the Taqman® Cells to CT kits for studying miRNA (let-7c, let-7e, miR-98 and miR-103) and mRNA (*COL1A1*) expression. Four biological replicates were assessed for each target and data normalized to the negative scramble controls. QPCRs were performed using Taqman® assays. *GAPDH*, *POLR2A*, *RNU44* and *RNU6B* served as housekeeping genes, and the delta CT method was used for data analyses. A live/dead viability/cytotoxicity assay (Life Technologies) was used for assessing toxicity of the treatments. **Results:** All four miRNAs tested were inhibited as expected with their respective inhibitors (at least 40-fold, min p=0.001). The expression of *COL1A1* was down-regulated after inhibition of either let-7c, let-7e or miR-98 (at least 2-fold, min p=5.9×10^-5), and up-regulated after inhibition of miR-103 (1.5 fold, p=0.007). The cytotoxicity assay findings did not reveal any adverse effects for any of the miRNA inhibitor treatments. **Conclusions:** Our findings show that scleral miRNAs can be manipulated in culture to regulate gene expression. The finding that scleral *COL1A1* mRNA expression is modulated by miRNAs holds promise for future *in vivo* therapeutic intervention studies. Our long-term goal is to control axial ocular elongation in myopia by inhibiting the underlying scleral changes.

Olfactory neuroepithelium (ONE) represents a site where neural stem cells can be recovered (NSC), besides being a readily accessible site. They can be cultured by neurosphere assay, forming spherical cluster with multipotent and progenitor cells in suspension, with ability to differentiate. These features make it a model for studying molecular and cellular neural processes. Maintaining these cells in an undifferentiated state and their ability to differentiate, requires the availability to changes cell expression, therefore to have epigenetic mechanisms related to modulate molecules that promote the multipotentiality and that suppress cells differentiation. One such mechanism depends on microRNAs, small molecule non-coding RNAs with roles in regulation of expression. miRNAs roles are relevant in brain diferentiation and function. miRNA dysregulation is present in brain disorders. Human NSCs are a powerful tool to investigate neural process, to evaluate miRNA expression in this cell model, could show new information about miRNAs roles. To this end, a nasal swab from ONE was taken from 4 healthy volunteers, Cells were cultured like neurospheres and their neural phenotype was determined by by immunofluorescence. Subsequently, miRNA expression assay was performed on plates TLDA A y B of applied V 2.0. Cq values equal or greater than 36 were removed. We assessed the expression level according to DCt method, normalizing with the global mean and by groups according to the mean plus / minus standard deviations. Finally, we performed an in silico analysis looking for possible nervous system pathways in which some microRNAs are involved. We analyzed a total of 667 microRNAs. 246 microRNAs were expressed in at least 3 of the 4 samples. According to the expression level, 56 miRNAs have very high expression (23%), 23 high (9%), 66 medium (27%), 34 low (14%) and 67 very low (28%). The 10 microRNAs with higher expression were miR-222, miR-200c, miR-191, miR-30a *, miR-30e *, miR-484, miR-146a, miR-378, miR-24 miR-574-3p. Some miRNAs are already described with roles in neurogenesis as miR-184, miR-132 family members miR-200c, miR-30, among others. As for his possible role, predictions point to possible involvement in neurodevelopmental pathways as well as in neural pathologies.

Epigenetic factors regulating DUX4 expression in muscle cells. *J. Balog[1], P.E. Thijssen[1], K.R. Strassheijm[1], Y.D. Krom[1], A. de Jong[1], R.J.L. Lemmers[1], P.J. van der Vliet[1], R. Tawil[2], S.J. Tapscott[3], S.M. van der Maarel[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Neuromuscular Disease Unit, Department of Neurology, University of Rochester Medical Center, Rochester, New York, United States of America; 3) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, Washington, United States of America.

Facioscapulohumeral dystrophy (FSHD) is a progressive, dominantly inherited myopathy affecting 1:14.000–20.000 individuals. A key factor in the pathomechanism of FSHD is DUX4, a double-homeobox germline transcription factor which misexpression causes muscle cell death. Sporadic expression of DUX4 in myonuclei is preceded by chromatin relaxation of the D4Z4 macrosatellite repeat array that contains a copy of the DUX4 gene in every single D4Z4 unit. These epigenetic changes in D4Z4 are a consequence of either a contraction of the D4Z4 repeat array in >95% of cases (FSHD1), or of mutations in SMCHD1 (Structural Maintenance of Chromosomes Flexible Hinge Domain Containing) in most other cases (FSHD2). We aimed to determine the epigenetic requirement of DUX4 transcription in primary human myoblasts and myotubes. First we established the dynamics of DUX4 expression during myogenesis in a series of control (n=6), FSHD1 (n=4) and FSHD2 (n=6) human primary myoblast and myotube samples. DUX4 transcripts were detected in FSHD1 and FSHD2 myoblasts and a robust increase of DUX4 transcript levels was observed in FSHD myotubes. To understand the epigenetic changes underlying transcriptional upregulation of DUX4 we quantitatively measured DNA methylation and activating histone modifications (H3K4me2, H3K4me3 and H3K36me3) or repressive histone modifications (H3K27me3 and H3K9me3) at D4Z4 in the same samples DNA methylation levels were lower in patient myoblasts and myotubes, but no significant change was found during myogenesis suggesting that increased levels of DUX4 in myotubes do not correlate with changes in DNA methylation. Activating histone modifications did correlate with transcription, with higher levels in patient samples compared to controls. We could not confirm the reported loss of H3K9me3 at D4Z4 in patient myotube samples. Furthermore downregulation of known chromatin modifiers involved in H3K9me3 mediated repression at D4Z4 such as SUV39H1 or cohesin subunits SMC3 and RAD21 did not induce DUX4 transcription in control myoblasts and myotubes while depletion of SMCHD1 resulted in transcriptional derepression of DUX4. Interestingly the level of H3K27me3 and PRC2 subunits EZH2 and SUZ12 were increased in FSHD myoblasts but subsequently decreased during myogenic differentiation possibly contributing to the leaky expression of DUX4. We conclude that SMCHD1 is a central chromatin regulator at D4Z4 controlling DUX4 expression in FSHD1 and FSHD2.

Integrative analysis reveals enhanced regulatory effects of human large intergenic noncoding RNAs in lung adenocarcinoma. *X. Kong[1], Y. Zhou[1], T. Huang[2], J. Jiang[3], J. Huang[1], P. Zhang[1], Y. Zhu[1], Y. Shi[1], L. Hu[1].* 1) Molec Gen, Inst Hlth Sci, Shanghai, China; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York, United States of America; 3) State Key Laboratory of Genetic Engineering, School of Life Sciences, Fudan University, Shanghai, China.

Although there is an accumulating appreciation of the key roles that large intergenic noncoding RNAs (lincRNAs) play in diverse cellular processes, our knowledge of how lincRNAs function in cancer remains sparse. Here, we present a comprehensive landscape of RNA-seq transcriptome profiles of lung adenocarcinomas and their paired normal counterparts from 72 South Korean patients to unravel the mysteries of lincRNA functions and mechanisms. We found asymmetric expression patterns of lincRNAs between cancer and adjacent paired normal tissues, with an increased breadth and quantity of lincRNAs during cancer progression. Consistent with previous findings, lincRNAs were typically coexpressed with their neighboring genes, albeit to an extent similar to that of pairs of neighboring protein-coding genes. By building a mathematical model based on correlated gene expression, we distinguished an additional subset of lincRNAs termed "regulatory lincRNAs," representing their dominant roles in gene regulation. The number of regulatory lincRNAs was significantly higher in cancerous compared to normal tissues, with greater enrichment of target protein-coding genes associated with cell growth and differentiation processes observed in cancer tissues. Moreover, dozens of lincRNAs switched from non-regulators in normal tissues to regulators in tumor tissues. Our integrated analysis reveals enhanced regulatory effects of lincRNAs in lung adenocarcinoma and provides a resource for the study of regulatory lincRNAs that facilitate tumorigenesis and may serve as new targets for clinical therapy.

A Neuroepigenomic Model of the Fetal Alcohol Exposure Spectrum.

B.I. Laufer, E.J. Diehl, M.L. Kleiber, A. Chokroborty-Hoque, B. Alberry, K. Mantha, S.M. Singh. Molecular Genetics Unit, Department of Biology, Western University, London, Ontario, Canada.

Maternal alcohol consumption during pregnancy causes a continuum of heterogeneous disorders termed Fetal Alcohol Spectrum Disorders (FASD). Patients affected with FASD show life long defects, particularly affecting the central nervous system and its complex traits. Our group has developed an animal model using C57BL/6J (B6) mice and genome-wide molecular technologies. The results show that exposure of alcohol during neurodevelopment in B6 mice causes behavioral disabilities matching FASD patients in resulting offspring. Further, the resulting mice show changes in brain gene expression as well as epigenetic marks, including DNA methylation, multiple histone modifications, and ncRNA expression. Interestingly, the genes affected by the epigenetic marks last a lifetime. Also, the genes affected participate in the critical neural processes of apoptosis, neurodevelopment, cellular identity, cell-cell interaction, and signalling. Using genome-wide arrays to interrogate the cytosine methylation and ncRNA expression within the whole brain and hippocampus of adult mice prenatally exposed to alcohol, we have identified an epigenomic footprint that is characterized by alterations to imprinted regions of the genomes, controlled by DNA methylation, that encode multiple developmentally important non-coding RNAs (ncRNAs) and are regulated by CCCTC-binding factor (CTCF), a zinc finger protein. These processes are developmentally integral to the outcome of larger scale cortical brain structure formation, since the events of both pre- and post-natal neurodevelopment are highly dependent on the (epi)genotype as well as the experience and environment of the differentiating cells at the molecular level. Taken together, our models suggest that ethanol can create significant long-term changes to the molecular mechanisms that create and maintain an epigenetic landscape that is essential to normal brain function and future neurodevelopment. The proposed model suggests a potential for effective attenuation of disease endophenotypes, given the plastic nature of the epigenome in response to enriched postnatal environments.

511S

Allele-aware ChIP-seq alignments identify allelic differences in transcription factor binding at disease-associated loci. *M.L. Buchkovich[1], K.E. Eklund[1], Q. Duan[1], L. Y[1,2,3], K.L. M[1], T.S. Furey[1,4].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Department of Computer Science, University of North Carolina, Chapel Hill, NC; 4) Department of Biology, University of North Carolina, Chapel Hill, NC.

Allelic differences in protein-DNA binding can influence gene transcription at disease-associated loci. These differences can be detected as allelic imbalance, or enrichment of one allele, in ChIP-seq data. Allele-aware alignments that use genotyping data during mapping more accurately align sequence reads to heterozygous sites than traditional, genotype-independent alignments, and are important for detecting imbalances. We used an allele-aware aligner, GSNAP, and heterozygous sites from complete (sequencing-based), partial (Human1MDuo array + imputation), or no sample-specific genotype data to map CREB1 ChIP-seq reads from GM12878, a human lymphoblastoid cell line. In the case of no genotype data, common variants (1000 Genomes; EUR MAF>.05) were considered heterozygous sites. Both CREB1, a transcription-activating protein, and B-lymphocytes are known to play a role in inflammation. Using complete genotype data and requiring a minimum of 5 sequences containing each allele, we detected 204 sites of allelic imbalance (binomial p<.01). We correctly identified 161 and 146 of these imbalances using partial and no genotypes, respectively, plus an additional 52 and 47 imbalances not detected using complete genotypes. Two sites of allelic imbalance, rs2382818 and rs713875, are in linkage disequilibrium (1000 Genomes EUR; r2>=.8) with inflammatory bowel disease (IBD)-associated variants, and are predicted to be strong enhancers (chromHMM) in GM12878 cells. While the imbalance at rs713875 was detected in the genotype-independent and all three allele-aware alignments, the imbalance at rs2382818 was only detected in allele-aware alignments using complete or partial genotypes. We performed electrophoretic mobility shift assays for these two variants with purified CREB1 protein and observed allelic differences in CREB1 binding of both variants in the directions consistent with the predicted imbalances. Together, these data suggest that differential binding of CREB1 to alleles of these variants may influence IBD by altering the transcription of one or more nearby genes. These findings highlight our ability to create allele-aware alignments in the absence of completely genotyped samples and the utility of these alignments in identifying sites with allelic differences in protein binding at disease-associated loci.

512M

Functional genomics approaches reveal novel role of a key hematopoietic transcription factor in blood disorders. *M. Byrska-Bishop[1], D. VanDorn[2], AE. Campbell[2], PR. Arca[2], Y. Yao[2], CA. Keller[1], BM. Giardine[1], P. Gadue[3], FF. Costa[4], RL. Nemiroff[5], GA. Blobel[2], DL. French[3], RC. Hardison[1], MJ. Weiss[2], ST. Chou[2].* 1) The Pennsylvania State University, Center for Comparative Genomics and Bioinformatics, Department of Biochemistry and Molecular Biology, University Park, PA; 2) The Children's Hospital of Philadelphia, Division of Hematology, Philadelphia, PA; 3) The Children's Hospital of Philadelphia, Department of Pathology and Laboratory Medicine, Philadelphia, PA; 4) University of Campinas, Department of Internal Medicine, School of Medicine, Campinas, Brazil; 5) The University of Pennsylvania School of Medicine, Department of Obstetrics and Gynecology, Philadelphia, PA.

GATA1 (MIM *305371) is a hematopoietic transcription factor important for the development of erythrocytes and megakaryocytes. Normally, a human hematopoietic cell expresses a full-length form of GATA1 and a short form, GATA1s, that lacks the N-terminal transactivation domain (NAD). Germline *GATA1* mutations that result in exclusive production of GATA1s (referred to as "*GATA1s* mutations") were identified in patients with congenital hypoplastic anemia and neutropenia (MIM #300835), as well as Diamond Blackfan anemia (MIM #300835). In individuals with Down syndrome (MIM #190685), somatic *GATA1s* mutations lead to transient myeloproliferative disease (TMD [MIM #190685]) and acute megakaryoblastic leukemia (AMKL [MIM #190685]). We investigated the function of the human GATA1s by creating and analyzing induced pluripotent stem cells (iPSCs) from somatic tissues of patients with Down syndrome-associated TMD, as well as congenital macrocytic anemia due to a germline *GATA1s* mutation. Microarray transcriptome profiles of iPSC-derived progenitors revealed that genes upregulated by GATA1s were enriched for megakaryocytic and myeloid genes, while the downregulated genes were enriched for erythroid genes. Furthermore, compared to controls, erythropoiesis by *GATA1s* iPSCs was markedly reduced, while megakaryopoiesis and myelopoiesis were enhanced. Single cell expression profiling of 91 selected hematopoietic genes revealed small, but significant differences in gene expression distributions for 40 genes between *wtGATA1* and *GATA1s* cells. This suggests that small changes in expression of many genes contribute to the GATA1s-mediated change in lineage bias from erythroid to myelo-megakaryocytic lineage fate. To provide a mechanistic explanation of the observed phenotype, we performed ChIP-seq experiments to study differences in binding patterns between full length GATA1 and GATA1s. ChIP-seq results indicate that GATA1s binding is specifically impaired at erythroid target genes, but normal at megakaryocytic genes, implicating the N-terminus as a chromatin occupancy factor selective for erythroid cells.

513T

Identifying rare, non-coding DNA variants in Systemic Lupus Erythematosus. *S.J. White[1], S. Cantsilieris[1], F.J. Rossello[2], D. Belluoccio[3], E.F. Morand[4].* 1) MIMR-PHI Institute of Medical Research, Monash University, Clayton, Victoria, Australia; 2) Victorian Bioinformatics Consortium, Monash University, Clayton, Victoria, Australia; 3) Agilent Technologies, Mulgrave, Victoria, Australia; 4) Southern Clinical School, Monash University, Clayton, Victoria, Australia.

Systemic lupus erythematosus (SLE) is a debilitating multisystem autoimmune disease. Patients with SLE suffer a marked loss of life expectancy, and severe morbidity, due to autoimmune-mediated inflammation of multiple organs. A classic hallmark of SLE is the presence of autoantibodies. This is a clear biological link between SLE and antibody-producing B-lymphocytes (B-cells), strengthened by the clinical efficacy of anti-B cell therapies in certain patients. Genetic studies have associated SLE susceptibility with a number of Single Nucleotide Polymorphisms (SNPs), many of which are found in or near genes with B-cell functions. However, the known SLE SNPs together only account for a small percentage of the genetic contribution to SLE, and as most SNPs are located in non-coding DNA, the mechanism of their effect is often unclear. Several SLE-associated SNPs are located in such DNA elements that control gene regulation, with sequence changes disrupting the binding of specific transcription factors. In 2012 the ENCODE consortium published papers outlining genome-wide studies of open chromatin in a range of cell types. These studies demonstrated that DNaseI hypersensitive sites (DHS) strongly correlate with known and predicted regulatory sequences. In addition, they are enriched for known and predicted transcription factor binding sites (TFBS). This provides a clear link between sequence variants and functional activity, and rare variants in B-cell regulatory loci (defined by open chromatin in B-cells) would explain genetic susceptibility to SLE in a way not detectable by GWAS. We have designed a custom capture approach using an Agilent SureSelectXT2 Custom Library to screen 49K B-cell DHS in genomic DNA from SLE cases. This covers ~ 17Mb of genomic sequence, with up to 16 samples being pooled in a single lane on the Illumina HiSeq 1500. We are currently analysing the sequence data from a cohort of SLE cases, and plan to perform functional validation using reporter constructs and changes in DNaseI-sensitivity.

Coordinated Regulatory Variation Associated with Maternal Glycemic Traits Regulates HKDC1 Expression. *T.E. Reddy[1,2], C. Guo[1], A.E. Ludvik[3], M.G. Hayes[3], L.L. Armstrong[3], D.M. Scholtens[4], C.D. Brown[5], B.T. Layden[3,6], W.L. Lowe[3].* 1) Institute for Genome Science & Policy, Duke University Medical School, Durham, NC; 2) Department of Biostatistics & Bioinformatics, Duke University Medical School, Durham NC; 3) Division of Endocrinology, Metabolism and Molecular Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Department of Preventive Medicine, Division of Biostatistics, Northwestern University Feinberg School of Medicine, Chicago, IL; 5) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 6) Jesse Brown Veterans Affairs Medical Center, Chicago, IL.

Genome wide association studies (GWAS) to understand the genetics of complex human traits strongly suggest that non-coding genetic variation is a major contributor to disease risk. One hypothesis is that variation in gene regulation may contribute to altered expression of disease-relevant genes. As one example, in our previous GWAS, we identified SNPs in 10q22 near the putative hexokinase gene HKDC1 that were associated with two hour glucose levels in an oral glucose tolerance test administered at ~28 weeks gestation during pregnancy. None of the associated SNPs were within the protein-coding regions of HKDC1, suggesting that the SNPs instead could have a regulatory effect on HKDC1. To address that hypothesis, we have comprehensively mapped regulatory variation in the 10q22 region associated with maternal glucose levels. We used open chromatin data from the ENCODE project and the Roadmap Epigenome Consortium to define regulatory elements, and measured regulatory function of each element across four different human ancestry groups using reporter assays constructed from DNA from the 1,000 Genomes Project. To disrupt linkage within regulatory elements and to better assay rare and personal variants, we complemented the set of natural haplotypes using site-directed mutagenesis. With this approach, we saturated the common and rare variation in regulatory elements across this gestational hyperglycemia locus. These assays revealed a surprising amount of regulatory variation controlling expression of HKDC1. The effects of regulatory variants were strongly and significantly coordinated across risk-haplotypes. Furthermore, when cloned into a single reporter construct, multiple regulatory elements acted independently. These results suggest that regulatory variants with a coordinated effect across a large haplotype contribute to a reduction in HKDC1 expression that is greater than would be expected for a single causal regulatory variant. We confirmed the reporter assay results using an eQTL analysis that revealed a genetic influence on HKDC1 expression in the same locus and in the expected direction at genome-wide significance. Together, these results provide evidence for a novel model of human disease in which coordinated regulatory effects across a risk haplotype have a magnified effect on endogenous gene expression, leading to subtle but significant effects on phenotype.

515M

HyCCAPP for functional proteomic analysis of promoter variants associated with plasma lipid levels and gene expression in Mexican Americans. *H. Guillen Ahlers[1], D. Perumalla[1], P. Rao[1], A. Jadhav[1], J.M. Proffitt[1], M.P. Johnson[1], J.E. Curran[1], H.H. Göring[1], P.J. Meikle[3], J. Blangero[1], M.R. Shortreed[2], L.M. Smith[2], M. Olivier[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Chemistry, University of Madison, Madison, WI; 3) Metabolomics Laboratory, Baker IDI Heart and Diabetes Institute, Melbourne, Australia.

Lipid and lipoprotein levels influence risk of cardiovascular disease; however, studies have traditionally focused on the assessment of plasma cholesterol and triglyceride levels. The plasma lipidome consists of many thousands of lipid metabolites, with large structural diversity. As part of the San Antonio Family Heart Study, lipidomic profiles (quantification of 319 lipid species) were generated from 1,240 Mexican American individuals from 30 extended families using electrospray ionization-tandem mass spectrometry. Individual lipid measures were correlated with gene expression profiles for 20,413 genes from PBMCs, and promoter variants (cis eQTL) were identified that were strongly associated with both expression and individual lipid profiles. Three variants were further characterized. Variants, rs8736 within 1000 bp of the TSS 5' of the TMC4 gene and rs887316 in the proximal promoter of the RAD9A gene, were associated with a phosphatidylinositol lipid levels ($p = 1.0\times10^{-5}$ and 4.2×10^{-7}). The rs606458 variant in the SF1 gene promoter was associated with levels of a phosphatidylcholine levels ($p = 1.7\times10^{-5}$). We tested the two alleles of each variant in luciferase reporter assays introducing promoter-containing plasmids in K562 cells. All variants resulted in differential activity in the reporter assay, suggesting altered gene expression for each allele. However, ChIP-seq data from ENCODE did not reveal the likely DNA-binding protein mediating the observed effect. Therefore, we adapted our novel methodology, Hybridization Capture of Chromatin-Associated Proteins for Proteomics (HyCCAPP) to isolate the desired promoter regions from crosslinked cells using hybridization capture with complementary oligonucleotide probes, as initially developed for the analysis of genomic regions in yeast. The methodology was developed to isolate individual chromatin regions after protein-DNA crosslinking, and use mass spectrometry to characterize and quantify the bound proteins. In our adaptation to the luciferase reporter system, the targeted promoter regions were captured with over 3% efficiency, and the isolated material was amenable to proteomic analysis. HyCCAPP now allows the effective characterization of DNA-binding proteins for promoter variants that show differential activity in luciferase reporter assays, and will help elucidate the underlying mechanisms by which the variants identified in our cohort modulate gene expression and plasma lipid levels.

Single cell allele specific expression (ASE) in Down syndrome and common aneuploidies. *G. Stamoulis[1], P.G. Fereirra[1], P. Makrythanasis[1,2], F. Santoni[1], M. Guipponi[1,2], M. Garieri[1], O. Delaneau[1], E. Falconnet[1], P. Ribaux[1], E.T. Dermitzakis[1,3], C. Borel[1], S.E. Antonarakis[1,2,3].* 1) University of Geneva, Department of Genetic Medicine and Development, University of Geneva Medical School, 1211 Geneva 4, Switzerland; 2) Geneva University Hospitals-HUG, Service of Genetic Medicine, 1211 Geneva 4, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, University of Geneva, 1211 Geneva 4, Switzerland.

Trisomy 21 is a model disorder of altered gene expression. Several studies have addressed the transcriptome differences between normal and affected individuals; however all of these studies suffer from the presence of ''noise'' due to gene expression variation among different individuals. We have previously used a pair of monozygotic twins discordant for trisomy 21 in order to study the global dysregulation of gene expression (Nature: 508; 7496,2014). The majority of previous studies focused on aneuploidies were conducted on cultured cell populations or tissues, but studies focusing on gene and allelic expression behaviour at the single cell level are lacking. In this study we explore the allele specific expression in Trisomy 21 using transcriptome studies in single cells. We have used 40 normal cells and 48 trisomic cells from the fibroblasts of the monozygotic twins discordant for trisomy 21 and compared the ASE (allele specific expression), and their transcriptional metrics in these two cell groups. Remarkably we have observed extensive monoallelic expression of genes in all autosomes including on chromosome 21. In addition a series of samples from mosaic trisomy 21, trisomy 13 and trisomy 18 are in different stages of investigation. These studies in single cells will provide a fundamental understanding of the gene expression dysregulation and allele specific expression in aneuploidies and may contribute to the understanding of the phenotypic heterogeneity of these syndromes.

517S

Analysis of long-range interactions in primary human cells reveals *CFTR* new regulatory elements. *S. Moisan[1,2,3], S. Berlivet[4,5], J. Dostie[5], C. Férec[1,2,3].* 1) INSERM U1078 Laboratoire de Génétique, Génomique Fonctionnelle et Biotechnologies, Brest, France; 2) Université de Bretagne Occidentale, Faculté de Médecine et des Sciences de la Santé, Brest, France; 3) CHU Brest, Hôpital Morvan, Laboratoire de Génétique Moléculaire, Brest, France; 4) Unité de Génétique et Développement, Institut de Recherches Cliniques de Montréal, Québec, Canada; 5)478 Departement of Biochemistry and Goodman Cancer Research Center, McGill University, Montréal, Québec, Canada.

The cystic fibrosis transmembrane conductance regulator (*CFTR*) gene was identified in 1989. Twenty five years later, the regulatory mechanisms controlling its complex expression are still not fully understood. Although, 1970 mutations have been identified, many cases of cystic fibrosis or CFTR Related Disorders remain still of unknown origin. The promoter which binds transcription factors and drives some aspects of *CFTR* gene expression, cannot alone account for tissue specific control. This implicates other distal cis- or trans-acting elements in cell-type-specific regulation of *CFTR* expression. The aim of our project is to study long-range regulatory mechanisms of the *CFTR* gene. Interestingly, the majority of the human genome is composed of non coding DNA whose function has not been thoroughly investigated. A significant number of conserved non-coding sequences (CNCs) are found in gene-poor regions, these large intergenic regions must have kept a function throughout evolution. We first developped the Chromosome Conformation Captures (3C) approach to map these potentials regulatory elements which could interact specifically with the *CFTR* gene by tridimensional folding mechanism. Subsequently, we enhanced our analyses with a high-throughput adaptation of 3C: the 3C-Carbon Copy (5C) technology. This approach allows the analysis of millions chromatin interactions. Thus, we have analyzed the spatial organization of a ~790kb region, comprising the *CFTR* gene, with 145 5C primers. Interactions between this locus and the *CFTR* promoter have been analysed by next generation sequencing with the Ion PGM™, in primary epithelial cells, which express the gene and primary skin fibroblasts, which do not express the gene. We compare chromatin conformation in order to identify uncharacterized regulatory elements that act especially in CFTR-expressing cells. Our approach is validated by the identification of previously characterized regulatory elements. Moreover, we identify novel chromatin contacts of the *CFTR* promoter with chromosomal regions, which could potentially be involved in *CFTR* gene expression regulation. Thanks to 3C and 3C-derivated analyses, we could identify new possible mutations far from the gene, which may lead to its dysfunction by modifying the chromatin conformation. These analyses will be pursued on patients affected by cystic fibrosis or by CFTR Related Disorders, in whom either a single mutation or none was found in the *CFTR* gene coding sequence.

518M

Assessing the functional significance of disease-associated cis-regulatory variants in vivo using a versatile dual colour transgenesis strategy in zebrafish. *S. Bhatia, DA. Kleinjan, VV. Heyningen.* MRC Human Genetics Unit, University of Edinburgh, Edinburgh, United Kingdom.

Disruption of gene regulation is a significant cause of human diseases. A class of noncoding region of the genome called cis-regulatory elements (CREs) or enhancers function as the primary determinants of precise spatial and temporal regulation of their target genes during development by serving as docking sites for tissue-specific transcription factors. Sequence variation in CREs disrupt transcription factor binding sites causing mis-regulation of their target genes thereby leading to a plethora of human diseases. The importance of these regulatory elements for human health is further highlighted by the finding that >70% of single nucleotide polymorphisms (SNPs), identified in genome-wide association studies (GWAS) to be associated with common and complex human diseases, are located in noncoding regions without any currently known function, but which are likely to be CREs. While technological advances in sequencing methods have led to the identification of a large number of putative disease-associated CRE variants, robust methods for discerning the functional CRE variants from background sequence variation are largely lacking. We have developed an efficient approach for the in-depth characterisation of putative regulatory variants using dual-colour reporter transgenics in zebrafish, allowing detailed in vivo comparison of spatial and temporal differences in regulatory activity between variants in the same animal. The method also allows for simultaneous assessment of multiple separate elements for subtle differences in spatio-temporal overlap, and the validation of putative binding factors by the effect of morpholino depletion on CRE activity. We validate the method on a number of known human disease-associated elements from the SHH, PAX6 and IRF6 locus, and use the approach to characterise a set of novel long-range SOX9 enhancers implicated in Pierre Robin Sequence. Our results provide compelling evidence for establishment of a robust in vivo method for functionally characterising disease associated CRE variants. The data reveals novel cis-regulatory elements controlling SOX9 expression during craniofacial development and simultaneously highlight how the functional activity of these elements can be affected by a variety of mutant enhancer alleles in patients with Pierre Robin Sequence.

519T

Systemic Lupus Erythematosus-associated functional variants influence the gene expression of UBE2L3 through the regulation of promoter and enhancer activities. *S. Wang[1], B. He[2], P. Gaffney[1,2].* 1) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma city, OK; 2) Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Genetic variants in the UBE2L3 region have been associated with multiple autoimmune diseases including Systemic Lupus Erythematosus (SLE), Crohn's disease, celiac disease, and rheumatoid arthritis. We previously reported an SLE-associated functional risk haplotype in the UBE2L3 region that led to significant increases in both mRNA expression of UBE2L3 and protein expression of UBCH7. However, the mechanism by which the risk haplotype influences UBE2L3 expression has not yet been described. In this report, we employed a combination of approaches including EMSA, Luciferase reporter assay, Western blotting, and RT-qPCR to evaluate the functional potential of SLE-associated variants in the UBE2L3 region and to characterize the mechanism by which these functional variants influence UBE2L3 gene expression. Through the use of EMSA, we observed functional evidence for two variants in and around the UBE2L3 promoter region. A functional variant (rs140490), located150 bps upstream of the UBE2L3 transcription start site increases nuclear protein binding (P=0.0031). Luciferase reporter assays demonstrated that the risk allele of this functional variant increases UBE2L3 promoter activity (P=0.0038) in EBV-transformed B cells. In contrast, another functional variant (rs2266959), located in the first intron of UBE2L3, reduces nuclear protein binding (P=0.0014). Luciferase reporter activity assays demonstrated that rs2266959 falls within an enhancer element, the risk allele of which leads to a significant increase in the enhancer activity (P=0.0118). These results are consistent with our previous finding in which the risk haplotype carrying these functional variants is associated with increased UBE2L3 gene expression. In conclusion, we identified two functional variants, rs140490 and rs2266959, carried on the SLE-associated risk haplotype of UBE2L3. The variant rs140490 increases binding of nuclear proteins to the promoter, while the variant rs2266959 reduces binding of nuclear proteins to the enhancer. However, both functional variants lead to significantly increased transcriptional activity of the promoter and the enhancer of UBE2L3. Our data suggest that these functional variants may be responsible for the gene expression phenotype produced by the risk haplotype of UBE2L3. Further mechanistic characterization of the functional variants of UBE2L3 is required to understand the role of this risk haplotype in autoimmune disease pathogenesis.

520S

Comparative genomics and abstraction of DNA sequences allow the identification of cis-regulatory signatures. *P.EM. Guimaraes[1], M.A.A. Almeida[2], T.J.P. Sobreira[3], H.A. Castillo[4], J.X. Neto[4], P.S.L. Oliveira[3].* 1) Laboratório de Evolução de Genes e Genomas, INGEB, UFU, Patos de Minas, MG, Brazil; 2) AT&T GCC, Department of Genetics, Texas Biomedical Research Institute, San Antonio TX USA; 3) Laboratório de Bioinformática, LNBio, CNPEM, Campinas, SP, Brazil; 4) Laboratório de Modificação do Genoma, LNBio, CNPEM, Campinas, SP, Brazil.

Gene expression fine regulation is achieved by the complex interaction between transcription factors (TF) and their respective binding sites (TFBS). Identify these short DNA motifs is a major current goal in modern molecular biology. However, the efficiency of current prediction algorithms is limited due to the sequence variation between TFBS and the complexity of transcription regulatory networks. As an endeavor to modify this scenario, here we present and validate a new computational routine to improve the prediction of functional TFBS. This pipeline uses a "phylogenetic footprint" filter and converts predicted TFBS to an alphabet, which describes evolutionary-functionally related families of TF. The "phylogenetic footprint" works as a selection step for orthologous sequences. Further, TFBS were predicted in syntenic blocks, for each species evaluated, and converted into strings of families of functional related transcription factors. The family clustering reduces TFBS variability and prediction redundancy. Finally, only TFBS families predicted at the same gene relative position and present in the set of selected species were considered. We carried our routine in order to identify functional cis-regulatory elements acting in *aldh1a2* gene, searching for syntenic sequences in a 30 kb window flanking the coding sequence of the mouse gene, including all intronic sequences, comprising a total of 138,191 bases. Orthologous segments were identified comparing the mouse to human, rat and chicken genomes. A total of 1,318 predicted TFBS families were considered constrained by our "spatial and evolutionary filter", reducing in 99.6% the original universe of 382,750 predicted elements. Despite the reduction of predicted TFBS, it could be accomplished of one undesired side effect: the lost of functional binding sites. To evaluate the efficiency of our routine we compared the final set of predicted TFBS to those previously experimentally identified as real regulators of *aldh1a2* gene. All validated TFBS were represented in our set, indicating that even with the considerable reduction of predicted TFBS we still clamped the real ones. Taken together, our data suggest that the routine can be applied to high-throughput analyses and help to draw more focused experimental validation protocols. The same strategy can be applied to identification of miRNA seed pairing, splicing enhancer elements and others regulatory signatures and structural elements.

521M

Detecting gene-by-environment interactions using allele specific expression. *D.A. Knowles[1], S.B. Montgomery[1], A. Battle[2].* 1) Stanford University, Stanford, CA; 2) Johns Hopkins University, Baltimore, MD.

The impact of environment and lifestyle on human health is dramatic, with major risk factors including substance use, pollution, diet and exercise. However, the interaction between environment and individual genetic background is poorly understood; detecting gene-by-environment interactions is both statistically and computationally challenging. Using RNA sequencing of primary tissue (whole blood) from 922 individuals in the DGN cohort, combined with extensive annotation of environmental factors including drug use and behavioral factors, we evaluate GxE effects at a cellular level. Even in this study, standard association methods detect only a handful of gene-by-environment interactions at a lenient FDR of 0.1 across 30 environment variables. RNA-seq offers an alternative strategy however: we look for genes whose allelic expression is associated with an environment variable of interest. Measuring two different alleles within a single individual and time point offers a highly controlled comparison of environmental modulation of genetic effects, not subject to the many biological and technical variables that differ between samples, and thus provides additional power and specificity to identify causal factors. To test for such associations, we have developed a hierarchical Bayesian model of allele-specific read counts that takes into account local cis-regulation, read depth, and technical influences on over-dispersion of RNA-seq data. This methodology significantly increases power by leveraging the controlled, within individual, nature of allelic expression and by integrating over potential causal cis-variants. Applying this method across 30 environment variables, we find dozens of GxE interactions at FDR 0.1, a substantial increase over the standard approach. Pathway analysis of genes responding to each environmental factor further uncovers relevant shared function, including enrichment in a platelet degranulation pathway for use of ACE inhibitors, the PYK2 pathway for exercise, and the Toll-like receptor signaling pathway for time of day. Individually significant genes include SESN3 for exercise, which regulates blood glucose levels, IL10RA for smoking, and CDH23 for decongestant medication, which is expressed in the neurosensory epithelium. In conclusion, we show it is possible to leverage the novel information provided by RNA-seq beyond total expression to unravel the influence of disease-associated environmental factors on gene regulation.

522T

An investigation of the correlation between cis-genetic and environmental factors regulating gene expression between cell types, exposures, and populations. *N. Zaitlen[1], J. Yang[2], A. Bakshi[2], A.L. Price[3,4], A. Regev[4,5,6], C.J. Ye[4].* 1) Medicine, University of California San Francisco, San Francisco, CA; 2) University of Queensland, Brisbane, Australia; 3) Harvard School of Public Health, Boston, MA; 4) Broad Institute, Cambridge, MA; 5) Massachusetts Institute of Technology, Cambridge, MA; 6) Howard Hughes Medical Institute.

RNA is the first intermediary between genetic variants and their downstream effects on human disease. Recent work has shown that SNPs altering gene expression as opposed to coding SNPs may be the major drivers of complex phenotypic variation. Therefore, characterization of how regulatory SNPs (eQTLs) change between tissues, environments, and populations is central to understanding of the genetic basis of human disease. In this work we leverage a unique data set of expression from 19,360 genes collected in CD4+ T cells and CD14+ monocytes, from 183 Europeans (Eur), 91 African Americans (AfAm), and 74 Asians (Asn) genotyped at 700K SNPs. We also profiled 415 genes in CD14+/CD16- dendritic cells after exposure to IFNβ, influenza, and LPS. We estimate components of heritability of genotyped SNPs within and between contexts averaged across all genes; determining cis-genetic heritability ($h^2_{g,cis}$) in each context as well as the correlation of cis-genetic and environmental effects betweens cell types ($\rho_{g,cel}$,$\rho_{e,cel}$) and exposures ($\rho_{g,exp}$,$\rho_{e,exp}$). Finally, we develop new theory to estimate a lower bound of cross-population cis-genetic correlation of gene expression for each pair of populations ($\rho_{g,pop}$). We estimate the $h^2_{g,cis}$ in (Eur,AfAm,Asn) at (0.039,0.041,0.031) for CD4s and (0.048,0.053, 0.045) for CD14s (s.e. < 0.001), observing higher $h^2_{g,cis}$ for CD14s than CD4s and an ordering of $h^2_{g,cis}$ in according to population genetic diversity (AfAm>Eur>Asn). The cross cell type genetic correlations $\rho_{g,cel}$=(0.353, 0.251,0.244), implying different sets of eQTLs between cell types. Upon exposure to LPS, flu and IFNβ, $h^2_{g,cis}$ estimates for Eur CD14 increased by (34.4%, 44.5%, 30.0%), with similar patterns in AfAm and Asn. In contrast to $\rho_{g,cel}$, the cross exposure correlations were dramatically higher with $\rho_{g,exp}$= (0.93,0.542,0.779). The higher value of $\rho_{g,exp}$ than $\rho_{g,cel}$, coupled with the increases in $h^2_{g,cis}$ are consistent with a model where upon exposure, the same causal variants regulate expression with larger effect sizes. In CD14 across populations we observe $\rho_{g,pop}$(Eur,AfAm)=0.56, $\rho_{g,pop}$(Eur,Asn)= 0.52, and $\rho_{g,pop}$(AfAm,Asn)=0.40. The cross population genetic correlations are higher than cross tissue and lower than cross exposure correlations and decrease as a function of population genetic distance. In all, our results suggest cross tissue analysis will uncover distinct regulatory regions while stimulation will increase the power to detect eQTLs.

Studies on the function of HCMV-encoded essential gene UL49. *H. LI, D. YANG, L. FENG, Y. RAN, H. LIU, T. ZHOU, Z. DENG.* Dept. Biotechnology, Jinan University, Guangzhou, Guangdong, China.

Human cytomegalovirus (HCMV), is a clinically important and ubiquitous herpesvirus, and affects individuals whose immune functions are compromised or immature. This virus is a leading cause of retinitis-associated blindness and other debilitating conditions such as pneumonia and enteritis among AIDS patients. Moreover, HCMV causes mental and behavioral dysfunctions in children that were infected in utero. HCMV- encoded UL49 gene is essential for viral growth and might serve as a potential target for combat HCMV infection. RNase P complexed with external guide sequence (EGS) represents a novel nucleic-acid-based gene interference approach to modulate gene expression and is used in this study to explore a potential therapeutic approach for inhibiting UL49 gene expressing and replication of HCMV. A functional EGS RNA was constructed to target the UL49 mRNA . The EGS RNA was shown to be able to direct human RNase P to cleave the target mRNA sequence efficiently in vitro. A reduction of 68 % in the mRNA and protein expression levels and a reduction of 1000-fold in viral growth were observed in human cells that expressed the functional EGS. Further studies of the function of UL49 gene indicate that the reduction of UL49 gene expression has no effect on HCMV genome replication and gene expression of IE2 and gB. However, it leads to the down-regulation on the gene expression UL99, which is highly immunogenic and play roles in the assembly and egress of virus particles. This observation has provided us a valuable new clue to understand the role of UL49 gene during HCMV lytic infections.

Deep genetic, transcriptomic and epigenetic maps of human blood elements. *L. Chen[1,2], S. Busche[3], A. Datta[4], O. Delaneau[5], K. Downes[2], S. Ecker[6], H. Kerstens[7], M. Kostadima[4,2], D.S. Paul[8], OBO. BLUEPRINT CONSORTIUM[9].* 1) Human Genetics, Wellcome Trust Sanger Institute, Cambridge, Cambridge, United Kingdom; 2) Department of Haematology, University of Cambridge, NHS Blood and Transplant, Cambridge Biomedical Campus, Cambridge, United Kingdom; 3) McGill Epigenome Mapping Centre, McGill University, Montreal, Quebec, Canada; 4) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, United Kingdom; 5) Département de Génétique et Développement (GEDEV) 1, Michel-Servet, CH-1211 Genève 4; 6) Structural and Computational Biology Group, Spanish National Cancer Research Center (CNIO), Madrid, Spain; 7) Department of Molecular Biology, Radboud Institute for Molecular Life Sciences, Radboud University, Nijmegen, The Netherlands; 8) UCL Cancer Institute, University College London, London, United Kingdom; 9) http://www.blueprint-epigenome.eu/.

Haematopoiesis, the formation of blood elements, has been studied as a paradigm of stem cell biology and development. The BLUEPRINT project (http://www.blueprint-epigenome.eu/) is generating deep genetic, transcriptomic and epigenetic maps of over 30 human blood cell types and their malignant counterparts that will be available to the scientific community. A first stream of research has focused on cataloguing the transcriptional and alternative splicing changes in rare blood progenitor cells. We performed high-throughput RNA transcriptome analysis of eight highly-purified cell populations (HSC, hematopoietic stem cells; MPP, multipotent progenitor cell; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; GMP, granulocyte monocyte progenitor; MEP, megakaryocyte erythrocyte progenitor;EB, erythroblasts and MK, megakaryocytes). We identified (1) 7,881 novel splice junctions that were specific to these progenitor cell populations; (2) 20,924 high-confident alternative-splicing junctions, where approximately 11% were cell-type-specific and included categories of genes such as RNA splicing and transcription factors; (3) two differentially spliced transcription factors that were important in megakaryopoiesis by using in vitro experiments. These results suggest that alternative splicing is a critical post-transcriptional regulatory mechanism in hematopoietic cell differentiation. A second stream of research has focused on the effect of common sequence variation on the epigenetic landscape using detailed and integrated analyses. In three peripheral blood cell types, monocytes, neutrophils and naïve CD4 T cells, we have generated data for whole genome sequencing, RNA-seq, ChIP-seq of two histone modifications and DNA methylation by 450K arrays in an initial set of 48 healthy individuals with European-ancestry. Here we describe the first epigenetic quantitative trait loci (QTL) analyses of this integrated data set to further understand the effects of genotype-phenotype correlations via epigenetic mechanisms in these immune cells.

525T

Analysis of monoallelic expression in human individual cells revealed novel imprinting genes. *F. Santoni, C. Borel, M. Garieri, E. Falconnet, P. Ribaux, S.E. Antonarakis.* Department of Medical Genetics and Development, University of Geneva, Geneva, Geneva, Switzerland.

Genomic imprinting in mammals results in the expression of one allele of a given gene depending on its maternal or paternal inheritance. There has been considerable interest in identifying imprinted genes since they have been associated both with rare syndromes, and with common diseases including diabetes and cancer. So far, less than 100 human imprinted genes have been identified; however, the total numbered of them has been estimated to be a few hundreds. The aim of our study is to identify novel imprinting genes using an innovative approach based on single-cell RNA sequencing. We captured and RNA sequenced 203 individual fibroblasts from 2 different individuals. Additionally, the DNA of these individuals has been whole-genome sequenced at 8x depth. In total, more than 400'000 heterozygous single nucleotide variants (hetSNVs in the coding genes) were identified for further allelic specific expression analysis using an in-house pipeline. We selected all the genes with at least one cell with a coverage superior or equal to 16 reads at the hetSNV position and showing a monoallelic ratio (ref/total) of 0-0.1 or 0.9-1 for all the analyzed single cells. We were able to detect 1007 putative imprinted genes for the first individual and 1926 for the second individual. By retaining only the genes in common, we were able to identify 198 putative imprinted genes in fibroblast cells. This included novel and 8 known imprinted genes. We only detected and validated the monoallelic expression of 42 genes with bulk cell samples. Our single-cell approach allowed the detection of low expressed imprinted genes that are undetectable in standard RNAseq protocol. We confirmed their status of imprinting genes by investigating their parent of origin-dependent transmission of allelic biases using sequenced data from independent parent-offspring fibroblast trios and from Caucasian and Yoruban parent-offspring trios as part of the 1000 genome project. We also documented their tissue specificity by analyzing their monoallelic expression in datasets from multiple tissues. C.B. anf F.S. contributed equally.

Somatic Rhodopsin transcriptional repression by artificial DNA-binding proteins targeted to cis-regulatory elements. *S. Botta[1], E. Marrocco[1], N. de Prisco[1], F. Curion[1], M. Sofia[1], M.L. Bacci[3], S. Rossi[2], F. Simonelli[2], E.M. Surace[1,4].* 1) Tigem (Telethon Institute of Genetics and medicine), Napoli, Italy;; 2) Dipartimento di Oftalmologia, Seconda Università degli Studi di Napoli, Napoli, Italy;; 3) Dipartimento di Scienze Mediche Veterinarie, Università di Bologna, Bologna, Italy; 4) Dept. of Translational Medicine, "Federico II" University, Napoli, Italy.

Artificial DNA-binding proteins are becoming a novel and versatile system to development therapeutics. The ZF protein (ZFPs) modular structure enables both the sequential assembling of multiple ZFs to generate a DNA-binding domain (DBD) with different target specificities and the use of various effector domains including transcriptional regulation domain or nucleases for either genomic regulation or editing. We showed that a selected artificial transcriptional repressor (Zinc-Finger 6 repressor, ZF6R) delivered by AAV2/8 vector down regulates selectively mutated human RHO expression levels, ameliorating the retinal phenotype in a mouse model of autosomal dominant Retinitis Pigmentosa (adRP). We speculate that a protein, which contains exclusively the DBD (ZF6-DBD) domain without the effector domain (KRAB), may confer a higher therapeutic efficacy and tolerability genome-wide (off target) than ZF6-KRAB. Therefore, we removed from the construct the KRAB domain. The adRP mouse model eyes treated with AAV8-CMV-ZF6-DBD demonstrate robust and consistent recovery of the ERG a-wave and b-wave responses along a wide range of luminance in both scotopic and photopic conditions when compared to EGFP treated eyes. In addition, ZF6-DBD treated eyes show significant higher responses compared to AAV8-CMV-ZF6-KRAB. Based on sequence identity between the human and the porcine ZF6-DBD target site, we next assess the functional ability of the construct in the porcine retina. To assess "pure" transcriptional effects and not possible secondary degeneration owed to rhodopsin knock-down, we performed an early sacrifice. Fifteen days after vector administration the retina regions transduced were harvested and RT-PCR studies were performed. Transcriptional levels of Rho showed that retinas that received ZF6-DBD demonstrate more than 40%; of transcriptional repression of Rho. Furthermore, next generation sequencing (NGS; RNA-seq) was used to assess the differential transcriptional profile of AAV8-CMV-ZF6 and AAV8-CMV-ZF6-KRAB treated eyes compared to controls. The dataset generated show specific down-regulation of Rho expression. Ongoing experiments are showing remarkably similar results with Transcription activator-like effector (TALE) technology. In summary, the data support the use of artificial DNA-binding proteins as therapeutics.

Epigenetic promoter silencing in Friedreich ataxia is dependent on the length of the GAA triplet-repeat mutation. *Y. Chutake[1], C. Lam[1], W. Costello[1], M. Anderson[3], S. Bidichandani[1, 2].* 1) Department of Pediatrics, Univ Oklahoma HSC, Oklahoma City, OK; 2) Department of Biochemistry, Univ Oklahoma HSC, Oklahoma City, OK; 3) Department of Biostatistics & Epidemiology, Univ Oklahoma HSC, Oklahoma City, OK.

Friedreich ataxia (FRDA) is an autosomal recessive disease caused by an expanded GAA triplet-repeat (GAA-TR) mutation in intron 1 of the *FXN* gene. Most patients are homozygous for expanded alleles containing 100–1700 triplets, which results in a severe deficiency of *FXN* transcript. Transcriptional deficiency and phenotypic severity are significantly correlated with the length of the shorter of the two expanded alleles. We show that repressive chromatin extends from the expanded GAA-TR in intron 1 to the upstream regions of the *FXN* gene, involving the *FXN* transcriptional start site (*FXN*-TSS). Using a chromatin accessibility assay and a high-resolution nucleosome occupancy assay, we found that the *FXN*-TSS, which is normally in a nucleosome-depleted region is rendered inaccessible by altered nucleosome positioning in FRDA. Consistent with the altered epigenetic landscape, the *FXN* gene promoter was found to be in a transcriptionally non-permissive state in FRDA. Both metabolic labeling of nascent transcripts and an unbiased whole transcriptome analysis revealed a severe deficiency of transcriptional initiation in FRDA. *FXN* transcriptional deficiency, measured by qRT-PCR in patient cell lines bearing a range of expanded alleles (200–1122), was significantly correlated with the length of the shorter of the two expanded alleles. Importantly, this was noted both upstream (R^2=0.84; p=0.014) and downstream (R^2=0.89; p=0.002) of the expanded GAA-TR mutation, suggesting that *FXN* promoter silencing in FRDA is related to repeat length. A bilinear regression model revealed that length-dependence was strongest when the shorter of the two expanded alleles contained <400 triplets. Direct measurement of *FXN* promoter function in patients with expanded alleles containing <400 versus >400 triplets in the shorter of the two expanded alleles revealed a significantly greater deficiency in individuals with longer GAA-TR alleles. Thus, deficient transcriptional initiation caused by epigenetic silencing of the *FXN* promoter is a major cause of *FXN* transcriptional deficiency in FRDA, and it is dependent on the length of the expanded GAA-TR mutation.

Characterizing the predictive features of regulatory genetic variants. *N.M. Ioannidis[1], N. Larson[2], Y. Zhang[2], A. Battle[1], S. Montgomery[1], S.N. Thibodeau[2], W. Sieh[1], A.S. Whittemore[1], C.D. Bustamante[1].* 1) Stanford University School of Medicine, Stanford, CA; 2) Mayo Clinic, Rochester, MN.

Whole-genome and whole-exome sequencing technologies are increasingly enabling studies of genetic variation in large numbers of healthy and diseased individuals; however, interpreting the clinical significance of the many genetic variants identified in these studies remains a critical challenge. One mechanism by which genetic variants can achieve clinical significance—even those that do not affect protein structure, such as noncoding, intronic, and synonymous variants—is by regulating gene expression. Here we use a machine learning approach to identify genomic features predictive of genetic variants that are associated with gene expression regulation. We test a large set of features including sequence conservation, overlapping functional elements from ENCODE and Ensembl, and position relative to the nearest transcription start site and splice site. We identify predictive features by training random forest models on known cis-expression quantitative trait loci (cis-eQTLs) in lymphoblastoid cell lines (LCLs). These models achieve an area under the receiver operating characteristic curve (AUC) of between 0.75 and 0.9 depending on the stringency with which cis-eQTLs are defined. We also characterize the tissue-specificity of the genomic features of regulatory genetic variants by comparing the predictive performance of our random forest on cis-eQTLs in LCLs versus cis-eQTLs found in normal prostate tissue from an independent sample of around 500 prostate cancer patients. We anticipate that our results will be useful in future studies of regulatory variation and for prioritizing the likely clinical significance of rare and novel genetic variants identified in large-scale clinical sequencing studies.

529S

Characterization of enhancer gene interactions using DNaseI and gene expression data across 110 cell types. *P. Kheradpour[1,2], M. Kellis[1,2], Roadmap Epigenomics Consortium.* 1) Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute, Cambridge, MA.

Recent efforts to characterize diseases through genome-wide association studies and annotate the genome using ChIP-seq experiments have led to a dramatic increase in putative functional genomic regions. While most of the implicated loci have fallen outside coding regions and are thought to be regulatory in nature, efforts to link these regions to their target genes, thereby permitting a better understanding of their importance, has lagged considerably. Generally, experimental linking techniques only permit the interrogation of a small number of specific regions or produce a genome-wide linking at very low resolution.

We utilize DNaseI hypersensitivity and expression data from 110 cell types produced by the ENCODE and Roadmap Epigenomics projects to produce linking confidences between hypersensitive regions and nearby genes. We find that high confidence links are supported by independent datasets such as eQTL annotations. Moreover, we find that after controlling for distance several factors, including the orientation of the upstream gene and the presence of an interleaving CTCF, greatly affect the linking confidence.

In addition to predicting links between genes and nearby putative enhancers, we are interested in answering fundamental biological questions such as the number of enhancers per gene and where these enhancers fall relative to a gene's transcription start site. We address these questions through a careful analysis of the distribution of confidence scores for each gene and by performing a scaling analysis on the number of cell types.

Allele-specific gene expression analysis of RNA-seq data in 471 healthy prostate tissue samples identifies extensive aseQTLs in the human prostate transcriptome. *N.B. Larson, S. McDonnell, A.J. French, Z. Fogarty, J. Cheville, S. Middha, S. Riska, S. Baheti, A.A. Nair, L. Wang, J. Cunningham, D. Schaid, S.N. Thibodeau.* Mayo Clinic, Rochester, MN.

Imbalance in allele-specific expression (ASE) of homologous copies of a gene may result from heterozygous SNP cis-acting eQTLs. Identifying these regulatory variants provides insight into the dynamics of the transcriptome and may highlight genetic variation relevant to complex traits. RNA sequencing is a powerful tool for quantifying ASE by directly capturing mRNA transcript sequence information. It is important to characterize such regulatory variation in a tissue-specific manner, as most publically available eQTL results are from lymphoblastoid cells and tissue-specific regulatory variation may go undetected. We recently conducted a genome-wide allele-specific eQTL (aseQTL) study on 471 samples of normal prostate tissue (from patients with prostate/bladder cancer) by generating gene expression (RNA-seq) and chromosomally-phased genotype (Illumina Infinium 2.5M) datasets. We additionally imputed common (MAF >1%) exonic SNPs using 1000 Genomes data to increase the proportion of ASE-informative reads, resulting in ~2.7% of all aligned reads being allele-specific. From ~1.6M QC-passed SNPs and 16,607 expressed genes, we evaluated 7,435,266 aseQTL (SNP × gene) associations, restricting our analyses to common autosomal SNPs within 500kb of gene transcription start/stop sites. We tested aseQTL associations by jointly modeling the total and ASE gene read counts, and inconsistent results (e.g., trans-acting or imprinting effects) were excluded. We identified 393,046 significant aseQTLs (FDR = 0.05), with 10,870 genes corresponding to ≥1 putative aseQTL. From the set of most significant aseQTLs per gene, 172 SNPs corresponded to multiple genes. Functional annotation for these SNPs was enriched for ENCODE enhancer histone marks, suggesting evidence of cis co-regulation. The effect size estimates were inversely correlated with MAF (Spearman ρ = -0.38), indicating purifying selection pressure on high-impact regulatory variation. Large-effect aseQTLs were highly concentrated near the TSSs of the regulated genes and tended to co-localize with ENCODE promoter histone marks. Our findings also highlight dynamic expression in genes preferentially expressed in prostate tissue. Of the 102 prostate-specific genes listed in the TiGER tissue-specific gene expression database within our expressed gene set, 81 were significantly associated with aseQTLs. Overall, our results demonstrate widespread and complex cis-acting functional variation in the prostate transcriptome.

531T

Uncovering SMCHD1 regulation of the Protocadherin Cluster. *A.G. Mason[1], J. Balog[1], R.J.L.F. Lemmers[1], R.C. Slieker[2], B.T. Heijmans[2,3], R. Tawil[4], S.J. Tapscott[5], S.M. van der Maarel[1].* 1) Human Genetics, Leiden University Medical Center, Leiden , Netherlands; 2) Molecular Epidemiology, Leiden University Medical Center, Leiden, The Netherlands; 3) Netherlands Consortium for Healthy Aging, PO Box 9600, Leiden 2300, RC, The Netherlands; 4) Neuromuscular Disease Unit, Department of Neurology, University of Rochester Medical Center, Rochester, NY, USA; 5) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Facioscapulohumeral muscular dystrophy (FSHD) is a rare disease affecting 1;15,0000–20,000 individuals and is clinically characterized by progressive weakness and wasting of the facial and upper extremity muscles. In FSHD individuals, due to the contraction of the D4Z4 macrosatellite repeat array on chromosome 4 (FSHD1), or due to *SMCHD1* mutations (FSHD2), the somatic repression of the retrogene *DUX4* is incomplete leading to the variegated expression of the germline transcription factor in muscle fibers. *SMCHD1* encodes a protein that regulates chromatin repression at different loci, and it has been shown to be important for the regulation of the protocadherin (*Pcdh*) gene cluster in mice. Protocadherins are important for cell adhesion and are predominantly, but not exclusively, expressed in the nervous system. *PCDH* genes create cell-surface diversity, are monoallelically expressed in neurons, and are important for neuronal connectivity, self-recognition, and self-avoidance. Studies in SMCHD1 knockout mouse embryos show that the Pcdh cluster is in fact dysregulated. We are interested in studying the role that SMCHD1 has on the *PCDH* cluster in a neuronal cell context as well as in FSHD muscle cells to fully decipher the normal function of SMCHD1. To investigate the regulation effects that SMCHD1 has on the *PCDH* gene cluster a series of knockdown experiments are being carried out followed by RNA-sequencing wherein we can interrogate the regulation of the *PCDH* gene cluster. For these studies we are using the neuronal like cell type SK-N-SH, which has been shown to express a specific set of protocadherins. In addition a series of quantitative chromosome immunoprecipitation followed by sequencing (ChIP-seq) and ChIP-qPCR experiments are being done to interrogate the regulation of the *PCDH* gene cluster in FSHD2 patient primary muscle cells and, as a reference, in neuronal SK-N-SH cells. Thus functional genomics strategies are being used to dissect the function and hierarchy of SMCHD1 in *PCDH* gene cluster regulation in human cells, and functional studies of muscle cell to establish the role of *PCDH* gene cluster proteins in a non-neuronal context. The long-term goal of these lines of investigation is to uncover the consequences of FSHD2 mutations on *PCDH* gene cluster regulation and to understand how these alterations in transcription are leading/contributing to FSHD phenotypes.

532S

Allelic expression in single human primary fibroblasts. *C. Borel[1], P.G. Ferreira[1], F. Santoni[1], O. Delaneau[1], A. Fort[2], K.Y. Popadin[1], M. Garieri[1], E. Falconnet[1], P. Ribaux[1], M. Guipponi[1], I. Padioleau[1], P. Carninci[1], E.T. Dermitzakis[1], S.E. Antonarakis[1].* 1) Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland; 2) RIKEN Center for Life Science Technologies, Division of Genomic Technologies, Yokohama, Japan.

The study of gene expression in mammalian single cells using genomic technologies is now possible and the rules of allelic gene expression are now being investigated. We have used single-cell RNA sequencing to detect the allele-specific mRNA level in 203 single human primary fibroblast cells over 133,633 unique heterozygous SNVs (hetSNVs). We have observed that at the time point of analyses each cell contains mostly transcripts from one allele from the majority of genes. We revealed that 76.49 % of the hetSNVs with a RPSM superior to 20 displayed a monoallelic ratio (RPSM: reads at a single nucleotide position per sequencing read length and per million mapped reads). The allelic specific expression in single cells correlated with the rate of transcription initiation, mRNA half-life, abundance of the cellular transcript. Haplotype analysis suggests that two neighboring genes show independent allelic expression (i.e. not in the same haplotype). These results have implications in cellular phenotypic variability. C.B. and P.G.F. contributed equally.

Exploring the Human Genome for Functional, Non-Coding Variation: Implications for Diseases of the Peripheral Nerve. *W. Law[1], A. Antonellis[1,2].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Neurology, University of Michigan, Ann Arbor, MI.

Sequence variations within transcription factor binding sites (TFBS) can result in dysregulation of gene expression and directly cause or alter the severity of human disease. The implicated variants are often single-nucleotide polymorphisms (SNPs) within TFBS that alter the DNA binding affinity. We hypothesize that such regulatory SNPs (rSNPs) impact the function of genes important for peripheral nerve development and function, and represent excellent candidate modifier loci for peripheral nerve disease. To address this hypothesis, we developed a pipeline to computationally identify and functionally characterize novel rSNPs impacting the peripheral nervous system. Specifically, we computationally identified candidate TFBS across the human genome based on: conservation of 5 base pair (or longer) genomic segments between human, mouse, and chicken; overlap with a known, validated SNP; and localization to non-protein-coding sequences. These efforts revealed 6,164 conserved SNPs in the human genome. To evaluate the efficacy of this approach, we characterized a pilot set of 160 SNPs on chromosomes 21, 22, and X. We also tested the ability of our computational pipeline to identify rSNPs in a transcription-factor centric manner focusing on SOX10, which is essential for peripheral nerve function. We filtered the above 6,164 SNPs to find those that reside within a SOX10 consensus binding site or a SOX10 ChIP-Seq binding peak. These efforts revealed 24 putative SOX10-relevant rSNPs. To evaluate the regulatory potential of our predicted rSNPs, a genomic segment surrounding each rSNP was cloned upstream of a luciferase reporter gene and transfected into immortalized Schwann cells, motor neurons, and muscle cells to approximate a peripheral nerve motor unit. Luciferase assays were performed to identify genomic segments with at least a 5-fold increase in activity over a control vector. This revealed 32 novel genomic segments with enhancer activity in at least one cell line. Of the 32 genomic segments, nine showed a significant difference in luciferase activity between the major and minor alleles. Currently, we are further characterizing a subset of prioritized rSNPs by deleting the genomic segment in cultured cells using CRISPR/Cas9 technology followed by RNA expression studies to identify the gene(s) regulated by the elements. Any SNP associated with altered gene expression will represent candidate modifiers of peripheral nerve-related diseases.

534T

Sex-specific Association of Alu Retrotransposons with Gene Expression. *S. Linker[1], D. Hedges[2].* 1) HIHG, University of Miami, Miami, FL; 2) The Ohio State University, Columbus, OH.

Transcriptional regulation is a highly coordinated process necessary for the proper function of an organism. Although many mediators of gene expression have been identified (e.g.: CpG methylation, promoter accessibility), much of the repetitive content of the genome remains unexamined for its direct association with expression. Retrotransposons (RT) have the potential to alter gene regulation. However, to date there have been limited studies analyzing that association of RTs with alterations in gene expression in humans. RTs are a major cause of variation both between individuals as well as within an individual, due to somatic retrotransposition. This indicates that if RTs are indeed modifiers of gene expression, then they can influence phenotypic variability among as well as within humans. It is therefore essential for disease studies to identify if RTs have an effect on gene expression. The research presented here examines the association of RTs with differential gene expression. Our results suggest that the presence of a RT within a gene is indeed associated with decreased expression of the same gene. More importantly, this effect of RTs on gene expression was sex-specific, and largely driven by effects in males. Lastly, the genes found to contain variations in RTs are enriched for Autism susceptibility genes, which are also enriched for differences in expression between the sexes. These results provide evidence for RTs in mediating sex-specific effects of human gene expression.

535S

MicroRNA Expression, *APOE* and *TOMM40*. *L.M. Bekris[1,2], Y. Shao[1], M. Shaw[1], B. McCue[1], J.B. Leverenz[3].* 1) Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 2) Department of Molecular Medicine, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University; 3) Lou Ruvo Center for Brain Health, Cleveland Clinic, Cleveland, OH.

MicroRNA (miRNA) play an essential role in post-transcriptional gene regulation in the brain. Differences in brain miRNA expression between Alzheimer's disease (AD) and cognitively normal controls have been reported. Genetic variants located at the *APOE* locus are the strongest risk factors for late-onset AD described to date. A complex regulatory structure exists at the *APOE* locus that includes putative regulatory sites within the *TOMM40* gene. Little is known about the influence of miRNA post-transcriptional regulation at this locus. The aim of this investigation was to demonstrate that brain miRNA correlate with *APOE* and *TOMM40* brain expression differentially according to brain region or the presence of AD. In addition, it was demonstrated, using bioinformatics tools, that a subset differentially expressed miRNA that correlated with *APOE* or *TOMM40* expression are predicted to target *APOE* or *TOMM40*. To achieve this aim, miRNA array and miRNA quantitative RT-PCR were used to measure miRNA expression in post-mortem brain from AD (n=21) or cognitively normal age-matched control (n=21) hippocampus (HP) and cerebellum (CB). Quantitative RT-PCR was used to measure *APOE* and *TOMM40* mRNA. Western blotting was used to measure brain ApoE and Tomm40 protein. Linear regression was used to determine if *APOE* and *TOMM40* mRNA expression correlate with protein expression in AD (n=8) compared to cognitively normal age-matched controls (n=8) or in HP compared to CB. Linear regression analyses were used to determine if miRNA qRT-PCR levels differentially correlate with *TOMM40* or *APOE* expression in AD (n=6) compared cognitively normal age-matched controls (n=6). Post-mortem brain miRNA were identified that significantly correlate with AD or control brain *APOE* or *TOMM40* expression levels. In addition, a subset of miRNA were predicted to target *APOE* or *TOMM40*. These results suggest that an intricate *APOE* locus regulatory structure may be further fine-tuned by miRNA post-transcriptional modulation according to brain region or disease status.

536M

Gene silencing mediated by endogenous miRNAs under heat stress conditions in mammalian cells. *M. Fukuoka, M. Yoshida, A. Eda, M. Takahashi, H. Hohjoh.* Department of Molecular Pharmacology, National Institute of Nuroscience, National Center of Neurology and Phychiatry, Kodaira, Tokyo, Japan.

MicroRNAs (miRNAs) are 21~23-nucleotide-long small non-coding RNAs that are processed from longer transcripts forming stem-loop structure by digestion with RNase III enzymes, Drosha in the nucleus and Dicer in the cytoplasm. The processed miRNAs are incorporated into the RNA-induced silencing complex (RISC) and functions as mediators in gene silencing. MiRNAs play essential roles in gene regulation by inhibiting translation of messenger RNAs (mRNAs), and by digestion of mRNAs, or by RNA interference, during various vital function and phenomenon. Heat shock is an external stress, and cells that are subjected to heat shock immediately respond to such an environmental stress for protecting themselves and for maintenance of homeostasis. A major response to heat shock is the expression of a certain set of proteins, referred to as heat-shock proteins, and heat-shock proteins play important roles in cells under heat stress conditions. A recent study (Mol Cell, 39, 292-299, 2010) suggested that HSP70 and HSP90 likely associated with the Ago2 protein that is a major component of RISC, and would participate in loading of small RNAs into RISCs, leading us to the possibility that there may be some sort of relationship between heat shock and gene silencing. In this study, we investigated gene silencing mediated by miRNAs in mammalian cells exposed to a mild hyperthermia (40 °C) by means of miRNA activity assay using a luciferase reporter gene as well as miRNA expression analysis using a DNA microarray. Our data indicated that the gene silencing activities involving miRNAs were enhanced without increasing in their expression levels under such a heat-stress condition. Additionally, the gene silencing activity appeared to be independent of the cytoprotective action involving heat shock proteins that are immediately activated in heat-shocked cells and that function as molecular chaperons for restoring heat-denatured proteins to normal proteins. Our findings suggested the possibility that gene silencing involving endogenous miRNAs might play a subsidiary role in heat-shocked cells for an aggressive inhibition of the expression of heat-denatured proteins.

537T

MicroRNA profiling of human lymphoblastoid, iPS and neural stem cell lines shows overlapping but distinct expression patterns. *S. Kumar, J.E. Curran, J. Blangero.* GENETICS, TEXAS BIOMEDICAL RESEARCH INSTITUTE, SAN ANTONIO, TX.

EBV immortalized lymphoblastoid cell lines (LCL) have been widely banked for studying a variety of diseases, including complex genetic disorders. These cell lines with the emerging induced pluripotent stem cell (iPSC) technology represent an important resource for disease modeling particularly in providing specific cells/tissue type to experimentally test the hypotheses developed by statistical genetics methods. Accumulating evidence now provides support that microRNAs (miRNAs) play a critical role in transcription factor-induced reprogramming of iPSCs, maintenance of pluripotency and differentiation. Deciphering the role of miRNAs in pluripotency, self-renewal and differentiation will reveal new molecular mechanisms involved in induction and maintenance of the pluripotent state as well as triggering the reprogramed iPSCs differentiation into a specific cell type of interest. We used episomal plasmids encoding reprogramming factors (OCT3/4, SOX2, KLF4, L-MYC and LIN28) to induce pluripotent stem cells from six LCLs of our San Antonio Family Heart Study (SAFHS) subjects. The reprogrammed iPSCs were then differentiated into neural stem cells (NSC). Both iPSC reprogramming and NSC inductions were confirmed by immunocytochemistry. Small RNAs from six LCLs and their generated iPSC and NSC lines underwent deep sequencing. The differential expression analysis of the miRNA across these three cell types (LCLs, iPSCs and NSCs) from six SAFHS individuals identifies 41 miRNAs that show statistically significant (*corrected p value < 0.05*) change in expression. Comparison of the average expression from LCLs to iPSCs shows ≥2 fold up-regulation of 6 miRNAs (miR-92b, miR-151a, miR-93, miR-182, miR-222, miR-17) and ≥2 fold down-regulation of 13 miRNAs (let-7a-3, miR-16-2, miR-181b-1, miR-181a-1, miR-193b, miR-10a, miR-21, miR-181a-2, miR-181b-2, miR-361, let-7a-2, miR-342, miR-16-1). Comparing iPSCs to NSCs, 4 miRNAs were ≥2 fold down-regulated (let-7a-3, miR-148a, miR-182, let-7a-2) and 23 were ≥2 fold up-regulated (miR-130b, miR-103a-2, miR-103a-1, miR-26a-1, miR-30c-1, miR-197, miR-92b, miR-484, miR-10a, miR-27b, miR-30d, miR-151a, miR-25, miR-93, miR-182, miR-222, miR-532, miR-92a-2, miR-30c-2, miR-148b, miR-26a-2, miR-17, miR-92a-1). In summary, our miRNA expression data encompassing human LCLs, iPSCs and NSCs shows a broad resetting of the miRNA profiles during reprogramming of pluripotent cells and their differentiation into neural lineages.

The AGO3 Slicer controls the dynamic mitochondria-nuage localization of Armitage and contributes to piRNA biogenesis. *Y. Li[1], H. Huang[2], K. Szulwach[1], G. Zhang[2], D. Chen[2], P. Jin[1].* 1) Dept Human Gen, Emory Univ, Atlanta, GA; 2) 1State Key Laboratory of Reproductive Biology Institute of Zoology, Chinese Academy of Sciences.

Piwi-interacting RNAs (piRNAs) silence transposons in animal germ cells. In Drosophila, although the reciprocal “Ping-Pong” cycle of piRNA-directed RNA cleavage, catalyzed by the PIWI proteins Aubergine (Aub) and Argonaute3 (AGO3) through their Slicer activity, has been proposed to expand the population of antisense piRNAs in response to transposon expression. It remains unclear whether and how the Slicer activity of AGO3/AUB promotes the process of the secondary piRNA amplification. Here we generate the transgenic flies that could express AGO3 Slicer mutant forms, and show that the Slicer activity of AGO3 is essential for germline development and piRNA amplification in general. Surprisingly, we find that the piRNA-binding but not the Slicer activity of AGO3 is required for its Nuage localization. Furthermore, we show that the AGO3 inhibits the Aub:Aub Ping-Pong process in a Slicer-independent manner. Finally, we observe that the AGO3 Slicer activity is essential for the proper sub-cellular localization of the key component in piRNA pathway, Armitage, between mitochondria and nuage. Thus, our findings reveal a novel mechanism that couples mitochondria and nuage to regulate the secondary piRNA amplification.

539M

The functional role of lncRNAs in breast tissue-specific gene regulation. *E. Wagner[1,2], Y. Hao[3], Y. Liu[3], C. He[1,2].* 1) Dept. of Epidemiology, Indiana University School of Public Health, Indianapolis, IN; 2) Indiana University Melvin and Bren Simon Cancer Center, Indianapolis, IN; 3) Dept. of Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

Long noncoding RNAs (lncRNAs) are a class of RNAs that are more than 200nt but do not code for protein. Increasing evidence suggested that lncRNAs play a key role in gene regulation. However, few studies have investigated the role of lncRNAs in gene regulation at genome-wide level, especially in target tissue. In order to determine the functional role of lncRNAs in tissue-specific gene regulation, we have conducted a genome-wide association study of co-expression of lncRNAs and mRNAs in 119 breast tumors and 23 normal breast tissue samples using RNA-seq data (2X100nt). After QC and normalization, the expression levels of 4,777 known lncRNAs and 21,128 mRNA were estimated. We used linear regression to examine the association between each mRNA and lncRNA expression, adjusting for age, race, tissue type, and sequencing batch. Multiple testing was corrected using Bonferrroni correction. We considered two possible underlying mechanisms: 1) differential co-expression mechanism in which the association between lncRNA and mRNA expression differs in normal and tumor breast tissue; 2) dose-response co-expression mechanism in which there is an association between lncRNA and mRNA expression and the association is similar in normal and tumor breast tissue. Accordingly, we tested an interaction term between lncRNAs and tissue type in regression model in order to detect the differential co-expression. We found that 694 pairs of lncRNA-mRNA (comprising of 524 lncRNAs and 76 mRNAs) are differentially co-expressed in tumor and normal breast tissue (p for interaction<1×10–12). Genes such as TFE3, DEDD, and DNAL1 were differentially co-expressed with multiple lncRNAs. These genes are involved in chromosomal translocation, apoptosis, and cellular movement, functions implicated in tumorigenesis. For dose-response co-expression, we found 804 pairs of lncRNA-mRNA (comprising of 13 lncRNAs and 706 mRNAs) are similarly co-expressed in tumor and normal breast tissue. To identify cancer-related co-expression, we further restricted the results by differentially expressed lncRNAs and mRNAs in tumor and normal breast tissue, and identify genes including GABARAPL1, DCTPP1, KIFC1, and MAGEF1. Ingenuity pathway analysis revealed that the identified genes are primarily clustered in inflammatory response, cell death and survival, and cellular movement. Our study suggested that lncRNAs play a key role in regulation of genes that are important for breast cancer initiation and progression.

Genome-wide discovery of tissue specific properties of human small non-coding RNAs. *Y. Leung, U. Lyle H, G. Brian D, W. Li-San.* University of Pennsylvania , Philadelphia, PA19104, U.S.A.

Small non-coding RNAs (sncRNAs) comprise many classes of distinct RNAs with diverse and unknown functions. Thus, a complete and accurate catalog of sncRNAs is essential for elucidating the non-coding repertoire. Here we report the first genome-wide study to explore the tissue specificity properties along with other characteristics of sncRNAs such as cleavage specificity and secondary structure. We collected publicly available small-RNA sequencing data from adipose, B-cell, blood, brain, colon, heart, kidney, liver, lung and skin samples from 275 human normal, non-diseased subjects. We first performed stringent data quality control steps to account for biological and inter-laboratory variation. We then quantified the expression values across all tissues and identified 2215 sncRNAs, 83% (85% in GENCODE) of which belong to the miRNA, tRNA, snRNA, snoRNA and rRNA classes. Overall, we find 33% of sncRNAs to be expressed in at least one tissue type, with no tissue expressing more than 46% of all possible sncRNAs. Distributions of expression levels were very similar across tissues, with miRNA having the highest absolute expression levels, followed by snoRNA C/D box, H/ACA box and tRNA. Clustering of overall expression levels of these tissues mimics the stem cell potency groups: liver and lung (endoderm), brain and skin (ectoderm), heart and kidney (mesoderm). We then analyzed the tissue specificity of sncRNAs using Shannon entropy introduced by Schug et al. Unexpectedly, the tRNA (58%), scRNA (51%), and snRNA(48%) classes were highly tissue specific even though they are generally thought to perform housekeeping cellular functions. Over half of the tissue-specific tRNAs were identified in B cells, similar to tRNA-derived miRNAs reported recently, and some of the scRNAs are residing in the same compartment as lincRNAs, which may suggest why scRNAs have diverse roles across tissues. In contrast, miRNAs and lincRNAs were found to be less tissue-specific (38% and 32%, respectively). We also found that tissue-specific miRNAs are enriched for functions in organ morphogenesis and development, pattern specification processes, regionalization and regulation. Tissue-specific miRNAs also have a more precise 5' end cleavage position as compared to ubiquitous miRNAs. Taken together, these results suggest that sncRNAs typically thought to function in basic biological processes may work through different mechanisms depending on tissue type.

541S

A tissue-specific lincRNA in the *TRAF1-C5* risk locus as a putative *cis*-regulator bridging genetics and disease. *T. Messemaker[1,2], R.B. Marques[1], T.W. Huizinga[1], A. Adriaans[1,2], A.M. Bakker[1], A.W.G. Berendsen[1], N. Daha[1], R.E.M. Toes[1], H.M.M. Mikkers[2], F. Kurreeman[1,3].* 1) Department of Rheumatology, Leiden Universitiy Medical Centre, Leiden, Netherlands; 2) Department of Molecular Cell Biology, Leiden Universitiy Medical Centre, Leiden, Netherlands; 3) Department of Human Genetics, Leiden Universitiy Medical Centre, Leiden, Netherlands.

In the last decade genome wide association studies (GWAS) have identified genetic polymorphisms that associate with Rheumatoid arthritis (RA). However, the way these genetic regions contribute to disease remains ill defined. We previously identified the *TRAF1-C5* locus as a predisposing risk factor to the development of RA. In the present study we investigated functional consequences of this risk locus. Using expression quantitative trait loci (eQTL) datasets, we observed an association between the risk allele and expression of *TRAF1* and *C5* at the mRNA level in various blood-related cell types. As part of an underlying mechanism we identified a novel large non-coding RNA intergenic of *TRAF1* and *C5* (*C5T1-lincRNA*). The lincRNA is transcribed in the same orientation as *TRAF1* and *C5* by RNA polymerase II, is highly transcribed in liver, and its expression is rapidly induced in different immune cells by specific immune stimuli. Expression of *C5T1-lincRNA* correlated with either *C5* or *TRAF1* expression in a tissue specific manner. In addition, knockdown of the intergenic transcript in a hepatocyte cell line resulted in decreased C5 levels. Together our data support the involvement of a novel lincRNA in regulating *C5* and *TRAF1* expression. We propose that this lincRNA, which is fully located within the associated region, is responsible for the RA associated altered RNA levels of TRAF1 and C5 and plays a role in RA susceptibility.

Conservation and Novel Functions of Non-coding RNAs. *T.R. Gingeras.* Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

The approximately three billion base pairs of the human DNA represent a storage devise encoding information for hundreds of thousands of processes that can go on within and outside of a cell. This information is partially revealed in distinguishable transcripts that are potentially derived from 12 billion nucleotides, considering strandedness and the diploid nature of the most genomes. Results stemming from the efforts to catalogue and analyze the RNA products made by many cells in the Encyclopedia of DNA Elements (ENCODE), in human, fly-worm (modENCODE) and mouse ENCODE projects have contributed to help shed light on both the functional content, how this transcriptional information is organized and its evolutionary conservation. Currently for the human genome, there are annotated a total of 196,520 transcripts (41 % coding) within 57,820genic regions (35% coding) based on v19 in Gencode. Analyses of both the regulatory and transcriptome data sets of phase 2 of the human ENCODE projects underscore several underappreciated lessons concerning the conservation and novel functions of long and short non-coding (nc)RNAs. These lessons include: a) specific short ncRNA classes are enriched in micro-vesicles and used for intercellular communication b) the conservation of long ncRNAs between mouse and human of several transcriptional features that appear to be independent of the degree of sequence similarity and c) a multiplicity of cap modifications present on short ncRNAs. These and other insights drawn from the multiple ENCODE and other genome-wide data sets assist in understanding what is often seen as dauntingly complex but elegantly organized genome and continues to prompt a reconsideration of the definition of a gene.

543T

The landscape of retrotransposon expression in human lung adenocarcinomas. *A. Biton[1], B. Xue[2], D. Risso[3], T. Speed[3,4], L. He[2], Biton.* 1) Department of Medicine, Lung Biology Center, University of California, San Francisco, San Francisco, California 94110 USA; 2) Department of Molecular and Cell Biology, Division of Cellular and Developmental Biology, University of California at Berkeley, Berkeley, CA 94720, USA; 3) Department of Statistics, University of California, Berkeley, CA 94720, USA; 4) Bioinformatics Division, Walter and Eliza Hall Institute of Medical Research, Parkville VIC 3052, Australia.

Nearly half of the human genome consists of repetitive elements. The largest class of mammalian repetitive elements are retrotransposons, a class of transposable elements that can duplicate in the genome through RNA intermediates using a “copy and paste” mechanism. Retrotransposons are considered a major source of genetic variation and de novo insertion of retrotransposons in the genome can introduce mutations and modify gene splicing and expression. Normally silenced in adult somatic cells, aberrant retrotransposon activation has been associated with cancer. For example, using exome sequencing data, de novo insertions of L1 elements have been detected in tumor suppressor genes of various cancer types (Helman E. 2014 Genome Res). In this study, we are interested in detecting potential aberrant retrotransposon expression in cancer genomes and determining their potential effect on proximal genes.

We studied the expression of retrotransposons (LINEs, LTRs, and SINEs) in RNA-Seq data from tumor/normal pairs of lung adenocarcinoma from public database including The Cancer Genome Atlas. The analysis of the retrotransposon expression was performed at two levels. First, at the level of the consensus sequence, by mapping the reads to the consensus sequences listed in RepBase, to crudely evaluate the abundance of each retrotransposon class. Second, at the locus-specific level, by using the RepeatMasker annotation in the genome and investigating the potential effect of the retrotransposons in regulating the adjacent genes.

We observed that lung adenocarcinomas have distinct retrotransposon expression profiles compared to the normal samples. Indeed we found that tumor and normal samples could be distinguished solely based on their retrotransposon expression profiles. Interestingly, in addition to LINEs and SINEs, we observed aberrant expression of LTRs (including but not limited to HERV18 or HERVK). Using the locus-centric approach, we found that derepression of some retrotransposons could be involved in inhibition of their adjacent gene. We also observed examples of concurrence of exonization of the retrotransposon and differential exon-usage within the same gene. Altogether, these results suggest that retrotransposons may play roles in cancer development.

544S

Overexpression of the *FMR1* mRNA in premutation carriers is isoform specific. *C. Yrigollen[1], D. Pretto[1], J. Eid[2], H-T. Tang[1], E. Loomis[1], C. Raske[1], B. Durbin-Johnson[3], P. Hagerman[1, 4], F. Tassone[1, 4].* 1) Department of Biochemistry and Molecular Medicine, University of California Davis, Sacramento, CA; 2) Pacific Biosciences, Inc., Menlo Park, CA; 3) Department of Public Health Sciences, University of California Davis, School of Medicine, Davis, CA; 4) MIND Institute, University of California Davis Medical Center, Sacramento, CA.

Premutation carriers of the *FMR1* gene are at risk to develop multiple fragile X associated disorders, including the neurodegenerative disorder fragile X-associated tremor/ataxia syndrome (FXTAS). Elevated *FMR1* mRNA levels have been observed in premutation carriers; whether all *FMR1* isoforms are differentially expressed or only specific ones, is currently unknown.

Thus, using *single* molecule real time (SMRT®) sequencing and qRT-PCR we have determined which of the potential transcribed *FMR1* isoforms are expressed and, more importantly, determined if all or only some of the transcripts are overexpressed in premutation carriers compared to normal controls.

The SMRT® sequencing approach has provided us complete cDNA sequence reads from exon 1 through exon 9 and exon 9 - exon 17 within a single *FMR1* transcript. Our results showed that out of the 24 predicted isoforms in human, only 16 *FMR1* isoforms are expressed in peripheral blood monocytic cells, brain, and primary fibroblast cells. Interestingly, although the isoforms missing exon 12 were the most abundant in both premutation carriers and controls in all three tissues, only two were differentially expressed in carriers.

Specifically, of the 16 observed isoforms, *Iso10* and *Iso10b*, both with exons 12 and 14 spliced, and differing only in the splicing acceptor site used at exon 17, were significantly overexpressed.

These findings demonstrate that the differential expression of *FMR1* observed in premutation carriers is isoform specific. The loss of exon 12 results in a shortened unstructured variable loop between two β sheets in the FMRP KH2 domain while the splicing of exon 14 results in the loss of a nuclear export signal and introduce a frameshift that alters the amino acid sequence from exon 15 - exon 17, giving rise to truncated proteins.

Why *FMR1* alternative splicing regulation is compromised in premutations is not yet understood, nor the functional consequences that result from abundance of *Iso10* and *Iso10b*, but these changes in expression of specific isoforms are likely to play a relevant role for understanding the pathogenesis of FXTAS and of the *FMR1* associated disorders.

High throughput identification of exonic sequence variation that exhibits allelic imbalance in RNA splicing. *R. Soemedi[1,2], K. Cygan[1], A. Leblang[3], W. Fairbrother[1,2,4].* 1) Center for Computational Molecular Biology, Brown University, Providence, RI; 2) Molecular and Cellular Biology and Biochemistry, Brown University, Providence, RI; 3) Department of Computer Science, Brown University, Providence, RI; 4) Center for Biomedical Engineering, Brown University, Providence, RI.

Introduction: The rate of discovery of causative mutations for human diseases has accelerated in recent years, but a significant proportion of published causality lacks direct evidence of pathogenicity of the observed variants. Recent studies have predicted that ~15–30% of exonic variants can alter RNA splicing, which may result in exon skipping and aberrant splice site usage; both can potentially lead to more deleterious changes due to frameshift. We have developed High Throughput Splicing Assays (HTSAs) capable to test thousands of wild-type/mutant pairs of splicing substrates simultaneously for the presence of allelic imbalance in RNA splicing. **Methods:** We designed a library of 200-mer oligonucleotides consisting of 5,192 pairs of mutant and wild-type version of exons (median exon length = 76 nt) and their flanking introns derived from reported missense and nonsense mutations at Human Gene Mutation Database (n=4964) and common SNPs (n=228). HTSA *in vivo* was done by incorporating the library into three-exons splicing constructs under CMV promoter that were subsequently transfected into Hek293 cells. HTSA *in vitro* was performed in HeLa nuclear extract using in vitro-transcribed library containing two-exons splicing constructs. Original pool of substrates and spliced RNAs were extracted, made into Illumina libraries and subjected to parallel sequencing in HiSeq2500. **Results:** We observed allelic imbalance in RNA splicing in 1,036 (21%) rare exonic mutations and 17 (7%) SNPs that were tested in both HTSA *in vivo* and *in vitro* (>1.5 fold-change and $P < 0.05$ by two-sided Fisher's exact test, followed by Benjamini-Hochberg FDR for multiple testing correction). We further identified alternative splice site usage and intron retention events that occur in mutant sequences exclusively in 373 (7%) and 49 (1%) mutant/wild-type pairs of the library substrates, respectively ($P< 0.001$ by two-sided Fisher's exact test). The resulting datasets were used to identify factors attributed to sequence variation that impact splicing. **Conclusions:** Our study facilitates a better characterization of exonic sequence variation of potential deleterious consequence resulting from aberrant splicing. Our findings indicate the urgency of integrating splice-altering variant hypothesis in characterizing causal variants in human disease. Machine learning approaches can be further applied to generate a superior prediction tool for identifying variants that lead to gene processing defects.

546T

Impact of microRNA binding site polymorphisms on gene expression variation. *T. Annilo[1], U. Võsa[1], T. Esko[1], A. Metspalu[1,2].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

Functional interpretation of GWAS-identified loci presents a major challenge since only a small fraction of variants has a direct effect on protein-coding regions. MicroRNAs (miRNA) bind to specific motifs called miRNA response elements (MREs) in the 3'-UTRs of mRNAs, repressing the activity of their targets by affecting mRNA stability and/or protein translation. Rapidly increasing number of known human miRNAs and SNPs in MREs provides an opportunity to systematically investigate the potential impact of common genetic variants on regulatory interactions between miRNAs and their target mRNAs.

We hypothesized that polymorphisms within the MREs that disrupt or generate a binding site can affect the expression of target genes, leading to allele-specific expression modulation. Cis-eQTLs (variants associated with gene expression changes) from the meta-analysis of 7 cohorts (~5 500 individuals) were retrieved from bloodeQTLBrowser (http://genenetwork.nl/bloodeqtlbrowser/). SNPs and proxies (R^2=1) were mapped to the 3' UTRs of the cis-eQTL-affected genes. Putative effect of the SNP on the binding of miRNA was estimated using polymiRTS 3.0 database.

In total, 4829 individual SNPs and proxies were found in the putative MREs of 2166 REFSEQ transcripts. Out of 2578 miRNAs present in miRBase v20, 2573 were predicted to be influenced by at least one SNP. All together, 24 858 SNP-transcript-miRNA associations were reported. To restrict the analysis to blood-specific miRNAs only, a list of 123 miRNAs was identified using 11 publicly available small RNA sequencing datasets using a threshold of 10 reads in at least 6 studies. In addition, to add confidence to miRNA binding site prediction, MRE SNPs were filtered against 36 independent AGO2, AGO3 and AGO4 PAR-CLIP and HITS-CLIP datasets from starBase database. The filtering using a consensus list of blood-specific miRNAs revealed a set of 1128 SNP-transcript-miRNA associations, consisting of 123 miRNAs, 771 SNPs and 614 transcripts. After filtering against AGO binding-sites, a conservative set of 331 SNP-transcript-miRNA associations remained, consisting of 101 miRNAs, 206 SNPs and 192 transcripts. We suggest that our analysis enables identification of miRNA-associated eQTLs for future functional studies and helps to prioritize genetic variants that are important in complex diseases or traits.

High-Resolution Genomic Analysis of Human Mitochondrial RNA Sequence Variation Reveals Genetic Determinants of Post-transcriptional Modification and Interplay with the Nuclear Genome. *A. Hodgkinson[1], Y. Idaghdour[1,2,3], E. Gbeha[1], J.-C. Grenier[1], E. Hip-Ki[1], V. Bruat[1], J.-P. Goulet[2], T. de Malliard[1,2], P. Awadalla[1,2].* 1) CHU Sainte-Justine Research Centre, Department of Pediatrics, Faculty of Medicine, Université de Montreal, 3175 Chemin de la Côte-Sainte-Catherine, Montreal, Quebec H3T 1C5, Canada; 2) CARTaGENE, 3333 Queen Mary Road, Office 493, Montreal, Quebec H3V 1A2, Canada; 3) Department of Biology, Division of Science and Mathematics, New York University Abu Dhabi, Post Office Box 129188, Abu Dhabi, United Arab Emirates.

Mutations in the mitochondrial genome have been associated with a wide range of diseases, as well as fundamental biological processes such as ageing. Previous studies have found that sequence variation across mitochondrial genomes within a single individual (heteroplasmy) is reasonably rare, however little is known about the extent and distribution of sequence variation in the mitochondrial transcriptome. By ultra-deeply sequencing mitochondrial RNA from the whole blood of ~1000 individuals at an unprecedented level of coverage (>6000X) from the CARTaGENE project, we find a remarkable level of variation across individuals, as well as sites that show consistent patterns of post-transcriptional modification. Using a genome-wide association study we find that the rate of post-transcriptional modification at functionally important sites in mitochondrial transfer RNAs is under strong genetic control, largely driven by a missense mutation in MRPP3 that explains ~22% of the variance. Furthermore, we find nuclear genetic variants that are associated with modifications in other mitochondrial genes, and explore the relationship between mitochondrial post-transcriptional modification and nuclear gene expression. These results reveal a major nuclear genetic determinant of post-transcriptional modification in mitochondria, develop our understanding on the level of cross-talk between the nuclear and mitochondrial genomes, and suggest that tRNA post-transcriptional modification may impact cellular energy production.

RCARE: RNA-Sequence Comparison and Annotation for RNA Editing. *SY. LEE[1], JG. Joung[2], CH. Park[1], JH. Park[3], JH. Kim[4].* 1) Seoul National University Biomedical Informatics (SNUBI) and Systems Biomedical Informatics Research Center, Division of Biomedical Informatics, Seoul National University College of Medicine, Seoul 110799, Korea, MS; 2) Seoul National University Biomedical Informatics (SNUBI) and Systems Biomedical Informatics Research Center, Division of Biomedical Informatics, Seoul National University College of Medicine, Seoul 110799, Korea, PhD; 3) Seoul National University Biomedical Informatics (SNUBI) and Systems Biomedical Informatics Research Center, Division of Biomedical Informatics, Seoul National University College of Medicine, Seoul 110799, Korea, BS; 4) University College of Medicine, Seoul 110799, Korea, MD, PhD, MS.

Posttranscriptional sequence modification of transcripts through RNA editing is an important mechanism for regulating protein function and is correlated with human disease phenotypes. The identification of RNA-editing sites is a fundamental step in the study of RNA editing. Determining the location of condition-specific RNA-editing sites and elucidating their functional roles will help toward understanding various biological phenomena that are mediated by RNA editing. In the present study, it is proposed that RCARE (RNA-sequence comparison and annotation for RNA editing), which searches, annotates, and visualizes RNA-editing sites using thousands of previously known editing sites, can be used for comparative analyses between multiple samples. This a new tool, RNA-sequence comparison and annotation for RNA editing (RCARE), which determines condition-dependent RNA-editing sites, provides rich and systematic annotations, and delivers 'executive summary' plots for the annotation and comparison of multiple samples with RNA-Seq data through a user-friendly web interface. RCARE provides a Python script that users can use to preprocess raw RNA-Seq data and convert FASTQ and BAM files into RNA VCF (variant call format) files in a practical time frame using a desktop computer. RCARE is freely available at http://www.snubi.org/software/rcare/.

549T

The RNA Editing Landscape in Acute Myeloid Leukemia. *E. Meduri[1,2], B. Huntly[1,2].* 1) Department Of Haematology, Cambridge Institute For Medical Research, Univeristy Of Cambridge, Cambridge, United Kingdom; 2) Wellcome Trust—Medical Research Council Cambridge Stem Cell Institute, Cambridge, United Kingdom.

Recent next generation sequencing efforts have annotated the role of somatic DNA mutations in the generation of malignancies such as acute myeloid leukemia (AML). However, growing evidence points to epigenetic variation as a further and perhaps equal contributor to the malignant phenotype. We present paired transcriptomic and whole genome/exome sequencing (WGS/WES) analysis for 172 AML patients from the Cancer Genome Atlas (TCGA) to examine the role of RNA editing in this epigenetic variation. The RNA editing gene Adenine deaminase, RNA specific (ADAR) is highly expressed across all samples, whereas ADARB1 and ADARB2 are expressed at very low levels. Analysis of WGS/RNA-Seq from a subset of 33 patients was performed, using a stringent pipeline to identify RNA editing events (REE). Surprisingly, we observed a marked heterogeneity in the number of editing events per sample, which ranged from <1000 to >13,000 events and these events demonstrated minimal overlap with available REE databases (RADAR, DARNED). The events were predominantly A>G and T>C, reflecting ADAR mediated A>I editing. Restricting our analysis to recurrent REE (arbitrarily defined as occurring in >20% of the 33 samples), we found editing events targeted ~2,300 protein-coding genes. As previously described the majority of the REE (>90%) occur in non-coding DNA, namely intergenic, intronic and UTR regions. However, of interest, for the events in coding regions the majority are predicted to alter the amino acid sequence of the protein (66% non-synonymous vs. 34% synonymous). Comparing the edited genes with gene ontology processes, we found significant enrichment in functions including regulation of transcription, gene expression and protein modification processes. We are currently extending our analysis to the remaining 139 samples in the TCGA database to further identify commonly edited genes and will assess the functional consequences of the REE in these genes including alterations of protein coding, RNA abundance and RNA splicing. We are also comparing these tumor specific patterns to normal tissue patterns of RNA editing and are correlating the patterns of REE with known prognostic and outcome measures in AML, such as cytogenetic and mutational status and overall survival.

Global identification of binding sites for the splicing regulatory factors SRSF5 and hnRNPA1. *G.H. Bruun[1], T.K. Doktor[1], S. Brøner[1], A. Masuda[2], B. Palhais[1], A.R. Krainer[3], K. Ohno[2], B.S. Andresen[1].* 1) Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark; 2) Division of Neurogenetics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan; 3) Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, NY 11724, USA.

RNA splicing is a fundamental process required for correct expression of almost all protein coding genes. It is critically dependent on numerous splicing-regulatory elements (SREs) throughout our genes and on correct expression and activity of the splicing regulatory factors (SRFs) that function by binding to the SREs. Thus, mutations/SNPs that affect SREs, may disrupt splicing and a rapidly increasing number of human diseases are now known to be caused by aberrant splicing. Unfortunately, the specific binding motifs are not precisely defined for even the best characterized and most abundant SRFs and maps of their location, as part of SREs in human disease genes, are missing or sparse. We have used iCLIP (Individual nucleotide-resolution Crosslinking and Immunoprecipitation) to identify the genome-wide binding sites of two SRFs, namely SRSF5 and hnRNPA1. HeLa cells expressing T7-tagged versions of the SRFs are UV-crosslinked to induce covalent bonds between RNA binding proteins and RNA. SRFs are immunoprecipitated with a T7-antibody, followed by SRF removal by proteinase treatment. Eventually this RNA is used as a template for cDNA synthesis and PCR. The amplified products are then submitted for next-generation sequencing and analyzed. SRSF5 and hnRNPA1 binding sites were identified across the genome and consensus binding motifs were generated. The consensus binding site for hnRNPA1 resembles the previously published hnRNPA1 binding matrices generated from other cell types, thus confirming the validity of our approach. Among the possible SRSF5 binding sites identified was exon 2 in the ACADM gene. A disease causing silent mutation, c.87A>G, causes ACADM exon 2 skipping in patient cells, and RNA affinity purification showed that SRSF5 binding to an SRE is disrupted by the c.87A>G mutation. One of the identified binding sites of hnRNPA1 is located across the weak 5'splice site of a disease-causing pseudoexon in the MTRR gene, indicating that hnRNPA1 inhibits pseudoexon inclusion in normal cells. In line with this, mutagenesis of this weak 5'splice site in a minigene results in pseudoexon activation. We have generated global maps of SRSF5 and hnRNPA1 binding sites and identified splicing events, which depend on SRSF5 and hnRNPA1. Moreover, we have illustrated how this can be used to identify and characterize disease causing aberrant splicing for instance caused by apparently neutral sequence variants.

Recursive splicing: a novel regulatory mechanism in the human brain that contributes to the processing of long genes. *W.A. Emmett[3], C.R. Silbey[1,2], N. Haberman[1], M. Briese[2,4], .D Trabzuni[1,5], M. Ryten[1,6], J. Hardy[1], M. Modic[2,7], T. Curk[8], V. Plagnol[3], J. Ule[1,2], UK Brain Expression Consortium.* 1) Department of Molecular Neuroscience, UCL Institute of Neurology, Queen Square, London, WC1N 3BG, UK; 2) MRC Laboratory of Molecular Biology, Francis Crick Avenue, Cambridge, CB2 0QH, UK; 3) University College London Genetics Institute, Gower Street, London WC1E 6BT, UK; 4) Institute for Clinical Neurobiology, University of Würzburg, Versbacherstr. 5, 97078, Würzburg, Germany; 5) Department of Genetics, King Faisal Specialist Hospital and Research Centre, Riyadh 11211, Saudi Arabia; 6) King's College London, Department of Medical & Molecular Genetics, Guy's Hospital, London SE1 9RT, UK; 7) Institute of Stem Cell Research, German Research Center for Environmental Health, Helmholtz Center Munich, 85764 Neuherberg, Germany; 8) Faculty of Computer and Information Science, University of Ljubljana, Ljubljana, Slovenia.

Recent studies have shown that expression of long genes in the mammalian brain is perturbed by specific regulatory factors linked to neurodevelopmental or neurodegenerative disorders, suggesting unique regulatory mechanisms. Here we find that most genes that are long in all vertebrate species are specifically expressed in the brain. Moreover, computational analysis of deep human post-mortem brain RNA-Seq data followed by extensive experimental validation showed that in some of these long genes, the longest intron uses a newly discovered regulatory mechanism in humans called recursive splicing.These recursive splice sites (RSS) are highly conserved across evolution and many of them appear to have common evolutionary origins. They are recognized by the spliceosome, and followed by a poison or alternative exon. Owing to the high level of conservation and their likely functional role, these sites are strong candidates to harbour disease causing mutations and should be considered in future genome sequencing projects, especially of neuro-developmental disorder cases.

552T

Complex alternative splicing patterns in human hematopoietic cell subpopulations revealed by third-generation long reads. *A. Deslattes Mays[1], E. Zheng[2], R. Sebra[3], P. Baybayan[2], M. Schmidt[1], A. Wellstein[1].* 1) Lombardi Cancer Center, Georgetown University, Washington, DC; 2) Pacific Biosciences, Menlo Park, CA; 3) Icahn School of Medicine at Mount Sinai, Institute for Genomics and Multiscale Biology, New York, NY.

Background: Alternative splicing expands the repertoire of gene functions and is a signature for different cell populations. Here we characterize the transcriptome of human bone marrow subpopulations including progenitor cells to understand their contribution to homeostasis and pathological conditions such as atherosclerosis and tumor metastasis. To obtain full-length transcript structures, we utilized long reads in addition to RNA-seq for estimating isoform diversity and abundance. Method: Freshly harvested, viable human bone marrow tissues were extracted from discarded harvesting equipment and separated into total bone marrow (total), lineage-negative (lin-) progenitor cells and differentiated cells (lin+) by magnetic bead sorting with antibodies to surface markers of hematopoietic cell lineages. Sequencing was done with SOLiD, Illumina HiSeq (100bp paired-end reads), and PacBio RS II (full-length cDNA library protocol for 1 - 6 kb libraries). Short reads were assembled using both Trinity for de novo assembly and Cufflinks for genome-guided assembly. Full-length transcript consensus sequences were obtained for the PacBio data using the RS_IsoSeq protocol from PacBio's SMRTAnalysis software. Quantitation for each sample was done independently for each sequencing platform using Sailfish to obtain the TPM (transcripts per million) using k-mer matching. Results: PacBio's long read sequencing technology is capable of sequencing full-length transcripts up to 10 kb and reveals heretofore-unseen isoform diversity and complexity within the hematopoietic cell populations. A comparison of sequencing depth and de novo transcript assembly with short read, second-generation sequencing reveals that, while short reads provide precision in determining portions of isoform structure and supporting larger 5' and 3' UTR regions, it fails in providing a complete structure especially when multiple isoforms are present at the same locus. Increased breadth of isoform complexity is revealed by long reads that permits further elaboration of full isoform diversity and specific isoform abundance within each separate cell population. Sorting the distribution of major and minor isoforms reveals a cell population-specific balance focused on distinct genome loci and shows how tissue specificity and diversity are modulated by alternative splicing.

553S

Analysis of the expression levels of chitinase-like proteins, Ym1, Ym2 and breast regression protein-39, in mouse tissues. *M. Ohno, Y. Kida, M. Sakaguchi, Y. Sugahara, F. Oyama.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Mice produce chitinase-like proteins (CLPs), which are structurally homologous to chitinases but lack the ability to degrade chitin. The CLPs belong to glycosyl hydrolases family 18. Mice express primarily three CLPs, including, Ym1, Ym2 and breast regression protein-39 (BRP-39). Recently, CLPs have attracted considerable attention due to their increased expression in a number of many pathological conditions, including asthma, allergies, rheumatoid arthritis and malignant tumors. Little is known, however, about the significance of CLPs increased expression levels during pathophysiological states. Because CLPs lack chitinolytic activity and detectable functions, their biochemical properties have only been partially defined. The quantification of Ym1, Ym2 and BRP-39 individually is important steps in gaining insight into the *in vivo* regulation of the CLPs. In this study, we established quantitative real-time PCR system to quantify the expression of Ym1, Ym2 and BRP-39 individually and compare their expression levels with those of mammalian chitinases and reference genes in mouse tissues. We found that Ym1 and BRP-39 mRNAs were expressed at a high level in the mouse lung, whereas Ym2 mRNA was the most abundant CLP in the stomach, followed by lung. Furthermore, the expression levels of Ym1 and BRP-39 in the mouse lung were higher than those of two active chitinases.

Cross-species gene expression analysis of chitinase-like proteins with mammalian chitinases using qPCR in mouse and human tissues. *F. Oyama, M. Ohno, Y. Kida, M. Sakaguchi, Y. Sugahara.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Mice and humans express two active chitinases, chitotriosidase and acidic mammalian chitinases. They also produce chitinase-like proteins (CLPs), which lack any detectable functions. Mice express Ym1, Ym2 and breast regression protein-39 (BRP-39), whereas humans produce YKL-40, the human homologue of BRP-39, but do not synthesize homologues of Ym1 and Ym2. The chitinases and CLPs exhibit sequence homology to bacterial chitinases and belong to glycosyl hydrolases family 18. YKL-40 levels have been shown to be elevated in patients with rheumatoid arthritis, atherosclerosis, asthma, allergies, and cancers. Here, we established and validated quantitative real-time PCR systems to quantify the expression of YKL-40 and compared their expression levels with those of mammalian chitinases and reference genes using the same scale in human tissues. We found that YKL-40 mRNA was widely expressed in human tissues. The highest levels of YKL-40 mRNA were detected in human liver, followed by the kidney and lung tissues. Then we quantified and compared the expression levels in mouse and human tissues using the human-mouse hybrid standard DNA. Our results indicate that BRP-39/YKL-40 mRNA was expressed at high levels in the mouse lung but was weakly expressed in normal human lung. There were prominent differences in BRP-39/YKL-40 expression in the lungs of humans and mice. In contrast, YKL-40 mRNA expression in human liver tissue was higher than BRP-39 expression in mouse liver.

Transcriptome Profiling of Gamma Secretase Inhibition in Breast and Ovarian Cancer Cells. *A. Mannermaa[1,2], H. Ahonen[1,2], H. Peltonen[1,2], M. Hiltunen[3], A. Haapasalo[3], M. Heinäniemi[4], M. Nykter[5], V. Kytölä[5], V-M. Kosma[1,2].* 1) School of Medicine, Institute of Clinical Medicine, Pathology & Forensic Med, University of Eastern Finland, Kuopio, Finland; 2) Imaging Center, Clinical Pathology, Kuopio University Hospital, Kuopio, Finland; 3) School of Medicine, Institute of Clinical Medicine, Neurology, University of Eastern Finland, Kuopio, Finland; 4) A. I. Virtanen Institute for Molecular Sciences, University of Eastern Finland, Kuopio, Finland; 5) Institute of Biomedical Technology, University of Tampere, Tampere, Finland.

Gamma secretase (GS) is a transmembrane protease complex that acts on over 90 substrates, many of which are involved in signaling networks dysregulated in cancer and Alzheimer's disease. GS inhibitors are known to inhibit cancer growth, and this is largely attributed to their ability to disrupt Notch signaling. It is, however, likely that the other substrates also play a role in the anticancer effect of GS inhibition. Here we report a whole transcriptome sequencing study assessing the effect of DAPT, a GS inhibitor, on gene expression in MCF7, MDA-MB-453 and OVCAR3 cells. The RNA-sequencing generated 73 Gb of raw sequence data. Our data shows that GS inhibition (GSI) by DAPT causes cell line specific and global alterations in gene expression in MCF-7, MDA-MB-453 and OVCAR-3 cells. The analysis (edgeR) yielded 15, 6 and 36 differentially expressed (DE) genes for MCF-7, MDA-MB-453 and OVCAR-3 cells (FDR = 1%). None of the genes were shared by all cell lines. Next, DE was analyzed between grouped treated and untreated samples. A total of 61 genes were identified to be differentially expressed, 30 of them downregulated and 31 upregulated (FDR = 1%). Notably, NOTCH1 was included in the downregulated group, and the upregulated genes included ribosomal and histone protein coding genes. The most prominent biological effects were downregulation of Notch signaling pathway and upregulation of ribosomal and histone proteins. In order to explore the biological effect of GSI, the list of DE genes was analyzed for KEGG pathway enrichment. Upregulated genes were enriched in Ribosome (q=2.25E-09) and Systemic lupus erythematosus (SLE) (q=0,011) pathways. The SLE pathway was enriched due to its pathway containing histone genes. As expected, the downregulated genes were found enriched in Notch signaling pathway, which included EP300, NOTCH1, CREBBP, HES1 and NCOR2 (q=0,0046). Further, Connectivity Map analysis applied to the GSI signature identified 16 compounds (FDR = 1%) suggesting that the gene expression signature of GSI shares significant similarity with CDK, HDAC and Topoisomerase 1 inhibitors. Overall, our data proposes that the effects of GSI are mediated through multiple mechanisms, implying that the cancer growth inhibiting properties of gamma secretase inhibitors are not exclusively due to inhibition of Notch signaling.

Understanding cellular heterogeneity of pancreatic islets of Langerhans using single-cell RNA-seq. *M. Garieri, C. Borel, F.A. Santoni, C. Howald, P. Ribaux, P.A. Halban, S.E. Antonarakis, E.T. Dermitzakis.* Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland.

Pancreatic islets of Langerhans consist of several endocrine cell types. Previous studies of sorted cell populations have provided limited insight into the cellular diversity within islets. Here, we investigate the heterogeneity of human islet cells by performing single cell (SC) RNA-seq. We studied islet cell transcriptomes using islets from 2 healthy organ donors and 2 individuals with type 2 diabetes (T2D). RNA-seq was performed in the whole islet (bulk) and 149 SCs from the healthy donors (respectively 68 SCs and 81 SCs) and 126 from T2D (respectively 63 SCs and 63 SCs). On average we obtained 36.6 millions reads per SC. Clustering analysis allowed us to identify the two most abundant cell types, one expressing high levels of insulin (INS) and the other glucagon (GCG); two additional but less abundant cell populations were each expressing the other major islet hormones, either somatostatin (SST) or pancreatic polypeptide (PPY). In particular we were able to identify in the samples of the two normal individuals the following gene specific SCs: 92 INS, 12 GCG, 2 SST and 4 PPY SCs. For the two T2D individuals we found respectively 31 INS, 26 GCG, 1 SST and 0 PPY SCs. Interestingly we notice that the previously assumed mutually exclusive expression of INS and GCG in beta and alpha cells respectively is not universally observed since many cells expressing high levels of both INS and GCG suggesting an intermediate alpha-beta cell phenotype: 16 from the two Normal individuals and 37 for the T2D SCs were expressing INS and GCG. This novel cell subpopulation was more abundant in the patients than in the normal individuals (Fisher p-value < 0.0003). Currently we are performing RNA-seq of sorted beta SCs from the same individuals to assess the variability within this specific cell subpopulation. In addition, comparison with known eQTLs and allele-specific expression analysis is ongoing in order to identify T2D specific gene expression regulation. This study of single cells is expected to provide a better understanding of the different cell types of the pancreatic islets in in health and disease.

557M

Analysis of Genome-Wide RNA-Sequencing Data Reveals Age of the CEPH/Utah (CEU) Lymphoblastoid Cell Lines Systematically Biases Gene Expression Profiles. *Y. Yuan, L. Tian, D.S. Lu, S.H. Xu.* Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China.

In human, Lymphoblastoid cell lines (LCLs) from the CEPH/CEU (Centre d'Etude du Polymorphisme Humain - Utah) family resource have been widely used for examining the genetics of gene expression levels. However, we noted that CEU/CEPH cell lines were collected and transformed approximately thirty years ago, much earlier than the other cell lines from the pertaining individuals, which we suspected could potentially affect gene expression, data analysis and interpretation of results. In this study, by analyzing RNA sequencing data of CEU and the other three European populations, we systematically examined and evaluated the potential confounding effect of LCL age on gene expression levels and patterns. Our results indicated that gene expression level and pattern of CEU cell lines have been biased by the older age of CEU cell lines. Interestingly, most of CEU-specific expressions are associated with functions such as cell proliferation which are more likely due to older age of cell lines rather intrinsic characters of the population. We suggested the results should be carefully explained when CEU LCLs were used for transcriptomic data analysis in future studies.

Transcriptome analyzes in human corneas derived from keratoconus and control individuals from Poland. *M. Gajecka[1,2], J.A. Karolak[1], M. Kabza[1], D.M. Nowak[1], P. Polakowski[3], J.P. Szaflik[3].* 1) Department of Genetics and Pharmaceutical Microbiology, Poznan University of Medical Sciences, Poznan, Poland; 2) Institute of Human Genetics, Polish Academy of Sciences, Poznan; 3) Department of Ophthalmology II, Medical Faculty, Medical University of Warsaw.

Keratoconus (KTCN, OMIM 148300) is a degenerating, usually bilateral disorder of the eye, characterized by progressive stromal thinning resulting in conical shape of the cornea. Here we present a pilot keratoconus study based on transcriptome analyzes in human corneas derived from keratoconus and control individuals from Poland. A total of 96 individuals from Polish population are included into this study: 48 keratoconus patients and 48 individuals without keratoconus phenotype. Detailed clinical evaluation in each individual involved in the study was completed. Protocol for RNA extraction from human cornea was established. Total RNA from corneas for RNAseq and small RNA analyzes was extracted. Illumina HiScan system is applied in transcriptome analyzes in this study. Transcriptome analyzes were initiated. Preliminary results of transcriptome analyzes in human corneas will be presented. Since genetic factors involved in keratoconus etiology are in majority unrecognizable, the newest available technologies are necessary to be involved in further keratoconus research. Support: National Science Centre in Poland, Grant no. 2012/05/E/NZ5/02127.

Defining tissue compartment gene expression dysregulation in asthma by multi-tissue whole transcriptome sequencing. *A. Wesolowska-Andersen[1], R. Davidson[1], C. Urbanek[1], G. Sajol[2], C. Eng[3], J. Rodriguez-Santana[4], M. Castro[2], E.G. Burchard[3,5], M.A. Seibold[1,6].* 1) Integrated Center for Genes, Environment and Health, National Jewish Health, Denver, CO; 2) Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO; 3) Department of Medicine, University of California, San Francisco, CA; 4) Centro de Neumologia Pediatrica, San Juan, PR; 5) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA; 6) Department of Pediatrics, National Jewish Health, Denver, CO.

The extent to which gene expression in asthmatics is dysregulated among systemic immune (blood) tissue relative to respiratory airway tissues is unclear. Additionally, although 22 genome-wide association study (GWAS) asthma risk loci have been identified, expression of 161 genes within these loci (+/–200 kb of the reported markers) in the blood and airway tissues has not been systematically examined nor has their differential expression in asthma disease. To investigate blood vs. airway gene expression patterns in asthma we performed whole transcriptome (WT) RNA-seq on whole blood and brushed nasal airway epithelium from Puerto Rican children with asthma (n=10) and controls (n=10); and whole blood and brushed bronchial airway epithelium from adults with asthma (n=12) and healthy controls (n=8). Whole transcriptome RNA-seq was performed in a 2×100bp paired end fashion using Illumina Truseq methodology. RNA-seq data was analyzed using the Tuxedo analysis pipeline. We identified 440, 347, and 70 genes differentially expressed among asthmatics in the bronchial, nasal, and blood WT data, respectively. There was substantial overlap (65 genes) in upper (nasal) and lower (bronchial) airway differential expression. In contrast, we found less overlap of blood differentially expressed genes with both the lower (14 genes) and upper airways (9 genes). Among the 161 GWAS genes, 72.3% (99 genes) were expressed in all tissues, 85.1% (137 genes) were expressed in at least one tissue, 23.4% (32 genes) were expressed only in airway tissues, and 2.2% (3 genes) were only expressed in the blood. There was a significant enrichment for GWAS genes among genes differentially expressed in the airway (17 genes, p=9.4×10–6), in contrast only 1 GWAS gene was among the genes differentially expressed in blood of asthmatics (p=0.38). Among differentially expressed GWAS genes were *IL1RL1*, which encodes for the IL-33 receptor, signaling of which is known to drive airway Th2 inflammation, and *IKZF3*, a chromatin remodeling factor important for B lymphocyte differentiation. Our results indicate asthma disease is associated with a larger number of airway (both upper and lower) vs. blood gene expression changes. Additionally, we find largely unique groups of differentially expressed genes in the asthmatic airway vs. blood. Our examination of GWAS loci genes suggests that risk conferred by multiple asthma GWAS genes may operate through modulation of gene expression, specifically in the airway.

Identification of Gene Expression Signatures in Alopecia Areata. *J. Cerise[1], A. Jabbari[1], J. Mackay-Wiggan[1], M. Duvic[5], M.K. Hordinsky[6], V.H. Price[7], D. Norris[8], R. Clynes[1,2,4], A.M. Christiano[1,3].* 1) Dept of Dermatology, Columbia University, New York, NY; 2) Dept of Pathology, Columbia University, New York, NY; 3) Dept of Genetics & Development, Columbia University, New York, NY; 4) Dept of Medicine, Columbia University, New York, NY; 5) Dept of Dermatology, MD Anderson Cancer Center, Houston, TX; 6) Dept of Dermatology, University of Minnesota, Minneapolis, MN; 7) Dept of Dermatology, UCSF, San Francisco, CA; 8) Dept of Dermatology, University of Colorado, Denver,CO.

Alopecia areata (AA) is a common autoimmune disease manifesting with hair loss that ranges from spontaneously resolving patches (patchy AA, AAP) to lifelong total scalp (alopecia totalis, AT) or total body (alopecia universalis, AU) involvement. AA is a highly prevalent autoimmune disease in which the hair follicle is attacked by cytotoxic T lymphocytes. Obstacles to identifying treatments for AA include limited understanding of disease pathogenesis, as well as the molecular signatures of affected lesions. In order to identify gene expression signatures that correlate with disease, we conducted a comprehensive expression analysis of affected scalp skin of patients with AA. Scalp biopsies from approximately 20 subjects with AAP, 20 subjects with either AT or AU, and 20 healthy control subjects were obtained from lesional/perilesional scalp skin of AA patients and normal scalp skin of healthy controls. Additionally, non-lesional samples were taken from patients with AAP. RNA was extracted from these samples and microarray analysis was performed on Affymetrix microarray data in order to identify genes differentially expressed among the three sample groups. Using Ingenuity Systems' IPA to interrogate genes upregulated in AT/AU and AAP compared with Normal biopsies, we identified two striking gene expression signatures in total skin from human AA, namely, an IFN-γ response (IFN) signature, including IFN-gamma and IFN-inducible chemokines, a cytotoxic T cell (CTL) signature, including CD8 and granzymes, implicating these effectors as the dominant inflammatory cells in AA pathogenesis. We identified a hair keratin (KER) signature using IPA, and the GO term Epidermis Development using Gene Set Enrichment Analysis (GSEA) as being enriched in genes that were downregulated in AA with respect to Normal human skin. Further, GEDI (Gene Expression Dynamics Inspector) was used as a computational tool that allowed us to correlate several predominant gene expression signatures with disease severity. Our findings uncovered new insights into distinct molecular signatures associated with the different forms of AA, and provide a framework for identifying biomarkers of disease and novel potential therapeutic targets. Our gene expression findings support the notion that AU/AT lesions exhibit an extreme inflammatory profile in the spectrum of disease seen in AAP.

Dynamic Transcriptome Changes in Cell-free Synovial Fluid following Meniscal Injury Suggests the Potential for Early Intervention. *D.D. Vance[1,3], E. Rampersaud[2], A. Mehta[2], S.N. Page[2], B.P. Lesniak[2], J.M. Vance[3], M.A. Pericak-Vance[2], L.D. Kaplan[3], L. Wang[2].* 1) University of Miami, Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics,University of Miami, Miller School of Medicine, Miami, FL; 3) UHealth Sports Performance and Wellness Institute, University of Miami, Miller School of Medicine, Miami, FL.

Meniscus injury is one of the leading causes of osteoarthritis (OA), often leading to knee joint replacement. Osteoarthritic changes in articular cartilage have been seen as early as 2 years post-meniscal damage. We hypothesize that molecular changes are initiated within the knee capsule at the time of meniscus injury and long before the manifestation of OA. Identification of those early changes via a minimally invasive procedure could facilitate early intervention to prevent OA development. Towards this end, we characterized transcriptome in synovial fluid (SV) at different time points (1 to 7 months) following a meniscal injury. Eight male patients ages 24~48 years with meniscal injury diagnosed by magnetic resonance imaging (MRI) were ascertained. SV was collected from the affected knee joint by needle aspiration at the time of meniscectomy, prior to initial incision. Total RNA was extracted from cell-free SV and sequenced on Illumina HiSeq2000. The RNA-Seq generated 18 million to 59 million reads for each sample. The STAR program was used to align the reads against human reference genome to map RNA species. Aligned reads were normalized by estimating effective library size. The normalized gene expression is expressed as count per million (CPM). The EdgeR program was used to perform clustering and differential gene expression analysis. In total, 764 RNAs (including coding, non-coding RNA and microRNA) were present in the SV (CPM>1 in at least one sample). Clustering analysis demonstrated that samples with longer injury duration (LID) and shorter injury duration (SID) formed distinctive clusters. Differential gene expression analysis revealed that 65 RNAs were down-regulated and 78 RNAs were up-regulated (false discovery rate [FDR]<0.05) in 4 individuals with SID compared to 4 individuals with LID. The most differentially expressed gene is *SLC2A9* ($P=1.2\times10^{-13}$, $FDR=9.6\times10^{-11}$), which is barely detectable in SID but is abundant in LID samples. *SLC2A9* is expressed in normal articular chondrocytes and can be induced by proinflammatory cytokines, e.g. IL-1beta. SLC2A9 is believed to play a role in the development and survival of chondrocytes in cartilage matrices. Our data demonstrate dynamic transcriptome changes in SV following meniscal injury and suggest the utility of using RNA biomarkers in SV to monitor disease progression and guide early intervention.

Defining the transcriptional landscape of microRNAs in human peripheral blood. *G. Hemmrich-Stanisak[1], Z. Du[1], M. Huebenthal[1], M. Paulsen[1], J. Hartwig[1], P. Rosenstiel[1], D. Kabelittz[2], A. Franke[1].* 1) Inst. of Clinical Molecular Biology, University of Kiel, Kiel, Germany; 2) Institute of Immunology, University of Kiel, Kiel, Germany.

Next generation sequencing of small RNAs (sRNAseq) is a widely used application to establish microRNA-based diagnostic or prognostic marker profiles for conditions like diseases. However, it remains a challenging task as PCR-based sRNAseq protocols suffer from the limitation that measurement of a particular miRNA is not independent from other miRNAs. The introduction of biases towards certain miRNAs during sequencing library construction leads to discrepancies in the overall abundance of sequenced miRNAs. Particularly in complex tissues such as peripheral blood these effects can be dramatic. Due to the differential miRNA expression in different blood cell types and the uneven distribution of cell types based on different conditions e.g. diseases, age, gender, etc. it is difficult to distinguish between true positive, false positive but also false negative signals. To enable correction for the above-described confounding effects and to understand in general how miRNAs are distributed in different cell populations in whole blood samples as drawn in clinical practice, we sought to investigate the transcriptional profiles of miRNAs in seven distinct peripheral blood cell populations of 40 healthy individuals using sRNAseq. To complete the picture we also examined circulating miRNAs from serum and investigated the miRNA content of isolated blood-borne exosomes. We used magnetic activated cell sorting (MACS) to purify CD56+ (NK cells), CD19+ (B cells), CD8+ (T cells), CD4+ (Th cells), CD14+ (Monocytes), CD15+ (Neutrophils) and CD235a+ (Erythrocytes) cell populations to gain comprehensive insights into the miRNA transcriptome of most blood cell types. The results indicate distinct cell type specific miRNA profiles that accurately reflect the developmental relationships between the different cell lineages. A substantial fraction of miRNAs is expressed in subsets or exclusively in one single cell type. Interestingly, Erythrocytes have a distinct miRNA signature containing more than 100 different miRNA species - a fact to be taken into account when investigating miRNA transcriptomes of whole blood samples. Clustering analysis revealed distinct groups of co-regulated miRNAs that in turn show close relationships in their respective validated target genes and the corresponding biological pathways. The here presented data will help to interpret miRNA-based marker profiles more carefully, taking into account technically and naturally occurring confounding effects.

Systematic Analysis of Age and Sex Effect Identified Different Behaviors between Coding and Non-coding Genes and Two Age-dependent Patterns of Gene Expression. *M. Narahara[1], Y. Tabara[2], T. Kwaguchi[2], F. Matsuda[2], R. Yamada[1].* 1) Statistical Genetics, Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Human Disease Genomics, Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Sexual dimorphism and aging lead to difference in a wide range of phenotypes (*e.g.* disease prevalence and courses). Elucidating the molecular mechanisms underlying the differences would provide new insights for complex diseases. We analyzed gene expression microarray data of human peripheral blood samples obtained from 298 individuals to characterize sexually dimorphic genes and aging genes. This study provides new insights particularly into differences between the autosomes and X chromosome, and between coding and non-coding RNAs.

We identified 2,570 (2,071) sex-biased transcripts (genes), 1,672 male-biased and 898 female-biased transcripts, by FDR<5%. Autosomal transcripts were more often male-biased, whereas X-specific transcripts were more often female-biased (P=8.9E-07). We estimated that ~7.05% of genes at X-specific regions were incompletely inactivated. Female-biased transcripts on the X chromosome were significantly enriched at the short arm compared to the long arm (P=0.0003). Such a difference was not evident for male-biased genes and ncRNAs.

We assessed aging effects by a LOESS regression, and, by FDR<5%, identified 5,254 (3,891) transcripts (genes) for females but no transcripts for males. Subsequently, we analyzed the 5,254 age-dependent transcripts with hierarchical clustering, which identified two clusters. 38% of aging transcripts were classified into the first cluster that showed increasing tendencies with age, and enriched by ncRNAs. 62% were classified into the second cluster that showed decreasing tendencies with age, and enriched by mRNAs.

Lastly, we analyzed age-sex interaction. We chose the most significant transcripts by FDR<30%, for which we conducted hierarchical clustering, and identified two clusters. Notably, in both clusters, female-male differences were largest at the youngest age and became smaller as age.

In conclusion, we identified large numbers of sexually dimorphic genes and aging genes for human whole blood samples. We analyzed these genes in details such as comparison among chromosomal regions and RNA types, and clustering analysis.

Whole Transcriptome Sequencing in Alzheimer's Disease Reveals Gene Expression Differences Related To *TGFβ1* Pathway. *K. Nho[1,2], V. Ramanan[1,3], S. Risacher[1], X. Xuei[4], H. Gao[2], Y. Liu[2,3], T. Foroud[2,3], H. Edenberg[3,4], A. Saykin[1,2,3,5].* 1) Radiology and Imaging Sciences, Indiana University, Indianapolis, IN; 2) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN, USA; 3) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA; 4) Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN, USA; 5) Department of Neurology, Indiana University School of Medicine, Indianapolis, IN, USA.

Background: Human brain function depends on the precise regulation of gene expression. Gene expression analysis (transcriptome profiling) has become a major focus of neurodegenerative disease research. Prior studies suggest that abnormal gene expression patterns may contribute to the onset and progression of Alzheimer's disease (AD). Our aim was to perform whole transcriptome analysis of blood-derived RNA to identify blood-based biomarkers in AD. **Methods:** We performed RNA-Seq on 37 participants (7 healthy control (HC), 8 subjective cognitive decline (SCD), 5 early mild cognitive impairment (EMCI), 10 late MCI (LMCI), 7 AD) from the extensively studied IMAS (Indiana Memory and Aging Study) cohort. The libraries were sequenced on SOLID 5500XL and the resulting 75 nt reads were mapped to human reference genome (hg19) and a splice-junction library, respectively, using BFAST. Read counts were calculated using bamutils from NGSUtils [Breese MR, 2013]. After normalization, we identified genes that are differentially expressed between any of the diagnosis groups (stages of AD development) using the edgeR package. Benjamini and Hochberg's algorithm was used to control the false discovery rate (FDR). We analyzed for pathways with enrichment of association in order to identify biological pathways overrepresented, with threshold for input defined as nominal gene-level significance (uncorrected $p<0.05$) using MetaCore. **Results:** We identified 31 differentially expressed genes between any of the diagnosis groups within FDR-corrected $p < 0.05$. These included *TGFβ1* (FDR-corrected $p = 3.93 \times 10^{-4}$) and *SERPING1* (FDR-corrected $p = 3.58 \times 10^{-3}$). The deficiency of *TGF*β1 signaling has been shown to increase both Aβ accumulation and Aβ-induced neurodegeneration in AD models. *SERPING1* encodes a protein that inhibits the inflammatory process. These significantly differentially expressed genes suggest possible early stage up-regulation. A pathway analysis of all differentially expressed 1,022 genes with uncorrected $p<0.05$ revealed enrichment in 10 functional pathways within FDR-corrected $p < 0.05$ including multiple pathways related to cell cycle, immune activation, and apoptosis. **Conclusions:** Whole transcriptome sequencing analysis of blood in AD reveals differentially expressed genes related to immune activation including *TGF*β*1*. These data add to the growing understanding of the genetics and pathobiology of AD that may lead to novel therapeutic targets for AD.

Predictive Gene Markers of Multipotent Stromal Cell Proliferation. *I.H. Bellayr, J.L. Lo Surdo, S.R. Bauer, R.K. Puri.* Center for Biologics Evaluation and Research, Food and Drug Administration, Bethesda, MD.

Multipotent stromal cells (MSCs) are known for their distinctive ability to differentiate into multiple cell lineages such as adipocytes, chondrocytes and osteocytes. They can be isolated from numerous tissue sources including bone marrow. Because of their differential potential and secretion of many growth factor(s), MSCs are thought to exhibit inherent qualities of regeneration and immune suppression. Based on these characteristics, MSCs are seen as advantageous for the field of regenerative medicine in treating a variety of injuries and disorders, in addition to graft versus host disease. Since the percentage of MSCs derived from bone marrow is low, MSCs must be cultured for several cell passages to obtain sufficient cell numbers for a desired cell-based therapy. However, after several rounds of passaging, we have shown previously that the quality of these cells declines as demonstrated by decreases in cell proliferation, increases in cell size, reduced multipotent differentiation potential and differences in gene expression. In this study, we wish to identify molecular markers of proliferation of MSCs that can predict the cell population quality. Human MSCs derived from the bone marrow of 8 different donors were grown under identical conditions and total RNA was harvested at cell passages 3, 5, and 7. The proliferative potential was measured for each donor/passage using two different assays, percent confluency at 96 hours and percentage of EdU positive cells after 6 hours in culture. Total RNA was hybridized on a two color microarray for each donor/passage and gene expression data was correlated with both cell proliferation assays. Using a regression model and a multiplicity adjustment, 28 genes were identified as statistically significant and highly correlated ($0.72 \leq r \leq -0.73$) with cell proliferation. When the significant gene lists were analyzed by Ingenuity Pathway Analysis software, these genes were involved in the top scoring networks ($p<0.05$) of cellular growth and proliferation, cellular development, and cell cycle. Thus, we have identified novel gene markers that are indicative of MSC proliferative quality and may be used to rapidly assess a population of MSCs.

TRANSCRIPTOME APPLIED TO A BLOOM'S SYNDROME: IMMUNOLOGICAL INSIGTHS. *M.M. Montenegro[1,2], G.M. Novo-Filho[1,2], E.A. Zanardo[1,2], R.L. Dutra[1,2], A.T. Dias[1,2], T.V.M.M. Costa[1,2], A.M. Nascimento[1,2], F.B. Piazzon[1,2], C. Milani[1,2], S.C.S. Andrade[3], G. Gasparin[3], C.A. Kim[2], L.D. Kulikowski[1,2].* 1) Department of Pathology, Cytogenomic Laboratory / LIM 03, HC-FMUSP, São Paulo, Brasil; 2) Genetic Unity, Department of Pediatrics, Children Institute, HC-FMUSP, São Paulo, Brasil; 3) Department of Zootechny, ESALQ-USP, Piracicaba, Brasil.

Transcriptome profiling of patterns of RNA expression could be a powerful approach to identify networks of genes that play a role in disease. We investigate the relevant genetic markers that could be associated to chromosomal instability in patients affected by a Bloom's syndrome. Methodology: We performed gene expression profiling using high throughput sequencing (deep-sequencing RNAseq) using the Illumina's HiSeq 2500 platform followed by differential gene expression analysis of samples derived from two patients affected by Bloom's syndrome and three unaffected controls. The data analysis was generated using specialized softwares for preprocessing (CASAVA 1.8.2 e Seqyclean), mapping and alignment (Bowtie2 v2.1.0 e Samtools v.0.1.18) and differential expression analysis (HTSeq-count v.05.4.p2). Results: The RNAseq assay revealed the precise location of transcription limits, with resolution of a single nucleotide and high level of efficiency showing high genetic complexity. It was possible the mapping of 22.334 genes, which 11.938 had minimum coverage required for analysis of differential expression. Of these, 399 were presented differentially expressed, being 216 up regulated in the group with Bloom syndrome and 183 up regulated in the control group. Unexpected all 216 genes of Bloom syndrome are connected to immunological systems. Conclusions: Our results suggested that gene expression network in Bloom's syndrome could interfere in the regulation of the pathways associated with the immunological systems regulation probably caused by disturbance of DNA repair mechanisms. The study of the transcriptome using next generation sequencing is a competent approach to the broad coverage of the sequence with presenting a good cost-coverage. Thus, enable construction of a genic interation network leading to new possibilities to investigate the pathogenesis of Bloom's syndrome just as well in another chromosomal instability syndromes.

Significant transcriptional changes in 15q duplication but not Angelman syndrome deletion dental pulp stem cell derived neurons. *L. Reiter[1,2], R. Memon[3], S. Goortha[1], C. Valdez[1], Q. Tran[4], M. Donaldson[3], D. Bridges[2,5], N. Urraca[1].* 1) Dept. Neurology, UTHSC, Memphis, TN; 2) Dept. Pediatrics, UTHSC, Memphis, TN; 3) Dept. Pediatric Dentistry, UTHSC, Memphis, TN; 4) Dept. Preventive Medicine, UTHSC, Memphis, TN; 5) Dept. Physiology, UTHSC, Memphis, TN.

A major problem in studying neurogenetic syndromes is obtaining live neurons from people with these disorders. We have taken a novel approach to studying gene expression in neurons from Angelman or Dup15q syndrome subjects using dental pulp stem cells (DPSC). Shed teeth were collected to generate DPSC lines from 3 AS deletion, 3 idic(15) and three neurotypical subjects. RNAseq was performed on DPSC and DPSC derived neurons. We identified 20 genes in AS, 120 genes in idic(15) and 3 genes in both groups (*DPT*, *MED12L* and *AKRIC1*) that were significantly different from control DPSC-neurons. Copy number correlated to gene expression for most genes across the 15q11.2-q13.1 critical region. Two thirds of the genes differentially regulated in idic(15) were down-regulated compared to controls including the transcription factors *FOXO1* and *HAND2*, while in AS the genes did not show a clear trend except in the 15q region. Pathway analysis revealed increased cytokine activity related genes including four genes that increased in idic(15) samples: *CCL7*, *CCL2*, *MMP1* and *MMP3*; while steroid hormone biosynthesis genes were slightly enriched in both idic(15) and AS neurons. Overall there were more dramatic changes in gene expression in the idic(15) duplication than AS deletion cell lines, perhaps because the mechanism of AS may be through protein targeting by UBE3A. Nonetheless, the finding of a significant increase in both *HERC2* and *UBE3A* expression in idic(15) neurons and significant decrease in these two genes in AS deletion neurons may impact the AS phenotype, at least in deletion cases.

Viral RNA detection with RNA-Seq using capture technology. *S.M. Gross, I. Khrebtukova, L.C. Watson, F. Schlesinger, S. Pathak, R. Kelley, T. Hill, T. Singer, G.P. Schroth.* Illumina Inc, San Diego, CA.

Identification of viral RNA in human samples is a useful tool for human pathology research and clinical diagnostics. However, most methods for detection of viral RNA, such as qPCR and microarray hybridization, are highly targeted, provide no sequence information, or fail to capture information regarding the broad range of viral RNA abundance reflective of viral load and/or transcriptional activity. Previously, we have demonstrated the utility of using biotinylated capture probes to enable generation of quality RNA sequencing (RNA-Seq) libraries from highly degraded formalin-fixed, paraffin-embedded (FFPE) samples. This capture approach provides a quantitative view of the human coding transcriptome by enriching for next-generation sequencing (NGS) RNA-Seq library fragments derived from exonic sequence over those derived from intergenic or ribosomal RNA, and is able to capture coding RNA that constitutes much less than 1% of the total transcriptome. Using this same concept of sequence enrichment, we are designing an assay to capture NGS library fragments derived from viral sequences of interest from the background of human host sequences. Initial test panels target some important human pathogens, such as human papilloma virus (HPV), enterovirus, hepatitis, and West Nile virus. This method aims to facilitate RNA-Seq for both quantitation of viral RNA in relation to the human host and the ability to collect sequence information useful for the discovery of novel viral variants.

Identifying conserved genomic responses to inflammation in vascular endothelial cells. *L. Antounians[1,2], A. Medina-Rivera[2], J. Dennis[3], L. Rapkin[4], F. Gagnon[3], M.D. Wilson[1,2].* 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) CIHR-STAGE Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 4) Department of Biochemistry, University of Toronto, Toronto, Ontario, Canada.

Vascular endothelial cells are involved in the inflammatory response associated with many diseases. In response to cytokines like tumor necrosis factor alpha (TNFα), a potent pro-inflammatory signaling molecule, NFKB and JNK signaling pathways become activated and regulate the genomic response to inflammation. Transcription factors (TF) and epigenetic modifications control the dynamic regulatory landscape of cells. It is not known if the epigenetic regulation of the inflammatory response is conserved in mammalian species, many of which serve as models for human disease. To understand the epigenetic regulation of vascular endothelial cells in the context of inflammation, we are studying regulatory regions of the genome. We are using chromatin immunoprecipitation followed by DNA sequencing (ChIP-seq) to identify epigenetic modifications and TF binding sites: H3K27ac, a mark of active enhancers; H3K36me3, a mark of active gene bodies; H3K4me2, a mark of active and latent enhancers and promoters; and two TFs cJun and RelA that are activated by the signaling cascades JNK and NFKB, respectively. To perform a controlled comparison of endothelial cell inflammatory gene regulation, we are culturing primary endothelial cells isolated from the aorta of four mammalian species - human, mouse, rat, and cow - with and without treatment of TNFα. Using multiple sequence alignments, we are comparing the location of epigenetic modifications and TF binding between species. Since evolutionary conservation of epigenetic modifications or TF binding sites has been shown to enrich for tissue-specific and process-specific functions, we aim to identify conserved and species-specific regulatory elements. Preliminary results show that approximately 16% of enhancers are conserved between human and rat, while 5% of cJun binding sites are conserved for aortic endothelial cells grown under basal conditions. We find that 74% of conserved cJun sites (N=995) and 84% of conserved H3K27ac sites (N=14,188) are shared with human umbilical vein endothelial cells. This suggests that conservation of regulatory regions is important for vascular endothelial cell identity. Evolutionarily conserved regulatory regions will be used to prioritize single nucleotide polymorphisms in regulatory regions related to disease.

Transcriptional and Epigenetic Landscape of Megakaryocytes derived from Human Induced Pluripotent Stem Cells. *L.J. Vasquez[1], TM. Moreau[2], C. Ghevaert[2], N. Soranzo[1,2].* 1) Human Genetics, Wellcome Trust Sanger Institute, Cambridgeshire, United Kingdom; 2) Department of Haematology, University of Cambridge, Cambridge, United Kingdom.

Every year 250 thousands platelet concentrates are issued by the UK Blood and Transfusion Service at a cost of 55 million GBP. One of the main challenge is to meet the demand for highly-matched products required by multi-transfused patients who have developed immunity against common products donated by the general donor population, and critically so for patients with chronic diseases who have long-term need of transfusion support. Platelets are enucleated circulating corpuscules released from bone marrow megakaryocytes (MKs) and can be irradiated to obtain safe end products. They are therefore ideal targets for in vitro production of blood products that are ABO- and HLA-typed from banks of human induced pluripotent stem cells (hiPSCs). Protocols for the derivation of MKs from hiPSCs are becoming available [1]. For instance, a novel transcription factor-driven forward programming protocol has been developed in the Ghevaert laboratory [2]. However, the genomic and functional equivalence of hiPSC-derived to primary blood cells remains to be verified before they are introduced in the clinic. We present here a genome wide characterization of the transcriptomics and epigenetic landscape of hiPSC-derived MKs exhibiting mature platelet markers and functionality. We present results of the global assay of histone markers of enhancer and heterochromatin (H3K4me1, H3K27Ac and H3K27me3). DNA methylation was probed genome wide using Illumina 450K arrays. Next we interrogated whether hiPSC-MKs were equivalent to MKs derived from neonatal cord blood (CB) or adult peripheral blood (PB). Finally, we associated down regulation of a number of platelet specific genes in the former such as CD9 and VWF with incomplete epigenetic remodelling of the hiPSC genome. Indeed, our study provides mechanistic insights in the reported phenotypic and functional differences between fetal, neonatal and adult MKs, offering new developments for in vitro derived platelets for transfuion. RNA polymerase III (Pol III) synthesizes tRNAs and other small non-coding RNAs to regulate protein synthesis. Dysregulation of Pol III transcription has been linked to cancer, and germline mutations in genes encoding Pol III subunits or tRNA processing factors cause neurogenetic disorders in humans, such as hypomyelinating leukodystrophies and pontocerebellar hypoplasia. Here we describe an autosomal recessive disorder characterized by intellectual disability and cerebellar hypoplasia as well as facial dysmorphic features, short stature, microcephaly, dental anomalies, and scoliosis. Whole exome sequencing revealed biallelic missense alterations of BRF1 as the cause of this syndrome, a finding supported by the recapitulation of key neurodevelopmental phenotypes upon suppression of brf1 in zebrafish embryos. BRF1 associates with BDP1 and TBP to form the transcription factor IIIB (TFIIIB), which recruits Pol III to target genes. Disease-causing mutations reduce BRF1 occupancy at tRNA target genes in S. cerevisiae and impair cell growth. Moreover, BRF1 mutations reduce Pol III-related transcription activity in vitro. The alleles were corroborated to be loss of function using the zebrafish in vivo model when tested in the context of the canonical isoform but not in an alternative transcript. These results show that BRF1 mutations that reduce protein activity cause a neurodevelopmental syndrome and that BRF1-mediated Pol III transcription is required for normal cerebellar and cognitive development and also highlight the biological importance of different transcript variants on human pathogenesis.

Association study of the Human Leukocyte Antigen-G and gallstone disease in Han Chinese. *H. Yang[1,2], S. Shih[2,3,4], Y. Lee[1,4,5,6,7].* 1) Medical Research, Mackay Memorial Hospital, New Taipei City, Taiwan; 2) Mackay Junior College of Medicine, Nursing and Management, Taipei, Taiwan; 3) Division of Gastroenterology, Department of Internal Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 4) Department of Medicine, Mackay Medical College, New Taipei City, Taiwan; 5) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 6) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan; 7) Institute of Biomedical Sciences, Mackay Medical College, New Taipei City, Taiwan.

Background and Goal: Gallbladder stone induce inflammatory responses and affect extra-hepatic bile ducts called gallstone disease (GSD). The pathology and environmental risk factors of GSD are well documented. However, genetic polymorphisms of immune or inflammatory regulation in GSD remain unclear. Human leukocyte antigen (HLA)-G was defined as non-classical Major histocompatibility complex class I based on relative low polymorphisms. HLA-G proteins have seven different isoforms from alternative splicing and have immunosuppressive properties. HLA-G expression is able to confer resistance to Nature killer cell- or cytotoxic T lymphocyte-mediated destruction. HLA-G exerts its inhibitory effect broadly as this molecule has been found to interact with numerous inhibitory receptors on a variety of immune cells. Although only a handful of studies have been published that evaluate a possible role for HLA-G in inflammatory conditions of the bowel, we believe it prudent to include this material to increase risk for the development of malignancy in the setting of inflammatory conditions of the chronic gastrointestinal and inflammatory diseases, such as GSD. In this study, we investigated whether polymorphisms of the HLA-G gene were associated with susceptibility of GSD. Methods: Genomic DNA was isolated from whole blood samples of 234 female patients with GSD and 399 gallstone-free female controls. HLA-G +1537A/C, 14-bp insertion/deletion, and +3142G/C polymorphisms were genotyped using PCR-RFLP or Pre-Developed TaqMan Allelic Discrimination Assay. Genotype, allele, and carrier frequencies of the three HLA-G SNPs were determined by direct counting. Hardy-Weinberg equilibrium was assessed for each SNP in both control and study groups using Haploview 4.2. Results: HLA-G +3142G/G genotype shows susceptibility to GSD in female patients (OR = 0.66, Pc = 0.03). Allele +3142G also shows the same result (OR = 0.75, Pc = 0.02). The other two polymorphisms site show the same frequencies with controls. Conclusions: Based on our findings, HLA-G +3142G/G confer as protective in female patient with GSD. Our results need to be replicated and verified in another large-sized cohorts or other ethnics.

573T

Structural Variation Analysis Using Nanochannel Genome Mapping to Evaluate Genome Integrity after Induction of Pluripotency of Human Fibroblasts. *E.H. Cho[1], H. Dai[1], A. Pang[1], R. Williams[2], K. Nazor[2], K. Bhutani[3], N. Schork[3], J. Loring[2].* 1) BioNano Genomics, Inc., San Diego, CA; 2) Center for Regenerative Medicine, The Scripps Research Institute, La Jolla, CA; 3) Human Biology, J. Craig Venter Institute, La Jolla, CA.

Four key genes, POU5F1, SOX2, KLF4, and MYC, are commonly used for reprogramming human fibroblasts into stem cells. Induced pluripotency of human fibroblasts into stem cells currently relies on three different transfection methods of these key genes: retroviral, Sendai virus, and mRNA. The latter two methods are non-integrating methods, while the former method integrates into the genome. Retroviral transfection to induce pluripotency is currently the most efficient method, but due to the potential damaging effects of viral integration into the chromosomes, it is thought to be of high risk for future clinical applications. To investigate whether structural changes result during the process of induction of pluripotency in stem cell genomes we used nanochannel genome mapping technology from BioNano Genomics (BNG) to compare structural differences among cell lines derived by the three reprogramming methods and the parental genome. By producing de novo genome map assemblies of each genome, comparing to a reference genome, and cross comparing all four assemblies, we determined sample-specific SV calls for each of the three methods. After automated assembly and comparison, followed by manual verification, 14 sample-specific SVs were found in the retrovirus-induced sample, 12 in the Sendai virus induced sample, and 8 in the mRNA induced sample, all with respect to the Hg19 human reference genome. Examination of this dataset provided no evidence that any of the methods used to induce pluripotency produced malignant SVs into the genome. Subsequent studies confirming these results using orthogonal methods, such as next-generation sequencing, could provide strong evidence for continued pursuit of clinical applications using any of these methods. Furthermore, confirmation of no significant SV differences using the more efficient retroviral transfection method may give more confidence in the use of this method in clinical therapeutic iPSC applications.

574S

An exercise filled lifestyle may alter the gut metagenome exposed to polychlorinated biphenyl. *E. Rampersaud[1], M. Veerapen[1], M. Toborek[2].* 1) John P. Hussman Inst Human Genomic, University of Miami Miller School of Medicine, Miami, FL; 2) University of Miami.

The gut microbiome comprises of multiple phyla of microbes which responds to environmental stressors. Moreover, the gut microbiome composition has been implied in the catabolism of drugs and other xenobiotic compounds such as polychlorinated biphenyl (PCB). PCBs are persistent organic pollutants which are carcinogenic. Our group has previously shown that exercise can attenuate changes conferred by oral PCB in the murine gut microbiome. However, the role of the gut microbiome in exercise-based PCB degradation remains unclear. We propose to study the composition and functional characteristics of the gut metagenome upon the exposure to PCB and exercise. 32 mice were used in 4 study groups comprising of sedentary and exercised mice which were either exposed to PCB or not (PCB delivery vehicle only). All mice were voluntarily exercised or remained sedentary for 5 weeks and were treated with oral gavage of relevant PCB congeners or vehicle. Mouse feces were collected before gavage and 2 days after gavage. Collected fecal matter was subjected to total DNA extraction and subsequently sequenced using the Illumina HiSeq 2000. All raw reads were assembled, mapped and analyzed using MG-RAST v3.3.6s and MatR v1.0.0. All samples were uploaded and analyzed successfully with MG-RAST. Our analyses revealed significant differences between sedentary and exercised mice gut microbiome -- observably, an increase in bacteroidetes in exercised mice ($p < 0.001$). The bacteroidetes increase is more apparent upon treatment with PCB in exercised mice but a notable decrease in microbiome diversity based on the α-diversity value. No observable microbiome clustering was found between groups. Based on preliminary functional analyses, PCB exposure increases presence of microbes involved in information storage and metabolic proteins ($p < 0.05$). Our results indicate and replicate that exercise attenuates the effects oral PCB exposure phenotypically and alters the gut metagenome. The gut microbiome is known to alter immune systems and the observed alteration likely indicates a possible change to immune responses responsible for PCB degradation. Further studies are required to elucidate specific pathways and mechanisms involved in PCB degradation with the gut microbiome. Potentially, this study can be used to remediate populations exposed to oral PCBs.

575M

Characterizing gut microbiota variation across diverse rural African populations. *M.E.B. Hansen[1], M. Rubel[1], A. Bailey[2], K. Bittinger[2], A. Laughlin[2], A. Ranciaro[1], W. Beggs[1], S. Thompson[2], F.D. Bushman[2], S.A. Tishkoff[1].* 1) Genetics Dept., University of Pennsylvania, Philadelphia, PA; 2) Microbiology Dept., University of Pennsylvania, Philadelphia, PA.

Africans harbor the greatest levels of human genetic variation, and differences in diet are likely to have produced distinct selection pressures resulting in genetic adaptations. An additional important source of variation that can influence both health and disease is the gut microbiome. To better understand how genetic adaptations, culture, and diet interact, we analyzed the gut microbiomes from ethnically diverse rural Africans and urban European and African Americans in Philadelphia using ribosomal marker classification (16s RNA V1/V2) from fecal samples. The African cohort is composed of populations with different diets and subsistence practices, including hunter-gatherers, nomadic pastoralists, and traditional agricultural groups. Samples from 120 rural Africans were extracted, sequenced, and compared with a dataset of 102 European and African American samples, using identical methods and the Roche 454 platform. The impact of diet and ethnicity was characterized by changes in relative abundance of bacterial taxa. Comparison of the rural African to the urban Philadelphia samples confirms previous studies that show marked differences between African and non-African gut flora. In contrast, within Africa there are relatively subtle differences between populations despite highly distinct diets and high levels of genetic differentiation. Among African populations we find that differences in the gut microbiome are not entirely diet dependent, but rather, are correlated also with geography and ethnicity. This represents the largest microbiome study to date of ethnically diverse Africans living indigenous lifestyles and provides novel data from previously uncharacterized African groups.

Interactions between host genetics and diet affect gut microbiota and influence metabolic traits in mouse and human. *E. Org[1], J. Wha[2], Y. Blum[1], B. Emert[1], E.Y. Kang[2], B. Parks[1], R. Knight[3,4], T. Drake[5], M. Laakso[6], E. Eskin[2,7], A.J. Lusis[1,7].* 1) Department of Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Computer Science Department, UCLA, Los Angeles, CA; 3) Department of Chemistry and Biochemistry, University of Colorado Boulder, CO; 4) Howard Hughes Medical Institute, Boulder, CO; 5) Department of Pathophysiology and Laboratory Medicine, UCLA, CA; 6) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 7) Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA.

An increasing body of evidence suggest that host genetics as well as the diet affects the composition of gut microbiota. Moreover, it is clear that shifts in microbial communities can lead to cardiovascular and metabolic diseases. In our study we examined natural variation in gut microbiota in a population of about 100 inbreed strains of mice from the Hybrid Mouse Diversity Panel (HMDP) and a population of a 200 men from the Metabolic Syndrome in Men (METSIM) study. Profiling of the gut microbiota in the HMDP (n= 599 mice) revealed that the genetic background strongly influences gut microbiota composition and that the gut microbiome composition explains a considerable portion of the variation in obesity traits. There was insufficient power to estimate heritability in the human sample, nevertheless associations with traits were observed. We also observed evidence of strain-specific shifts in gut microbiota after feeding mice with obesifying, high fat/high sucrose (HF/HS) diet, suggesting a strong effect of host genetics on the plasticity of gut microbiota. Genome-wide association of the panel identified 7 significant loci in mouse genome associated with relative abundances of the families Clostridiaceae, Ruminococcaceae, Lachnospiraceae, Turicibacteracea and Lactobacillaceae. Integrating datasets from multiple intermediate phenotypes (clinical parameters, metabolite levels and gene expression) provided additional support for relationships between specific microbes and metabolic traits. Consistent with our findings in mice, we detected significant correlations between Roseburia intestinalis and metabolic phenotypes in the human study. In addition, we showed similar microbial affinities in human and mice by inferring microbial co-occurrence networks. Our findings suggest that gut microbiome may be one of the key factors in the missing heritability of complex diseases and the integration of microbiota data with different intermediate phenotypes may allow us to obtain valuable insights into diseases-associated metabolic pathways.

577S

Drosophila fragile X mental retardation protein is associated with chromatin and regulates replication stress-induced DNA damage response. *Y. Cheng[1, 2], W. Zhang[2], Y. Li[1], Z. Chen[2], D. Chen[2], P. Jin[1].* 1) Human Genetics, Emory University, Atlanta, GA., USA; 2) State Key Laboratory of Reproductive Biology, Institute of Zoology, Chinese Academy of Sciences, Beijing, 100101, P.R. China.

Fragile X syndrome, a common form of inherited mental retardation, is caused by the loss of the fragile X mental retardation protein (FMRP). As a selective RNA-binding protein, FMRP has been shown predominately localized in cytoplasm regulating the translational control. However, it is known that a small portion of FMRP is present in nucleus and its nuclear function has been elusive. We have found that Drosophila dFmr1 is required for replication stress-induced H2Av phosphorylation in DNA damage response (DDR). Replication stress could induce the expression of dFmr1 and promote the nuclear accumulation of dFMR1. We show that dFMR1 is associated with chromatin in a domain-specific manner upon the stimulation of replication stress, which is essential for its ability to induce the phosphorylation of H2Av. Furthermore, we have performed ChIP-seq analyses using dFMR1 antibody and identified specific dFMR1 binding sites in S2 cells. By comparing the distributions of dFMR1 between control and UV exposure conditions, we found that the sites bound by dFMR1 upon UV treatments significantly overlap with replication origins identified previously. These results together reveal an unexpected nuclear role of FMRP in DDR, and uncover a feed-forward mechanism by which dFmr1 and early DDR induced by replication stress reciprocally regulate each other, thereby synergistically triggers the activity of DDR signaling cascade.

578M

Impact of Structural Variants on the three-dimensional multi-scale chromatin conformation of the human genome. *D. Plewczynski[1,2,3], P. Szalaj[2,3], J. Kim[2], C. Zhang[2], A. Malhotra[2].* 1) ICM, University of Warsaw, Warsaw, mazovia, Poland; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 3) The Centre for Innovative Research, Medical University of Bialystok, Bialystok, podlasie, Poland.

In this study we investigate the causative relation between copy number variants (CNV) and three dimensional chromatin structure of various cell types. Spatial arrangement of chromosomes can play a very important role in many biological processes. By rendering distant genomic regions to a close spatial proximity it can precipitate long-range interactions between genes and transcription factors. Recently developed Chromosome Conformation Capture (3/4/5C) techniques allow us to quantify interaction frequency between genomic regions and infer their spatial arrangement. On the other hand recent studies such as the 1000 Genomes Project suggest that Human genomes are very variable, not only in terms of single mutations, but also large scale structural variants. Our three-dimensional simulation method uses homo-polymer modeling techniques, yet is done separately at different scales: whole nucleus, chromosomes, 10mb regions modeled as random walk, 1mb giant loops structures, 100kb rosettes and random loops, 10kb local neighborhoods. For all spatial scales we use the same evolutionary algorithm that constructs an ensemble of chromatin conformations based on a given experimental contact map containing interaction frequencies. Moreover, in order to overcome limitations of homo-polymer models, we map various local genomic features such as active genes, open chromatin marks, GC ratio and others onto 1D chromatin chain. We also consider structural constraints: resistance to stretching and bending, which accommodate for biophysical chromatin fiber properties. As evolutionary operators we employ three mutation operators (single bead displacement, fragment displacement, fragment rotation) as well as a crossover operator (splitting two structures at a random position and gluing them cross-wise), which are chosen with predefined probabilities. In our study we combine the data being generated by various studies including the 1000 Genomes Project regarding structural variants type, size and location, with their spatial localization in three-dimensional model of the nucleus. We use public HiC maps of contacts and the resources from ENCODE project in order to further characterize local 3D neighborhoods. We hypothesize that the shape of chromatin fiber around deletion, duplication, inversion and mobile element insertions is strongly correlated with the type of CNV, suggesting a causative link.

Higher order chromatin structure and *CFTR* gene regulation: roles of *cis*-regulatory elements and CTCF/cohesin complex. *R. Yang, N. Gosalia, J. Kerschner, S.H. Leir, A. Harris.* Lurie Children's Research Center and Department of Pediatrics, Northwestern University, Feinberg School of Medicine, Chicago, IL.

The cystic fibrosis transmembrane conductance regulator (*CFTR*) gene encodes a cAMP-activated chloride ion channel, which when mutated, causes the genetic disease cystic fibrosis. *CFTR* expression is highly tissue-specific and it has been shown that *cis*-elements play an important role in the regulation of *CFTR*. Some of these elements are located far (>100kb) from the gene promoter and regulate gene expression through chromosome looping which establishes physical interactions. In order to better understand the molecular mechanism of *CFTR* gene regulation and look for additional distal regulatory elements we used 4C-seq (chromosome conformation capture combined with high-throughput sequencing). This technique can identify and quantify interactions between selected genomic sites (viewpoints) and rest of the genome. 4C-seq experiments were performed in human intestinal and airway cell lines that use different *cis*-regulatory elements, and also in primary human airway and epididymis cells. Viewpoints were used at the *CFTR* promoter, at intronic and distal enhancers, and at CTCF-binding insulators flanking the gene. The data correlate well with previous 3C data we generated for the *CFTR* locus and also reveal potential novel *cis*-regulatory elements. Moreover, results confirmed the cell type-specific properties of these chromatin interactions. We subsequently performed studies in which we 1) manipulated the levels of the architectural proteins CTCF and cohesin, or 2) removed specific cis-regulatory elements from the endogenous *CFTR* gene by CRISPR/Cas9-mediated targeting and examined the impact on 3D locus structure and *CFTR* expression. These data provide substantial insight into higher order chromatin structure mediated by both *cis*-regulatory elements and the CTCF/cohesin complex and their critical role in *CFTR* gene regulation.

The Chromatin Architecture of a Haploid Human Cell Line. *D.A. Cusanovich, J. Shendure.* Department of Genome Sciences, University of Washington, Seattle, WA.

In contrast with model organisms, human cell lines have not historically been readily compatible with mutagenesis screens to identify genes involved in specific cellular phenotypes. Recent advances in genome editing technologies - specifically, with the CRISPR/Cas9 system - have enabled efficient genome-wide recessive genetic screening in haploid human cell lines (Wang et al. Science 2014). However, taking advantage of haploid genetics limits the choice of a cellular model primarily to KBM-7, a near-haploid chronic myelogenous leukemia cell line, and its haploid derivative, HAP1. While both have been used successfully in previous studies, HAP1 has not been well characterized. HAP1 was derived in a failed attempt to induce pluripotency and has several notable distinctions from KBM-7, including the fact that it is adherent and that it no longer maintains a second copy of chromosome 8 (Carette et al. Nature 2011), but little else has been reported regarding its cellular state. To facilitate further efforts to dissect the genetic architecture of human phenotypes in these haploid cellular models, we have generated RNA-seq and ATAC-seq data from the HAP1 cell line. For comparison, we are also generating equivalent datasets from other myeloid cell lines, including the parental line (KBM-7), and a lymphoblastoid cell line (GM12878) that has been extensively characterized in previous studies. Beyond serving as a reference dataset for further experimentation, characterization of the nuclear architecture of a haploid cell line may offer insights into fundamental human biology. Both the RNA-seq and ATAC-seq datasets allow for hierarchical clustering of the samples to better understand how related their cellular phenotypes are. Furthermore, genes differentially expressed between HAP1 and KBM-7 may help to both define the cellular identity of HAP1 and explain how this cell line can stably maintain a haploid genome. While the primary goal of this work is to aid further interpretation of ongoing functional genomic experiments in this haploid model cell line, the results may also yield a more nuanced understanding of gene regulation in human cells.

581M

A Computational Pipeline for Characterization, Identification, and Significance Analysis of the Somatic Copy Number Variations from Genome Sequencing Datasets. *A. Harmanci[1], A. Serin Harmanci[2], M. Gunel[2], M.B. Gerstein[1].* 1) Molecular Biophysics and Biochemistry, Yale University, Hew Haven, CT 06527, USA; 2) Departments of Neurosurgery and Genetics, Yale Program in Brain Tumor Research, Yale School of Medicine, New Haven, CT 06510, USA.

Large scale genomic aberrations, namely the structural variations, are important driving factors for tumorigenesis and tumor evolution. Among these variants, the unbalanced variants, the copy number variants, are significant because they may change the dosage of the tumor suppressor or oncogenes and drive the formation of tumor. We are presenting a complete pipeline for identification and significance analysis for somatic CNVs using genome sequencing (exome and whole genome) datasets. Our pipeline takes multiple datasets as input and uses a signal processing based segmentation method to identify CNV calls for each sample. Following CNV identification, pipeline utilizes a genome wide test to assign a significance of recurrence for each copy number variant segment. In addition, our pipeline estimates the ploidy, tumor purity and clonal fraction for each segment, generates the closest subclonal events and computes significance for these segments. We compare our pipeline with several other CNV identification tools and present benchmarking results. We also applied our pipeline on several exome sequencing datasets of patients with brain tumor and present significantly altered clonal and subclonal events including tumor suppressor and oncogenes. In addition to coding elements, we also generate significantly altered non-coding elements.

Method for classifying candidate structural variants into true positives and false positives. *H. Parikh[1], J. Zook[1], M. Pratt[2], G. Bartha[2], M. Eberle[3], M. Salit[1].* 1) Genome Scale Measurements Group, Biosystems and Biomaterials Division, National Institute of Standards and Technology, Gaithersburg, MD 20899, USA; 2) Personalis Inc., 1350 Willow Road, Suite 202, Menlo Park, CA 94025, USA; 3) Illumina Inc., San Diego, CA 92122, USA.

The human genome contains genomic variants ranging in size from small single nucleotide polymorphisms to large structural variants (SVs). SVs include variations such as novel sequence insertions, deletions, inversions, mobile-element insertions, tandem duplications, interspersed duplications and translocations. SVs have long been implicated in phenotypic diversity and human diseases; however, identifying SVs in a whole genome has proven elusive. Recent advances in next-generation sequencing technologies have facilitated the analysis of SVs in unprecedented detail. However, clinical adoption of human genome sequencing requires methods with known accuracy of SV calls across genome. Hence, we developed methods to make highly confident SV and non-SV calls for NA12878, the pilot genome for the Genome in a Bottle Consortium, for which we recently published high-confidence small variants and homozygous reference sites. Because numerous methods have been developed to find candidate SVs, we decided to develop methods to look for evidence of these SVs in mapped sequencing reads from multiple sequencing technologies. We collected 9 different Gold Standard SV call sets totaling 12,738 deletions that were derived from pedigree sequencing, microarrays, and other validation methods. We annotated these candidate SV sites with parameters such as mean coverage, mean insert-size, numbers of discordant pairs, numbers of soft clipped reads, mean mapping quality score, and numbers of heterozygous and homozygous SNP genotype calls from 3 sequencing technologies (Illumina, Moleculo, and PacBio). In addition, we annotated randomly generated regions to understand characteristics of non-SV regions. Graphical visualization of the annotation parameters has shown clear distinction between true positive and false positive SVs. A key advantage of the proposed method is its simplicity and flexibility to generate various annotation parameters from aligned sequence data based on different sequencing datasets from the same genome. This allows integration of multiple sequencing datasets to identify high-confidence SV and non-SV calls that can be used as a benchmark to assess false positive and false negative rates. We are currently creating a classification method based on the annotation parameters to generate both high-confidence SV calls and high-confidence non-SV calls for genomes selected as reference materials by the Genome in a Bottle Consortium.

583S

Genomic CNVs can cause sudden infant death syndrome (SIDS). *A. Pfeufer[1,2], M. Arnold[1], M. Cohen[3], S. Herms[4], T. Dörk[5], T.A. Plötz[1], I. Sinicina[6], E.A. Mitchell[7], M. Donner[8], D.T. Mage[9], E.R. Behr[10], T.W. Mühleisen[11], S. Cichon[4], T. Meitinger[1,2], A. Peters[1,6], H.W. Mewes[1,2], M. Klintschar[5], T. Bajanowski[12], M. Vennemann[13].* 1) Helmholtz Zentrum München, Neuherberg, Germany; 2) TU München, München, Germany; 3) University of Sheffield, Sheffield, UK; 4) University of Basel, Basel, Switzerland; 5) MHH Hannover, Hannover, Germany; 6) LMU München, München, Germany; 7) University of Auckland, Auckland, New Zealand; 8) Dupont Haskell Global Centers for Health & Environmental Sciences, Newark, USA; 9) Biomolecular Core Laboratory, AI duPont Hospital for Children, Wilmington, USA; 10) St. Georges University of London, London, UK; 11) Forschungszentrum Jülich, Jülich, Germany; 12) Universität Essen, Essen, Germany; 13) Universität Münster, Münster, Germany.

The contribution of monogenic disorders to in sudden infant death syndrome (SIDS) is established (most commonly LQTs and MCAD deficiency). In contrast the importance of complex genetic predispositions is less clear. Also copy number variations (CNV) involving critical genes may predispose to SIDS. Patients: We performed genome-wide SNP and CNV genotyping of 368 SIDS cases using the Illumina HumanHap 660v3 quad array. 320 cases originated from the multi-center German study on sudden infant death (GeSID) and 48 cases were recruited from the Sheffield SIDS study in the U.K. As controls we used 823 population based individuals from the KORA cohort. Methods: In a GWAS design we compared SIDS cases with population controls for genome-wide SNP association. As age matching is not feasible in SIDS we performed sex matching of controls and geographical adjustment by multidimensional scaling. We included Chr.X markers as SIDS exhibits 2:1 male:female sex bias indicating possible genetic risk factors on the sex-chromosomes. Markers were imputed to 4.8 Mio SNPs using the haplotype backbone provided by the 1000 Genomes project. Autosomal SNP-markers were analyzed using an additive model adjusted for sex. Markers on Chr. X were analyzed stratified by sex and then meta-analyzed. In another line of analysis we called genome-wide CNVs in the SIDS cases using the CRLMM algorithm. Results: The GWAS analysis showed no significant association beyond genome-wide significance level ($p<5\times10–8$) neither with autosomal markers nor with markers on Chr.X. CNV analysis revealed deletions in five cases: One case had a 5.2 Mb deletion in 5q3, another case had a 2.2 Mb deletion in 18p1 and a third case had a 370 kb deletion in 5q2. Two further unrelated cases had nearly identical 400 kb deletions in 4q1. None of these CNVs involved genes previously identified to be involved with SIDS or Mendelian diseases involved with premature death. Conclusion: Our GWAS was powered to detect common SNP association signals with OR≥1.8 and MAF≥0.2 with ≥95% power. The failure to detect such associations in the human genome is well in accordance with the expectation of strong evolutionary selection against any common genetic SIDS risk factors. The detection of CNVs in 1,4% of cases (5/368) indicates a small but significant contribution of structural genomic mutations to SIDS etiology.

584M

In vivo dissection, causality identification, and network analysis of copy number variants associated with autism spectrum disorders. *C. Golzio[1,2], S. Moon[1], J.R. Willer[1], M.A. Savidan[1], S.C. Brodar[1], I. Blumenthal[3], A. Ragavendran[3], M.E. Talkowski[3], N. Katsanis[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC, USA; 2) Department of Psychiatry and Behavioral Sciences, Duke University School of Medicine, Durham, NC, USA; 3) Department of Neurology, Massachusetts General Hospital, Boston, MA, USA; Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; Harvard Medical School, Boston, MA, USA.

Copy number variants (CNVs) are frequent lesions involved in both rare and complex human traits. This has raised the challenge of identifying which genes within a CNV drive clinical traits. We have shown previously how the combinatorial use of surrogate phenotypes in zebrafish embryos and genomic studies can help dissect CNVs on 1q21.1, 8q24.3, and 16p11.2. However, although successful in identifying primary drivers, these data also indicated that each of the primary dosage-sensitive transcripts within each CNV were not sufficient to drive the CNV-associated pathology. We therefore extended our study to model *cis*-epistasis within CNVs and to determine global transcriptional changes and dissect likely contributory transcripts. We focused on the 1q21.1 CNV, encompassing a minimal nine-gene region, deletion of which is associated with microcephaly, while the reciprocal duplication is associated with macrocephaly. Systematic overexpression and suppression of all genes in the CNV showed that dosage perturbation of the chromodomain-helicase-DNA-binding protein *CHD1L*, gave significant head size changes: overexpression of human *CHD1L* mRNA led to macrocephaly, while suppression of *chd1l* lead to a significant decrease in head size. However, given that a) human genetic data suggested that *CHD1L* might not be sufficient to explain causality of this CNV, we asked whether *cis*-CNV and *trans*-CNV genetic interactions might contribute to pathogenesis. To answer the first question, we systematically tested the pairwise interaction of *CHD1L* with each of the other 8 genes within the CNV, though which we identified several epistatic partners that modulate the expressivity of micro- and macrocephaly. For the second question, we generated RNA-seq data from heads of control, *CHD1L* RNA-, and *chd1l* MO-injected embryos; we identified ~700 differentially expressed transcripts; strikingly, the top 20 genes in this cohort have been implicated in the genetic causality of autism. Epistatic analysis of candidates whose dosage is perturbed reciprocally by the CNV showed strong complementation for a subset of genes, indicating that their transcriptional misregulation is likely relevant to the observed neurodevelopmental phenotypes. The combination of CNV dissection with *in vivo* genetic interaction studies highlights the genetic complexity of genomic lesions and informs functional networks relevant to ASD pathomechanism.

585T

Increased relative mitochondrial DNA content in Keratoconus patients. *A. Kondkar[1], K. Abu-Amero[1,3], TA. Azad[1], T. Sultan[1], H. Kalantan[2], A. Al-Muammar[2].* 1) Department of Ophthalmology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 2) Anterior Segment Unit, Department of Ophthalmology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 3) Department of Ophthalmology, College of Medicine, University of Florida, Jacksonville, Florida, USA.

Mitochondrial DNA (mtDNA) is extremely prone to oxidative stress. To investigate the possible association of oxidative stress with Keratoconus we estimated the changes in relative mitochondrial DNA (mtDNA) content. The study included119 patients with Keratoconus and 208 controls matched for gender, ethnicity and systemic disease status. We selected controls with higher age group than those of the patients as the mtDNA copy number tend to increase with age. The age mean (SD) was 26.4 (7.6) and 54.5 (14.4) y for patients and controls respectively. Relative mtDNA copy number was estimated by real-time quantitative polymerase chain reaction (qPCR) method using ND1 as a mtDNA gene and human globulin (HGB; also known as cytoglobin gene - CYGB) as the reference single-copy nuclear gene. The mean relative mtDNA content was found to be significantly higher in patients with Keratoconus (1.20 copies) than the normal control subjects (1.04 copies) [mean difference = 0.164 copies, 95% confidence interval (CI) = 0.07 to 0.25; P = 0.0004]. Subjects with high mtDNA content (>1.259 copies i.e, greater than 75th percentile) were found to be at an increased risk of the disease (odds ratio = 2.62, 95% CI = 1.40 to 4.89; P = 0.0025). High mtDNA content appears to be associated with increased risk of Keratoconus. Increased mtDNA content in Keratoconus patients may imply a response to oxidative stress, possibly in part because of mitochondrial respiratory chain defects.

586S

Structural haplotypes of the human amylase locus and their relationship to obesity. *C.L. Usher[1], R.E. Handsaker[1,2], T. Esko[1,2,3], J.E. Moon[1,2], A. Metspalu[3], J.N. Hirschhorn[1,2], S.A. McCarroll[1,2].* 1) Genetics, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Estonian Genome Center, University of Tartu, Tartu, Estonia.

The three human amylase genes (*AMY2B*, *AMY2A*, and *AMY1*) encode enzymes that digest starch into sugar. These genes reside in a complex genomic locus characterized by inversions, deletions, and tandem duplications. Only a handful of the structural haplotypes are known, yet there is evidence of other, unknown haplotypes segregating in populations.

We first identified these structural haplotypes, as well as their population frequencies and evolutionary history, by tracking their transmission in a hundred father-mother-offspring trios using droplet digital PCR (ddPCR) and sequencing read-depth analysis. We found 10 structural haplotypes, each with different combinations and copy numbers of *AMY2B*, *AMY2A*, and *AMY1*. These structures help define a long history of recurrent mutation and provide clues for more accurate copy number genotyping at this locus.

The presence of higher *AMY1* copy numbers in populations with high starch diets has led to speculation that *AMY1* copy number contributes to obesity. Supporting this idea, a recent study reported that *AMY1* copy number has the largest effect yet observed for common variation on obesity. To investigate the amylase locus's effect on BMI, we used the advanced methods that we had already developed for amylase to genotype copy number for all amylase genes in 500 Estonians from each of the BMI extremes (BMI < 22 and BMI > 33). This design had >99% power to detect effects one-tenth as strong as those reported in the recent study. As expected, we observed strong associations between obesity and SNPs within previously implicated loci, such as *FTO*, which confirms that this sample had sufficient power to detect genetic associations. However, we found no association between obesity and the copy number of any amylase gene.

587M

Constitutional chromothripsis: A novel phenomenon in congenital disorders. *A. Alharini[1], M. Pronold[2], A. Slavotinek[1,3], J. Shieh[1,3].* 1) Department of Pediatrics, Division of Medical Genetics, UCSF, San Francisco, CA; 2) Department of Pathology and Laboratory Medicine, UCSF, San Francisco, CA; 3) Institute of Human Genetics, UCSF, San Francisco, CA.

Chromothripsis (chromosomal shattering) is characterized by complex multiple genomic rearrangements recently observed in cancer genomes (Stephens et al., 2011). It is rarely seen in constitutional studies, and the clinical consequences and implications of these genomic alterations are poorly defined. We investigated whether chromothripsis was observed in patients without known malignancies. We analyzed their clinical course. Out of more than 1800 arrays at our institution run from 2009 until present, two patients with chromothripsis were identified. Patient 1 is an 18 month old term male, a product of an in vitro fertilization (IVF) via intracytoplasmic sperm injection (ICSI) due to low sperm count and motility in the father. He presented with hypotonia and global developmental delay and dysmorphic features including microcephaly, hypertelorism, epicanthal folds, downturned mouth, inverted nipples, bilateral congenital ptosis. Oligonucleotide-SNP array demonstrated eight chromosomal changes, one copy loss and seven copy gains on chromosomes 1, 2, 7, 12, 13 and 14. Six out of those eight genomic changes were de novo. Patient 2 is a 12 month old term male with hypotonia, developmental delay and dysmorphic features including microcephaly, anomalous right ear, unilateral radioulnar synostosis, limb length discrepancy, and digital differences. Microarray revealed two deletions and ten duplications of the chromosome 4. We conclude that chromothripsis can involve multiple chromosomes simultaneously or it can have a predilection to certain chromosomes like chromosome 4 (Kloosterman et al., 2011). With these above cases of chromothripsis present in patients with congenital disorders, it will be important to recognize this phenomenon and its implications for the patients. Further studies are needed to provide the mechanism of chromothripsis and the subsequent clinical approach and management.

End-point zygosity and CNV determination from crude samples. *C. Liu, S. Dong.* MBS R & D, Life Technologies, south san francisco, CA.

End-point zygosity and CNV determination based on post PCR Rn/ΔRn reading is expected to reduce the cost and increase throughput as compared to current real time Cq-based measurement. There is an immediate need by AgBio customers to screen seed zygosity and copy number of transgenes through end-point reading. Moreover, Agbio customers expect to determine zygosity and CNV using crude samples in order to stream-line their workflow. For end-point quantification, the major challenge is to control the saturation of PCR to maintain the segregation of end-point intensity according to the input copy number of the target transgenes in reference to a control gene. We have tried a few approaches such as Asymmetric PCR, ARCS (Amplification Ratio Control System) PCR, Dual Tailing PCR, pyrophosphate removal and controlling plateau of PCR by running a third PCR in the background. Among the tested approaches, controlled plateau of PCR (CoP'ed PCR) showed best separation of copy number through end-point PCR reading. We further optimized CoP'ed PCR conditions using purified DNA and crude plant and blood samples. By CoP'ed PCR, we are able to do zygosity with crude plant samples to satisfy the immediate needs for Agbio customers. Furthermore, since this approach improves the sensitivity for the copy number separation for not only end-point but also real-time PCR for crude blood samples, in the future, it can be used for CNV analysis directly from human blood, such as prenatal chromosome copy number variation detection since the percentage of fetal DNA in the maternal blood sample is only 10%-15%. It is impossible to detect the copy number abnormality through traditional real time or end-point PCR.

Sequencing the genomes of single cells. *P. Ribaux, C. Borel, F. Santoni, E. Falconnet, S.E. Antonarakis.* Dept Genetic Medicine, Univ Geneva Medical School, Geneva, Switzerland.

Whole-genome amplification and next-generation sequencing advances enable investigation of somatic structural and nucleotide variation to single-cell resolution. The ultimate goals of our study are (i) to identify disease-associated somatic mutations and (ii) to uncover the extent of low-abundance DNA variations in individual cancer cells in order to underlie mechanisms of tumor evolution. Because of the technical challenge of detecting and analyzing genomic heterogeneity among single cells, we first analyzed individual cells in culture and tested the robustness of our experimental workflow. We choose the K562 cells, a human immortalized myelogenous leukemia line and F-T21, a human primary Trisomy 21 fibroblast cell line. We used the C1 Single Cell Auto Prep System (Fluidigm) to capture hundreds of individual cells and to generate high quality of individual amplified DNA. So far, 96 barcoded whole-exome libraires were sequenced at deep coverage (PE, 100bp). Variant calls (CNVs and SNVs) were generated with an in-house analysis pipeline. Here, we will discuss the amplification uniformity, the detectable fraction of the exome and the level of DNA contamination. By comparing single cells and bulk of cells datasets, we will assess the percentage of allelic drop out for each each single-cell exome based on the heterozygous SNVs. High quality single-cell genome sequence will greatly enhance the genetic analysis of somatic genomic disorders. C.B. and P.R. contributed equally.

Recent data from genome-wide chromosome confirmation capture analysis (Hi-C) indicate that the human genome is divided into conserved megabase-sized local chromatin self-interacting regions called topological domains. These topological domains form the regulatory backbone of the genome and are separated by regulatory boundary elements or barriers. Copy-number variations (CNVs) can potentially alter the topological domain architecture by deleting or duplicating the barriers and thereby allowing enhancers from neighboring domains to ectopically activate genes causing misexpression and disease, a mutational mechanism that has recently been termed “enhancer adoption". In this study the Human Phenotype Ontology (HPO) database was used to relate the phenotypes of 922 deletion cases recorded in the DECIPHER database to monogenic diseases associated with genes in or adjacent to the deletions. We sought combinations of tissue-specific enhancers and genes adjacent to the deletion and associated with phenotypes in corresponding tissue, whereby the phenotype matched that observed in the deletion. We compared this computationally with a gene-dosage pathomechanism that attempts to explain the deletion phenotype based on haploinsufficiency of genes located within the deletions. Up to 11.8% of the deletions could be best explained by enhancer adoption or a combination of enhancer adoption and gene-dosage effects. Our results suggest that enhancer adoption caused by deletions of regulatory boundaries may contribute to a substantial minority of CNV phenotypes and should thus be taken into account for their medical interpretation.

591T

Sensitive and efficient analysis of somatic mosaicism using genomewide SNP arrays and haplotypes. *S. Vattathil[1,2], L. Huang[2], P. Scheet[2,1].* 1) Human and Molecular Genetics Program, University of Texas at Houston Graduate School of Biomedical Sciences, Houston, TX; 2) Epidemiology, University of Texas MD Anderson Cancer Center, Houston, TX.

More comprehensive characterization of somatic mosaicism allows better inference of background mutation rates and mechanisms and will help define the relevance of somatic mutation to human phenotype. Among the challenges to practical survey of somatic mutations is that detection methods must be at once sensitive (since mutations may exist in only a small fraction of sampled cells), efficient (since the rate of mosaicism is low and many samples must be analyzed), and agnostic (since mutation locations are not known *a priori*). hapLOH, a computational algorithm we developed, provides sensitive, efficient, and agnostic profiling of somatic chromosomal imbalance using best-guess haplotype estimates and whole-genome SNP array data. We used hapLOH to characterize mosaicism in 31,223 individuals from 10 studies conducted as part of the GENEVA Consortium. We called 1,134 mosaic mutations (ranging in size from 42 Kb to 146 Mb [all of chromosome 8]) in 895 individuals, which is a substantially higher rate than the original published analysis of these data (Laurie *et al.*, Nat. Gen., 2012). The results validate recent predictions that the extent of somatic mosaicism has been underestimated due to lack of sensitivity for low-frequency mutations, and confirm the value of using haplotype information for sensitive detection of allelic imbalance. We describe the locations of recurrent somatic mutations, which are likely to contain genes important for proliferation, and copy number classifications for events with sufficient log R ratio evidence. Since hapLOH is sensitive to very low-frequency events, more than half of the observed calls cannot be classified even though the signal of imbalance is strong. Sample-specific empirical null simulations and comparisons of observed B allele frequency and log R ratio shifts to predicted values suggest the rate of false positives is low. Incidentally, we found that depressed phase concordance can distinguish inherited from somatic mutations.

592S

Monozygotic Twin Pairs: CNV and sequence concordance. *A. Abdellaoui[1], E. Ehli[2], J.J. Hottenga[1], Z. Weber[2], H. Mbarek[1], G. Willemsen[1], T. van Beijsterveldt[1], A. Brooks[3], J.J. Hudziak[4], P.F. Sullivan[5], E.C.J. de Geus[1], K. Ye[6], P.E. Slagboom[7], G.E. Davies[2], D.I. Boomsma[1].* 1) Biological Psychology, VU University Amsterdam, Amsterdam, Noord Holland, Netherlands; 2) Avera Institute for Human Genetics, Avera McKennan Hospital & University Health Center, Sioux Falls, SD, USA; 3) Department of Genetics, Rutgers, The State University of New Jersey, Piscataway, New Jersey, USA; 4) University of Vermont, College of Medicine, Burlington, VT, USA; 5) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 6) The Genome Institute, Washington University School of Medicine, St. Louis, Missouri, USA; 7) Molecular Epidemiology, Leiden University Medical Center, Leiden, Netherlands.

Monozygotic (MZ) twins are genetically identical at conception, making them informative subjects for studies on somatic mutations. Copy number variants (CNV) are responsible for a substantial part of genetic variation, have relatively high mutation rates, and have been associated with susceptibility to disease, such as autism and schizophrenia. We conducted a genome-wide survey for post-twinning de novo CNVs (i.e., not shared by co-twins) in ~1,100 MZ twin pairs who had been repeatedly phenotyped across a wide range of traits, and of which a large proportion has gene-expression and methylation data available. CNVs from 1,097 MZ twin pairs were measured in DNA from peripheral blood samples (mostly in adults) or buccal epithelium (mostly in children) with the Affymetrix 6.0 microarray. Whole-genome sequencing was performed in DNA from blood samples from 13 MZ twin pairs and their parents (12x coverage - Illumina, and 2 twin pairs additionally sequenced with Complete Genomics). We found a total of 153 putative post-twinning de novo CNVs >100 kb, of which the majority resided in the same unstable genomic region (15q11.2). Based on how well the raw intensity signals visually agreed with CNV calls made by the two algorithms, a first selection was made of eleven de novo CNVs from 15q11.2 for a first series of qPCR validation experiments. Two out of eleven post-twinning de novo CNVs were validated with qPCR in the same twin pair. This 13-year old twin pair did not show large phenotypic differences. The remaining putative de novo CNVs from 15q11.2 were found significantly more often in older twins, suggesting that we are capturing real signals. The large putative de novo CNVs detected with microarray data were not present in the subsample that had whole-genome sequence data available. We do expect the whole-genome sequence data to allow us to search for smaller de novo CNVs that cannot be detected with micro-array data.

593M

Even and odd: defining the structure of variation at the human amylase CNVs. *J.A.L. Armour[1], D. Carpenter[1], S. Dhar[1], L.M. Mitchell[1], B. Fu[2], J. Tyson[1], N. Shwan[1], F. Yang[2], M.G. Thomas[3].* 1) School of Life Sciences, University of Nottingham, Nottingham, UK; 2) Wellcome Trust Sanger Institute, Hinxton, UK; 3) Research Department of Genetics, Evolution and Environment, University College London, UK.

The human amylase genes are a long-established example of a human gene CNV, and may have undergone adaptive changes in human evolution. Genotyping amylase variation accurately has been problematic because of both the wide range of salivary (*AMY1*) CNV (with copy numbers commonly in the range 2–14), and the high sequence similarity between *AMY1* and neighbouring pancreatic amylase (*AMY2A/AMY2B*) genes. Most published work has measured *AMY1* gene copy number using qPCR, and presented this CNV as a quasi-continuous variation independent of *AMY2A/2B*. Using PRT and other methods capable of resolving individual repeat unit differences, we have been able to characterise the amylase CNVs in unprecedented detail, demonstrating that in all populations studied most amylase haplotypes contain an odd number of copies of *AMY1*, and therefore that most people have an even diploid total. These conclusions match those defined by Groot *et al.* 25 years ago using segregation analysis of Southern blot hybridization patterns, and are supported by new fibre-FISH analysis. We have now also defined less common haplotypes containing even numbers of *AMY1*, which are associated with CNVs of pancreatic amylase (*AMY2A/2B*) genes. We have defined four different series of variant haplotypes containing even numbers of *AMY1* in combination with *AMY2A/2B* deletions or duplications. These haplotypes show significant differences between populations studied, with about 20% of Europeans carrying an odd number of copies of *AMY1* and a deletion or duplication of *AMY2A*. Our measurements, including fibre-FISH data, also suggest error in the qPCR calibration of data presented by Perry et al, resulting in the systematic underestimation of *AMY1* copy number in their study claiming natural selection for high copy numbers in populations with traditionally high-starch diets. Calibration derived from Perry *et al.* was adopted by the recent BMI association study of Falchi *et al.*, suggesting that the copy number determination in that study may also have been subject to a similar systematic error. Overall, our conclusions would not be accessible to those measurement methods (such as qPCR) incapable of accurately resolving individual repeat unit differences at high copy number.

594T

Genome-wide analysis of copy number variants and their association with kidney transplantation outcomes. *L. Bassaganyas[1,2], PY. Kwok[1,2].* 1) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA.

Kidney transplantation is the treatment of choice for end-stage renal failure in terms of patient survival and quality of life. However, acute rejection (AR) and chronic allograft nephropathy (CAN) remain obstacles to post-transplant health in most of patients. The success/failure of kidney transplantation mainly depends on inflammatory and immune factors that might be influenced by genetics, but the specific association between gene variants and graft survival/rejection is still poorly understood. Copy number variants (CNVs) affect both normal phenotypic variation and disease and are mostly enriched by genes involved in inflammation and immune response. We examined the potential influence that immune-related genes within CNV regions might have in different transplant outcomes. Using DNA microarray data and the PennCNV-Affy algorithm, we obtained the CNV profiles for 536 (270 donors and 266 recipients) patients previously grouped in three different outcomes: normal working transplant (TX), AR and CAN. The comparison between CNVs detected for each group revealed a higher number of gains in CFHR3 and CFHR1 genes among TX samples and a higher frequency of losses of these genes in AR subset, suggesting a role of the complement system regulation in the graft survival. Moreover, we found more CNVs affecting KIR genes in AR recipients and CAN donors in comparison with TX samples, implying that specific genomic architecture of the polymorphic KIR locus might have an influence to the renal transplant outcome. This study constitutes the first report on the risk association between CNVs and the kidney transplantation outcomes.

Inverted repeats mediate complex genomic rearrangements including quadruplication. *C.R. Beck[1], C.M.B. Carvalho[1,2], L. Banser[3], T. Gambin[1], D. Stubbolo[3], B. Yuan[1], K. Sperle[3], S.M. McCahan[3,4], M. Henneke[5], P. Seeman[6], G.M. Hobson[3,4,7], J.R. Lupski[1,8,9].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Centro de Pesquisas Rene Rachou- FIOCRUZ, Belo Horizonte, MG, Brazil; 3) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 4) Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA; 5) University Medical Center Göttingen, Georg August University, Department of Pediatrics and Adolescent Medicine, Division of Pediatric Neurology, Germany; 6) Department of Pediatric Neurology, 2nd Faculty of Medicine, Charles University and Motol University Hospital, Prague, Czech Republic; 7) University of Delaware, Department of Biological Sciences, Newark, DE; 8) Department of Pediatrics and Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 9) Texas Children's Hospital, Houston, TX.

Inverted repeats (IRs) predispose loci to inversions and can lead to copy number alterations by mediating complex genomic rearrangements (CGRs). Clustering of breakpoints in cases of duplication and triplication of the dosage sensitive *PLP1* gene occurs within three sets of distal (telomeric), nested inverted repeats. These CGRs result in Pelizaeus-Merzbacher disease (PMD, MIM #312080), and approximately 80% of PMD individuals have amplification of *PLP1*. We systematically investigated the region encompassing *PLP1* in both unaffected and affected individuals to identify the IRs responsible for the CGRs and the mechanism of rearrangement. In phenotypically normal individuals, we identified a copy number neutral polymorphism between a set of IRs in the cluster. Southern blotting determined that the inversion is prevalent in the population, with a frequency of approximately 40%. Furthermore, integrating these data with sequence information for the locus showed that inversion alleles were present on two haplotypes in the region. Therefore, there is a common polymorphic inversion at this locus that appears to be recurrent. We have assembled a cohort of 17 Individuals affected with PMD who have breakpoints clustering within the distal IRs. The 17 patients all have CGRs, and duplication-inverted triplication-duplication rearrangements were observed in 16 individuals. Through array comparative genomic hybridization, Southern blotting, quantitative PCR, and cloning methodologies, we determined that the IRs responsible for the inversion are implicated in these rearrangements. Breakpoint junction analysis has underscored the presence of point mutations close to CGRs that are replicative in origin and the presence of additional template switches at 5/17 or ~30% of these events. Finally, in one patient, a CGR resulting in duplication of *PLP1* and quadruplication of a proximal genomic region was identified. In this patient, junction sequencing revealed that the mechanism of formation is consistent with rolling-circle amplification; a mechanism predicted by the microhomology-mediated break-induced replication (MMBIR) model. Thus, detailed analysis of the *PLP1* locus has provided experimental evidence for another mechanism by which inverted repeats affect genomic change.

The 600kb 16p11.2 duplication and deletion (BP4-BP5) are among the most frequent copy number variants, and the duplication is associated with neurodevelopmental disorders, including autism spectrum disorder, schizophrenia, and a decrease in head circumference and BMI. The 16p11.2 locus, like duplications of other genomic regions, shows highly variable expressivity and incomplete penetrance. To decipher the complex effects of the 16p11.2 duplication on cognitive, behavioral, medical, and anthropometric traits, we studied a cohort of 270 duplication carriers as well as a group of 184 deletion carriers from the 16p11.2 European and Simons Variation in Individuals Project (Simons VIP) consortia. We used linear mixed models to estimate the effect of the duplication, compared to non-carrier family members, on cognitive and anthropometric traits, while accounting for age, gender, head circumference (HC), consortium, and family effects. Global cognition is significantly impacted by the duplication. The largest effect is observed in probands with an average decrease in full scale IQ (FSIQ) of 21 points relative to non-carrier family members after adjusting for covariates. In carriers ascertained through cascade family testing, this decrease is 12 points in pediatric non-proband carriers and 9 points in adult carriers. The large FSIQ variance is a striking feature of the duplication with increased proportions at both extremes of the IQ distribution when compared to the 16p11.2 deletion group. Paradoxically, while the mean FSIQ in duplication carriers is higher than that of the deletion carriers (79.1 vs. 77.4), the frequency of very low FSIQ (<40) is increased 15-fold in the duplication compared to the deletion group (7.7% vs 0.5%). ASD was diagnosed in 13.7% of the duplication carriers. Additional DSM-IV diagnoses were present in 41% of the carriers. The duplication was associated with a 0.5 and 1 standard deviation decrease in HC and BMI, respectively, compared to their non-carrier family members. The duplication is associated with a greater range in neurocognitive phenotype when compared to the reciprocal deletion. Although carriers of second deleterious CNVs were excluded from this analysis, additional genetic variants may be contributing to the phenotype of the cognitively severely impaired duplication carriers.

597T

Population genetics and mutation analysis of an exceptionally copy number variable sperm gene. *A. Davis[1,2], S.A. McCarroll[1,2].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) The Broad Institute of Harvard and MIT, Cambridge, MA.

Though multiallelic copy number variants (mCNVs) cover thousands of genic and intergenic regions of the human genome, little is known about their population distributions and even less about their mutability. It is commonly assumed that mCNVs mutate with high frequency, but their mutational events and other population genetic properties have been hard to observe, as mCNVs have been difficult to analyze molecularly. We have investigated these properties for *SPANXB* (sperm protein associated with the nucleus on the X chromosome family member B), a sperm protein-encoding gene that is extremely copy number variable in humans. We developed molecular assays that yield crisp integer measurements of *SPANXB* copy number. We observe from one to ten copies of the 12kb *SPANXB*-containing duplication per chromosome, and see striking differences in copy number distribution between African, Asian, and European populations (HapMap/1000 Genomes YRI, CHS, CEU, and IBS). This copy number variation is not well captured by SNPs, as the highest correlation (r^2) between a SNP and SPANXB copy number is 0.37. In analysis of phased haplotypes containing SNP and CNV alleles, we find that individual copy number alleles are captured with r^2 ranging from 0.006 to 0.61. We also determined that copy number of *SPANXB* is correlated with its RNA expression in sperm by examining DNA and RNA from sperm samples from 30 individuals. Few new copy number mutations have been observed for highly multiallelic CNVs such as *SPANXB*, though the presence of many copy number alleles in human populations suggests that they have mutated many times among human ancestors. Due to the presence of many segregating copy number alleles, new mutations are difficult to observe using the canonical method of examining offspring for differences in genotype from their parents. We have leveraged genotype and sequence data to identify pairs of men with recent shared ancestry in the genomic region surrounding *SPANXB* and determined *SPANXB* copy number in these individuals. Among 50 pairs with recent shared ancestry drawn from a cohort of 7079 males, we observe three copy number mutation events at *SPANXB*, all in pairs of men whose shared ancestry at the locus is at least seven generations old. As we expand our approach to larger and different cohorts, we anticipate building more complete models of the mutational properties of this and other mCNV loci.

598S

Functional Effects of Copy Number Variant Junctions. *K. Dumas[1], J.T. Shieh[1,2].* 1) Division of Medical Genetics, Department of Pediatrics, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA.

Copy number variation can cause genic interruptions and novel transcripts. Investigating the functional impact of these events may yield insight into an important source of human genetic variation. The goal of this investigation is to study the impact of rare, disruptive germline CNVs on protein behavior. Rare copy number variants in 13 patients of the UCSF study of congenital anomalies were identified using Affymetrics SNP 6.0 genotyping arrays. After stringent CNV calling, predicted breakpoints within genes were identified and validated by sequencing CNV boundaries. Endogenous and truncated transcripts, representing wild type and disrupted alleles respectively, were cloned and eGFP fusion constructs generated for protein studies. Expression studies in 293T cells, imaging, and western blot analysis were performed to determine protein production, stability and secretion in culture. We found that duplications have the potential to create novel, altered transcripts. Sequencing and RT-PCR analysis revealed that one such CNV breakpoint led to transcript truncation but successful RNA expression in primary patient tissue. As full length and truncated (69% of full length amino acid content) products were possible, both products were investigated. Protein made from a full length construct in transfected cells was expressed normally and secreted, whereas protein made from the truncated construct was produced but altered in expression and behavior. These data demonstrate rare CNVs can create novel transcripts that alter the protein repertoire. Further investigation should be directed at understanding the role of disruptive CNVs in protein function.

Identifying Population-Specific Structural Variation in Human Blood Group Genes. *K. Fox[1], T. Shaffer[1], D. Crosslin[1], M. Delaney[2,3], J. Johnsen[2,4], D. Nickerson[1].* 1) School of Medicine, Genome Sciences, University of Washington, Seattle, WA, USA; 2) Puget Sound Blood Center, Research Institute, Seattle WA, USA; 3) University of Washington, Department of Laboratory Medicine, Seattle, WA, USA; 4) University of Washington, Department of Medicine, Seattle, WA, USA.

Blood type determination *via* hemagglutination is the clinical gold standard. Assigning units of blood based on serological typing can sometimes fail to identify less common blood type variants, risking exposure of the recipient to clinically significant allo-antigens. Blood types reflect genetic variation at blood group genes, which harbor low frequency variants encoding hundreds of blood types not detected by conventional blood typing. High throughput sequencing approaches, such as exome sequencing, have the potential to assign high resolution blood types based on DNA sequence data. Rh (*RHD, RHCE*) and MNS (*GYPA, GYPB, GYPE*) blood group genes contain known, common structural variants (SVs) that result from unequal crossing-over or gene conversion events. However, the influence of SV characterization on blood typing for cross-matching has yet to be fully explored.

Allosensitization is most common in chronically transfused patients, particularly in sickle cell disease (SCD) which affects 1 in 500 African-Americans. SCD patients are exposed to multiple blood donors over their lifetimes, and are at high risk (>20%) of developing significant alloantibodies. The National Heart, Lung, and Blood Institute (NHLBI) funded the Exome Sequencing Project (NHLBI-ESP), and, through this effort, subjects of African-American (n=1,714) and European ancestry (n=3,405) with heart-, lung-, and blood-related phenotypes were exome sequenced. Using these data, we present read-depth-based SV calls, including 70 unique duplications and 66 unique deletions in six human blood group genes (*ABO, RHD, RHCE, GYPA, GYPB, GYPE*) from 5,119 exomes with >20X coverage. We confirmed known deletions (Rh D-, MNS GPB null) and have identified novel SV in the ABO blood group gene (deletion of *ABO* exons 5–7, predicting blood type O). These analyses highlight the need for further studies not only to characterize the diversity of SV in these genes, but also to explore the phenotypic effects of such variation in the context of transfusion medicine.

600T

Characterization of Copy Number Variation and Loss of Heterozygosity Using high resolution SNP MicroArray -The Miami Experience. *G. Ghaffari[1], B.J. Ilagan[1], C. Hung[1], S.A. Hosseini[1], P. Benke[2], R. Yusupov[2], L. Brenton[1], M. Rodriguez[1], B. Johnson[1], O.A. Bodamer[1].* 1) Division of Clinical and Translational Genetics, Dr. John T. Macdonald Foundation, Department of Human Genetics, University of Miami, Miller School of Medicine, Miami, FL 33136, USA; 2) Memorial Regional Hospital, 1150 N 35th AVE # 490, Hollywood, FL., 33021, USA.

Background: MicroArray analysis is considered the first-tier clinical diagnostic test for individuals with unexplained developmental delay/intellectual disability (DD/ID), autism spectrum disorders (ASD), and/or multiple congenital anomalies (MCA). In addition to clarification of chromosome deletions and duplications; Microarray provides information regarding long contiguous stretches of homozygosity (LCSH). Here we report the results of MicroArray analysis from patients with DD, ASD, and MCA referred to the Clinical Molecular Genetic Laboratory (CMGDL), at the University of Miami from June 2012 to May 2014. Methods: The Illumina HumanOmni1-Quad or CytoSNP-850K BeadChip (Illumina,CA) array platforms were used to determine the presence of Copy Number Variations (CNVs) and or Loss of Heterozygosity (LOH) from 150 . CNV was reported based on gene content and phenotype previously mapped to the called regions. LOH was reported based on the size and gene content related to the reported clinical phenotype. ACMG-recommended terminology was used to report the results. Results: Pathogenic copy number variations were detected in 19/150 (12.6%) patients ranging from 77Kb to whole chromosome gain or loss. Pathogenic CNVs were detected in the following chromosomes: chr. 16 in 5 patients (16p11.2;16p12.2; 16q23.1q23.2); X chr.in 5 patients, including a Mosaic Turner syndrome; chr. 1 in 3 patients (1q31.3;1q43q44;1q41q44); chr. 22 in 2 patients (22q11.22 q11.23; 22q11.21); chr. 5 (5q13.2); chr. 6 (6q27); chr. 18 (18p11.32q23). LOH was detected in 18/150 (12.0%) patients ranging from 6 Mb to 600 Mb. 83 (55.3%) patients had no CNVs or LOH spanning any genes or genes known to be associated with disease. Their results were reported as normal. In 30 (20%) patients we detected CNVs of uncertain significance. Conclusion: These results demonstrate the utility of SNP genotyping data for the detection of clinically significant abnormalities including CNVs, mosaism or LOH which may harbor recessive mutations. Interpretation of LCSH and CNVs remains challenging particularly without detailed clinical information.

601S

The role of the genomic architecture of transposable elements in the formation of copy number variants: evidence from one schizophrenia family. *G. Guffanti[1], S. Gaudi[2], P. DeCrescenzo[1], H. Mangalam[3], A. Rodriguez[4], R. Madduri[4], C. Pato[5], F. Macciardi[6].* 1) Department of Psychiatry Division of Epidemiology & Division of Child and Adolescent Psychiatry Columbia University/NYSPI New York, NY; 2) Istituto Superiore di Sanita', Rome, Italy; 3) OIT, University of California, Irvine, Irvine, CA; 4) MCS Argonne National Laboratory Computation Institute, University of Chicago; 5) Department of Psychiatry and the Behavioral Sciences Keck School of Medicine, USC, Los Angeles, CA; 6) Dept of Psychiatry & Human Behavior, University of California, Irvine, Irvine, CA.

Many CNVs are flanked by transposable elements (TE). It is emerging that the genomic architecture of TE might predispose certain regions to the mutational mechanisms that result in CNVs. The breakpoints of CNVs are frequently observed within the repetitive sequences of TEs, including SINE, LINE, and LTR, which suggested that regions of the genome that possess repeat sequences are more prone to rearrangements arising independently in different individuals. We sought to explore the role of TEs flanking de novo and inherited CNVs in a family of four siblings, three schizophrenia probands and one unaffected sibling, descending from a schizophrenia affected mother and an unaffected father. This family is part of the Genomic Psychiatric Cohort (GPC) sample (Pato et al, 2013). We used ForestSV to assess CNVs from whole genome sequences (~40x). CNV deletions were included in the analysis if the prediction confidence score was >0.7, which keep the error rate below 5%. First, we determined pattern of transmission of CNV deletions from the affected mother and the unaffected father to three probands and sibling; second, we estimated the prevalence of reference TEs (hg19) in 1,000 bp regions upstream and downstream the breakpoints of de novo and inherited CNVs. The number of CNVs per individual ranged from 2,020 to 2,131 unique deletions. We discovered a total of 3,780 inherited autosomal deletions, including 657 transmitted to probands and 101 to the unaffected sibling, respectively. 575 deletions were found in one or more siblings but not in the parents and were classified as de novo. Of these, 327 de novo deletions were unique to the probands, 61 to the sibling and 191 were shared by siblings, both affected and unaffected. Structurally, more than 60% of de novo deletions were flanked with Alus, 50% with LINEs and 65% with LTR at either the 5' or 3'. Our survey of regions at the breakpoints of CNVs deletions confirm the pattern of genomic instability introduced by the repeat sequences of TE and support their role in the mechanisms that lead to copy number variants formation.

602M

De novo Germline Variants from WGS of Autism Spectrum Disorder Trios. *M. Gujral[1], W. Brandler[1], D. Malhotra[1], J. Estabillo[1], T. Gadomski[1], A. Watts[1], T. Chapman[1], D. Antaki[1], T. Solomon[1], A. Moyzis[1], A. Bhandari[1], L. Wong[1], C. Corsello[1], N. Akshoomoff[1], L. Iakoucheva[1], E. Courchesne[2], J. Sebat[1].* 1) Psychiatry, University of California, San Diego, La Jolla, CA., USA; 2) Neuroscience, University of California, San Diego, La Jolla, CA., USA.

Autism spectrum disorder is a genetic anomaly with diverse footprints. Based on the recent clinical estimates, it impacts more than 1% of the children around the globe. In last few years, there has been considerable effort to delineate the genetic basis of the disorder through genome sequencing projects. Despite finding several rare de novo genetic variants from exome and whole genome sequence studies, many rare variants remain to be discovered. Here, we report rare de novo genetic variants through the whole genome sequencing of 161 samples comprising of 47 probands, 19 healthy siblings, their 46 parent-pairs, and a healthy family trio contributed by total of 47 families. All de novo single nucleotide variants (SNVs) and copy number variations (CNVs) were detected through the machine learning approaches applied to the processed data for 67 trios. Our findings include three novel de novo nonsense mutations, five de novo deletions and one duplication, all six CNVs are > 10 kb. These CNVs, five de novo deletions and a single duplication, have been validated through Affy6 and Illumina array platforms. The three nonsense mutations observed in probands are likely pathogenic. All the four de novo deletions observed in probands are rare and encompass exons. Largest de novo SV in our samples is ~500 kb duplication observed in a proband spanning through several genes. Taken together, it is clear that the burden of de novo nonsense SNVs and CNVs is heavily skewed towards the probands. We have been able to determine the parent of origin for about 30% of total de novo SNVs and one forth of the SNVs are contributed by mother.

603T

Multi-allelic copy number variation humans. *R. Handsaker[1,2,3], V. Van Doren[2], L. Boettger[2], S. McCarroll[1,2,3].* 1) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 2) Department of Genetics, Harvard Medical School, Boston MA; 3) Stanley Center for Psychiatric Research, Cambridge, MA.

Copy number variation (CNV) is widespread in human populations, affecting thousands of genes and functional elements. Progress has been made in recent years in understanding simple, di-allelic CNVs that arise by one-step deletion or duplication. A substantial fraction of all inherited CNVs in humans, however, is contributed by variants that appear in different genomes at high frequency and in widely different numbers of copies (from 2 up to 12 or more copies). The inability to molecularly type multi-allelic CNV (mCNV), due to the wide range of copy numbers present in different genomes and the difficulty of molecularly discriminating high copy numbers, have excluded mCNV from most studies of human genetic and phenotypic variation. The structural alleles and haplotypes that segregate at such loci and their relationship to phenotypes remain largely unknown.

To address these questions, we first developed novel ways to use increasingly abundant whole genome sequencing data to identify mCNV loci and the copy number alleles that segregate at these loci. We applied these methods to 849 genomes sequenced in Phase 1 of the 1000 Genomes Project at low coverage and to hundreds of other deeply sequenced genomes, creating a locus, allele and haplotype map for human duplication CNV. We typed 3,926 duplication CNVs, of which 1,432 appear to exhibit three or more alleles. We also developed new molecular-biological assays to evaluate genotype accuracy at these loci. The discrete integer copy number determinations from these assays are highly (99%) concordant with our computational inferences from sequencing data, even at high copy numbers (4–9), suggesting that both methods are highly accurate.

We evaluated the impact of CNV on gene dosage and find that 90% of the impact on gene-dosage variation arises from about 100–200 highly polymorphic mCNVs. Using published RNAseq data, we observe that differences in gene dosage almost always lead to corresponding changes in gene expression. We describe a phenomenon of “runaway” duplication haplotypes, on which specific genes have mutated to high copy number on specific haplotypes in specific human populations during the past 50,000 years. We developed methods and data resources to statistically impute mCNV alleles from SNP haplotypes, and describe both successes and limitations in imputing these genetic variants, as a means to relate them to phenotypes in large association studies.

604S

Comparative performance analysis of high-resolution, genome-wide array platforms for copy number variation detection. *R.R. Haraksingh[1], A. Abyzov[2], A.E. Urban[1].* 1) Psychiatry, Stanford University, Palo Alto, CA; 2) Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN.

Copy Number Variation (CNV) is a major class of genomic variation in humans. Many CNVs are benign and constitute normal variation while others have pathogenic effects. Detecting CNVs genome-wide at high resolution and determining their nature (i.e. deletions or duplications) is important for both clinical diagnostics and biomedical research. At present, sequencing-based CNV detection cannot affordably compete with array-based methods. Clinical cytogenetics relies heavily on arrays for detecting pathogenic CNVs. Array-based genome-wide CNV detection platforms are also used to efficiently and cost effectively study genome structure in large cohorts and to track genome structural stability for quality control in cell cultures, particularly in stem cell model systems. Array-based CNV calls also provide orthogonal validation of sequencing-based calls. In this study, we characterize the relative performances of all currently available commercial high-density oligonucleotide arrays for genome-wide CNV detection. This follows up on our earlier study [PMID: 22140474] using a previous generation of arrays. Here, we collected CNV data from 15 different array designs: two Affymetrix, four Agilent, and nine Illumina designs. The extensively characterized HapMap/1000 Genomes sample, NA12878, was hybridized to each array in two technical replicates. Two sets of CNVs were then called from each array. One set was called by the company-recommended software. The other was called using Nexus Copy Number software by Biodiscovery as a uniform process for all the platforms. Each call set was then compared to a gold standard derived from the 1000 Genomes Project sequencing data. The gold standard contains only very high confidence CNVs found by sequencing in NA12878, and supported by multiple analytic principles (e.g. paired-end, split-read, or read-depth analysis), experimental validation (e.g. PCR), or both. We determined the overall sensitivities of the platforms for genome-wide CNV calling, and whether any of the platforms perform better at discovering particular subtypes of CNVs such as those in a specific size range or genomic context, or of a specific nature. Generally, arrays with more probes and those targeted to known CNV regions while maintaining sufficient genome-wide coverage show the highest number of CNV calls and sensitivities, most accurate breakpoint resolution, and largest size range of CNV calls. A breakdown of results for each platform will be presented.

Discovering Copy Number Variations in ClinSeq®: A Large-Scale Whole Exome Sequencing Study. *C.S Hong[1], D. Ng[1], L.N. Singh[1], N.F. Hansen[2,3], J.C. Mullikin[2,3], L.G. Biesecker[1,2].* 1) Medical Genomics and Metabolics Genetics Branch, National Human genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 2) NIH Intramural Sequencing Center, National Human genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 3) Comparative Genomics and Cancer Genetics Branch, National Human genome Research Institute, National Institutes of Health, Bethesda, MD.

Copy number variations (CNVs) can alter gene expressions and cause pathological conditions. Using CNV prediction tools, we comprehensively examined exome sequences from the ClinSeq® project for CNVS using publicly available software: the XHMM software suite. ClinSeq® is a clinical sequencing project composed of 971 individuals from the metro D.C. area who are enrolled for whole exome sequencing. For each individual, more than 100 clinically relevant phenotypes and family history are measured and recorded. The exome sequences were analyzed for copy number variations (CNVs) using publicly available software: XHMM software suite. A total of 12,606 CNVs were (1695 deletions and 7910 duplications) called in 971 samples. The median size of all calls was 12,960 bp. Real-time PCR validations of putative CNVs in CYP2D6 of 26 samples were all verified at 100% confirmation rate, suggesting highly sensitive predictions. Functional enrichment analysis by DAVID showed that the list of non-singleton genes in putative CNV regions was enriched for Ca2+ dependent cell-cell adhesion, keratin/intermediate filament, and olfaction. The most prevalent CNV occurred in TYRO3, with 188 individuals (19% of ClinSeq® population) predicted to have a CNV in TYRO3. This result is in agreement with the high prevalence of a polymorphic retrocopy insertion of TYRO3 into an intron of the ENOX1 gene on chr13. We also observed evidence of a fusion gene, TFG-GPR128. Our findings demonstrate the value of CNV and structural variant analysis from exome sequence in clinical settings.

Optimization of a High-Throughput, Cost-effective, Reliable Method for Large-Scale Screening of CNVs at Candidate Loci using qPCR. *C. Kao, R. Pellegrino, J. Garifallou, T. Guettouche, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Copy number variations (CNVs) are known to contribute to phenotypic diversity and can be causative factors for many types of human disorders and diseases. Array-based methods are the most common and reliable means for detecting CNVs and providing estimates of CNV length and boundaries. However, these array-based technologies are not necessarily cost-effective for assessing small numbers of candidate loci and require turnaround times of weeks to months for custom-designed arrays to be produced, which becomes impractical for particular applications. We were interested in screening for rare CNVs across five known pathogenic loci (22q11.21, 16p11.2, 15q13.3, 2p16.3, and 2p25.3) across the biobank collection at the Center for Applied Genomics, which contains samples approaching 200,000 in total. Herein, we describe the development of a cost-effective workflow to screen candidate loci for CNVs via quantitative, real-time PCR in a high-throughput format. We find that particular "master mix" reagents perform more robustly than others in terms of stability/shelf-life, ability to withstand variations in DNA quality, and uniformity across different primer/probe sets. We also establish quality control (QC) metrics based on amplification curve parameters to "weed out" false-positives arising from poor sample quality and developed a robust clean-up protocol for problematic samples that fail QC. The sensitivity and selectivity of this qPCR workflow is compared in ~1,000 samples where CNV calling based on an orthogonal approach (i.e. SNP-based whole-genome arrays) was also done, and the performance of both approaches showed remarkable concordance. Thus, our approach provides a cost-effective means for screening for candidate CNVs across large (multi-thousand) sample sets in a rapid, high-throughput manner with an unprecedented level of rigor and consistency that previously had not been achieved using standard qPCR-based workflows.

SVA retrotransposon insertion-associated deletion represents a novel mutational mechanism underlying large genomic copy number changes with non-recurrent breakpoints. *H. Kehrer-Sawatzki[1], J. Vogt[1], K. Bengesser[1], S. Bammert[1], K.B.E. Claes[2], K. Wimmer[3], V.F. Maunter[4], R. van Minkelen[5], E. Legius[6], H. Brems[6], M. Upadhyaya[7], C. Lazaro[8], J. Högel[1], T. Rosenbaum[9], L. Messiaen[10], D.N. Cooper[7].* 1) Human Genetics, University of Ulm, Ulm, Germany; 2) Centre for Medical Genetics, Ghent University Hospital, Belgium; 3) Division of Human Genetics, Medical University Innsbruck, Austria; 4) Department of Neurology, University Hospital Hamburg Eppendorf, Germany; 5) 5 Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 6) Department of Human Genetics, KU Leuven, Belgium; 7) Institute of Medical Genetics, School of Medicine, Cardiff University, UK; 8) Molecular Diagnostics Unit, Hereditary Cancer Program, Catalan Institute of Oncology (ICO-IDIBELL), L'Hospitalet de Llobregat, E-08908 Barcelona, Spain; 9) Department of Pediatrics, Duisburg General Hospital, Germany; 10) Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, Alabama, USA.

Background: Genomic disorders are caused by copy number changes that may exhibit recurrent breakpoints processed by nonallelic homologous recombination. However, region-specific disease-associated copy number changes have also been observed which exhibit non-recurrent breakpoints. The mechanisms underlying these non-recurrent copy number changes have not yet been fully elucidated. Results: We analyze large NF1 deletions with non-recurrent breakpoints as a model to investigate the full spectrum of causative mechanisms, and observe that they are mediated by various DNA double strand break repair mechanisms, as well as aberrant replication. Further, two of the 17 NF1 deletions with non-recurrent breakpoints, identified in unrelated patients, occur in association with the concomitant insertion of SINE/variable number of tandem repeats/Alu (SVA) retrotransposons at the deletion breakpoints. The respective breakpoints are refractory to analysis by standard breakpoint-spanning PCRs and are only identified by means of optimized PCR protocols designed to amplify across GC-rich sequences. The SVA elements are integrated within SUZ12P intron 8 in both patients, and were mediated by Target-Primed Reverse Transcription of SVA mRNA intermediates derived from retrotranspositionally-active source elements. Both SVA insertions occurred during early postzygotic development and are uniquely associated with large deletions of 1 Mb and 867 kb, respectively, at the insertion sites. Conclusions: Since active SVA elements are abundant in the human genome and the retrotranspositional activity of many SVA source elements is high, SVA insertion-associated large genomic deletions encompassing many hundreds of kilobases could constitute a novel and as yet under-appreciated mechanism underlying large-scale copy number changes in the human genome.

Genome-wide association study of copy number variation with hematological traits using family-based Samples. *B. Kim[1], S. Moon[1], M. Liu[2], Y. Kim[1], M. Hwang[1], Y. Kim[1], R. Elston[3], B. Han[1], S. Won[2].* 1) Korea National Institute of Health, Chungwon-gun, South Korea; 2) Chung-Ang University, Seoul, South Korea; 3) Western Reserve University, Cleveland, OH.

Copy number variants (CNVs) are widely distributed throughout the human genome (Feuk et al., 2006; Sharp et al., 2006) and have been considered as important genetic factors for human diseases (Lupski, 2008; McCarroll and Altshuler, 2007). It is known to play an important role in the genetics of complex diseases. In this study, we performed genome-wide CNV association analyses of hematological traits on 522 Korean family samples to infer a genetic architecture underlying quantitative traits. Statistical methods for CNV association analysis can be categorized into two different strategies. First, the observed probe intensity measurement can be directly used to detect association of CNV with the phenotypes of interest. Second, the most probable copy number is estimated by maximum likelihood and association of the most probable copy number with the phenotype is tested. Genome-wide CNV association study identified a region significantly associated with mean corpuscular hemoglobin concentration (MCHC) (P = 2.5710-5). CNV genotypes at this region were validated with a PCR experiment and the same association result was replicated in 4694 additional independent samples (P = 7.0010-5). Conclusions: This finding may contribute to alleviate the issue of copy number uncertainty in the CNV association analysis with hematological traits.

Comprehensive analysis of large structural variants in well-characterized human genomes. *E. Lam[1], A. Hastie[1], A. Mak[2], Y. Lai[2], H. Cao[3], D. Cao[3], W. Andrews[1], H. Dai[1], M. Austin[1], F. Trintchouk[1], M. Saghbini[1], T. Anantharaman[1], K. Haden[1], X. Xu[3], P.-Y. Kwok[2], H. Cao[1].* 1) BioNano Genomics, San Diego, CA; 2) University of California, San Francisco, San Francisco, CA; 3) BGI-Shenzhen, Shenzhen, China.

Genome mapping in nanochannel arrays (BioNano Genomics) represents a new single-molecule platform complementary to short-read sequencing for genome assembly and structural variation analysis. Extremely long molecules of hundreds of kilobases fluorescently labeled at sequence motifs and elongated in nanochannels enable direct interrogation of genome structure at a high resolution.

The high throughput of the BioNano Irys system has made possible, for the first time, rapid analysis of multiple genomes and cross-sample comparison to identify genome structural variation at high resolution. To date, we have de novo assembled more than 20 normal and diseased human genomes and analyzed their structural variation content. Our genome map assemblies cover at least 90% of non-N-base portions of the genome and also extend into subcentromeric and subtelomeric regions of the genome.

Here, we present results from extensive analysis of an Asian genome and a CEPH trio. We detected hundreds of large structural variants per genome and haplotype differences in these genomes. In the YH genome, we found 708 insertions/deletions and 17 inversions larger than 1 kb. Without considering 59 SVs that overlap with N-base gaps in hg19, 609 out of 666 (90%) are supported by orthogonal experimental methods (resequencing- and/or fosmid assembly-based) or historical evidence in public databases. For the CEPH trio, we identified novel and previously reported structural variants consistent with Mendelian inheritance. We also used publically available sequence read data to confirm and refine our SV calls.

Overall, our genome map assemblies provide valuable structural information otherwise difficult or impossible to decipher with short-read sequencing data alone.

De novo germline-transmitted duplications arise during gamete formation (possibly driven by meiotic recombination) and represent the genesis of a genetic polymorphism that has been associated with both complex and Mendelian forms of human disease. Details of their formation, however, are not well understood. For example, there are two possible sources for the extra copy of DNA in the offspring (de novo duplication); the parent in which the duplication arose (1) transmitted one copy from each homologous chromosome, or (2) transmitted two identical copies from a single chromosome. Here we present a new computational approach to interpret the source of DNA in parental chromosomes contributing to a de novo duplication using population genetic data from family-based genome-wide association (GWA) studies. Specifically, we first use trios to identify de novo duplications in offspring. We then check for consistency among plausible combinations of transmitted haplotypes and observed SNP array data (genotypes implied by the "B allele" frequencies) for the offspring (duplication carrier), under the two scenarios described above. To examine this phenomenon we leverage two large family-based studies. In a preliminary analysis of one of these, we identified 61 de novo duplications in 2,078 independent trios. Application of our method to these events indicates a tendency for duplications to derive from the same parental chromosome (situation 2 above). We are currently attempting to strengthen our conclusions with additional analyses of monozygotic twins from the other study and by ruling out sources of artifact, such as somatic mutation.

Copy number variants identified in Japanese women. *O. Migita[1,2], K. Maehara[2], K. Nakabayashi[2], K. Okamura[3], K. Hata[2].* 1) Department of Pediatrics, St. Marianna University School of Medicine, Kanagawa, Japan; 2) Department of Maternal-Fetal Biology, National Research Institute for Child Health and Development, Tokyo, Japan; 3) Department of Systems BioMedicine, National Research Institute for Child Health and Development, Tokyo, Japan.

Using a high-resolution SNP array, we examined copy number variations (CNVs) found within 411 healthy Japanese women. With increasing public concern about infertility and the frequent involvement of chromosomal anomalies in miscarriage, analyses of CNVs have been used to identify the genomic regions responsible for each process of childbearing. Although associations between CNVs and phenotype have been reported, previous studies accumulated unsusceptible CNVs with insufficient phenotypic information on pregnancies. It will be necessary to collect large number of control data that focused on normal parity. We collected samples from Japanese women who have experienced normal delivery without significant complications and have compiled 1043 copy number variable regions. The copy number differences in these regions may be irrelevant not only to infertility but also to a wide range of diseases. The utility of this resource are assumed to be useful for reducing the number of candidate pathogenetic variants, especially in Japanese subjects. Because our identification strategy was based on a microarray technique, it is inevitable that cross-hybridization would have occurred. We carefully curated output data for each CNVR and validated 9 regions out of 12 homozygous deleted regions by conventional PCRs and 10 copy variable regions by the NanoString analysis system. We found that many implausible calls were situated in regions with high GC contents; for example, in subtelomeric regions. Those were mostly gain-type CNVs rather than loss-type CNVs. Development of more sophisticated methods and algorithm to determine CNV regions are awaited.

Rare large CNVs are associated with intellectual disability, education level, and female fertility in general population. *K. Männik[1,2], R. Mägi[3], A. Mace[4,5], A. Maillard[5], H. Alavere[3], A. Kolk[3,6], L. Leitsalu[3], A.M. Ferreira[1], M. Noukas[2,3], J.S. Beckmann[4], S. Jacquemont[5], Z. Kutalik[4,7], A. Metspalu[3], A. Reymond[1].* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 3) Estonian Genome Centre, University of Tartu, Tartu, Estonia; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 5) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 6) Department of Neurology and Neurorehabilitation, Children's Clinic, Tartu University Hospital, Tartu, Estonia; 7) Institute of Social and Preventive Medicine, Lausanne University Hospital, Lausanne, Switzerland.

The impact of large rare CNVs has almost exclusively been evaluated using clinical cohorts and it is unclear how these variants affect health in general populations. To investigate the burden of rare large CNVs in the general population, we analyzed the Estonian Genome Centre cohort. It is a longitudinal, prospective, population biobank encompassing 5% of the Estonian adult population and linked to comprehensive personal, educational, medical and daily life data. Within a subset of 7877 individuals, we identified 65 carriers of known genomic disorder lesions, equivalent to a prevalence of 0.8% in the general adult population. Their phenotypes are reminiscent of those described for carriers of identical rearrangements identified in disease cohorts. Importantly some of the associated traits appear to have been previously overlooked due to age-dependent penetrance. We then generated the genome-wide map of rare autosomal CNVs and identified ~20% of the screened population (n=1567) as carriers of CNVs ≥125kb with frequency ≤0.05%. When compared to the population, carriers of deletions ≥250kb and duplications ≥1Mb show a decrease in education achievement (a proxy for intelligence), an increase in the prevalence of intellectual disability and an alteration of females' fecundity. In addition to CNV size, these effects are associated with the number and "quality" of contained genes. They are pronounced in carriers of deletions and duplications that encompass ≥2 and ≥11 genes, respectively. Concordantly, we found that the cumulative set of protein-coding genes encompassed by rare deletions is significantly enriched for GO processes involved in neurodevelopment, behavior, learning, memory and cognition (13 out of top-20 most significant processes). Stratification of deletions by presence of at least a neurodevelopmental gene within the rearrangement embedded genes or high haploinsufficiency score, but not presence of a ohnolog, correlated with ID prevalence. Our results suggest that rare CNVs account for a substantial portion of the population variance of educational attainment. Carriers of syndromic genomic lesions or of non-recurrent rare CNVs identified in reference cohorts should not readily be considered as healthy carriers. Rare large CNVs represent a significant public health issue as they impact life quality on multiple levels including medical and socioeconomic metrics.

613S

The impact of smaller CNVs and inherited gene-disruptive SNVs in sporadic autism. *T. Turner[1], N. Krumm[1], S.S.C. Sequencing Consortium[2], B.P. Coe[1], A.N. Raja[1], E.E. Eichler[1,3].* 1) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 2) Simons Foundation Autism Research Initiative, New York, NY; 3) Howard Hughes Medical Institute, Seattle, WA.

The Simons Simplex Collection (SSC) consists of ~2,500 sporadic autism families with one affected child. We analyzed 9,483 exomes (2,377 families) for a complete spectrum of genetic variation, including *de novo* and rare inherited single nucleotide variants (SNVs) and copy number variants (CNVs). To maximize sensitivity, we re-mapped all data using BWA-mem and applied multiple methods for each class of mutation, including CoNIFER and XHMM for CNVs and GATK HaplotypeCaller and FreeBayes for SNVs. We generated targeted genotypes across all exome-derived CNV calls using SNP-probe copy number estimates (via CRLMM) in order to validate CNV events as small as 1 kb (median size = 30kb) and increasing our yield by 31%. Our comprehensive scan enables the assessment of small CNV events (both *de novo* and rare) and rare inherited SNVs, neither of which have been previously assayed in autism spectrum disorder (ASD) families. To assess the relative burden of small CNVs, we focused on 1,200 families with data available for parents, affected proband, and unaffected sibling. *De novo* events showed an overall 2.1 proband/sibling burden for rare *de novo* events ($p = 1.03\times10^{-3}$), and CNVs were larger in probands (median = 93 kb) than in siblings (median=51 kb) ($p = 9.6\times10^{-4}$). For rare, inherited genic CNVs (median size = 30kb), we detected a 1.13 proband/sibling burden with ~50% of samples containing such an event, and found this burden was specific to proband-sibling pairs with strongly discordant phenotypes (via SRS score). We analyzed inherited SNVs and found a similar significant excess (OR = 1.14, $p < 0.0002$) of private inherited truncating mutations in highly conserved genes (RVIS score < 50); furthermore, this burden increased in the most conserved genes (reaching OR = 1.4 for the 1% most conserved). Finally, we combined all types of mutations into a comprehensive map and identified a set of genes with multiple *de novo* or inherited CNVs and SNVs, including *TNRC6B*, *CHD2*, *CSMD1*, and *DSCAM*. These data strongly support an inherited risk component for gene-disruptive events even among cases of sporadic autism.

Somatic Copy Number Variation at Birth. *A. Valind[1], C. Haikal[1], M.EK. Klasson[1], M.C. Johansson[2], M. Soller[1], B. Baldetorp[2], D. Gisselsson[1].* 1) Department of Clinical Genetics, Lund University, Lund, Sweden; 2) Department of Oncology, Lund University, Lund, Sweden.

A dogma in genetics for the last century has been that all cells in an individual's body are genetically identical, with the exception of germ cells and some cells in the immune system. Recent technological advances have made it possible to measure variation in a genome-wide fashion, giving scientists the possibility to measure genomic variation between different organs in the same individual. This development, while still in its infancy, has forced scientists to reconsider the dogma of genetic identicalness of somatic cells within an individual. We have used high resolution SNP-arrays to quantify somatic variation at the segmental level, and fluorescence in situ hybridization (FISH) to quantify variation at the chromosome level in a cohort of stillborn fetuses and neonates. This revealed two organ-specific types of somatic variation. In the thymus, a recurrent genomic signature of T-cell receptor rearrangement was detected, reinforcing the view that most T-cells undergo TCR gamma/delta rearrangements early in development. In the liver, we found an intercellular variation in chromosome copy number that was higher than in other organs, indicating that the high-grade aneuploidy seen in livers of adults is manifest already in utero. In contrast to reports from adult liver, this occurred in the absence of polyploidy. We also found that that the overall level of organ specific copy number variation was considerably lower in fetuses and neonates compared to adults, providing additional evidence for the accumulation of copy number variants over time also in a non-neoplastic context.

615T

Complex structural variant in a family with Autism Spectrum Disorder discovered by whole genome sequencing. *S. Walker, R.K.C. Yuen, K. Tammimies, M.J Gazzellone, B. Thiruvahindrapuram, T. Nalpathamkalam, D. Merico, S.W. Scherer.* Genetics and Genome Biology, Hospital for Sick Children, Toronto, M5G 0A4, Ontario, Canada.

Autism Spectrum Disorder (ASD) is a highly heterogeneous neurological condition with many contributing risk genes and loci. Genome wide microarray and sequencing studies have implicated numerous genes, for example members of the NRXN and SHANK families, *PTCHD1*, *CHD8*, and *SCN2A* as risk candidates in ASD. Mutations in voltage gated sodium channel *SCN2A*, many of which *de novo* in origin, have previously been associated with several forms of epilepsy. In recent whole exome and genome sequencing data in ASD, *SCN2A* has emerged as one of only a small number of genes with multiple independent *de novo* loss of function mutations, making it one of the best new candidate genes. Through our own ASD whole genome sequencing project, we have uncovered a complex structural variant at *SCN2A* in a family quartet comprised of parents and two affected female offspring. Initially, a 1.7kb single exon (exon 18) deletion was discovered as a *de novo* variant in both children thought to have arisen by germline mosaicism. However, further analysis revealed that the deletion breakpoint can also be detected in a blood DNA sample from the father, despite his having two copies of exon 18. Using detailed molecular analyses, we have shown that in the father there is a complex rearrangement such that he carries one intact allele and in addition to the transmitted deletion, he also possesses a third structure carrying a neighbouring intronic deletion. We are pursuing a number of different technical approaches to resolve the nature of this variant and the mechanism by which it has arisen. We are also assessing mRNA transcripts from all family members to investigate the functional impact of the variant structures. Resolving this complex variant will aid in the interpretation of the exonic deletion in the affected individuals in this family and also demonstrates the importance of detailed genomic data in understanding disease risk variants. Our data have further implications for studying models of genetic disease as other similar complex events could give rise to cryptically inherited variants misinterpreted as *de novo* events. Furthermore, this example highlights the power of whole genome sequencing to reveal variants not detectable by other technologies.

616S

Genome-wide copy number variants analysis identifies deletion variants associated with ankylosing spondylitis. *S. Yim[1], S. Jung[1], T. Kim[2], S. Shim[3], Y. Chung[1].* 1) The Catholic University of Korea, College of medicine, Seoul, South Korea; 2) Hanyang University Hospital for Rheumatic Diseases, Seoul, Korea; 3) Chungnam National University Hospital, Daejeon, South Korea.

We aimed to discover ankylosing spondylitis (AS)-associated copy number variants (CNVs) in Korean subjects and their synergistic roles in the development of AS. We performed genome-wide association study (GWAS) in 309 AS patients and 309 controls using Agilent CNV microarray. AS-associated CNV regions (CNVRs) were replicated in two independent sets (625 cases and 891 controls in total) by qPCR and deletion-typing PCR. In the CNV-GWAS, we identified 227 CNVRs significantly associated with AS. Of the candidate CNVRs, nine were successfully replicated in the first replication; 1q32.2 (HHAT), 1p34.2 (BMP8A), 2q31.2 (PRKRA), 6p21.32 (HLA-DPB1), 11q22.1 (CNTN5), 13q13.1 (EEF1DP3), 14q24.2 (RGS6), 16p13.3 and 22q11.1 (IL17RA). Five deletions of them in 1q32.2, 2q31.2, 6p21.32, 13q13.1 and 16p13.3 were risk-increasing CNVRs and the other four were protective. In the second replication, four CNVRs in 1q32.2, 2q31.2, 6p21.32, and 16p13.3 were replicated. Subjects with CNVRs in four or more risk-increasing loci had 18.0 times higher risk than those without any deletions (OR=17.98, P=2.3×10−7). Subjects with CNVRs in two or more protective loci had 5.2 times lower risk than those without any deletions (OR=0.19, P=4.0×10−10). The additive effects of simultaneous events showed a CNVR frequency-dependent manner. Through deletion-typing PCR and sequencing, the exact sizes and breakpoint sequences were defined in three CNVRs. The mechanism of all three deletions were found to be microhomology-based nonhomologous end joining. Our results can help to identify the pathogenic mechanisms of AS and can easily be applied for developing the prediction algorithm of AS development.

617M

Correction of artefacts in estimation of rare copy number variants for analyses of burden and association in type 1 diabetes. *N.J. Cooper, C. Shtir, J.A. Todd.* Diabetes and Inflammation Laboratory, University of Cambridge, United Kingdom.

Copy number variations (CNVs) have been proposed as a possible source of 'missing heritability' in complex human diseases. Several studies of type 1 diabetes (T1D) have found null associations with common copy number polymorphisms (CNPs), but CNVs of low frequency and high penetrance could still play a role. We used the Log-R-Ratio (LRR) intensity data from a dense single nucleotide polymorphism (SNP) array, ImmunoChip, to detect rare CNV deletions (rDELs) and rare CNV duplications (rDUPs) in 6,808 T1D cases, 9,954 controls, and 2,206 families with T1D-affected offspring. Our initial analyses using a standard approach with PennCNV software were affected by biases that led to detection of CNVs subsequently confirmed by quantitative polymerase chain reaction (qPCR) to be false positives. We developed a series of quality control (QC) tests that were demonstrated to identify and correct probe intensity biases. Systematic testing and validation showed that the ImmunoChip-wide case-control odds ratio (OR) for rDELs and rDUPs was highly sensitive to QC thresholds and procedures. Analysis using an optimal QC pipeline, with the highest validated accuracy, suggested no overall CNV burden for T1D, but some association for rDELs longer than 500 kb (OR=1.67, p=.003), noting that ImmunoChip genome coverage is mostly concentrated in known autoimmune regions. No specific CNV regions (CNVRs) showed association at a corrected p-value threshold, although CNVR frequencies were lower than expected (most less than 0.1%), significantly reducing statistical power. Transmission disequilibrium tests (TDT) run on the family dataset provided no support for CNVRs contributing to familial clustering of T1D. We present an R-package, plumbCNV, that provides an automated approach for QC and detection of rare CNVs, which can facilitate equivalent analyses of large-scale SNP array datasets in any disease. A power analysis indicating sample sizes required to obtain convincing evidence for single locus tests is also provided.

618T

The structural architecture of SNP effects on complex traits. *L. Davis, E. Gamazon, N. Cox.* Section Genetic Medicine, The University of Chicago, Chicago, IL.

Despite this year marking the tenth anniversary of the discovery of copy number variation (CNV), current SNP based analysis methodologies continue to collapse the homozygous (A/A), hemizygous (A/0), and duplicative (A/A/A) genotype states treating the genotype variable as irreducible or unaltered by other co-occurring forms of genetic (e.g., structural) variation. Our understanding of common, genome-wide CNV suggests the canonical genotype construct may belie the enormous complexity of the genome. Here we present multiple analyses of several phenotypes and provide novel methods supporting a conceptual shift that embraces the structural dimension of genotype. We developed a method we call “copy number integrated GWAS” (cni-GWAS), which properly accounts for allelic dosage, and applied it to the detection of expression quantitative trait loci, in LCLs, finding that 20% of expression-associated SNPs (eSNPs) increased in significance by at least nearly 3.3 orders of magnitude. We investigated their functional consequences and found enrichment for enhancer elements and DNase hypersensitivity sites at transcription factor binding sites with greater binding affinity than expected (p=0.03). We then developed a method to calculate the heritability attributable to these “unmasked” eSNPs in multiple phenotypes. Second, to determine the impact of CNV and copy number stability on rare coding variants likely to increase disease risk, we assessed the overlap between CNV regions and loss of function (LOF) variants from the 1000 Genomes project, and from published exome sequencing in autism. We found that regardless of phenotype or de novo status, approximately 80% of all LOF variants fall within structurally variable regions of the genome; furthermore, a much larger proportion of LOF variants in copy number stable (CNS) regions trigger nonsense-mediated decay (p=0.016). Lastly, we determined the aggregate phenotypic variance accounted for by SNPs distributed across CNV or CNS regions of the genome in Tourette Syndrome and obsessive-compulsive disorder. We find very different results across these two neuropsychiatric phenotypes and argue that dosage sensitivity is a genomic property, which may elucidate genetic architecture. Taken together, these results argue for the inclusion of a structural dimension and suggest that some portion of the “missing” heritability may be recovered through integration of the structural dimension of SNP effects on complex traits.

619S

Genetic variation in introns that flank alternatively spliced exons: A new way to look for disease-related variants. *A. Neininger[1], W.C.L Stewart[1,2,3], D.A. Greenberg[1,2].* 1) Battelle Center for Mathematical Medicine, Nationwide Children's Hospital, Columbus, OH., 700 Children's Drive; 2) The Ohio State Department of Pediatrics, Columbus, OH., 700 Children's Drive; 3) The Ohio State Department of Statistics, Columbus, OH., 1958 Neil Ave.

Simple exonic mutations are not the only kinds of genetic variants that can lead to inherited disease. Intronic variation is also important, but the relatively high degree of variability in introns makes the identification of specific disease-related alleles difficult. For example, the gene BRD2 is related to epilepsy susceptibility and it contains no exonic disease-related mutations, but certain sequences of an intron are associated with disease. This intron is highly variable and it also contains an alternatively spliced (AS) exon. This led us to ask: Are introns surrounding AS exons more variable than other introns? AS exons are found in approximately 75%-90% of genes, and 1/3 of these exons can introduce a premature termination codon (PTC). Therefore, understanding the variability that regulates alternative splicing could allow us to identify intronic sequences that are related to disease. Using sequence data from 1000 Genomes, we first compared the frequency of common variants in the introns flanking AS and regularly spliced exons. We found statistically significant differences between introns that flank AS exons compared to those that flank regularly spliced exons. This finding suggests that this variation influences regulation of splicing. We also subdivided the introns flanking AS exons into two groups: those that introduce a PTC leading to nonsense-mediated decay, and those that do not. We then explored a method that evaluates different intronic sequences on the basis of physical similarity and free energy. Our preliminary results from the analysis of 46 epilepsy patient haplotypes and 48 control haplotypes suggest that the free energy of the hypervariable BRD2 intron that flanks the AS exon appeared able to predict which sequences exist in the population and which do not. Moreover, sequence similarity alone does not appear to be associated with disease. We did not observe any statistical differences between these two groups. In conclusion, approaches that account for differences in the physical gene structure may give us a better way to understand intronic sequence variation, and consequently, a better way to identify disease related “alleles”.

620M

Expression of human acidic mammalian chitinase in *Escherichia coli* and analysis of its properties. *K. Okawa, A. Kashimura, Y. Kobayashi, M. Ohno, M. Sakaguchi, Y. Sugahara, F. Oyama.* Applied Chemistr, Faculty of Engineering, Kogakuin University, Hachioji, tokyo, Japan.

Acidic mammalian chitinases (AMCase) have been shown to be closely associated with asthma in mouse model, allergic inflammation and food processing. AMCase is expressed in mice and humans. The amino acid sequence of human AMCase shares 81% identity with that of mouse counterpart. There are several variants with the amino acid substitutions in human AMCase. Recent genetic association analyses of AMCase haplotypes for asthma revealed significant associations between the variant haplotype in several asthma cohorts. However it still remains to elucidate the pathophysiological significance of human AMCase *in vivo*. To study the roles of AMCase, we expressed human AMCase as a fusion protein A and V5-His in *E. coli* and compared its chitinolytic activity with that of mouse counterpart. The chitinolytic activity of human AMCase was about 1/50 of that in the mouse counterpart. These results indicate that the specific activity of human AMCase is notably low when compared with mouse AMCase.

621T

Beyond the 1000 Genomes Project. *L. Clarke, H. Zheng-Bradley, A. Datta, I. Streeter, D. Richardson, P. Flicek, The 1000 Genomes Consortium.* Vertebrate Genomics, European Molecular Biology Laboratory - European BioInformatics Institute (EMBL-EBI), The Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom.

The 1000 Genomes Project provides an essential reference catalog of human variation with more than 60 million variant sites ranging from single nucleotide polymorphisms to structural variant events including inversions and duplications. Also provided are global allele frequencies and genotypes for 2535 individuals from 26 different populations across Europe, Africa, East and South Asia and the Americas, which enable many other projects to better interpret their results. Primary uses for the 1000 Genomes data sets include imputation panels to create whole genome variant sets from exome or array-based genotypes; as filters of “normal” or shared variation in rare disease or cancer sequencing projects; and to explore demography and selection in human populations. The 1000 Genomes Project is now drawing to a close. Here we describe plans to maintain the resource in order to ensure it remains the valuable data set it is today by providing long-term support for the 1000 Genomes Project resource. For example, we will continue to host both the FTP site (ftp://ftp.1000genomes.ebi.ac.uk/vol1/ftp) and the project website (http://www.1000genomes.org) to ensure the community can access both the raw data and the documentation about the project. We will also create a stable version of the 1000 Genomes Browser (http://browser.1000genomes.org) based on the project's final date release. This project specific Ensembl-based browser displays all of the 1000 Genomes variants as soon as possible and will use the GRCh37 assembly of the human reference genome. We will also maintain the existing tools and incorporate new ones as appropriate to enable users to easily access the data they desire. Our most popular tools are the Data Slicer—that allows users to select genomic subsections of our alignment (BAM) and variant (VCF) files and thus download just the piece of the file they need—and the Variation Pattern Finder, which allows users to discover patterns of shared variation in a specific region of the genome. Other tools include the VCF to PED converter, which allows users to generated PLINK format files from remotely hosted VCF files and the recently introduced the Allele Frequency Calculator that will calculate allele frequencies in bulk for specific sub populations from our VCF files.

622S

Empirical and computational survey of functional regulatory genetic variants. *G.A. Moyerbrailean[1], C.T. Harvey[1], C.A. Kalita[1], X. Wen[2], F. Luca[1], R. Pique-Regi[1].* 1) Wayne State University, Detroit, MI; 2) University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have been instrumental to identify genetic variants associated with complex traits. However, risk variants tend to fall in non-coding regions and likely affect gene regulatory mechanisms. Even with increasing regulatory annotations provided by ENCODE and others, predicting the impact of a sequence change on gene regulation remains a challenge. Identification and functional characterization of sequence variants in regulatory elements is crucial for understanding the molecular determinants of complex traits. Here, we integrate DNA sequence with DNaseI footprinting data to predict the impact of a sequence change on transcription factor binding. Applying this approach to 653 DNase-seq samples, we identified 3,831,862 regulatory variants predicted to affect active regulatory elements for a panel of 1,891 transcription factor motifs. We observe that these variants are enriched for having a MAF < 1%, are more likely to be in enhancer regions, and tend to affect factors active in < 5 cell-types. Using our newly developed method, QuASAR (Quantitative Allele-Specific Analysis of Reads), we examined the data for variants exhibiting allele-specific binding (ASB). We identified 3,217 binding variants within footprints that are significantly imbalanced (20% FDR). Overall, we estimate that 56% of our predicted regulatory sites in footprints show an ASB signal. To assess the effect these variants may have on complex phenotypes, we examined their association with complex traits and observed that ASB-SNPs are enriched 1.22-fold for complex traits variants (from GWAS). Using results from meta-studies for lipid levels and height, we identified factors whose binding sites were enriched for associated SNPs. Factors for lipid levels include GR and HNF4a, as well as regulators of immune function such as CREB, PU.1, IRF-1 and IRF-2. Factors for height include stem cell and developmental regulation factors such as Oct-4 and Nkx2-5. Additionally, these annotations can be very useful for fine-mapping. For example, because rs532436 (a genetic loci associated with an increase in LDL) is in a footprint for the factor USF, the annotation increases the likelihood from 40% to 70% that this is the functional SNP in the loci. These results show that integration of footprint annotations into GWAS meta-study results improves the identification of likely causal SNPs and provides a putative mechanism by which the phenotype is affected.

The success of whole exome sequencing diagnosis in a large cohort of patients with Mendelian disorders. *T. Roscioli[1,2,3], L. Ewans[1,2], M.J. Cowley[3], K. Ying[3], Y. Zhu[4], C. Walsh[5], E. Lee[5], M. Field[4], A.M. Turner[1], D. Mowat[1], A. Hackett[4], E.P. Kirk[1], R. Sachdev[1], M.L Freckmann[1], M. Lipke[1], M. Buckley[5], M. Dinger[3].* 1) Department of Medical Genetics, Sydney Children's Hospital, Sydney, NSW, Australia; 2) School of Women's and Children's Health, University of New South Wales, Randwick, NSW, Australia; 3) Kinghorn Centre for Clinical Genomics, Garvan Institute of Medical Research, Darlinghurst, NSW,; 4) Newcastle GOLD Service, Hunter Genetics, Waratah, NSW, Australia; 5) SEALS laboratory, Prince of Wales Hospital, Randwick, NSW, Australia.

Molecular diagnosis in patients with Mendelian disorders has been improved significantly by advances in next generation sequencing (NGS). NGS has resulted in enhanced mutation identification, genetic management and in some cases the creation of novel therapies. Mendelian disorders are most amenable to diagnosis though whole exome sequencing (WES) as the coding 2% of the genome is highly enriched for disease-causing mutations. WES was applied to a cohort of 52 patients from 37 families who were selected from clinical genetics clinics in New South Wales and for whom no molecular diagnosis was known. This cohort is phenotypically heterogeneous, however the majority of patients presented with intellectual disability (62%) consistent with population frequency and diagnostic importance. Other diagnoses included skeletal dysplasias (14%), retinitis pigmentosa (8%), haematological disorders (8%), seizures (3%), metabolic conditions (3%), and dysmorphic syndromes (3%). DNA from annotated exons and splice sites, untranslated regions, and the mitochondrial genome were captured with a Nextera extended exome kit on Illumina HiSeq 2500 sequencers. Genomic data was annotated with the Variant Effect Predictor (VEP) and common variants were excluded based on population polymorphism data and impact on protein function using the GEMINI (Genome MINIng) software. The most likely inheritance model was applied to each family based on pedigree analysis and indication for referral and in consanguineous families, regions of homozygosity were identified and applied as an additional filter. Mutation pathogenicity scoring systems were applied including PROVEAN and CADD scores for missense and other mutations. We present an overview of the testing outcomes including a preliminary cost-effectiveness analysis. Initial results from 13 families show a diagnostic success rate of approximately 25% for mutations in known disease-related genes, and a likely novel disease gene for intellectual disability involved in neurite growth in a consanguineous family.

624T

Identifying tagging SNPs for African specific variation from the African Diaspora Genome. *H.R. Johnston[1], Y. Hu[1], J. Gao[1], G. Abecasis[2], M. Hansen[3], R. Genuario[3], D. Bullis[3], R.A. Mathias[4], K.C. Barnes[4], Z.S. Qin[1], CAAPA Consortium.* 1) Department of Biostatistics and Bioinformatics, Emory University Rollins School of Public Health, Atlanta, GA; 2) University of Michigan School of Public Health, Ann Arbor, MI; 3) Illumina, Inc. San Diego, CA; 4) Department of Medicine, Johns Hopkins University, Baltimore, MD.

The Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) includes high coverage whole genome sequence data (~30x depth) on ~1,000 subjects of African ancestry and extends the patterns of variation catalogued in the Thousand Genomes Project and Exome Sequencing Project to a spectrum of populations representing a wide range of African ancestry in the Americas. An interim data freeze (N=643) of CAAPA includes: 329 African Americans; 125 African Caribbeans; 164 African ancestry samples with a notable Latino component; and 25 samples from Nigeria. One of the primary goals of CAAPA is to develop an 'African Diaspora Power Chip' to address the concern that current commercially available GWAS chips have made a limited effort to tag African specific variation. The goal of the African Diaspora Power Chip project is to utilize sequence variants within CAAPA to build a genotyping chip that tags as much African specific variation as possible. Since many GWAS studies have already been conducted using the Illumina OmniExpress chip, it was chosen to be the primary partner chip for the African Diaspora Power Chip.

47.9 million SNPs were observed in the CAAPA samples. 15.6 million variants with a minor allele frequency ≥1% were included in the set to be tagged. Variants that could be well imputed based on the OmniExpress chip using the 1000 Genomes Phase I African Reference Panel were removed from the selection pool. Fugue, a haplotype construction software package, was used to determine the pairwise LD between each pair of SNPs in the remaining set. These LD estimates were used by FESTA, a software package designed to select the optimal set of tagSNPs, to select SNPs using an r^2 threshold of .8. All tag SNPs with an MAF >= 1.6% were retained. Additional content including SNPs targeting African specific diseases and the HLA region, plus a "GWAS backbone" was added.

Analysis of our coverage of SNPs >= 1% MAF in the CAAPA population was conducted to ensure tagSNP selection success. On Chromosome 22, the Power Chip alone tags 11% of variants at .9 r^2. This increases to 14% at .8 and 28% at .5. In conjunction with the OmniExpress array, the pair of chips tags 26% of the variants at .9 r^2. This increases to 32% at .8 and 50% at .5.

625S

The role of the host genetic variability in the influenza-A virus susceptibility. *A.C. Arcanjo Silva[1,7], G. Mazzocco[2,6], S.F. Oliveira[1,3], D. Plewczynski[2,3,5], J.P. Randomski[2,4].* 1) Programa de Ps Graduao em Biologia Animal, Universidade de Braslia, Braslia, DF 70910-900, Brazil; 2) Interdisciplinary Center for Mathematical and Computational Modeling, Warsaw University, Pawińskiego 5A, Bldg. We have explored genomic variability of the genes responsible for host-pathogen interactions and the host-specific immunological response to influenza-A infection, which represents a serious health threat for a significant part of the world's population. The aftermath of influenza infection is determined by a complex set of host-pathogen interactions, where genomic variability on both sides influences the final outcome. Although a large body of literature describes influenza virus variability, only a small fraction covers the issue of host variance. The goal of this work was to explore the variability of host genes responsible for host-pathogen interactions in three different phases of infection: binding of the virus to a target cells, viral detection mechanisms inside the host cell and immune response mechanisms aimed at virus clearance. Seven to ten genes were selected in each of the phases of infection, and then their variability was assessed in the 1000 Genomes Project database. Some variants that were described in the literature as associated to influenza infection were accessed to determine their frequency in the populations of the database. The majority of the variants found in the selected genes were present in intronic regions, except for the ST6GAL1 and TRIM25 genes, which showed higher number of variations in the 3'UTR region. Of the known variants related to influenza infection, Japanese and Chinese samples show the bigger frequencies of protective alleles (as in TLR3 rs5743313C and IL1A rs17561C alleles). The IL1B rs1143627C allele, on the other hand, increases susceptibility to influenza infection, and it is present in high frequencies in all populations of the 1000 Genomes Project, corroborating the rapid dispersion of the virus in the human population. Moreover frequencies of the rs2564978T/T genotype (promoter of CD55 gene that is highly associated with a severe form of influenza infection) in the populations of the database were concordant with mortality and morbidity rates described for 2009 pandemic H1N1. These results suggest that the susceptibility to influenza has an important heritable component. Although the clinical outcome of an influenza virus infection can't be entirely attributed to the effects of host genomic variability, these factors have been shown to play a crucial role within this context.

The European Genome-phenome Archive (EGA) as a federated effort to provide secure global access to genome and phenotype data for hundreds of thousands of samples. *I. Lappalainen[1], J. Almeida-King[1], C. Gonzalez[1], J. Kandasamy[1], V. Kumanduri[1], I. Medina[1], G. Saunders[1], A. Senf[1], J.D. Spalding[1], S. ur-Rehman[1], M. Alberich[2], A. Cerreno Torres[2], J. Rambla de Argila[2], O. Martinex Llobet[2], A. Navarro[2,3,4], P. Flicek[1], J. Paschall[1].* 1) EMBL-EBI, Hinxton, Cambridge, United Kingdom; 2) Centre for Genomic Regulation, Barcelona, Spain; 3) Insitute of Evolutionary Biology, Barcelona, Spain; 4) 4Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

The European Genome-phenome Archive (EGA) is now a joint service from the European Bioinformatics Institute (EBI), UK and the Centre for Genomic Regulation (CRG), Spain. This service provides a permanent archive for all types of genetic, -omics and phenotypic data that has been consented for use in biomedical research, but where the data access is managed through an application and secure encrypted data delivery process to limit risks to the privacy of research participants. Accepted submissions include raw data from genome sequence, transcriptome, epigenome or proteomics experiments. The EGA also stores called variants, genotypes, study summary statistics and associated sample phenotypes. Access to the data is managed by appropriate data access committees (DACs) that will approve access based on requests that meet the data-use and patient consent rules governing their studies. Here we describe how EGA service will scale for future submission, data archiving and dissemination including key improvements in phenotypic query of studies as well as the provision of new models of data access including cloud-based and real-time data streams in addition to traditional file download. EGA service is accessible at https://www.ebi.ac.uk/ega/home and at https://ega.crg.eu/.

Integrative Japanese Genome Variation Database from the cohort study of Tohoku Medical Megabank Organization (ToMMo). *Y. Yamaguchi-Kabata, Y. Kawai, T. Mimori, F. Katsuoka, N. Nariai, K. Kojima, I. Danjoh, S. Saito, X. Pan, J. Yokozawa, R. Saito, Y. Sato, K. Tsuda, Y. Kuroki, K. Kinoshita, J. Yasuda, M. Yamamoto, M. Nagasaki.* Dept. Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku UniversityTohoku University, Sendai, Miyagi, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) was founded to establish an advanced medical system to foster the reconstruction from the Great East Japan Earthquake. The organization will develop a biobank that combines medical and genome information during the process of rebuilding the community medical system and supporting health and welfare in the Tohoku area. We have started the prospective cohort study in the region, with genome analyses, to establish the advanced, personalized medicine based on the individuals genomic data. Although reports of common variants with their frequencies are accumulating for each population, many of low-frequency variants remain undetected or lack of their frequencies. Therefore, cataloging genomic variants from whole-genome sequencing and estimation of variant frequency are necessary for foundation of genomic medicine for each population. To make a reference panel of genomic variation of Japanese, we have sequenced whole genomes of about 1,000 cohort participants, and collected single nucleotide variants (SNVs). Integrative Japanese Genome Variation Database provides data of genomic variations obtained by whole-genome sequencing of Japanese individuals who participate the genome cohort study of ToMMo. The current release provides SNV data obtained from the individuals from the cohort. The first release contains data of SNVs (about 5 millions on autosomes) that exist at least 5.0 % frequency in the samples. This browser can be used to search those SNVs and get their information such as frequency. The database and variants data would be useful for genome analysis and strategy of genomic populations for local populations.

Complete haplotypes of the human light chain immunoglobulin loci from a hydatidiform mole BAC library provide insights into locus-specific signatures of genetic diversity. *K. Meltz Steinberg[1,2], C.T. Watson[3,4], T.A. Graves-Lindsay[1], R. Warren[5], M. Malig[2], J. Schein[5], R.A. Holt[5], R.K. Wilson[1], E.E. Eichler[2,6], F. Breden[4].* 1) The Genome Institute, Washington University, St. Louis, MO; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Department of Biological Sciences, Simon Fraser University, Burnaby, British Columbia, Canada; 5) Genome Sciences Centre, BC Cancer Agency, Vancouver, British Columbia, Canada; 6) Howard Hughes Medical Institute, Seattle, WA.

Immunoglobulin gene (IG) loci and their associated germline variation are critical for pathogen-mediated immune response, but establishing complete reference sequences is problematic because of large-scale duplications and the fact that many genomic resources are established from somatically rearranged material. Here, we present a complete haplotype from the essentially haploid hydatidiform mole, CHM1. We sequenced a set of tiling BAC clones from CHM1 across the light chain IG loci, kappa (IGK) and lambda (IGL), to create single haplotype representations of these regions. The IGL haplotype is 1.25Mb of contiguous sequence from nine clones with four novel V gene and one novel C gene alleles. There is also an 11.9kbp insertion that does not contain any functional genes. The IGK haplotype is comprised of a 644kbp proximal and a 466kbp distal contig separated by a gap that is also present in the GRCh37 reference genome sequence. Our effort added an additional 49kbp of unique sequence that extended into the gap. The IGK haplotype contains six novel V gene and one novel J gene alleles. In addition, we identified a 16.7kbp region with increased sequence identity between the proximal and distal IGK contigs with signatures of interlocus gene conversion. In two instances, we observed the presence of functional alleles that had been previously classified as either “distal” or “proximal” alleles residing at loci in the alternate location. Due to the large inverted duplications, over 80% of the IGK variable (IGKV) locus consists of segmental duplications with >95% sequence identity suggesting that, unlike in the heavy chain locus (IGH), the duplications may be responsible for sequence homogenization rather than diversity. When we compared nucleotide and structural diversity among the light chain and heavy chain haplotypes, we find a three to six fold enrichment of diversity in the IGH locus compared to the light chain loci, that supports the theory that the heavy chain is more important in determining antigenic specificity.

Defining Variation Sensitive Regions in Genes Associated with Hearing Loss. *A.N. Abou Tayoun[1,4], C.A. Cassa[2,4], D.M. Jordan[2], A.L. Muirhead[1], K.A. Lafferty[1], A.L. Hernandez[1], J. Shen[1], M.S. Lebo[1,3], S.R. Sunyaev[2], H.L. Rehm[1,3], S.S. Amr[1].* 1) Laboratory for Molecular Medicine, Partners Healthcare Personalized Medicine, Cambridge, MA; 2) Division of Genetics, Brigham and Women’s Hospital, Harvard Medical School, Boston, MA; 3) Division of Pathology, Harvard Medical School, Cambridge, MA; 4) Authors with equal contribution.

The classification of novel variants is a major challenge facing clinical genetics laboratories. Because most novel variants do not have functional, genetic or population data to support clinical classification, in silico approaches are commonly used to prioritize candidate disease-causing variants. We have previously shown that a systematic evaluation of gene-disease associations can largely eliminate unnecessary interpretation of variants in genes with weak disease association. Applying this approach to 145 genes included in hearing loss panels, we found 54 genes (37%) with insufficient association to hearing loss that may be excluded from testing panels. Here, we extend this approach to the domain level in the remaining 91 genes with sufficient evidence for disease association, to test the hypothesis that systematic evaluation of domain-disease association can improve variant interpretation. Using Pfam predicted domain boundaries (http://pfam.xfam.org), the frequency of variation in the general population (Exome Sequencing Project, N=6,503), and clinically classified variants from ClinVar (http://www.ncbi.nlm.nih.gov/clinvar), we determine the domain level tolerance to variation within each gene. We statistically identify regions that are most sensitive to functional variation in the general population and also most commonly impacted in symptomatic individuals. This approach leverages domain functional annotation and associated disease in each gene. Our data show that this approach has utility in finding regions of greatest interest in predicting variant pathogenicity in known disease genes. For example, almost all pathogenic missense variation is confined to the ion channel domain of the KCNQ4 gene and the DNA binding domains of the PAX3 and SOX10 genes. These domains represent 15–46% of the total coding region in their respective genes, and are almost devoid of functional variation in the general population. In contrast, regions outside these domains had a high level of variation in the general population, but almost no pathogenic missense variants in symptomatic individuals. This knowledge helps define variation sensitive regions in hearing loss genes that can be used to prioritize candidate disease variants, increasing the sensitivity and specificity of novel variant assessment within these genes.

630T

Deep targeted sequencing of SLE associated LD blocks reveals multiple putatively functional variations in strong LD with SLE GWA SNPs: A haplotype based assessment of disease risk. *P. Raj[1], QZ. Li[1], D. Karp[1], E. Rai[1], C. Liang[1], B. Wakeland[1], K. Viswanathan[1], I. dozmorov[1], N. Olsen[2], JA. James[3], JA. Kelly[3], B. Lauwerys[4], PK. Gregersen[5], BP. Tsao[6], P. Gaffney[3], EK. Wakeland[1].* 1) Immunology, UT South western Med Center, Dallas, TX. 5323 Harry Hines Blvd. Dallas, Texas, 75390; 2) 2Division of Rheumatology, Penn State Hershey Medical Center, 500 University Drive, Hershey PA 17033; 3) Oklahoma Medical Research Foundation, 825 North East 13th Street, Oklahoma City, Oklahoma 73104, USA; 4) 4Service de Rhumatologie, SSS/IREC/RUMA, Cliniques Universitaires Saint-Luc & Université catholique de Louvain Avenue Hippocrate 10, bte B2.5390, 1200 BRUXELLES, Belgium; 5) Feinstein Institute for Medical Research in Manhasset, New York; 6) Division of Rheumatology, University of California Los Angeles, Los Angeles, California, United States of America.

A strong genetic predisposition has been observed in susceptibility to SLE. Genome-wide association analyses (GWAS) have identified more than 30 SLE risk loci in humans thus far, and ongoing analyses by the SLE immunochip consortium will probably define even more. We performed deep targeted sequencing of the SLE associated LD blocks with aim to develop a genomic strategy for the functional characterization of all the genetic risk alleles in SLE. For this, we sequenced ~4.4 Mb of the human genome in 773 SLE patients and 576 controls using a custom target enrichment sequencing strategy. We called 146K pass quality variations with an average of 107-fold coverage of the entire linkage disequilibrium (LD) blocks at more than 70 potential disease risk loci, thus providing detailed sequence information for all of the identified SLE risk loci. We obtained 98 percent genotype concordance between sequencing and immunochip genotypes on subset of sample. The common (MAF>0.05) genetic variants identified in this dataset were used to assemble a list of potentially functional variations in both coding and non-coding (from ENCODE) regions within these LD blocks, thus allowing the disease associations within SLE risk loci to be integrated with functional properties. Then, haplotype were formed including known GWAS and potentially functional variations in strong LD with it. We found multiple functional variations in strong LD with SLE GWA SNP in many SLE genes. For example, in case of STAT4, SLE risk haplotype formed based on STAT4 SLE GWA SNP and functional variations (ENCODE SNPs and eQTLs) pose increased risk (increased odds ratio of 1.7) than SLE GWA SNP alone (OR=1.4). Also, this risk haplotype associate with the up regulation of STAT1 and STAT4 gene expression. Thus, similar haplotype analysis was done in other SLE associated loci and phylogenetic relationships were determined between various risk and protection haplotypes by constructing Median-Joining (MJ) networks. On the other hand, low frequency and rare variations (MAF<0.05) were analyzed using KBAC and CMC methods. In conclusion, study demonstrate that how multiple functional variation can contribute to disease risk in an additive fashion and also identify loci in which both common and rare variations may contribute to SLE susceptibility.

Autism spectrum disorder (ASD) is genetically heterogeneous with >100 susceptibility genes known. We used whole-genome sequencing (WGS) of 85 quartet families (two parents and two ASD-affected siblings) to comprehensively examine mutation characteristics. In 34/85 (40%) of families, potentially relevant mutations were identified. *De novo* damaging missense and loss-of-function (LoF) mutations (single nucleotide and structural variants) were detected in ASD-risk genes in 11/85 (12.5%) families. We also identified 17 additional families carrying inherited LoF mutations in known ASD-susceptibility genes, and 6 more families with *de novo* or inherited LoF variants in genes linked to autosomal dominant forms of neurodevelopmental disorders. In only one of these families was the same *de novo* mutation (1.8kb deletion in *SCN2A*) found in both ASD siblings; in another 10 families inherited ASD-risk variants were shared between affected siblings. Taken together, in 11/34 (32%) of families a *de novo* or inherited ASD risk variant(s) identified in the index case was also found in the other sibling who developed ASD. Our results emphasize using personalized WGS to maximize the detection of all classes of mutations potentially involved in autism, and to enable the interpretation of that data in confirmatory and predictive diagnosis in different individuals in a family.

632M

Identifying candidate genes and domains for X-linked diseases using population exome data. *X. Ge[1, 2], P. Kwok[2, 3, 4], J. Shieh[1, 2].* 1) Division of Medical Genetics, Department of Pediatrics, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Department of Dermatology, University of California, San Francisco, San Francisco, CA; 4) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA.

Many new human disease genes can be identified through high-throughput sequencing. Yet variant interpretation for the large amounts of genomic data remains a major challenge. There is an abundance of variation of uncertain significance, and it is difficult to interpret variants in genes that lack disease annotation. As clinically-significant disease genes may be subject to negative selection, we predicted these genes might have a paucity of nonsynonymous variation in the population. The aim of this study was to develop methods to predict pathogenicity using population exome data. We analyzed and integrated human X-chromosome bulk variant data from six thousand individuals (the NHLBI Exome Sequencing Project) to assess intra-human ratios of substitution rates at non-synonymous and synonymous sites (dN/dS) as a potential measure for gene-based pathogenicity. Indeed, we find that the dN/dS ratio is significantly lower in OMIM disease genes, supporting the sensitivity of this intra-human method. Interestingly, genes that are associated with childhood disease outcome also demonstrate a significant relationship to dN/dS, and we have performed some validation using a secondary exome dataset. By analyzing all X-chromosome genes, we identified new candidates for diseases with early mortality, and several of these have been verified by recent exome and gene identification studies. Furthermore, we demonstrate intragenic localized patterns of variants that suggest pathogenic hotspots, which could be used to identify new candidate protein domains linked to diseases. Our results suggest intra-human substitution analysis is a valuable tool to help prioritize novel disease genes in sequence interpretation.

633T

A15924G mt-tRNAT Gene Mutation is not the Primary Cause of Mitochondrial Myopathies. *A. Cakiris[1], N. Abaci[1], Z. Emrence[1], F. Pacal[1], C. Gurses[2], B. Kara[3], D. Ustek[1].* 1) Genetics, Institute for Experimental Medicine, Istanbul, Turkey; 2) Neurology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; 3) Pediatric Neurology, Kocaeli University Medical Faculty, Kocaeli, Turkey.

Mitochondria are essential organelles present in all nucleated mammalian cells. Mitochondrial genome has a very high mutation rate at 10–17 folds higher than the nuclear genome. Those MtDNA mutations may occur within proteins, tRNA or rRNA genes. But more than half of mutations that are disease related are located in mt-tRNA genes. Some of these are polymorphic and the others are pathogenic mutations. In order to analyze mitochondrial DNA mutations, the entire mitochondrial genome was amplified in two overlapping polymerase chain reactions. Mitochondrial DNA was deep sequenced by next generation sequencing technology. The blood or muscle tissue of the 267 patients diagnosed with undefined mitochondrial myopathy and 330 healthy individuals have been analyzed. A15924G mt-tRNA mutation was detected to be homoplasmic in 12 patients and 6 healthy control samples. A15924G mt-tRNA mutation can alter the free energy of the thermodynamic ensemble for the secondary structure of wild type TRNT and affect the structure of tRNAs. This mutation was previously shown to be associated with the LIMM disease as a pathogenic mt-TRNT mutation. In another study, this mutation has been reported as a common mtDNA polymorphism and not the primary cause of LIMM. In our study, this mutation was found in 12 patients, 7 of which belongs to haplogroup I, 2 to F1b1, 1 to U7b, and 1 to T2h haplogroup. Among the healthy individuals, this haplogroup distribution is as follows; 4 haplogroup I, 1 U7b, and one to haplogroup F1b1. According to the above results, the A15924G mutation in both patients and healthy individuals is considered as a haplogroup marker. These results suggest that the A15924G mutation is a common mtDNA polymorphism, rather than a pathogenic mtDNA mutation.

A Mouse Mutagenesis Scheme to Isolate Lethal X-Linked Recessive Mutations. *F.J. Probst[1], R.R. Corrigan[2], M.N. Bainbridge[3], S.N. Jhangiani[3], H.V. Doddanpaneni[3], J. Hu[3], R.A. Gibbs[3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Neuroscience, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Large-scale mutagenesis of the mouse has yielded numerous new autosomal mutants, but X-linked recessive phenotypes have been virtually nonexistent. We have devised a two-generation mouse mutagenesis screen to capture lethal and sub-lethal X-linked recessive mutations. C57BL/6J (B6) male mice are mutagenized with the chemical "supermutagen" ENU. These mice are then bred to 129S6/SvEvTac (129) females to generate G1 progeny. The females from this cross will be X(B6*)X(129) (i.e., they will have inherited a mutagenized B6 X chromosome from their father and a 129 X chromosome from their mother). These G1 animals are then bred to 129 males to generate G2 progeny. In theory, the X(B6*)X(129) G1 female from each pedigree will transmit her X(B6*) chromosome to half of her male progeny and her X(129) chromosome to the other half. When meiotic "crossing over" is considered, this means that, for each X-linked allele, about 1/2 of the male progeny should have the B6 allele, and the other half should have the 129 allele. However, if the X(B6*) chromosome carries an X-linked recessive lethal mutation, then there will be no male mice with B6 alleles at the markers flanking the mutation, since all of these mice will not survive to weaning. DNA from 10 G2 male progeny of each G1 female are therefore combined to create a single "pool" of DNAs for each pedigree. Each pool is then run on an Illumina Mouse Medium Density Linkage Panel. If the female carries a lethal X-linked recessive mutation, the male mice that inherited this mutation will have died prior to weaning, and there will be no B6 alleles in the pools for the markers around the mutation. Though some drift is to be expected in the data, the chance of a particular region of the X chromosome appearing to be homozygous for the 129 alleles is less than 1/1,000, and additional mice can be bred from potential mutant G1 carriers in order to confirm the result. DNA from critical G1 female animals is then subjected to exome capture via a Roche Nimblegen EZ Library, and the products are analyzed by next-generation sequencing on an Illumina apparatus. Causative mutations are confirmed via linkage analysis and additional phenotypic and biochemical studies. Many of the resulting mutants are likely to be models of human X-linked diseases, thus providing new insights into the cause and pathophysiology of X-linked diseases.

The relative impact of DNA mutation and RNA editing as sources of somatic sequence variation in the transcriptomes of normal adult tissues. *D. Conrad[1], N. Huang[1], P. Kheradpour[2,3], M. Kellis[2,3], K. Ardlie[3], The GTEx Consortium.* 1) Department of Genetics, Washington University School of Medicine, St Louis, MO; 2) MIT Computer Science and Artificial Intelligence Lab, Cambridge, MA; 3) Broad Institute, Cambridge, MA.

The full extent and origins of somatic mosaicism in humans are unknown but could have profound implications for our understanding of human health and disease. We have developed a statistical framework for inferring DNA mutations from multi-tissue RNA sequencing data, which considers sequencing error, sampling error, RNA editing and allele-specific expression as alternative explanations for apparent sequence differences among transcripts from the same locus. We have applied this framework to the GTEx Consortium data to detect RNA editing and somatic mutation from 1,514 non-cancerous tissues obtained from 175 donors. We identified 174 putative somatic mutations across 77 donors (min/donor=0; max = 8). In contrast, we observed some evidence for RNA editing in one or more tissues at an average of 1,733 sites per donor (min, 669 sites; max, 6,522). Thus, RNA editing appears to dominate over somatic mutation as a process creating high-frequency somatic sequence variation in the transcriptomes of normal cells. We constructed an expression fingerprint combining *ADAR*, *ADARB1* and *ADARB2* that is strongly correlated with the average extent of RNA editing within individual tissues (R=0.88 in brain tissues, $p< 5.7 \times 10^{-5}$ and R=0.76 in other tissues, $p<4.7 \times 10^{-6}$).

Like RNA editing by the *ADAR* family of enzymes, somatic mutations can be "programmed" to some extent by directed enzymatic activity. V(D)J recombination, catalyzed by *RAG1* and *RAG2*, and somatic hypermutation, catalyzed by *AID*, act on the variable regions T-cell receptor and/or immunoglobulin genes. Of the 174 somatic mutation calls, 86 (49%) occur in the immunoglobulin genes, and lung is the single tissue with the most antibody mutations (24/86, 28%). Partly motivated by this observation, we have performed extensive QC on all somatic mutation calls by read realignment and manual curation, but definitive evidence will be provided by experimental validation of the entire callset, which is ongoing. Of the non-antibody mutation calls, 18 (20%) are observed across multiple tissues in the same person, while 26 (30%) are observed only in blood or LCLs. As these data are derived from transcript sequences, many of the mutations are likely to be functional, and we interpret their origin and impact by investigating their sequence context, relation to cancer genes, and medical history of the donors.

636T

Distinct variation in the LILRB3 and LILRA6 genes encoding a myeloid inhibitory and activating receptor pair. *A. Bashirova[1, 2], C. O'hUigin[1], M. Carrington[1, 2].* 1) Leidos Biomedical Research , Frederick, MD; 2) Ragon Institute of MGH, MIT, and Harvard, Boston, MA.

The leukocyte immunoglobulin-like receptor (LILR)B3 and LILRA6 genes encode homologous inhibitory and activating orphan receptors. Both genes are expressed in monocytes and exhibit a strikingly high level of polymorphism at the amino acid level. We have demonstrated recently that LILRA6 (but not LILRB3) can be present in variable copy numbers in the genome, probably due to crossovers between the two genes. In a cohort of 228 healthy white individuals, we observed that 64% had two copies of LILRA6 per diploid genome, while 32% had more than two and 4% had only one LILRA6 copy. We have now characterized SNPs in the two genes in a subset of individuals with two copies of LILRA6 (N=91). Across seven exons encoding the signal peptide and extracellular D1-D4 domains, we have identified 46 and 38 amino acid changing SNPs in LILRB3 and LILRA6, respectively. Among these, 35 SNPs were located at identical positions within the two genes. While minor allelic frequencies (MAFs) of more than two thirds of the SNPs in each gene were greater than 10%, there were substantial differences in MAFs of many SNPs between LILRB3 and LILRA6. In exons encoding the signal peptide and the D3/D4 domains, some SNPs had MAFs of <2% in one gene and up to 40% in the other gene. These differences were also reflected in distinct patterns of linkage disequilibrium (LD) between pairs of SNPs in the two genes, with LILRA6 demonstrating a higher degree of LD. The dataset on LILRB3/A6 SNPs will be useful in further functional and evolutionary characterization of this highly polymorphic locus, which may be involved in regulation of immune responses in disease pathogenesis.

637S

Finding effectively neutral sequence in the presence of coding and noncoding conserved elements. *A.E. Woerner[1,3], K.R. Veeramah[2], M.F. Hammer[3].* 1) Computer Science, University of Arizona, Tucson, AZ; 2) Department of Ecology and Evolution, Stony Brook, NY; 3) Arizona Research Laboratories, University of Arizona, Tucson, AZ.

Early studies that have attempted to utilize putatively neutral loci in the genome for demographic inference have focused on pseudogenes, introns, and repetitive elements such as Alus. More recent studies have attempted to reduce the impact of positive and negative selection as well as background selection and genetic draft by finding loci that are either in regions of low gene density and high recombination rate, or are at a maximal distance from the nearest gene in genetic units. However, nucleotide diversity may not only be reduced near genes, but also near noncoding conserved elements. Because ~5% of primate genomes is composed of evolutionarily conserved elements, with ~2/3 of these elements being noncoding, skews in diversity in regions in linkage with such elements could have large effects on genomic patterns of nucleotide variation. Here, we show that the combination of multiple conserved noncoding elements has more of an influence on nucleotide diversity than the distance to the nearest gene. Using an approach that models the combined effects of linkage to coding and noncoding elements, we predict levels of polymorphism on both the autosomes and the X chromosome. Based on our predictions we identify loci that we consider to be effectively neutral, i.e., regions whose expected diversity is at least 99% of our inferred neutral rate. Using the relationship between diversity and the local recombination rate as a proxy for the effects of directional selection on neutral sites, we show that unlike other loci in the genome, our effectively neutral loci show no correlation between the local recombination rate and diversity. We conclude that "neutral" sequence is extremely rare in the genome. Finally, we use these neutral regions to estimate the relative effective population size of the X chromosome vs. the autosomes in African and non-African human populations.

638M

The associations of multiple genes with systemic sclerosis by next generation sequence technology. *H. Li, X. Guo, S. Assassi, J. Reveille, M. Mayes, X. Zhou.* University of Texas - Houston Medical School, Houston, TX.

Systemic sclerosis (SSc) is a rare and complex immune-mediated disease characterized by vasculopathy, fibrosis of skin and internal organs and the presence of autoantibodies. According to genome-wide association studies, the HLA region contains the strongest SSc-associated loci. Classical HLA class II genes (DPB1, DQB1 and DRB1) have been clearly associated with SSc. However, the non-classical HLA genes have not been systemically investigated. Here we investigated the HLA genes, PSORS1C1, CCHCR1, MICA, MICB, NFKBIL1, NOTCH4, C6orf10, BTNL2, TAP2 and TNFAIP3 in association with SSc by using next generation sequencing technology (NGS, Ion torrent personal genome machine). We sequenced all exons for the above genes in a large US cohort. A total of 979 sequence variants were identified in these genes. Variant counts for PSORS1C1, CCHCR1, MICA, MICB, NFKBIL1, NOTCH4, C6orf10, BTNL2, TAP2, TNFAIP3 were 44, 138, 85, 42, 57, 232, 102, 101, 107, 71 respectively. These variants included 654 exonic and 325 intronic variants. A nominal association with SSc ($p < 0.05$) was observed in 77 variants of the examined genes with 30 variants of NOTCH4. NOTCH4 is part of an ancient signaling system involved in cell fate decision, and it was reported to be involved in kidney fibrosis and patterning and development of blood vessels. A subsequent confirmation study of NOTCH4 with Sanger sequencing was conducted. Seven out of nine exonic variants were confirmed to be correct and two deletions were confirmed to be substitutions. NOTCH4 rs520692 (p. D272G), rs915894 (p. K117Q) and rs422951 (p.T320A) are the missense variants; rs204987 (p.T1367T), rs520803 (p. Q284Q), rs520688 (p.P271P) and rs423023 (p.G348G) are the synonymous variants. The haplotype of rs520692, rs520803 and rs520688 was associated with anti-TOPO I ($p = 1.1 \times 10^{-8}$, OR 0.37). Rs423023 and rs422951 were also associated with anti-TOPO I at $p = 3.3 \times 10^{-8}$, OR 0.36 and $p = 4.9 \times 10^{-5}$, OR 0.44. NOTCH4 rs204987 was associated with the anti-centromere autoantibody subset ($p = 2.1 \times 10^{-6}$, OR 6.59). These variants showed no association with HLA-DRB1 and are reported to be associated with SSc for the first time. Our results indicate there are many susceptible genes in the non-classical HLA region that are associated with SSc, which further supports the concept that SSc is a complex genetic disease with contributions from multiple loci. NOTCH4 is an important and independent gene from HLA-DRB1 associated with SSc.

639T

Evolutionary constraint and disease associations of post-translational signaling sites in human genomes. *J. Reimand, G.D. Bader.* The Donnelly Centre, University of Toronto, Toronto, Ontario, Canada.

Interpreting genome variation in the context of phenotype and molecular function, distinguishing disease variants, and assessing personal risk are central challenges of biomedical genomics, hindered by predominantly rare inter-individual variation. Potentially functional protein-coding variants found from genome sequencing and genome-wide association studies are often ranked by evolutionary conservation and population frequency. However it is also likely that certain intrinsic protein features carry special functional significance. We hypothesized that protein regions involved in post-translational modifications (PTMs) are functional hotspots of human genomes. PTMs are biochemical alterations of amino acids that extend the functional repertoire of proteins, conducted by enzymes that recognize substrate proteins through short linear motifs (SLMs) in protein sequence. Currently we have public experimental data on ~130,000 PTM sites in human proteins. The centrality of PTMs in biological processes suggests the functional importance of underlying genome sequence. Here we found that PTM-associated protein regions representing ~11% of protein sequence follow a specific constraint in the human population. This is distinct from major sources of variation such as conservation, recombination, or GC content. PTM regions are also enriched in disease and cancer mutations, further emphasizing the deleteriousness of their variation. PTM constraint is exemplified in chromosomal context, gene signatures of most human tissues, and across a thousand processes and pathways. PTM regions include ~250,000 protein residues whose substitution would disrupt SLMs bound by PTM enzymes. Intriguingly these residues are enriched in disease mutations, confirming their importance in physiology. As many PTM enzymes are targetable with approved drugs, we use their substrate specificity data to build a network of drug-disease interactions mediated by enzymes that bind mutated sites in disease genes. This represents a useful resource for drug screen design and hypothesis generation. Finally, we applied our ActiveDriver model to study disease mutation hotspots in PTM regions. For example, we propose a new mechanism to variants of the PTPN11 gene responsible for Noonan syndrome. In summary, we describe a novel constraint of the protein-coding genome, and demonstrate use of proteomics data to interpret genome variants, improving associations to phenotypes, molecular mechanism and disease.

Genetic analysis of dendritic cell responses to influenza using RNA sequencing reveals novel genotype by stimulation effects on alternative splicing. *C.J. Ye[1], J. Chen[1,7], A.C. Villani[1], M.N. Lee[1,2,3], T. Raj[1,2,4], B.E. Stranger[5], P. De Jager[1,2,4], C.O. Benoist[2,4], T. Bhangale[6], W. Ortmann[6], T. Behrens[6], A. Regev[1,7,8], N. Hacohen[1,2,3].* 1) Broad Institute, Cambridge, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts General Hospital, Boston, MA; 4) Brigham and Women's Hospital, Boston, MA; 5) University of Chicago, Chicago, IL; 6) Genentech Inc., South San Francisco, CA; 7) Massachusetts Institute of Technology, Cambridge, MA; 8) Howard Hughes Medical Institute.

Genetic variation affecting splicing plays an important role in human disease both through cis effects on splice isoforms and by trans effects mediated through the splicing machinery. Genetic variants are known to modulate gene expression levels (eQTLs) in response to in vitro stimulation, yet systematic genome-wide investigation of how variants affect alternative splicing has not been widely explored. RNA-seq opens the possibility to directly estimate isoform usage ratios and assess the underlying genetic variants (irQTL). Here, we sought to identify cis irQTLs, and to elucidate the functional mechanisms by which they act in the anti-viral transcriptional response of innate immune cells using RNA-seq. We sequenced primary dendritic cells from 279 individuals in response to stimulation with influenza virus and the cytokine IFNβ. Post flu stimulation, in addition to 3474 genes with significant cis eQTLs (with 52% replication in GEUVADIS, correlation of effect sizes $\rho(\beta)=0.59$), we identified 1069 genes with significant cis irQTLs, higher than previous estimates. Three lines of evidence support our findings: (i) 67% internal replication with IFNβ stimulation ($\rho(\beta)=0.97$), (ii) 54% replication with the GEUVADIS samples ($\rho(\beta)=0.8$) using our computational pipeline, and (iii) replication with allele specific isoform usage analysis. As a class, cis irQTLs cluster near known splice sites and overlap with GWAS loci at the same frequency (17%) as cis eQTLs suggesting the potential importance of differential splicing in disease pathogenesis. We highlight ERAP2, and a IBD associated loss-of-function (LoF) cis variant, rs2248374, that induces the alternative splicing of a longer isoform predicted to undergo non-sense mediated decay (NMD). We observed the expected ERAP2 cis irQTL post IFNβ stimulation. But remarkably, in flu-stimulated cells, we observed near complete abrogation of the cis irQTL and rescued expression of the NMD isoform, confirmed by allele specific analysis. These results suggest potentially a new host response mechanism of NMD-escape or a flu specific mechanism for NMD inhibition, either of which alters our interpretation of an apparent LoF polymorphism. Taken together, our results suggest that modulation of alternative splicing may be a widespread and important mechanism by which genetic variants control transcript diversity by creating proteins of differing function or transcripts with altered transcript processing or stability.

Expression quantitative trait analysis in human platelets. *L. Simon[1], E. Chen[1], L. Edelstein[2], P. Bray[2], C. Shaw[1].* 1) Baylor College of Medicine, Houston, TX; 2) Thomas Jefferson University, Philadelphia, PA.

Human platelets are responsible for coagulation physiology and maintenance of haemostatic balance. Abnormal platelet reactivity is associated with various disease states such as bleeding disorders, atherosclerosis, occlusive or thrombotic cardiovascular disorders, inflammation and cancer, resulting in significant morbidity and mortality. The Platelet RNA and eXpression-1 study was designed to investigate significant heritable inter-individual variation in platelet functional properties. This study profiled platelet mRNA and microRNA expression as well as genotype of 154 healthy human subjects. To study the regulatory landscape of the human platelet, we conducted expression quantitative trait locus (eQTL) analysis and identified a large number of loci significantly associated with gene expression levels in cis and trans. The comprehensive approach to cataloging all platelet eQTLs can be of great help in future studies, such as the prioritization of trait-associated loci implicated in genome-wide association studies.

642T

Accurate and fast multiple testing correction to identify eGenes in eQTL studies. *J. Sul[1,2], B. Han[1,2], T. Raj[2,3,4], P. de Bakker[1,2,5], S. Raychaudhuri[1,2,6], B. Stranger[7,8], E. Eskin[9,10].* 1) Division of Genetics, Brigham & Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) Harvard Medical School, Boston, Massachusetts, USA; 4) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham & Women's Hospital, Boston, Massachusetts, USA; 5) Departments of Epidemiology and Medical Genetics, University Medical Center Utrecht, 3584 CG Utrecht, the Netherlands; 6) Arthritis Research UK Epidemiology Unit, Musculoskeletal Research Group, University of Manchester, Manchester Academic Health Sciences Centre, Manchester M13 9PT, UK; 7) Section of Genetic Medicine, Department of Medicine, University of Chicago, Chicago, Illinois, USA; 8) Institute for Genomics and Systems Biology, University of Chicago, Chicago, Illinois, USA; 9) Computer Science Department, University of California, Los Angeles, California, USA; 10) Department of Human Genetics, University of California, Los Angeles, California, USA.

Expression quantitative trait loci (eQTL) studies attempt to detect genetic variations called eQTLs that alter expression levels of genes. Those studies are especially interested in identifying genes called eGenes that contain eQTLs because genes are primary entities utilized in a disease pathway analysis. A traditional approach to detect eGenes is to find a genetic variant with the minimum p-value among all variants in *cis* with each gene and to perform a multiple testing correction to obtain a gene-level p-value. The permutation test is widely used for the multiple testing correction because it considers LD structure among variants. However, the sample size of eQTL studies has recently grown larger, and the permutation test has become a computational bottleneck in eQTL studies. In this paper, we propose an efficient approach to correct for multiple testing utilizing a multivariate normal distribution (MVN) that approximates the null distribution of test statistics. Our approach takes into account LD structure among variants, and its time complexity is independent of the sample size. However, one challenge is that the true null distribution of statistics does not exactly follow the MVN, especially in datasets of the small sample size. We propose an accurate method that corrects for this discrepancy between the true null distribution and MVN. We show that our approach yields gene-level p-values very close to those from the permutation test using three human eQTL datasets including Genotype-Tissue Expression project (GTEx). Our method is 38 times faster than the permutation test when the sample size is 300 and much faster for the larger sample size.

643S

Ttn as a likely causal gene for QTL of alcohol preference on mouse chromosome 2. *L. Wang[1], Y. Jiao[1], Y. Huang[1], B. Bennett[2], R.W. Williams[3], D. Li[4], H. Zhao[5,6], J. Gelernter[4,6,7,8], H.R. Kranzler[9,10], L.A. Farrer[11], W. Gu[1].* 1) Orthopaedic Surgery, University of Tennessee Health Science Center, Memphis, TN; 2) Pharmacology, University of Colorado Denver, Aurora, CO; 3) Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN; 4) Psychiatry, School of Medicine, Yale University, New Haven, CT; 5) Epidemiology and Public Health, School of Medicine, Yale University, New Haven, CT; 6) Genetics, School of Medicine, Yale University, New Haven, CT; 7) VA Connecticut Healthcare Center, West Haven, CT; 8) Neurobiology, School of Medicine, Yale University, New Haven, CT; 9) Psychiatry, School of Medicine, University of Pennsylvania, Philadelphia, PA; 10) VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 11) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Genetics & Genomics, Biostatistics, and Epidemiology, Schools of Medicine and Public Health, Boston University, Boston, MA.

Many quantitative trait loci (QTL), influencing mouse model phenotypes for alcoholism, have been mapped genetically. However, the gene(s) comprising the QTL (QTG) are largely unknown. In previous work, Dr. Bennett and colleagues created congenic strains carrying the DBA/2IBG (D2) region for alcohol preference (AP) on chromosome 2, on a C57BL/6IBG (B6) background. Subsequently, interval specific congenic recombinant strains (ISCRS), in which the full D2 QTL region was broken into smaller, partially overlapping regions of introgression, were generated and tested. With information from two ISCRS ,the QTL has been mapped onto mouse chromosome 2 (Chr2) in a region of 3.4Mb by using C57BL/6J (B6) × DBA/2J (D2) recombinant inbred (RI) strains as well as by using F2 populations. Several candidate genes, Gad1, Atp5g3, Atf2, Sp3 and Sp9, have been evaluated but none of them is confirmed for a definitive role in the regulation of the QTL of AP on Chr2. We have been searching candidate gene for this QTL intensively by using an integrative approach including 1) bioinformatics tools to search potential function relevant genes of alcohol preference within the QTL region; 2) searching for single nucleotide polymorphisms (SNPs) within the exons of every gene between B6 and D2 in the QTL region; 3) conducting real time PCR to examine the differentialyl expressed genes between B6 and alcohol preferred interval-specific congenic recombinant strains (ISCRS); and 4) analysis of association of candidate gene in human population. Titin (Ttn) is known as a giant muscle protein expressed in the cardiac and skeletal muscles. However, its expression level in the tongue is known to be higher than that in the heart. We therefore investigated if Ttn plays a role in the regulation of AP. Our data indicated that 1) the expression level of Ttn in the less AP congenic strains is significantly higher than that in B6; 2) the expression of a Ttn probe in the BXD RI strains is negatively correlated to that of AP; 3) One SNP is in up- and the other is in down-stream of Ttn. The alcohol consumption of the B6 genotype is significantly higher than that of D2 genotype in the BXD RI strains, based on data from multiple reports using two-bottle of choice; and 4) the polymorphism of TTN in human population is highly associated with alcoholism. We conclude that Ttn is a likely causal gene for the QTL on Ch2 for the AP.

Cross-population Meta-analysis of eQTLs: Fine-mapping and Functional Study. *X. Wen[1], G. Moyerbrailean[2], F. Luca[2], R. Pique-Regi[2].* 1) Dept Biostatistics, Univ. of Michigan, Ann Arbor, MI; 2) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI.

Data sets collected from multiple ethnic groups provide great potentials to understand the genetic basis of gene regulations. Nevertheless, the joint analysis of multiple-population eQTL data presents great challenges, mainly due to varying LD patterns and heterogeneity of genetic effects presented in multiple populations. In this study, we develop a set of statistical and computational tools to tackle the problem of cross-population meta-analysis of eQTLs, primarily focusing on the applications of fine mapping and functional study. Our approach holds three distinct advantages over the existing methodologies:

1. Our method effectively identifies eQTL signals that show consistent genetic effects across populations while accounting for the potential heterogeneity based on a powerful Bayesian meta-analysis framework (Wen and Stephens, 2014 AOAS; Flutre et al, 2013 PLoS Genetics).
2. Our approach performs efficient multiple SNP fine-mapping analysis across multiple populations allowing varying LD patterns.
3. Building on the fine-mapping results, our method enables high-resolution functional analysis of eQTL signals accounting for LD.

We apply our methods to re-analyze the GEUVDIS data consisting of five population groups. Furthermore, we use base-pair resolution annotation obtained with an improved CENTIPEDE method using ENCODE DNase-seq data. Our preliminary results show that

1. Meta-analysis is more powerful and robust in identifying eQTL signals. We identify 6,555 genes harbouring at least one eQTL, at FDR 5% level, in their cis-regions (eGenes) using the joint meta-analysis approach. In comparison, separate subgroup analysis identifies 1803 (TSI), 2078 (GBR), 2100 (FIN), 960 (CEU) and 1042 (YRI) eGenes.
2. Many genes contain multiple independent cis-eQTLs in their cis-regions. With the meta-analysis powered fine-mapping approach, we are able to confidently identify 674 genes containing 2 or more independent cis-eQTL signals and 67 genes containing 3 or more signals.
3. Binding variants are significantly enriched in the identified population consistent eQTL signals (p-value < 1.6×10^{-11}).

Linking systems genetics and co-expression analysis to elucidate diabetic kidney disease regulatory networks. *T. Leak[1], C. Komorosky[1], V. Nair[1], H. Huang[1], B. Keller[1], A. Randolph[1], R. Nelson[2], M. Kretzler[1], T. Werner[1,3].* 1) Internal Med-Nephrology, Univ of Michigan, Ann Arbor, MI; 2) 2National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Phoenix, Arizona; 3) Genomatix Software GmbH, Munich, Germany.

Expression quantitative trait loci (eQTL) analysis associates genetic and transcriptomic data, but does not provide insight into how eQTLs influence sets of genes in complex diseases. Using diabetic kidney disease (DKD) as a case study, genome-wide SNPs, protocol biopsy gene expression and clinical data were obtained from 65 Pima Indians. Genome-wide systems genetic analysis paralleled with weighted co-expression network analysis (WGCNA) was performed on gene expression profiles from microdissected glomeruli. Integration of glomerular eQTL analysis and WGCNA was carried out to identify transcriptional coregulation-modules. Matrix eQTL was employed to test allele dosage effect on gene expression levels. An in silico promoter analysis approach was used to identify common transcription factor binding sites (TFBS) frameworks shared between the promoters of cis-eQTL transcripts and potentially within LD blocks of associated expression (e)SNPs. Multivariate linear regression was then used on the module eQTLs, promoter gene matches, TF belonging to TFBS families represented in the framework and additive genotypic model, to test for association with indices of renal function and diabetes traits. A total of 13,179 transcripts were parsed into 37 co-expression modules and Matrix eQTL resulted in 3,112 cis-eQTL gene pairs. To establish a mechanistic link between correlated cis-eQTL modules, a module with a similar number of transcripts and eSNPs was analyzed via an in silico promoter analysis approach (dark magenta module). Framework analysis of tag-eSNP LD block sequences with kidney associated promoters revealed a four-element framework (ETS-SP1-PAX5-HOMF; 5.64 fold over presented) that matched 2 of the 3 eQTLs (TAF9, HPGD). The LD block spans TAF9, RAD17 and MARVELD2, two of which (TAF9 and RAD17) have matches of the framework in their promoters. A genome-wide search of all human promoters (N=101,492) revealed only 17 matches. Four of these genes, ETS TFs and rs6450041 (located in the same LD block and an eSNP for RAD17) showed suggestive evidence of association with decreased renal function ($P \leq 0.000001$). Our integrative framework potentially highlights how eSNPs may influence the expression of several genes linked in a LD block with renal function. Preliminary data indicate that other eQTLs may also act on gene sets employing similar strategies, i.e TFframeworks that could coordinate transcriptional regulation, all of which is linked with DKD.

Mediation analysis identifies causal relationships among SNPs, cis-CpG methylation, and cis- and trans-transcripts. *B. Pierce[1], L. Tong[1], R. Rahaman[1], L. Chen[1], M. Kibriya[1], M. Argos[1], J. Farzana[1], S. Roy[1], R. Paul-Brutus[1], R. Zaman[2], T. Islam[2], M. Rahman[2], J. Baron[3], H. Ahsan[1].* 1) Health Studies, Univ Chicago, Chicago, IL; 2) UChicago Research Bangladesh, Mohakhali, Dhaka, Bangladesh; 3) University of North Carolina, Lineberger Comprehensive Cancer Center, Chapel Hill, NC.

A large fraction of human genes are regulated by genetic variation. However, our understanding of the mechanisms by which genetic variants influence transcription is incomplete. A more in-depth understanding of eQTLs (expression quantitative trait loci) can be gained by identifying cellular features that mediate the effects of genetic variants on gene expression. In this work, we use Sobel tests of mediation to determine (1) if trans-eQTL associations are mediated by transcripts in cis with the SNP showing the trans-association and (2) if cis-eQTL associations are mediated by local chromatin structure (measured as DNA methylation). Using data on 1,799 Bangladeshi individuals with genome-wide SNP and array-based expression data, we demonstrate that among 197 independent trans-eQTLs (FDR= 0.05), 76 were also cis-eQTLs, and evidence of mediation was detected for 55 of these 76 trans-eQTLs (Sobel P <0.01). Using a subset of these participants (n=377) with genome-wide DNA methylation data (Illumina 450K), we detect mediation by cis-CpG methylation status for 22% of 2,598 observed cis-eQTLs, suggesting that alteration of chromatin features is a common mechanism by which genetic variation influences gene expression. In these analyses, "partial" mediation, rather than "full" mediation, is most often observed, and using simulated data, we show that this result is expected. More specifically, in the presence of mediator measurement error or imperfect LD between measured and causal variants, complete mediation will be observed as partial mediation. Our results also show that eQTL associations can become significantly stronger after adjusting for a potential mediator, a counterintuitive observation. Using simulated data, we demonstrate that this phenomenon can occur when the when the analyzed mediator is not the true mediator, but is correlated with the true (unmeasured) mediator. In this work we demonstrate mediation for a large fraction of cis- and trans-eQTLs; however, our ability to detect mediation would be enhanced by the use of more comprehensive data on potential mediators (e.g., RNA-seq and bisulfite-seq). Mediation analysis will be useful for validation and discovery of eQTLs and is a valuable tool for characterizing the biological mechanisms underlying eQTLs.

Characterizing the genetic basis of innate immune response in TLR4-activated human monocytes. *S. Kim[1], B. Pütz[3], M. Bechheim[2], J. Becker[1], M. Nöthen[1], B. Müller-Myhsok[3], V. Hornung[2], J. Schumacher[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Institute of Molecular Medicine, University of Bonn, Bonn, Germany; 3) Statistical Genetics, Max-Planck-Institute of Psychiatry, Munich, Germany.

Toll-like receptors (TLRs) play a key role in innate immunity. Apart from their function in host defense, dysregulation in TLR-signaling can confer risk to autoimmune diseases, septic shock or cancer. Despite major advancements in our understanding of how the innate immune system recognizes pathogens, the genetic basis for differences in innate immune responses is only poorly defined. This study was aimed to characterize the genetic basis of variation in gene expression in TLR4-stimulated human monocytes. For this purpose we isolated monocytes of 137 individuals and stimulated them with lipopolysaccharide (LPS) to activate Toll-like receptor 4 (TLR4). From these donors, we performed transcriptome profiling and genome-wide SNP-genotyping. Comparing unstimulated versus TLR4-stimulated monocytes revealed expression quantitative trait loci (eQTLs) that are unique to TLR4 stimulation. Among these, we show that SNPs conferring risk to primary biliary cirrhosis (PBC), inflammatory bowel disease (IBD) and celiac disease are immune response eQTLs for novel candidate genes, bringing new insights into the pathophysiology of these disorders in the context of TLR4-activation.

Analysis of genetic and environmental determinants of gene expression. *F. Luca[1], C. Harvey[1], G.O. Davis[1], G. Moyerbrailean[1], D. Watza[1], X.W. Wen[2], R. Pique-Regi[1].* 1) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

The effect of genetic variants on a molecular pathway, and ultimately on the individual's phenotype, is likely modulated by "environmental" factors. However, it is generally difficult to determine in which tissues and conditions genetic variants may have a functional impact. We denote the functional genetic variants that show cellular environment-specific effects as GxE expression quantitative trait loci (GxE-eQTLs). Achieving a better understanding of the mechanisms underlying GxE-eQTLs is a critical step in understanding the link between genotype and complex phenotypes. To identify and characterize GxE-eQTLs we have established a new two-step and cost-effective experimental approach. In the first step, we identify global changes in gene expression using low-coverage sequencing of pools of highly multiplexed samples. In the second step, we select a subset of samples for deep sequencing and allele-specific analysis. For the first step, we generated 1056 RNA-seq libraries in pools of 96 spanning 250 cellular environments across 5 cell-types (3 individuals), and 50 different treatments (including hormones, dietary components, environmental contaminants and metal ions). Relevant GO categories were enriched in the observed global gene expression changes (e.g. immune response for Dexamethasone, ion homeostasis for Zinc). We then analyzed allele specific expression (ASE) using a novel method (QuASAR) that allows for joint genotyping and allele specific analysis on RNA-seq data. Across 21 cellular environments we discovered 2469 instances of ASE (FDR<10%), corresponding to 1402 unique ASE genes. Using Bayesian model across treatments within cell types, we observed that 95.9% ASE signals are shared (95% credible interval [93.4%-99.3%]) and their effect sizes are highly concordant (posterior correlation coefficient 0.9). This is highly consistent with previous analysis of condition-specific eQTLs. Nevertheless, we still identified 270 loci with a Bayes factor supporting GxE (200 sites treatment-specific and 70 sites control-specific GxE-eQTLs). We are now in the process of expanding the ASE analysis to 32 additional cellular environments. Our results constitute a first comprehensive catalog of GxE-eQTLs and we anticipate that it will contribute to the discovery and understanding of GxE interactions underlying complex traits.

649S

Identification of novel trans-acting eQTLs at *SLC25A38-MYRIP-EIF1B* and *CIITA* in subcutaneous adipose tissue. *Y. Wu[1], M. Civelek[2], C.K. Raulerson[1], A. He[3], C. Tilford[3], C. Fuchsberger[4], A.E. Locke[4], H.M. Stringham[4], A.U. Jackson[4], N.K. Saleem[5], N. Narisu[6], P.S. Chines[6], P. Gargalovic[3], T. Kirchgessner[3], F.S. Collins[6], M. Boehnke[4], M. Laakso[5], A.J. Lusis[2], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Medicine, University of California, Los Angeles, CA; 3) Bristol-Myers Squibb, Pennington, NJ; 4) Department of Biostatistics, University of Michigan School of Public Health, Ann Arbor, MI; 5) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 6) National Institutes of Health, Bethesda, MD.

Mapping of expression quantitative trait loci (eQTLs) can identify genetic variants that influence gene expression and subsequent clinical traits. To identify trans-acting eQTLs that affect distal (> 1 Mb) gene expression and to characterize regulatory gene networks, we analyzed subcutaneous adipose tissue from a subset of 1,381 individuals from the METabolic Syndromes In Men (METSIM) study. A total of 43,145 transcripts were assayed using the Affymetrix Human Genome U219 Array and tested for association with ~10 million SNPs genotyped using the Illumina OmniExpress array or imputed (1000 Genomes Project). Among the 427 billion SNP-transcript associations tested for trans eQTLs, 376,941 (0.00009%) exhibited significant evidence of association at $P < 5\times10^{-8}$. In addition to confirming the reported *KLF14* master regulator of adipose gene expression, we identified a potential novel master trans regulator at *SLC25A38-MYRIP-EIF1B* on chr 3. SNP rs11714871 (MAF = 0.40) was strongly associated with transcript levels of 16 distal genes ($P = 3.4\times10^{-29}$-4.1×10^{-8}) and modestly associated with transcript levels of 3 local (<1 Mb) genes, *SLC25A38* ($P = 2.5\times10^{-4}$), *MYRIP* ($P = 0.042$) and *EIF1B* ($P = 0.099$). Of the 16 distal transcripts, levels of 15 were correlated with expression of the local *SLC25A38* (|r| = 0.19-0.07; $P = 2.8\times10^{-13}$-0.014), and levels of 2 were correlated with expression of *EIF1B* (|r| = 0.07, $P = 0.011$). Of these 19 distal and local transcripts, *EIF1B*, *ATXN7L2* and *CD164* were associated with levels of triglycerides and LDL-cholesterol ($P = 0.025$–0.040). We identified a second novel trans-eQTL near *CIITA* on chromosome 16. SNP rs11074932 (MAF = 0.36) was associated with the transcript levels of four class II major histocompatibility complex (MHC) genes on chr 6 and *CD74* on chr 5 ($P = 7.1\times10^{-15}$-1.1×10^{-10}). The rs11074932 allele associated with higher expression levels of these transcripts was associated with higher *CIITA* expression ($P = 1.1\times10^{-4}$). CIITA is a transcriptional coactivator long known as a master regulator for class II MHC gene transcription, thus our result, which may reflect adipose tissue or infiltrated lymphocytes, supports a genetic influence on this regulatory control. These findings of trans regulatory effects should help construct regulatory networks in adipose tissue that may lead to an improved understanding of disease etiology.

650M

Long intergenic non-coding RNA eQTLs are enriched for complex trait-associated SNPs and do not distally regulate the expression of protein-coding genes. *I. McDowell[1], C. Guo[2], G. TEx Consortium[3], A. Pai[4], C. Brown[5], T. Reddy[3], B. Engelhardt[3].* 1) Computational Biology & Bioinformatics, Duke University, Durham, NC; 2) University Program in Genetics and Genomics, Duke University, Durham, NC; 3) Biostatistics & Bioinformatics, Duke University, Durham, NC; 4) Biology, MIT, Boston, MA; 5) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Long intergenic non-coding RNAs (lincRNAs) participate in a variety of biological processes including mammalian X-chromosome inactivation, telomere maintenance, adipogenesis, and cancer progression. Expression quantitative trait loci (eQTL) studies have proved effective in characterizing the genetic regulation of protein-coding genes but have largely neglected lincRNA genes for a number of reasons. Here, we performed a genome-wide association study to identify regulatory variants associated with lincRNA and protein-coding gene expression in the Genotype-Tissue Expression (GTEx) pilot data. Genotypic variation at 10 M single nucleotide polymorphisms (SNPs) including SNPs imputed from over 3.5 M quality-filtered SNPs was associated with the expression of 4000 lincRNA genes and 18,000 protein-coding genes as quantified by RNA-seq. We performed association mapping in four tissue types independently by an additive effects Bayesian regression model and across all four tissues jointly using a multi-tissue Bayesian regression model. We identified cis-lincRNA-eQTLs (linc-eQTLs) associated with 1,566 lincRNA genes (36%) and cis-protein-coding eQTLs (pc-eQTLs) associated with 9,794 protein-coding genes (54%) at a 5% FDR. We found substantial sharing of linc-eQTLs and pc-eQTLs across tissues, suggesting that the regulation of both lincRNA and protein-coding gene expression relies on regulatory elements that are similarly active across tissues. Nevertheless, linc-eQTLs were more tissue-specific overall than pc-eQTLs after controlling for tissue-specific expression levels, suggesting greater tissue-specificity of linc-eQTLs relative to pc-eQTLs. While both linc-eQTLs and pc-eQTLs were enriched for linkage to complex trait-associated SNPs, pc-eQTLs had greater relative enrichment. These results suggest that genetic variants that alter lincRNA expression may contribute to genetic risk for human diseases. For example, we identified several lincQTLs in adipose tissue in genomic regions associated with adiponectin levels and with anthropomorphic measures of adiposity in adults and newborns. LincRNAs have been speculated to function mainly in the transcriptional regulation of protein-coding genes. We tested this hypothesis by using cis-linc-eQTLs and cis-pc-eQTLs as candidate sets for trans-eQTL association. Through these analyses we did not find support for the hypothesis that lincRNAs play a substantial role in distal regulation of transcription of protein-coding genes.

Massively parallel identification of non-coding causal alleles driving genetic associations. *R. Tewhey[1,2], K.G. Andersen[1,2], E.A. Brown[2,3], S. Winnicki[1,2], T.S. Mikkelsen[2], P.C. Sabeti[1,2].* 1) Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) Department of Human Evolutionary Biology, Harvard University, Cambridge, MA.

Although genome-wide association studies (GWAS) have implicated thousands of common variants in various human diseases, our ability to localize association signals to individual causal alleles - and thereby elucidate mechanisms of pathogenesis - remains poor. This is partially due to our inadequate understanding of the effects of non-coding variation, which includes the majority of disease associations. To address this, we extended the use of the massively parallel reporter assay (MPRA) as a tool for the identification of non-coding causal alleles. We introduced modifications to MPRA allowing us to empirically measure the regulatory potential of 29,000 single nucleotide polymorphisms (SNPs) and the differential allelic effects at those sites in a single experimental setup. To evaluate the assay, we tested all variants in perfect linkage disequilibrium with the highest-ranking SNP for each of 3,992 eQTLs found in the 1000 Genomes lymphoblastoid cell lines (LCLs). In addition, we performed more comprehensive testing at eQTL peaks overlapping 163 variants from the NHGRI GWAS catalog. Overall, we successfully interrogated >95% of the targeted loci and detected thousands of regions that enhance expression activity. The identified regulatory loci are highly enriched for DNase hypersensitivity sites, as well as for histone marks predicting enhancer and promoter activity. At the same time, a substantial proportion of regulatory sequence remains unaccounted for by current markers. We identified putative causal alleles for hundreds of eQTL peaks and show strong correlation with traditional luciferase reporter assays. We will also discuss in detail several instances where the causal allele localizes to known disease-associated loci. Having experimentally identified regulatory alleles in two separate 1000 genome cell lines, we evaluated the same regions in a hepatocyte cell line, thus providing direct evidence of hundreds of tissue-specific regulatory elements. This work demonstrates the application of MPRA to functional genetics, allowing us to pinpoint causal alleles and investigate the molecular mechanisms underlying disease/trait associations.

Uncovering expression variability and eQTLs on the X chromosome. *K. Kukurba[1,2], A. Battle*[3], S.M. Montgomery*[1,2].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Pathology, Stanford University, Stanford, CA; 3) Department of Computer Science, John Hopkins University, Baltimore, MD.

The X chromosome plays a distinctive role in genotype-phenotype relationships. However, many existing genetic association and eQTL studies have entirely disregarded it due to the special challenges of conducting analyses on the X chromosome; in particular, accounting for properties including random X-inactivation, dosage compensation, and distinct modes of inheritance relative to autosomes. To deal with these challenges and to better identify genotype-phenotype patterns on the X chromosome, we compared the utility of different statistical models for eQTL discovery on the X chromosome. By applying well-performing models, we studied X chromosome eQTL within the Depression Genes and Networks (DGN) study cohort of 922 genotyped individuals with RNA-sequencing data from whole blood. In the male and female populations, we detected a high proportion of shared eQTLs (85% of X-chromosome eQTLs are shared between sexes) as well as identified sex-specific eQTLs on the X chromosome. We further characterized the properties of these eQTLs by comparing effect sizes and evidence of selective constraint between the X chromosome and autosomes, specifically evaluating variants in lower frequency ranges. In addition, we investigated the contributions of sex to overall expression variance across the transcriptome. We discovered that females have higher variance in expression on the autosomes. Conversely, we found that males have higher expression variance on the X chromosome than females, a pattern expected in males where hemizygosity results in more extreme effects arising from genetic variation. Lastly, we examined the phenomenon of random X-inactivation in females across different ages. We found that older individuals typically have more allelic skewing on the X chromosome compared to younger individuals; an observation which may be explained by clonal selection in the hematopoietic stem cell population. Together, this work advances our understanding of how sex and eQTLs shape human expression variation on the X chromosome contributing to sexual dimorphism.

653M

Universal eQTL: discovery and replication across cell type and population. *S.A. Shenoy[1], T.L. Vincent[1], R.G. Crystal[1], J.G. Mezey[1,2].* 1) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Expression Quantitative Trait Loci (eQTL) describe a fundamental aspect of biology: inherited allelic variation that impacts gene expression. Universal eQTL (e_uQTL) describe cases where the same eQTL relationship, indicated by repeated identification of an association between genotypes in the same genomic region and expression of the same gene, is almost always present regardless of the tissue analyzed or ancestry of the sample population. These e_uQTL are inherently interesting because they indicate a strong connection between the regulation of gene expression and the genetics that influence expression, and because they represent cases of super-replication that can be leveraged to infer the genetic causes and impacts of e_uQTL. While the existence of e_uQTL has been indirectly acknowledged there has not been a targeted effort to discover e_uQTL.

Making use of an eQTL detection pipeline developed in our lab capable of independently testing billions of genotype-expression associations in a few hours, we analyzed >35 publicly available and new datasets, including HapMap lymphoblastoid cell lines and cancer/healthy tissues in the TCGA catalog, where together our combined analysis included over 20 distinct tissue/cell types and 8 distinct ancestry groups. For each dataset, we independently tested every genotype-expression variable measured by microarray or RNA-Seq genome-wide after minimal filtering. By employing stringent false-positive controls and data fitting metrics, we identified 22 e_uQTL that were in almost every dataset and 64 additional e_uQTL that replicate across natural groupings of datasets. Most of these were cis-e_uQTL, where a number of trans-e_uQTL were identified when considering less conservative multiple test corrections. Taking advantage of e_uQTL replication across populations, we leveraged patterns of linkage-disequilibrium to narrow the genomic region containing the causal genotype(s) to <1–5 kb in a number of cases, a "drilling down" approach that is only possible with e_uQTL. The result of this work is a picture of the nature and generality of e_uQTL, the causal polymorphisms responsible, and the regulatory impacts of these e_uQTL, which together provide an understanding of why e_uQTL exist, their regulatory and genetic basis, and their downstream impacts.

654T

Sex-biased genetic effects on the transcriptome of monocytes and T-cells. *N.L. Tignor[1], T. Raj[2,3,4,5], E.R. Gamazon[1], K. Rothamel[6], P.L. De Jager[2,4,5], B.E. Stranger[1,7], The ImmVar Consortium.* 1) Section of Genetic Medicine, Department of Medicine, The University of Chicago, Chicago, IL; 2) Program in Translational NeuroPsychiatric Genomics, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, MA; 3) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) The Broad Institute of MIT and Harvard, Cambridge, MA; 6) Division of Immunology, Department of Microbiology and Immunobiology, Harvard Medical School, Boston, MA; 7) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL.

Sexual dimorphism is observed across a variety of complex phenotypes in model organisms and humans, including immune function in healthy individuals, as well as autoimmune disorders and neuropsychiatric disorders, among others. In model organisms, and to a lesser extent in humans, sex-specific quantitative trait loci have been identified for sexually dimorphic traits. To extend our understanding of the contribution of sex to the genetic basis of human immune function and dysfunction, we performed a sex-aware expression quantitative trait locus (eQTL) study of highly purified CD4(+) T cells and monocytes, representing adaptive and innate immunity, in a cohort of 212 healthy individuals, as part of the Immunological Variation (ImmVar) Project. We estimate that of genes with significant cis-eQTLs in each sex, less than 10% are unique to one sex, with the degree of sex bias approximately equal in each of the two cell types. Where associations are shared across sexes, we see strong correlation between effect sizes of male- and female eQTLs (r^2=0.94, CD4; r^2=0.87, CD14), suggesting little in the way of sex-specific modification of allelic effects. We do not observe cases where cis-eQTLs are shared across sexes but show opposite direction of allelic effects across sexes. We do, however, observe cis-eQTL allelic direction changes across cell-types, as has been reported previously. Although the degree of sex-bias between males and females is similar across the cell-types, we observe tissue-specificity in the genes with sex-biased eQTLs. Functional analysis of sex-specific eQTLs within cell types identifies different categories of significant enrichment, with sex-specific eQTL genes enriched in antigen and immune function in CD14, and glutathione and oxidative stress in CD4. We identified genetic variants previously associated with complex traits in human diseases as cataloged in the NHGRI catalog of genome-wide association studies that are also significant sex-specific eQTLs in our datasets. These include variants associated with diseases that exhibit sexually dimorphic characteristics, including Crohn's disease, bipolar disorder, and rheumatoid arthritis. Our results characterizing the sex-specific genetic architecture of the transcriptome in these immune cells will be compared and contrasted to our parallel analyses of the same cell-types in populations of different ancestry, as well as in tissues of the Genotype-Tissue Expression (GTEx) Project.

655S

ERAL1 Stabilization of miRNA: A Novel Regulatory Mechanism of Gene Expression. *K. Aquino-Michaels[1], V. Trubetskoy[1], E.R. Gamazon[1], M.G. Larson[3], J. Freedman[3], J. Rong[3], S. Lacey[3], T. Huan[3], D. Levy[3], R.S. Huang[2], N.J. Cox[1], H.K. Im[1].* 1) Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, IL; 2) Department of Medicine, Section of Hematology/Oncology, University of Chicago, Chicago, IL; 3) Framingham Heart Study, Population Sciences, Branch National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD.

Genetic mechanisms of gene regulation create a rich source of variation between individuals and are essential to complex traits and biological function. These mechanisms can influence local gene transcription or act in trans through complex regulatory interactions. Trans gene regulation can occur through small non-coding RNAs such as microRNAs that act as regulatory hubs for many downstream targets. While cis-acting regulation of microRNA expression shares similar mechanisms with cis-regulation of messenger RNA (mRNA), trans regulation of microRNA remains poorly understood. Furthermore, currently only a handful of trans-microRNA quantitative trait loci (mirQTLs) have been reported and fewer still have been replicated. To systematically identify mechanisms of trans-microRNA expression, we conducted mirQTL mapping in 4902 participants from the Framingham Heart Study--the largest single mirQTL cohort to date. We discover widespread trans-regulation of microRNAs with 720 mirQTLs (q-value <= 0.05) mapping to 90 microRNA transcripts. Of the 720 mirQTLs, 189, corresponding to 78 SNPs and 8 microRNAs, are clustered within 100kb upstream of the gene ERAL1. We replicated 22 of the 189 mirQTLs at the ERAL1 locus (q-value <= 0.05) using the gEUVADIS cohort (n=334). In addition, of the 78 SNPs at this locus we found that 74 are cis-eQTLs for ERAL1 exon specific probes, suggesting coregulation of ERAL1 and microRNA. ERAL1 is an RNA binding GTPase that acts as a ribosomal RNA chaperone. We therefore hypothesize that cis-eQTLs of ERAL1 act as trans-mirQTLs for microRNA through stabilization of RNA structures that in turn regulate downstream mRNA.

Genome-wide Identification of microRNA Expression Quantitative Trait Loci in the Framingham Heart Study. *T. Huan[1,2], J. Rong[3], C. Liu[1,2], X. Zhang[1,2], K. Tanriverdi[4], R. Joehanes[1,2,5], B. Chen[1,2], J. Murabito[3], C. Yao[1,2], P. Courchesne[1,2], P. Munson[5], C. O'Donnell[1,2], N. Cox[6], A. Johnson[1,2], M. Larson[3], D. Levy[1,2], J. Freedman[4].* 1) The National Heart, Lung, and Blood Institute's Framingham Heart Study, 73 Mt. Wayte Avenue, Framingham, MA, USA; 2) The Population Sciences Branch, Division of Intramural Research, National Heart, Lung, and Blood Institute, Bethesda, MD, USA; 3) Department of Mathematics and Statistics, Boston University, Boston, MA, USA; 4) Department of Medicine, University of Massachusetts Medical School, Worcester, MA, USA; 5) Mathematical and Statistical Computing Laboratory, Center for Information Technology, National Institutes of Health, Bethesda, MD, USA; 6) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

Introduction: Identification of miRNA expression quantitative trait loci (miR-eQTL) may yield insights into regulatory mechanisms of miRNA transcription, and thus may help elucidate important roles of miRNAs as mediators in complex traits. Several published miR-eQTL studies were based on modest sample sizes (n<200). These studies revealed a few cis-miR-eQTLs, but uncertainty persists regarding the number of miR-eQTLs and their relations to regulatory elements in the human genome. Methods: We analyzed the associations of approximately 10 million 1000 Genomes Project imputed SNPs (at minor allele frequency >0.01) with whole blood miRNA expression levels measured by Taqmen qPCR using a Fluidigm platform in 5239 Framingham Heart Study (FHS) participants. Associated SNPs residing within 1Mb of the mature miRNA (cis) and those occurring more than 1 Mb away (trans) were identified separately using an additive regression model adjusted for age, sex, and family structure. Replicability of the identified cis and trans miR-eQTLs was tested by splitting the overall samples 1:1 into pedigree independent sets. Results: 280 miRNAs were expressed in >200 individuals and were used for analysis. At a false discovery rate <0.1, we identified 5269 cis miR-eQTLs (representing 982 loci at linkage disequilibrium r2<0.7) for 76 mature miRNAs. cis miR-eQTLs showed high concordance across both pedigree independent sets (the concordance rate is 50%). We found that most cis miR-eQTLs were located upstream of their associated miRNAs (57% for intragenic and 84% for intergenic miRNAs). 59% of cis miR-eQTLs were located 300–500kb upstream of their associated intergenic miRNAs, suggesting that distal regulatory elements may affect interindividual variability in miRNA expression levels. We also found that cis miR-eQTLs were highly enriched for cis mRNA eQTLs and regulatory SNPs (e.g., SNPs in promoter, enhancer, and transcription factor binding sites annotated by ENCODE). By cross-linking cis miR-eQTL SNPs with GWAS SNPs and by linking cis miR-eQTL miRNAs with differentially expressed miRNAs for complex traits we identified 245 cis miR-eQTLs that are associated in GWAS with complex traits. Several of the cis miR-eQTL miRNAs displayed differential expression in relation to the corresponding GWAS trait in the FHS. Conclusion: Our study provides a roadmap for understanding the genetic basis of miRNA expression, and sheds light on miRNA involvement in a variety of complex traits.

Dissecting the genetic regulation of exosome RNA cargo in a large family. *E.K. Tsang[1,5], X. Li[2,5], V. Anaya[2], K.J. Karczewski[1], D.A. Knowles[3], K.S. Smith[2,6], S.B. Montgomery[2,4,6].* 1) Biomedical Informatics Program, Stanford University, Stanford, CA., United States; 2) Department of Pathology, Stanford University, Stanford, CA, United States; 3) Department of Computer Science, Stanford University, Stanford, CA, United States; 4) Department of Genetics, Stanford University, Stanford, CA, United States; 5) Co-first authors; 6) Co-senior authors.

Many studies have characterized genetic variation affecting gene expression through mapping of expression quantitative trait loci (eQTLs) in a variety of isolated cell types and conditions. Meanwhile, little attention has been paid to the impact of such genetic variation on intercellular communication. Exosomes are one mechanism through which cells transfer information. They are small extracellular vesicles that package biomolecules, including RNA and protein, from their cell of origin, and can deliver this cargo to influence neighboring cells. Exosomes are produced by many different cell types and are thought to be involved in the progression of certain diseases, including cancer, as well as being important for maintaining homeostasis. However, while exosomes may be relevant to several biological processes, the regulation of exosome contents remains poorly understood. In this work, we sequenced the small RNA transcriptomes of lymphoblastoid cell lines and their exosomes from a seventeen-member three-generational family. We investigated which transcripts were specifically exported in exosomes or retained in cells through differential expression analyses. By combining publicly available whole genome sequence data for the seventeen individuals with our RNA sequence data, we mapped eQTLs in both cells and exosomes and evaluated the amount of sharing between the two groups.

For the different types of small RNAs we studied, between 13% and 40% of genes were differentially expressed between cells and exosomes. This finding suggests that the RNA contents of exosomes are actively regulated and are not simply a reflection of the cellular transcriptome. We also searched for motifs enriched in the transcripts more highly expressed in exosomes than in cells to find evidence of export signals. To characterize the effect of genetic variability on exosome contents, we performed the first eQTL study in exosomes. We found evidence of sharing of small RNA eQTLs between cells and exosomes, but also identified cell- and exosome-specific eQTLs. Since exosomes are mediators of intercellular communication, our characterization of eQTL in exosomes highlights the impact of regulatory variants beyond the level of individual cells.

Analysis of hypothalamus transcriptome and proteome in 100 strains of mice on high fat diet. *Y. Hasin[1], A. Khan[2], V.A. Petyuk[3], B.W. Parks[1], C.D. Rau[1], C. Pan[1], P.D. Peihowski[3], R.D. Smith[3], A.J. Lusis[1], D.J. Smith[2].* 1) David Geffen School of Medicine, Cardiology, UCLA, Los Angeles, CA; 2) Department of Molecular & Medical Pharmacology, University of California, Los Angeles; 3) Biological Sciences Division and Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington.

Regulation of body weight and appetite are multifaceted processes, in which hypothalamic nuclei play a pivotal role. We here report the first integrated transcriptome and proteome analysis in the mouse hypothalamus, using paired end RNA sequencing and LC-MS Proteomics Analysis in 100 inbred mouse strains from the Hybrid Mouse Diversity Panel (HMDP). HMDP strains allow high resolution mapping and we were able to identify thousands of new transcripts and isoform variants as well as mapping 283 pQTLs. We are currently constructing gene co-expression network from these data, using linear and non linear correlation measurements. In addition these mice were extensively phenotyped for various of metabolic phenotypes, such as plasma metabolites and lipids, which allows us to associate gene and protein expression with particular phenotypes.

659M

Quantifying Context Specificity of Gene Regulation using Predicted Gene Expression Levels. *S.V. Mozaffari[1,2], E.R. Gamazon[2], K. Aquino-Michaels[2], N.J. Cox[2], H.K. Im[2].* 1) Committee of Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL., USA; 2) Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, IL.,.

Genetic regulation of gene expression is likely to play an important role in the etiology of complex traits as indicated by the enrichment of expression-associated variants (eQTLs) and DNase hypersensitivity sites among trait-associated variants. Tissue specificity and other context dependent regulation of the transcriptome is an area of current interest. We propose a method to quantify the degree of context specificity by using prediction models trained and tested in different contexts. For example, we examined the context specificity of gene regulation by quantifying the ability to predict gene expression levels using models trained in whole blood, tibial nerve, and muscle, and tested on expression levels assayed in lymphoblastoid cell lines. We generated predictive models of gene expression levels using single variant regression coefficients. SNPs significantly associated with gene expression levels were kept in an additive model with p-value threshold of 0.05 for variants in the vicinity of the gene and 10-6 for distant ones. We used expression data from whole blood, tibial nerve, and muscle from the GTEx pilot data for training and independent lymphoblastoid cell lines (LCL) from 1000 Genomes as test set. When using whole blood models, we found that for 8.5% of the genes, the predicted levels were significantly associated with the observed levels in LCLs with FDR <5%. For 15% of the genes, correlation was better than 10%. ERAP2 was the best predicted gene with correlation between predicted and observed of 0.87. When using models trained with tibial nerve and muscle data, 7.5% and 7.4% of the genes show correlation with FDR less than 5%. Performance is slightly inferior to whole blood indicating more similarity between LCL and whole blood than with tibial nerve or muscle. As expected, we found that genes with higher heritability, higher expression levels, and higher variability tended to be better predicted. In conclusion, we propose a novel prediction-based method to quantify context specificity of gene regulation and find that a substantial portion of the regulatory mechanism is likely to be common across tissues.

Genetic architecture of the transcriptome of four tissues in a twin cohort. *A. Buil[1], A. Viñuela[2], A.A. Brown[3], M. Davies[2], K. Small[2], R. Durbin[3], T.D. Spector[2], E.T. Dermitzakis[1].* 1) Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Understanding the genetic architecture of gene expression is an intermediate step to understand the genetic architecture of complex diseases. To explore the underlying causes of gene expression regulation we sequenced the mRNA fraction of the transcriptome of ~400 female MZ and DZ twin pairs from the TwinUK cohort in four tissues: fat, skin, blood and lymphoblastoid cell lines (LCLs) (2330 samples in total) and used genotype information imputed into the 1000 Genomes Phase 1 reference panel. Using a linear regression approach with SNPs in a 1Mb window each side of the TSS for each gene and tissue we identified 9166 significant cis-eQTLs in fat, 9551 in LCLs, 8731 in skin and 5313 in blood (1% FDR). But cis-eQTL are only a small part of the genetic effects that affect gene expression. By exploiting the twin structure of our sample, we dissected the proportions of gene expression variation which is due to different genetic and non-genetic causes. We observed that, on average, common cis-eQTL only explained about a 20% of the heritability of gene expression while other genetic variants in cis (mainly rare variants or common variants with small effects) explained about 30% of heritability. The remaining 50% of the heritability was explained by genetic variants in trans. Moreover, we observed that between 70% and 80% of the SNPs that were cis-eQTL in one tissue have at least a weak cis-eQTL signaling another tissue. Genetic variation may also affect gene expression by modifying mRNA splicing processes. We calculated the association of cis SNPs and the frequencies of exon-exon links per individual and identified between 1566 and 4104 splicing QTLs (sQTLs) per tissue. We observed that between 35% to 60% of the sQTLs replicate among tissues, highlighting the importance of tissue specific effects in alternative splicing. Finally, we looked for genetic variants that have a cis effect in one tissue and, at the same time, a downstream effect, in trans, in another tissue. We selected cis-eQTLs that are active in a single tissue (tissue 1) and looked for its associations with trans genes in another tissue (tissue 2). Then, we used causal model inference to test that the association between the eQTL and the trans gene in tissue 2 is more likely mediated through effects from the cis-eQTL in tissue 1 than through a cis effect of the eQTL in tissue 2. We found several examples of these cross-tissue effects and we are now in the process of validating them.

Genome-Wide Analysis of Expression Short Tandem Repeats. *M. Gymrek[1,2,3], S. Georgiev[4], B. Markus[1], D. Zielinski[1], J. Pritchard[5,6], Y. Erlich[1].* 1) Whitehead Institute, Cambridge, MA; 2) Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Departments of Genetics and Biology, Stanford University, Palo Alto, CA; 6) Howard Hughes Medical Institute, Chevy Chase, MD.

A central goal in genomics is to elucidate the genetic architecture of complex traits. So far, efforts to discover eQTLs (expression Quantitative Trait Loci) have mainly focused on the contribution of SNPs to gene expression. Several candidate gene studies in human and model organisms have suggested that Short Tandem Repeat (STR) variations can modulate expression levels and splicing of nearby transcripts. Here, we report the first genome-wide survey to identify STRs that regulate the transcriptome. We analyzed STR variations across hundreds of samples from the 1000 Genomes Project using a custom algorithm. We then performed association tests between multi-allelic STR genotypes and expression levels of nearby genes while controlling for SNPs in linkage disequilibrium. This process identified significant associations between STR variations and expression profiles (eSTRs) of more than 1,000 genes. These associations were replicated across populations and in orthogonal expression assays (RNA-sequencing and expression array). Predicted eSTRs are found near transcription start sites and near splice junctions, and are strongly enriched in annotated regulatory elements and regions under purifying selection. We used a variance components analysis to dissect the contribution of STRs to gene expression. This analysis showed that eSTRs explain on average about 22% of the cis-heritability of the expression levels after controlling for nearby SNPs. Overall, our results highlight the contribution of STRs to the genetic architecture of gene expression and raise the possibility that these variants may contribute to the missing heritability of complex traits.

662M

Cross-platform validation and cross-tissue activity of expression quantitative trait loci (eQTL). *A.J. Jasinska[1], S. Service[1], I. Zelaya[1], C. Blum[1], Y. Huang[1], L. Navarro[1], M.J. Jorgensen[2], G. Weinstock[3], R. Wilson[4], W. Warren[4], E. Eskin[5], R. Woods[6], G. Coppola[1,6], N.B. Freimer[1].* 1) UCLA Center for Neurobehavioral Genetics, University of California, Los Angeles, CA; 2) Department of Pathology, Section on Comparative Medicine, Wake Forest School of Medicine, Winston-Salem, NC; 3) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 4) The Genome Institute, Washington University School of Medicine, St Louis, MO; 5) Department of Computer Science and Human Genetics, The University of California, Los Angeles, CA; 6) Department of Neurology, The University of California, Los Angeles, CA.

Genetic regulation of transcript levels by expression quantitative trait loci (eQTL) is a key contributor to the regulatory mechanism underlying higher order traits. Therefore, eQTL can be useful for interpreting and determining the biological relevance of trait mapping results. However, to improve the interpretability of the eQTL results some questions still need to be addressed and answered. For example: How replicable are eQTL, especially trans-acting or distant eQTL? Which eQTL act in a tissue-specific manner, and which act across tissues? In order to provide more insight into gene regulation organization, we conducted a cross-platform and cross-tissue comparison of eQTL signals using data from two gene expression platforms, RNA-seq and expression microarrays, in a genetically-characterized pedigree of vervet monkeys (Chlorocebus aethiops sabaeus) obtained from the Vervet Research Colony (VRC). For eQTL mapping of steady-state transcript levels, we used two data sets: 1) RNA sequencing (RNAseq) in a matched set of five tissues (blood, skin fibroblasts, caudate, adrenal, and pituitary) from each of 35 monkeys (a total of 175 samples), and 2) microarray gene expression in peripheral blood samples from 327 monkeys. The gene expression data was inverse-normal transformed. We used genotype data from a genetic mapping set consisting of 500K common autosomal SNPs that was generated based on whole genome sequencing (WGS) from the VRC monkeys. For association analysis between genotypes and gene expression levels, we used the EMMAX statistical test, using age, sex, batch and pregnancy status as covariates. Among the 5,539 gene expression probes that passed our filter for high quality probes, 3,134 probes (57%) were heritable at FDR<0.01 (SOLAR). Among the heritable probes, we identified a Bonferroni-significant association signal for 281 probes in cis and 37 probes in trans (i.e., on a different chromosome than a probe). The trans signals include two eQTL hotspot regions where five or more probes (gene expression) were mapped (on chromosomes 5 and 9). Forty percent of the trans-regulated probes (15/37) were associated to the same trans SNPs in the RNAseq dataset at the significance level of p<0.05. Despite a small sample size with the RNAseq data, we identified 59–238 genes per tissue that were regulated by eQTL (p<5e-08). That includes genes regulated across tissues: LRRC37A3 in five tissues, three genes in three tissues, and 23 genes in two tissues.

663T

Transcriptome sequencing of a large human family identifies the impact of rare non-coding variants. *X. Li[1], A. Battle[2,3], K.J. Karczewski[2], Z. Zappala[2], K.S. Smith[1], K.R. Kukurba[2], E. Wu[1], N. Simon[4], S.B. Montgomery[1,2,3].* 1) Department of Pathology, Stanford University School of Medicine; 2) Department of Genetics, Stanford University School of Medicine; 3) Department of Computer Science, Stanford University; 4) Department of Biostatistics, University of Washington.

Recent and rapid human population growth has led to an excess of rare genetic variants that are expected to contribute to an individual's genetic burden of disease risk. To date, much of the focus has been on rare protein-coding variants where potential impact can be estimated from the genetic code, while determining the impact of rare non-coding variants has been more challenging. To improve our understanding of such variants, we combine high-quality genome sequencing and RNA-sequencing data within a 17-individual, three generation family to contrast expression and splicing quantitative trait loci (e/sQTLs) within a single family to e/sQTLs within a population sample. Using this design, we identify substantial numbers of genes exhibiting larger effect-sizes within the family than the population. We further observe that those e/sQTLs with large effects in the family are enriched for rare regulatory and splicing variants (MAF<0.01) and they are also more likely to influence essential genes and genes involved in complex disease. In addition, we found rare variants are much more likely to cause e/sQTLs than common variants given same functional annotations. We found that distance to the transcription start site, evolutionary constraint and epigenetic annotation are considerably more informative for predicting e/sQTL of rare variants than common variants. We postulate that lack of selective pressure increased capability for genomic annotation to predict the impact of those rare non-coding variants. These results highlight that rare non-coding variants are significant contributors to individual gene expression profiles, especially to large and potentially deleterious effects.

Allele specific expression and eQTL in diploid genomes. *S.C. Munger, N. Raghupathy, K. Choi, D.M. Gatti, P. Simecek, G.A. Churchill.* The Jackson Laboratory, Bar Harbor, ME.

The emergence of high throughput sequencing (HTS) technologies has coincided with the development of advanced genetic reference populations including the mouse Diversity Outbred (DO) heterogeneous stock. The application of HTS to genetically diverse mapping populations has the potential to provide nucleotide resolution of causal variants underlying phenotypic differences. However the increase in information content comes at the cost of increased analytical complexity. We have developed novel methods and software to exploit the high genetic diversity and heterogeneous diploid genomes of the DO to yield new layers of information and inform fine mapping of phenotypic and expression QTL (eQTL). Importantly, these methods can be readily applied to any human expression dataset where genotyping data is available.

RNA-seq alignment to individualized diploid genomes yields direct, accurate estimates of allele specific expression (ASE), and improves eQTL identification and resolution. To illustrate this, we profiled the liver transcriptomes of 450 DO mice by RNA-seq and estimated gene, isoform, and allele expression. We correlated gene expression differences to genetic variation and identified 9,000 local expression QTL (eQTL) and 900 distant eQTL, showing that most of the variation in transcript abundance derives from segregating local genetic variation. Allelic expression differences confirmed that cis-acting mechanisms underlie most local eQTL, and DO allele estimates correlate well with gene expression in livers from the eight DO founder strains. Most eQTL appear biallelic suggestive of a single causal variant, however complex 3- and 4- allele patterns are observed. Cis-eQTL with allelic expression patterns that deviate from the known strain ancestry are most amenable to fine mapping, and in some cases we predict a single causal variant. Distant eQTL with large effects are rare in the adult liver transcriptome, however we have developed conditioning methods to amplify trans effects and test candidate regulatory genes in the interval.

Seqnature software for constructing individualized diploid genomes and gene annotation files is available at github.com/jaxcs/Seqnature. Analytical pipelines described above can be found at do.jax.org. All eQTL results are available as an interactive web application at do.jax.org.

An integrated framework for evaluating the pathogenicity of rare, population-specific non-coding variation. *Z. Zappala[1], M. Pala[2,6,7], M. Marongiu[2], A. Mulas[2], R. Cusano[2], F. Crobu[2], F. Reinier[3], R. Berutti[3,6], M.G. Piras[2], C. Jones[3], D. Schlessinger[5], G. Abecasis[4], A. Angius[2], S. Sanna[2], F. Cucca[2,6,8], S.B. Montgomery[1,7,8].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Research Institute of Genetics and Biomedicine, Monseratto, Italy; 3) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 5) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA; 6) Department of Biomedical Science, University of Sassari, Sassari, Italy; 7) Department of Pathology, Stanford University, Stanford, CA; 8) co-senior authors.

Large-scale genome sequencing efforts have revealed a great diversity of coding and non-coding genetic variation. Identifying the impact of rare, non-coding genetic variation on phenotypic variation in a population remains an open challenge in population genomics. In the absence of large sample sizes, rare variants do not have an appreciable frequency to power traditional expression quantitative trait loci (eQTL) association tests. Using population-scale full genome and RNA-Seq data for 624 Sardinian individuals, we have developed a framework for combining population structure, genetic background, gene expression, and allele-specific expression (ASE) to find rare variants that are associated with family-specific patterns of gene regulation. Our analysis of 66 trios in the Sardinian population reveals a number of gene expression traits that co-segregate in a family with significant signals of ASE. These signatures are consistent with the model of a rare, causal *cis*-regulatory element that also segregates within the family. Within these outlier individuals, we test for rare non-coding variants that overlap with functional annotations such as conservation, DNase hypersensitivity, and transcription factor binding. We further integrate these variants with genome-wide association study (GWAS) hits and disease annotations to identify rare variants that may contribute to complex diseases. By utilizing this pipeline, we have identified rare variants in the Sardinian population that contribute to family-specific regulatory traits and hold pathogenic potential. We have additionally designed this pipeline so that it will work with any large-scale genome and RNA sequencing project, allowing the general integration of these genome-wide datasets to reveal rare variant associations with complex traits and diseases.

Modeling uncertainty in RNA-seq analysis: Beyond differential expression. *G.E. Hoffman, B.A. Kidd, E.E. Schadt.* Icahn Institute for Genomics and Multiscale Biology, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York, USA.

RNA-seq is becoming the standard technique for assessing gene expression in medical and experimental genomics. The large dynamic range and ability to capture alternative splicing make RNA-seq a rich data source for asking an array of biological questions beyond the standard analysis of differential expression. Yet efforts to address complex biological questions must consider the complexity of RNA-seq data. For example, typical RNA-seq data is generated by sequencing RNA molecules, mapping reads to a reference genome, and counting the number of reads corresponding to each gene. The count nature of the data imply that RNA-seq has a complex error structure where the sampling variance increases with number of read counts per gene. Widely used methods for differential expression have established that appropriately modeling the error structure is essential for maintaining power and reducing false positives. Yet other applications of RNA-seq make strong simplifying assumptions and do not address the complex error structure. Here we consider the general question of how to best utilize RNA-seq data to perform complex analysis such as eQTL detection, principal components analysis (PCA) and coexpression network reconstruction. To date these applications have been applied to processed count data, where processing involves transforming the counts for each gene based on rank (i.e. quantile transformation) or read fraction (i.e. RPKM/FPKM, count per million (CPM)), which do not directly model the error structure. We consider transformations based on a statistical model accounting for uncertainty in counts (i.e variance stabilizing transform, precision-weighted CPM) and demonstrate that the processing of the count data affects the quality of the results. Using simulations, public data from the GEUVADIS project and disease datasets, we illustrate how modeling the error structure of RNA-seq data affects power in cis-eQTL detection, power of PCA to distinguish between know subgroups, and stability of inferred coexpression models. This work proposes a unified framework for addressing an array of biological questions by modeling the complexity of RNA-seq data.

Meta-Analysis of Liver eQTL Studies and Cross-tissue eQTL Comparison using GTEx Data. *E.L. Seiser[1], K. Xia[2], F.A. Wright[3], F. Innocenti[1].* 1) Division of Pharmacotherapy and Experimental Therapeutics, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Statistics, North Carolina State University, Raleigh, NC.

Identification of liver-specific expression quantitative trait loci (eQTLs) may aid in determining genes and genetic variants relevant to the pathogenesis of complex liver-associated diseases and the biological mechanisms underlying drug pharmacology by providing a functional link between genetic variation and gene expression levels. Previous liver eQTL studies have resulted in low replication rates, suggesting the need for a larger overall sample size to increase the statistical power for identifying eQTLs. We performed a meta-analysis of four human liver eQTL studies (n= 149, 206, 427, 960), including three previously published, to identify cis-eQTLs (within 100kb of transcription start/stop site). Genotype microarray data from each study was used for determining sex, genetic ancestry, and common samples between studies, leading to a total of 1,226 Caucasian liver samples for analysis. Imputation of genotype data using Impute2 produced a set of 6,684,896 SNPs common among all studies. Probe sequences from each expression microarray platform were mapped to Entrez genes and a set of 13,669 genes common to all platforms was identified. Using expression data from each study, probabilistic estimation of expression residuals (PEER) was employed to determine hidden variance components. Matrix eQTL was used to test for cis- associations, incorporating sex, age, genetic ancestry, and PEER factors into an additive genetic model. A meta-t-statistic was calculated using SNP/gene pair t-statistics from each study, and p-values for the meta-t-statistics were generated using the normal distribution. Testing of 8,236,407 SNP/gene pairs identified significant cis-linked genetic effects on expression levels (Bonferroni corrected p-value<6.1×10–9) for 3,334 genes, including numerous genes related to drug processing. Ongoing comparative analysis of the liver eQTL data with the Genotype Tissue Expression (GTEx) project eQTL data from 9 tissues (whole blood, adipose, muscle, heart, artery, lung, skin, nerve and thyroid) will allow for a comprehensive identification of liver-specific eQTLs, and may help to further elucidate pathogenic and biological processes in the liver.

668M

Functional mapping of eQTL signals for prostate cancer risk SNPs. *L. Tillmans, S. McDonnell, A. French, Y. Zhang, S. Riska, M. Larson, Z. Fogarty, N. Larson, J. Cheville, S. Baheti, S. Middha, D. Schaid, S. Thibodeau.* Mayo Clinic, Rochester, MN.

In order to define the functional role of previously reported risk-SNPs for prostate cancer (PC), we created a normal prostate tissue eQTL database using 471 tissue samples from patients with prostate cancer. Genotyping was performed using the Illumina Human Omni 2.5 M SNP array and expression was measured by RNA sequencing. Our initial eQTL analysis focused on those risk-SNPs previously identified by multiple PC GWAS studies (n= 123), plus all SNPs (included imputed) that were in linkage disequilibrium (r2>0.5) with each risk-SNP. Additionally, we focused on cis-acting associations only testing all transcripts within 2Mb of the risk-SNP interval. Of 5116 SNPs identified in the risk-regions, 1002 demonstrated a Bonferroni significant eQTL signal (p<1.96e-7) and these were associated with 43 genes. To identify possible functional SNPs for each of the risk-regions associated with a candidate gene, we utilized a variety of publicly available databases and bioinformatics tools. These included various GEO datasets that were specific for prostate tissue or PC cell lines (with and without androgen treatment) and a variety of analysis tools (Regulome, Funcpred, GWAS3D, etc.) to obtain regulation potential scores for each of the candidate SNPs. Some of the information retrieved from these databases included transcription factor binding sites and motifs, previous eQTL data, miRNA binding, conservation and reported long range interactions. Results from these analyses were then compiled to determine possible functional regions. For example, for the risk-SNP rs4962416 on chromosome 10, there were 25 SNPs in LD that had significant eQTL signals (all p-values <3.71E-12) with the CTBP2 gene (a transcriptional repressor). Of these, we were able to map the 14 most significant to a probable enhancer region as defined by markers DNase I, H3K27Ac, H3K4me1 and H3K4me2. The top variant (rs12769019) as determined by Regulome score and GWAS3D for LnCap cells is located in an AR binding site (chip-seq) and is shown to possibly disrupt the binding affinities of numerous transcription factors that could be important for prostate cancer regulation through interactions with the AR (ie NKX3-1, FOXA1, GR and POU6F1). Utilizing publically available data and bioinformatics tools provides a powerful strategy for mapping and identifying candidate functional elements for PC susceptibility loci to help guide subsequent laboratory studies.

669T

Sex-specific genetic architecture of the transcriptome. *E.R. Gamazon[1], N.L. Tignor[1], B.E. Stranger[1,2], GTEx Consortium.* 1) Section of Genetic Medicine, Department of Medicine, The University of Chicago, Chicago, IL; 2) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL.

Sexual dimorphism has been observed in a broad spectrum of complex phenotypes, including autoimmune disorders, psychiatric disorders, and cancers. Here, in support of our efforts to investigate the sex-specific genetic architecture of complex traits, we examine potential functional mechanisms underlying sexual dimorphism. Using RNA sequencing data from the Genotype-Tissue Expression (GTEx) Consortium, we assessed sex-specific gene regulation and mapped sex-biased expression quantitative trait loci (eQTLs) in a diverse set of human tissues. We identified tissue-specific gene expression patterns with some genes showing differential expression (p<10-6) between the sexes in some tissues but not in others. Our approach facilitated the comprehensive analysis of non-coding RNAs, putatively regulatory, with substantial sexually dimorphic expression profiles. We identified eQTLs associated with the expression of a gene in one sex and not the other, quantified the proportion of shared eQTLs, and highlighted traits with distinct regulatory variation in the sexes. Notably, our unique dataset allowed us to evaluate the tissue-specificity and the degree of sharing between tissues of sex-biased eQTLs. We found in each tissue substantial variation in the presence of sex-specific eQTLs among different classes of genes, including, most prominently, antisense transcripts and long intergenic non-coding RNAs. We identified sex-specific eQTLs among known disease susceptibility and quantitative trait loci (for example, Parkinson's disease, Crohn's disease, systemic lupus erythematosus, aortic dimension, and folate pathway levels) as curated in the NHGRI catalog of published genome-wide association studies. On the basis of eQTL targets, we propose novel genes, distinct from the originally reported genes, for some of these phenotypes. Analyses of WTCCC, the Psychiatric Genomics Consortium, and GIANT GWAS data reveal that sex-biased eQTLs show tissue-dependent enrichment for trait associations. Sex-specific eQTL target genes in such tissues as tibial artery and blood are enriched for antigen processing and presentation as well as immune-related function whereas those in muscle are, in addition, enriched for metabolic processes and for proteins that localize in mitochondria. Our study shows that genotype-sex interactions have a broad influence on the human transcriptome and that sex-specific genetic architecture of gene expression is likely to mediate higher-order traits.

Activating mutations in STIM1 and ORAI1 cause overlapping syndromes of tubular myopathy and congenital miosis. *M. Kousi[1], V. Nesin[2], G. Wiley[3], E.C. Ong[2], T. Lehmann[4], D.J. Nicholl[5], M. Suri[6], N. Shahrizaila[7], P.M. Gaffney[3], K.J. Wierenga[8], L. Tsiokas[2], N. Katsanis[1].* 1) Cell Biology, Duke University, Durham, NC; 2) Department of Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 4) Department of Hematology, Center for Laboratory Medicine, Kantonsspital St. Gallen, Switzerland; 5) Department of Neurology, City Hospital, United Kingdom; 6) Nottingham Clinical Genetics Service, Nottingham University Hospitals National Health Service Trust, United Kingdom; 7) Division of Neurology, Department of Medicine, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia; 8) Section of Genetics, Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Signaling through the store-operated Ca2+ release-activated Ca2+ (CRAC) channel regulates critical cellular functions, including gene expression, cell growth and differentiation, and Ca2+ homeostasis. Loss-of-function mutations in the CRAC channel pore-forming protein ORAI1 or the Ca2+ sensing protein stromal interaction molecule 1 (STIM1) result in severe immune dysfunction and nonprogressive myopathy. Here, we identify gain-of-function mutations in the cytoplasmic domain of STIM1 (p.R304W) associated with thrombocytopenia, bleeding diathesis, miosis, and tubular myopathy in patients with Stormorken syndrome, and in ORAI1 (p.P245L), associated with a Stormorken-like syndrome of congenital miosis and tubular aggregate myopathy but without hematological abnormalities. Heterologous expression of STIM1 p.R304W results in constitutive activation of the CRAC channel in vitro, and spontaneous bleeding accompanied by reduced numbers of thrombocytes in zebrafish embryos, recapitulating key aspects of Stormorken syndrome. p.P245L in ORAI1 does not make a constitutively active CRAC channel, but suppresses the slow Ca2+-dependent inactivation of the CRAC channel, thus also functioning as a gain-of-function mutation. These data expand our understanding of the phenotypic spectrum of dysregulated CRAC channel signaling, advance our knowledge of the molecular function of the CRAC channel, and suggest new therapies aiming at attenuating store-operated Ca2+ entry in the treatment of patients with Stormorken syndrome and related pathologic conditions.

High-resolution personal genome-wide maps of meiotic double-strand breaks in humans. *F. Pratto[1], K. Brick[1], P. Khil[1], F. Smagulova[2], G. Petukhova[2], R.D. Camerini-Otero[1].* 1) National Institutes of Health, Bethesda, MD; 2) Uniformed Services University of Health Sciences, Bethesda, MD.

Meiotic recombination is initiated by the formation of DNA double-strand breaks (DSBs) that are directed to specific genomic loci called hotspots by a meiosis-specific protein called PRDM9. To date, the most comprehensive map of hotspots sites in humans was generated using computational analysis of patterns of linkage disequilibrium (LD), however, this method cannot resolve gender-specific hotspots or hotspots defined by different alleles of PRDM9. In this work, we exploit a sequencing based method we recently developed to perform the first direct high-resolution genome-wide analysis of meiotic recombination initiation hotspots in individual human males. We mapped up to 39,000 DSB hotspots in each of five individuals with different combinations of PRDM9 alleles. Our PRDM9-specific DSB maps demonstrate that the LD-derived recombination maps reflect hotspots defined by different alleles of PRDM9 and we find that the relatively infrequent C-allele of PRDM9 (an allele found predominantly in African populations) contributes significantly to the LD map. About 75% of DSB hotspots are found at an LD-defined hotspot, yet DSB sites without an LD-hotspot still show a significant elevation in the recombination rate. Thus, our PRDM9-specific DSB hotspot maps greatly expand our knowledge of sites where recombination occurs in the human genome. We observed significant inter-individual variation in DSB frequency at hotspots, however most differences could not be explained by sequence variation at PRDM9 binding sites. Additional factors therefore dictate the efficiency of DSB formation. While sequence changes can influence recombination, we also found that recombination can influence the genomic sequence. Characteristic patterns of polymorphisms at hotspots offer compelling evidence for both GC-biased gene conversion and for a mutagenic effect of meiotic recombination. DSB hotspots were also enriched at structural variants that arise via homology-mediated mechanisms and at chromosomal breakpoints associated with many well-documented genomic diseases. Finally, an analysis of the relationship between meiotic DSBs and crossovers suggests that meiotic DSB initiation frequency is a primary determinant of the genetic crossover landscape.

Investigating the maternal age effect on meiotic recombination in multiple cohorts. *H.C. Martin[1], J. Hussin[1], J. O'Connell[1,2], S. Gordon[3], K. McAloney[3], H. Mbarek[4], J.J. Hottenga[4], J. Marchini[5], D. Boomsma[4], N.G. Martin[3], P. Donnelly[2,5].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Illumina, Inc; 3) Queensland Institute for Medical Research, Brisbane, Australia; 4) Department for Biological Psychiatry, Vrije Universiteit, Amsterdam; 5) Department of Statistics, University of Oxford, Oxford, United Kingdom.

Multiple studies have reported that recombination rate increases with maternal age, but several have found an effect in the opposite direction. We investigate this question in new cohorts from the Australian and Dutch twin registries. Our rationale was that the use of dizygotic twins would allow measurement of the variability in recombination rate at a single point in a mother's lifetime. We analyse these twin cohorts in combination with several previously published studies, and compare different methods for calling crossovers. We then fit a Bayesian hierarchical model to the recombination rates, accounting for differences in the mothers' baseline rates, and test the hypothesis that the maternal age effect is the same in all cohorts.

673S

Mapping of two neurogenetic disorder genomes with a single molecule nanochannel array platform for genome-wide structural variation analysis. *Y.Y.Y. Lai[1], E.T. Lam[2], A.C.Y. Mak[1], V. Searles[3], C. Chu[1], C. Lin[1], N. Anderson[3], J.M. Sikela[3], P.Y. Kwok[1].* 1) UCSF, San Francisco, CA; 2) BioNano Genomics, San Diego, CA; 3) Department of Biochemistry and Molecular Genetics, University of Colorado School of Medicine, Aurora, CO.

Copy number variation of sequence encoding DUF1220 protein domains has been shown to be associated with human brain size and a number of neuropsychiatric disorders. DUF1220 motifs are embedded in the NBPF and PDE4DIP genes that are mostly found in Chr1q21. They are poorly assembled in the human reference genome due to the repetitive property of that region. Different methods, such as quantitative PCR, array comparative genomic hybridization (aCGH), Sanger or next-generation sequencing have been used for identification of these polymorphic loci. However these methods are too labor-intensive and do not provide positional (break-point) information for the structural variants. Genome mapping utilizes highly parallel nanochannel arrays in which hundreds of very long, fluorescently labeled, single DNA molecules are linearized and imaged. This novel approach is automated on the Irys System (BioNano Genomics, La Jolla, CA), which can scan the entire genome rapidly to generate physical maps that provide a more comprehensive view of the genome. Here, we use this genome mapping approach to detect genome-wide structural variation, including the copy number variation of DUF1220 in the PDE4DIP and NBPF genes, in two diploid cell lines from patients with neuropsychiatric disorders (autism and schizophrenia). To date, we generated over 50X coverage data and constructed de novo assembled genome maps that cover about 90% of hg38 reference genome using an automated assembly pipeline. We identified many structural variants including those are found in the Chr1q21 region. Overall, this genome mapping approach is simple and provides a list of genome-wide candidate structural variations that are associated with autism and schizophrenia.

Association study of COL11A2 with aspirin exacerbated respiratory disease and its FEV1 decline. *J. Kim[1], C. Park[2], H. Shin[1].* 1) Research Institute for Basic Science, Sogang University, Seoul, South Korea; 2) Division of Allergy and Respiratory Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea.

Aspirin exacerbated respiratory disease (AERD) induces bronchoconstriction in asthma patients and is characterized with a clinical condition of severe decline in forced expiratory volume in one second (FEV1) after ingestion of aspirin. Genetic association studies of several candidate genes within human major histocompatibility complex (MHC) region on chromosome 6p21-24 have reported that this MHC genomic region is implicated in asthma and related respiratory diseases. This study investigated the genetic association of collagen, type XI, alpha 2 (COL11A2) within the MHC genomic region with AERD and its FEV1 decline by genotyping of 19 tagging COL11A2 SNPs in 93 AERD patients and 96 aspirin-tolerant asthma controls. As a result, polymorphisms of COL11A2 showed potential associations with AERD (minimum P = 0.02 in rs2269346), along with the increased significances for the FEV1 decline by aspirin provocation (minimum P = 0.002 in rs2855459). In the haplotype analysis, no significant signals were observed. Despite the need for further replications in larger cohorts and functional evaluations, our preliminary findings suggest that COL11A2 may be a predisposing factor for FEV1 decline-related symptoms.

675T

Bovine animal model for spermatic and scrotal alterations: additional clues for an X-chromosome component. *P.A.S. Fonseca[1], M.P. Almeida[1], G.S. Moura[2], F.C. Santos[1], D.J. Santos[3], G.C. Oliveira[4], V.R. Vale Filho[2], M.V.G.B. Silva[3], M.R.S. Carvalho[1].* 1) Departamento de Biologia Geral, Universidade Federal de Minas Gerais, Belo Horizonte, 31.270-901, Brazil; 2) Escola de Veterinária, Universidade Federal de Minas Gerais, Belo Horizonte, 31.270-901, Brazil; 3) Embrapa Gado de Leite, Juiz de Fora, 36038-330, Brazil; 4) Centro de Pesquisas René Rachou (CPqRR)—FIOCRUZ, Belo Horizonte- MG, 30190002, Brazil.

Bovines are a subtilized, but interesting animal model for reproductive defects, mainly in males, because reproductive performance is attentively monitored over the selection process. In addition, male reproductive traits present high heritability in bovines. Genome-wide association studies (GWAS) in bovines can provide important clues for the genetic etiology of reproductive diseases not only in cattle, but also in others species. Here we describe an in-family GWAS for sperm defects and testis hypoplasia in a sample composed by 30 affected and 30 normal bulls of the Dairy-Gir breed (Bos taurus indicus). The phenotypes ascertained were gonadal hypoplasia and spermatic defects analysis. Animals were genotyped using Axiom Genome-Wide BOS 1 Array from Affymetrix, composed by 648K SNPs. Phenotypes were corrected for fixed effects (father, age, farm, and season). Pairwise Association Study (PAS) was developed for quantitative and numeric continuous phenotypes. For Haplotype Association Study (HAS) two dichotomic variable were construct: testes morphology abnormalities plus spermatic defects (ALL) and spermatic defects (Sperm Only). GWAS was conducted with SNP and Variation Suit 7 (Golden Heliz, Inc.). X-chromosomal associations were detected in both PAS and HAS. In PAS, near significant association was detected for four markers after Bonferroni correction. These markers map close to the following genes: serine/threonine protein kinase MST4 (*MST4*), oculocerebrorenal syndrome of Lowe (*OCRL*), *mir*2488 and Nance-Horan syndrome (*NHS*). In HAS, two significant associations were detected: Cullin 4B (*CUL4B*) gene for ALL phenotype and zinc finger and BTB domain containing 33 (*ZBTB33*) for Sperm Only phenotype. *CUL4B* plays a crucial role in post-translational modification, involving ubiquitin, of proteins involved in cell cycle regulation, DNA replication and embryonic development. *CUL4A*, a *CULB4B* homologue, has been associated to spermatic development. *ZBTB33* encodes Kaiso zinc finger protein associated with embryonic development, homeostasis of adult tissues, maintenance of progenitor cells, cell fate determination and differentiation and with reproductive traits in bovine males. These findings, although still in the need of confirmatory functional studies, point to new heterologous candidate genes for human reproductive disturbances.

676S

De novo genome assembly and structural variations detection by genome mapping on nanochannel arrays. *A.C.Y. Mak[1], E.T. Lam[8], Y.Y.Y. Lai[1], A.K.Y. Leung[3], T.P. Kwok[4], C.M.L. Li[6], A.R. Hastie[8], W. Stedman[8], T. Anantharaman[8], W. Andrews[8], X. Zhou[8], H. Dai[8], K.Y. Yip[4,5], T.F. Chan[5], S.M. Yiu[6], J.W. Li[3,5], A.K.Y. Yim[3,5], S. Chan[8], Z. Dzakula[8], H. Cao[8], J. Sibert[7], M. Xiao[7], P.Y. Kwok[1,2].* 1) Cardiovascular Research Institute, Univeristy of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) School of Life Sciences, The Chinese University of Hong Kong, Hong Kong; 4) Department of Computer Science and Engineering, The Chinese University of Hong Kong, Hong Kong; 5) Hong Kong Bioinformatics Centre, The Chinese University of Hong Kong, Hong Kong; 6) Department of Computer Science, The University of Hong Kong, Hong Kong; 7) School of Biomedical Engineering, Science & Health Systems, Drexel University, Philadelphia, PA; 8) BioNano Genomics, San Diego, CA.

Despite recent advances in next-generation sequencing technologies, de novo genome sequence assembly and genome-wide structural variation (SV) detection based on 'short reads' remain challenging. For efficient de novo sequence assembly and complete SV characterization, we generated genome maps with long DNA molecules (>150kb) fluorescently labeled at Nt.BspQI sites (GCTCTTCN/), linearized and imaged in massively parallel nanochannel arrays [1]. We obtained single-molecule data at 80X genome coverage on CEPH CEU trio samples, NA12878, NA12891 and NA12892, that were extensively analyzed by many groups, including the 1000 Genomes Project. Single-molecule maps were assembled de novo into consensus genome maps that cover >90% of the reference human genome. We confirmed previously reported and identified novel structural variants that were consistent with Mendelian inheritance. We also analyzed genome features of interest (e.g. subtelomeric and subcentromeric regions). Our genome maps provide valuable information on genome features and structural variants that are otherwise hard to discover with short read sequencing data alone. 1. Lam ET et al. Genome Mapping on Nanochannel Arrays for Structural Variation Analysis and Sequence Assembly. Nat Biotechnol (2012) 30(8):771-776.

An integrated platform for the collection of biospecimens to support the Genotype-Tissue Expression (GTEx) Project. *JC. Keen[1], L. Carithers[1], A. Undale[2], A. Rao[1], M. Barcus[2], P. Branton[1], L. Sobin[2], P. Guan[1], N. Roche[2], C. Shive[2], A. Smith[2], K. Valentino[2], S. Volpi[3], J. Struewing[3], S. Koester[4], R. Little[4], HM. Moore[1] on behalf of the GTEx consortium.* 1) Biorepositories and Biospecimen Research Branch, National Cancer Institute, Bethesda, MD; 2) Leidos Biomedical Research, Inc., Rockville, MD; 3) National Human Genome Research Institute, Bethesda, MD; 4) National Institute of Mental Health, Bethesda, MD.

The Genotype-Tissue Expression (GTEx) project is an NIH Common Fund study that aims to clarify our understanding of how genetic variation influences gene expression in normal human tissues. As of May 2014, GTEx has collected 25+ tissue types per donor from over 650 deceased tissue or organ donors. To facilitate the collection and storage of tissues and data, the NCI Biorepositories and Biospecimen Research Branch (BBRB) has developed an integrated biospecimen collection platform. This platform includes collection and storage facilities, a data warehouse, a team of board-certified pathologists, and a molecular analysis core facility. Together, this system has allowed for the acquisition of high quality, well-annotated biospecimens that met established quality criteria for molecular analysis. Clinical data, genotype and gene expression data are available at dbGaP for each donor and tissue type collected. These data will enable scientists to better understand the genomic and molecular variation in normal human tissues and may facilitate the identification of genes involved in disease states.

678T

Functional characterization of recent single nucleotide mutations on HSPA1A, a human Hsp70 gene. *K. Hess, M. Siracusa, P. Nguyen, A. Bilog, C. McCallister, N. Nikolaidis.* Department of Biological Science, Center for Applied Biotechnology Studies, and Center for Computational and Applied Mathematics, California State University Fullerton, Fullerton, CA.

A fundamental question in molecular evolution is how mutations enable organisms to adapt to their environments and survive. At the cellular level the same essential question relates to the ability of cells to adapt and survive homeostatic imbalances due to stress. To maintain homeostasis the cellular stress response system, which is composed by several protein networks, has evolved. Molecular chaperones and in particular the 70-kD heat shock proteins (Hsp70s) are key regulators of the stress response system and alterations in their function have direct physiological consequences. Therefore, it is of paramount importance to determine how natural mutations alter the function of Hsp70s and how these changes affect cellular and organismal adaptation and survival. To shed light to this important biological question we capitalized on the presence of multiple natural single nucleotide polymorphisms (SNPs) found on HSPA1A, the major stress inducible Hsp70 gene in humans, and determined whether these mutations alter protein function. Specifically, the wild-type HSPA1A sequence was subcloned into both bacterial and mammalian expression vectors and the mutated gene variants were generated using site directed mutagenesis. Recombinant proteins corresponding to the WT and mutated variants were then generated and tested for their ability to hydrolyze ATP. Based on the Km values obtained, the WT had the highest affinity for binding to ATP, but based on the Vmax values, some mutants were able to hydrolyze ATP at a much faster rate. The different affinities for both ATP and ADP were verified using Isothermal titration calorimetry (ITC), which also revealed differences in the reaction entropy. The mutant proteins' ability to properly localize intracellularly within mammalian cells was also tested by tagging HSPA1A to GFP, using fluorescent dyes to stain the mitochondria, lysosomes, and plasma membrane, and viewing where the proteins localized via confocal microscopy. These results revealed that the mutants and the WT protein had similar subcellular localization. However, live-dead and cell proliferation assays revealed that some of these mutations significantly change cellular growth and survival after heat stress. Given that these natural variants are either population-specific or clinical we suspect that the observed functional differences alter the ability of cells and the individuals carrying them to cope with stress or disease.

679S

Impact of genetic polymorphisms in FADS1, FADS2, and FADS3 genes on fatty acid metabolic mechanism on methadone therapy in Taiwan. *R. Wang[1], H.T. Yang[2], H.Y. Lane[3], C.L. Huang[4], Chieh-Liang Huang.* 1) Department of Public Health, china Medical Univ, Taichung, Taiwan; 2) Department of Nutrition , China Medical University, Taiwan; 3) Institute of Clinical Medical Science, College of Medicine, China Medical University, Taichung, Taiwan; 4) Department of Psychiatry, China Medical University Hospital, Taichung, Taiwan.

It had been observed that abnormal fatty acid metabolism in patients with psychological disorders, such as major depression, schizophrenia, and Alzheimer's disease , etc. Illegal drugs is not only associated with the increased risk of the mental health problems, family and social economic burden, but also the elevated risk of HCV and AIDS infection. Drug abuse is an important public health issue. Heroin is one of the most common increasing abuses in Taiwan. Methadone, a synthetic μ-opioid receptor agonist, is extremely effective to treat to reduce illegal drug use, AIDS-caused infectious transmission and mortality in heroin dependent abusers patients. The aim of the study is to explore the association between the 7 tagSNPs (rs174547, rs174550, rs174570, rs174602, rs498793, rs526126, rs174634) of FADS1, FADS2, and FADS3 (fatty acid desaturase 1, 2, and 3) and fatty acid variation before and after methadone maintenance treatment in drug abusers. A total of 89 subjects with heroin dependence or methamphetamine were recruited from the methadone clinic in China Medical University Hospital. Based on the Chinese Han hapmap LD structure, seven tagSNPs were selected from FADS1, FADS2 and FADS3 genes. Genotyping were carried out using the Applied Biosystem Assay on Demand reagents and were implemented using an ABI Prism 7900HT Sequence Detection System. Fatty acid profiles of RBC were analyzed with gas chromatography. This study was approved by the institutional review board of China Medical University Hospital in Taiwan. All the informed consent was obtained from all participants during their initial clinic visit. All data analyses were performed using SAS version 9.1.3 (SAS Inc., NC, USA). The study results showed that all the 7 tagSNPs are significantly associated with the variation of PUFA and AA/EPA ratio ($p<0.0001$) but not associated with C18:2n6, C18:3n6 before and after methadone treatment. The data pointed out that methadone treatment would interfere fatty acid metabolism, especially PUFA desaturation in subjects. As abnormal fatty acid profiles were readily associated with several psychological disorders, the correlation between fatty acid metabolism and drug abusers with certain tag SNPs. In conclusion, our study may provide further information regarding the 7tagSNPs of the FADS1, FADS2 and FADS3 were associated with fatty acid metabolism for drug abuser with MMT treatment in Taiwan.

680M

Drug Metabolizing Enzyme and Transporter Gene Variation, Nicotine Metabolism, and Cigarette Consumption. *A.W. Bergen[1], M. Michel[1], D. Nishita[1], R. Krasnow[1], H.S. Javitz[1], K.N. Conneely[2], C.N. Lessov-Schlagger[3], H. Hops[4], A.Z.X. Zhu[5], J.W. Baurley[6], J.B. McClure[7], S.M. Hall[8], T.B. Baker[9], D.V. Conti[10], N.L. Benowitz[11], C. Lerman[12], R.F. Tyndale[13], G.E. Swan[14].* 1) Center for Health Sciences, SRI International, Menlo Park, CA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) Department of Psychiatry, Washington University School of Medicine, St Louis, MO; 4) Oregon Research Institute, Eugene, OR; 5) Department of Pharmacology and Toxicology, University of Toronto, Toronto, ON; 6) BioRealm, LLC, Monument, CO; 7) Group Health Research Institute, Seattle, WA; 8) Department of Psychiatry, University of California, San Francisco, CA; 9) Center for Tobacco Research and Intervention, Department of Medicine, University of Wisconsin School of Medicine and Public Health, Madison, WI; 10) Department of Preventive Medicine, University of Southern California, Los Angeles, CA; 11) Departments of Medicine and of Bioengineering & Therapeutic Sciences, University of California San Francisco; 12) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 13) Centre for Addiction and Mental Health, and Departments of Psychiatry, and of Pharmacology and Toxicology, University of Toronto, Toronto, ON; 14) Stanford Prevention Research Center, Department of Medicine, Stanford University School of Medicine.

The Nicotine Metabolite Ratio (NMR), the ratio of trans-3'-hydroxycotinine and cotinine, two nicotine metabolites, is significantly associated with CYP2A6 activity, response to smoking cessation treatments, and cigarette consumption. We searched for drug metabolizing enzyme and transporter (DMET) gene variation associated with the NMR and with prospective abstinence in 2,946 participants of clinical laboratory studies of nicotine metabolism ("laboratory studies") and of randomized comparative efficacy trials of smoking cessation therapies ("clinical trials") using a two-stage design. The first stage was a meta-analysis of the association of 507 common single nucleotide polymorphisms (SNPs) at 173 DMET genes, using the Affymetrix DMET™ Plus Array, with the NMR in 449 participants of two laboratory studies. Nominally significant associations with the laboratory-based NMR were identified in ten DMET genes after adjustment for intragenic tested SNPs, and two CYP2A6 SNPs attained experiment-wide significance after adjusting for 507 SNPs (rs4803881, PACT=4.5E-5, PBonferroni=6.7E-5; rs1137115, PACT=1.2E-3, PBonferroni=1.6E-3). In the second stage, we genotyped selected DMET SNPs and performed mega-regression analyses with the pretreatment NMR and with prospective abstinence in clinical trial participants. rs1137115 was significantly associated (P=4.2E-14, N=614) with pretreatment NMR. DMET SNPs analyzed in the validation stage were not associated with prospective abstinence outcomes in up to 2,497 participants of eight clinical trials. rs1137115 accounts for 8% of pretreatment NMR and 0.33% of cigarette consumption (P=2E-3), among clinical trial participants. We have identified and validated significant associations of one CYP2A6 SNP with the NMR at experiment-wide and at genome-wide significance in laboratory study and clinical trial participants.

681S

Genetic variation in glutamate signaling influences response to cognitive behavioral therapy in pediatric anxiety. *C.G. Bhat, C.P. Laughlin, G.S. Hellemann, J.C. Piacentini, J.T. McCracken, E.L. Nurmi, The CAMS Study Group.* University of California Los Angeles, Los Angeles, CA.

Background: Selective Serotonin Reuptake Inhibitors (SSRIs) and cognitive-behavioral therapy (CBT) are effective therapies for pediatric anxiety; however, response to treatment is highly variable. Differential treatment response may be explained by genetic factors. Due to the role of glutamate in learning and memory, we examined genetic variation in the glutamate pathway on the effectiveness of sertraline vs. CBT vs. combination therapy for pediatric anxiety in the randomized, placebo-controlled Child/Adolescent Anxiety Multimodal Study (CAMS). Methods: We examined 15 key variants in glutamate signaling candidates for association with treatment response: NMDA glutamate receptor GRIN2B and transporters regulating synaptic glutamate levels (the cysteine-glutamate exchanger (SLC7A11) and neuronal (SLC1A1) and glial (SLC1A2) glutamate transporters). Results: Influences of the glutamate system were apparent only in the CBT treatment group. One SLC1A1 variant was significant in omnibus analyses across all groups. Minor allele carriers (C+) at the glutamate transporter (SLC1A1) rs3933331 variant demonstrated minimal symptom reduction over time with CBT monotherapy ($p= 9.06 \times 10^{-5}$), whereas GG homozygotes showed an excellent response. Interestingly, the opposite allele showed a greater symptom drop with placebo. Within the CBT group, SLC7A11 rs11723658 ($p<0.0005$) and GRIN2B rs1806195 ($p<0.005$) also predicted treatment response. Conclusion: While no effects on medication response were observed, our data support a possible role for genetic variation in glutamate signaling pathways in response to CBT monotherapy. Our results show promise for eventual personalization of anxiety treatment algorithms and warrant replication in independent samples.

682M

Clinical and pharmacogenomic features of cisplatin-induced ototoxicity in Asian nasopharyngeal carcinoma patients. *S.L. Chan[1], L.S. Ng[2], C.H. Siow[2], C.J. Ross[3,4], B.C. Carleton[4,5], M.R. Hayden[1,3], B.C. Goh[6,7,8,9], K.S. Loh[2], L.R. Brunham[1,3,10].* 1) Translational Laboratory in Genetic Medicine, Agency for Science, Technology and Research, Singapore; 2) Department of Otolaryngology-Head & Neck Surgery, National University Health System, Singapore; 3) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada; 4) Division of Translational Therapeutics, Department of Pediatrics, Child and Family Research Institute, University of British Columbia, Vancouver, BC, Canada; 5) Pharmaceutical Outcomes Programme, BC Children's Hospital, Vancouver, BC, Canada; 6) Department of Haematology-Oncology, National University Cancer Institute, National University Health System, Singapore; 7) Cancer Science Institute, Singapore; 8) Department of Pharmacology, Yong Loo Lin School of Medicine, National University Health System, Singapore; 9) Haematology Oncology Research Group, National University Cancer Institute, National University Health System, Singapore; 10) Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore, Singapore.

Background: Cisplatin-induced ototoxicity (CIO) is a common and debilitating adverse drug reaction (ADR) that affects up to a quarter of adults and more than half of children receiving the drug, and Asian populations may be at increased risk. Inter-individual variability in susceptibility to CIO suggests a genetic component to this ADR that has not been fully defined. In European populations, *TPMT* rs12201199 and *COMT* rs9332377 have been found to be associated with CIO. However, these variants are very rare or absent in healthy individuals from the Chinese and Malay populations. We therefore hypothesized that other pharmacogenomic variants influence the risk of CIO in these Asian populations. **Methods:** Nasopharyngeal carcinoma patients were recruited from the National University Hospital of Singapore and genotyped on a custom Illumina Infinium panel containing 7907 SNPs in genes involved in drug absorption, distribution, metabolism and excretion (ADME). Clinical and audiometric data were collected from all patients. Trends of hearing loss were first delineated in terms of threshold change from baseline averaged across both ears over time. Genetic association was then performed only on patients who received cisplatin. CIO cases were defined as >15dB mean threshold shift at 1 year and controls defined as ≤15dB shift. **Results:** Out of 115 patients with complete clinical and audiometric data, 24 received radiotherapy (RT) only and 91 received both RT and cisplatin (chemoRT). There was no significant threshold shift at lower hearing frequencies (0.5–2kHz). However at 4kHz, there was a substantial threshold increase from as early as 3 months after initiation of therapy in patients who received chemoRT. At 12 months, 32% of patients who received chemoRT compared to 0% who received RT displayed a threshold increase of >15db. After QC, 82 patients (24 cases and 58 controls) and 4281 SNPs were included in the genetic association study. *COMT* and *TPMT* variants reported previously were extremely rare in this population. None of the ADME variants reached statistical significance after correction for multiple testing. **Conclusion:** High frequency hearing loss in NPC patients at time points up to one year is due primarily to cisplatin. Established risk variants for CIO are rare in this population, suggesting the presence of novel genetic factors. Given the small sample size of this preliminary study we did not detect evidence of ADME variants with large effect size on CIO.

683S

Genetic moderators of treatment response to dexmethylphenidate in children and adolescents with ADHD. *S.N. Chang, E.L. Nurmi, C.P. Laughlin, G.S. Hellemann, S.K. Loo, J.J. McGough, J.T. McCracken.* Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA.

Background: The stimulant dexmethylphenidate (d-MPH) is an effective treatment for hyperactive and inattentive symptoms associated with pediatric attention deficit hyperactivity disorder (ADHD). Treatment-induced growth slowing, however, is a common adverse effect associated with morbidity and poor treatment adherence. Substantial variation in response and growth effects is common and may be explained by genetic factors. This study investigated whether genetic variation in drug targets (SLC6A3/DAT1, SLC18A2/VMAT2, TAAR1) and metabolic enzymes and transporters impacting drug disposition (ABCB1, NR1I2) could help explain differential outcomes in treatment response to d-MPH. Methods: In 202 children participating in the NIMH TRECC Study, height and weight were measured at baseline and at Weeks 4 and 8. A subset continued treatment for 18 months and growth was measured regularly. Treatment response was determined by scores on the ADHD-rating scale (ADHD-RS) and Clinical Global Impression Improvement (CGI-I) Scale. Variants previously associated with similar phenotypes or shown to impact protein function were genotyped using TaqMan allelic discrimination assays. Results: Homozygotes for the minor allele (GG) of exonic NR1I2 variant rs7643645 demonstrated rare guanfacine-associated growth suppression ($p=1.78 \times 10^{-13}$). A second NR1I2 variant (rs1523130) showed differential effects across treatment groups ($p=4.09 \times 10^{-10}$). Heterozygotes for the intronic ABCB1 variant rs1128503 ($p=1.17 \times 10^{-10}$) and 5'-UTR TAAR1 variant rs5008782 ($p=3.24 \times 10^{-6}$) revealed amplified effects of growth suppression when treated with d-MPH and acceleration when treated with guanfacine. Homozygotes for the minor allele (TT) of 3'-UTR SLC6A3 variant rs27072 ($p=4.27 \times 10^{-7}$) and intronic SLC18A2 variant rs363227 showed a paradoxical growth acceleration when treated with d-MPH (rs363227). Minor allele carriers (A+) of the SLC18A2 variant rs363227 show a relatively poor response to either guanfacine or stimulant monotherapy. In contrast, SLC18A2 A+ carriers achieved a significantly greater symptom reduction to combination treatment (p=0.01). Conclusion: Genetic variants impacting d-MPH pharmacokinetic and pharmacodynamic effects influenced treatment outcomes and adverse effects to common ADHD treatments. Understanding the pharmacogenomic factors moderating treatment response and adverse effects could lead to strategies to individualize treatment matching and develop improved interventions.

684M

Genetic vulnerability to adverse child attachment quality and stress reactivity. *E.H. Gail[1], J.L. Borelli[2], A. Nguyen[1], C.M. Laubacher[2], G.S. Hellemann[1], E.L. Nurmi[1].* 1) University of California, Los Angeles, Los Angeles, CA; 2) Pomona College, Claremont, CA.

Background: Stressful parent-child interactions are known to have effects on both child attachment quality and physiological autonomic reactivity. In this pilot study, we examined the relationship between environmental stress and genetic vulnerability at four polymorphisms that have been linked to stress and attachment phenotypes: serotonin transporter promoter polymorphism (HTT-LPR), oxytocin receptor (OXTR) rs53576, mu-opioid receptor (OPRM1) rs1799971, and glucocorticoid receptor chaperone (FKBP5) rs3800373. Methods: The sample consisted of 45 mother-child dyads recruited from the community. The Child Attachment Interview (CAI) and the Parental Stress Index were collected, as well as cortisol saliva levels during a stressful task. Individual genotypes were assayed and combined genetic load was calculated by adding the number of risk alleles carried by each child. Results: The minor allele at FKBP5 rs3800373 was associated with cortisol reactivity (p=0.038) and attachment quality (p=0.015), both with medium effect sizes (f2 = 0.1). Combined genetic load positively correlated with higher scores on CAI (r=0.32, p=0.036). The correlation of a higher number of risk alleles with greater attachment security may be due to a reversal of effects in the absence of stress, which has been previously observed. While this preliminary study was underpowered to sufficiently analyze gene-environmental interactions, the level of parent-child stress moderated the interaction between risk alleles and both child attachment and cortisol reactivity at the trend level (p<0.1). Conclusions: These data suggest that genetic risk alleles may have opposite effects on child attachment quality and stress reactivity in the context of high versus low parent-child stress. Our findings are consistent with and extend prior observations. A larger study to further explore these potential gene-environment interactions is currently underway. An understanding of the interactions of parenting behavior and genetic load may help predict the development of child anxiety and inform the subsequent development of targeted interventions.

685S

Genetic variation in mitochondrial pore protein ANT1 predicts antipsychotic-induced weight gain in the NIMH RUPP Autism sample. *K.J. Hwang, K.S. Mallya, G.S. Hellemann, J.T. McCracken, E.L. Nurmi.* Semel Institute for Neuroscience at University of California, Los Angeles, Los Angeles, CA.

Background: The atypical antipsychotic drug, risperidone, has been shown to decrease irritability and aggression in children with autism spectrum disorder (ASD); however, weight gain is a common adverse event. Genetic background may explain the substantial variability in this treatment-limiting side effect. As previous data suggests a potential mitochondrial contribution to antipsychotic-induced weight gain (AIWG), we attempted to replicate prior findings at three specific mitochondrial gene variants (SLC25A4, TSPO and NDUFS1). Methods: 225 subjects participating in the NIMH Research Units on Pediatric Psychopharmacology (RUPP) Autism Risperidone trials were genotyped and individual BMIs were measured weekly for eight weeks to examine association of AIWG with mitochondrial gene variants. Results: The rs10024068 promoter variant in SLC25A4 strongly moderated AIWG over the course of just 8 weeks of treatment in both the complete sample ($p = 3.21\times10^{-8}$) and the Caucasian subset ($p = 2.49\times10^{-6}$). Individuals homozygous for the minor G-allele gained significantly more weight (Z-Score change GG = 1) than A-allele carriers (Z-Score change AG=0.58 and AA = 0.61). This single variant explains 6% of the variation in AIWG in our sample. SLC25A4 encodes the Adenine Nucleotide Translocator 1 (ANT1), part of the mitochondrial permeability pore. There was no evidence for association of weight gain with genetic variants in NDUFS1 or TSPO. As seen in prior studies, however, a significant interaction between SLC25A4 and TSPO was observed ($p = 0.018$), which is especially relevant given the biological association of ANT1 and translocator protein TSPO in forming the mitochondrial permeability pore. Conclusion: Genomewide significant association at SLC25A4 supports the involvement of mitochondrial energy pathways in AIWG and suggests the examination of additional mitochondrial candidates as well as replication in independent samples. These data may help uncover pathways underlying AIWG and may eventually be used to optimize treatment matching.

The application of personalized medicine for understanding clinical variability in rasagiline response in early Parkinson's Disease. *J. Knight[1,2,3], S. Collinson[1], N. Freeman[1], M. Tampakeras[1], J. Levy[4], A. Tchelet[4], E. Eyal[4], E. Berkovich[4], R. Eliaz[4], V. Abler[4], I. Grossman[4], A. Tiwari[1], J.L. Kennedy[1,2,3], M. Masellis[3,5,6,7], A.E. Lang[5,8,9], ADAGIO investigators.* 1) Campbell Family Mental Health Research Institute, Centre of Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 3) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 4) Teva Pharmaceutical Industries, Israel; 5) Department of Medicine, Division of Neurology, University of Toronto, Toronto, Canada; 6) Movement Disorders Clinic, Sunnybrook Health Sciences Centre, Toronto, Canada; 7) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, Canada; 8) Morton and Gloria Shulman Movement Disorders Clinic, Toronto Western Hospital, University Health Network, Toronto, Canada; 9) The Edmond J. Safra Program in Parkinson's Disease, Toronto Western Hospital, University Health Network, Toronto, Canada.

Objective: To identify candidate gene polymorphisms associated with peak motor benefit to rasagiline at 12 weeks and associated with sustained benefit over a 36-week evaluation period. **Background:** Rasagiline, a selective irreversible monoamine oxidase-B (MAO-B) inhibitor, has been shown to be safe and effective for the treatment of Parkinson's disease (PD). As with all drugs, there is variability among individuals in their clinical benefit to rasagiline, this study is designed to identify genetic factors that may influence this variability. **Methods:** We performed a retrospective genetic association study using clinical data from the ADAGIO trial. Candidate genes encoding proteins involved in catecholamine synthesis and metabolism, rasagiline metabolism, as well as those reported in Genome Wide Association Studies (GWAS) of PD susceptibility were selected. We examined association between genetic polymorphisms and peak change in Unified Parkinson Disease Rating Scale (UPDRS) score from baseline to 12 weeks, using a linear model. We also examined association between genetic polymorphisms and change in UPDRS score from baseline over 12, 24, and 36 weeks, using a mixed effects linear model. Both models controlled for placebo response. **Results:** 204 Single Nucleotide Polymorphisms (SNPs) and 5 Variable Number Tandem Repeat (VNTR) from 28 candidate genes were successfully genotyped in 694 samples Analysis 1: Two SNPs in strong linkage disequilibrium within the dopamine D2 receptor gene (DRD2) were found to be significantly associated with peak change in UPDRS scores at 12 weeks (rs1076560 and rs2283265, False Discovery Rate [FDR] p=0.045 for each) as well as one in Norepinephrine Transporter (SLC6A2) (rs36023, FDR-corrected p=0.045). Analysis 2: No allelic associations were identified in the model assessing longitudinal data. **Conclusions:** To our knowledge, this is the largest pharmacogenetic study of an anti-Parkinsonian drug conducted to date. The D2 receptor is a major target of dopamine and its stimulation relates to motor benefits in PD. Prior literature indicates that the two associated SNPs alter transcriptional processing of DRD2. Together with the dopamine transporter, the norepinephrine transporter is involved in the pre-synaptic reuptake of catecholamines, including dopamine. Further investigation of these genes is clearly warranted.

687S

Evaluation of candidate gene SNPs in the International Clopidogrel Pharmacogenomics Consortium (ICPC) reveals genetic variation that significantly impacts on-treatment platelet reactivity. *J. Lewis on behalf of the International Clopidogrel Pharmacogenomics Consortium.* Endocrinology, Diabetes & Nutrition, University of Maryland, Baltimore, Baltimore, MD.

Antiplatelet therapy with clopidogrel is standard of care in improving outcome in secondary prevention for cardiovascular patients. While generally effective, substantial inter-individual variation in response to clopidogrel exists, and high on-treatment platelet reactivity to adenosine diphosphate (ADP) is associated with recurrent cardiovascular events. To better assess the genetic determinants of clopidogrel response, we evaluated 28 previously reported single nucleotide polymorphisms (SNPs) on platelet reactivity in 2054 coronary artery disease patients of the ICPC. Consistent with previous investigations, we detected strong association between the loss-of-function *CYP2C19*2* [rs4244285] variant and increased on-clopidogrel ADP-induced platelet aggregation ($P=9.83 \times 10^{-25}$, Beta = 0.48). Conversely, on-treatment ADP-induced platelet aggregation was significantly decreased in subjects with the gain-of-function *CYP2C19**17 variant both before and after adjustment for *CYP2C19*2* ($P=2.33 \times 10^{-7}$, Beta = -0.23 and $P=3.54 \times 10^{-4}$, Beta = -0.12, respectively), as well as a functional SNP in *CES1* (G143E [s71647871]), which metabolizes clopidogrel to an inactive form ($P=7.76 \times 10^{-6}$, Beta = -0.62). A variant in *P2YR12* (rs1472122), which encodes the platelet ADP receptor was also significantly associated with on-clopidogrel platelet reactivity ($P=3.82 \times 10^{-4}$, Beta = 0.13). We observed no evidence of association between platelet aggregation and genetic variants in other candidate genes including *ABCB1* C3435T [rs1045642] and C1236T [rs1128503]), *PON1* (Q192R [rs662] and L55M [rs854560], *ITGB3* (rs5918), and other CYP enzymes (e.g. *CYP2B6*, *CYP2C9*, and *CYP1A2*). Our data suggest that, in addition to *CYP2C19*, genetic variation in genes responsible for generation of the inactive clopidogrel metabolite formation and regulating the P2Y12 ADP-receptor impact on-treatment platelet reactivity and may influence overall clopidogrel efficacy.

688M

Genetic variation in the oxytocin/vasopressin locus is associated with treatment-dependent improvement in social functioning in autism spectrum disorder. *W. Li, E.L. Nurmi, C.P. Laughlin, J.T. McCracken, NIMH RUPP Autism Network.* Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA.

Background: While social functioning is a key deficit in autism spectrum disorders (ASD), few current treatments specifically target these impairments. In the NIMH Research Units on Pediatric Psychopharmacology (RUPP) study, risperidone reduced social withdrawal ratings in children with ASD; however, variability was substantial. We examined genetic variability in the oxytocin and vasopressin signaling pathways, which are known to play a role in social behavior, for hypothesized association with treatment response. Methods: Risperidone response in 225 children and adolescents with ASD in the NIMH RUPP Risperidone trials was measured by weekly Aberrant Behavior Checklist (ABC) Social Withdrawal subscale (II) ratings over 8 weeks of treatment. Complete common variation at the Oxytocin (OXT), Arginine Vasopressin (AVP), and Arginine Vasopressin Receptor (AVPR1 and 2) loci was captured with 16 tSNPs. Additionally, we included 10 Oxytocin Receptor (OXTR) SNPs with evidence for prior association with various social phenotypes. A repeated measures general linear mixed model was used to examine genetic association with symptom improvement. Analyses were restricted to the Caucasian subset to limit effects of ethnicity. Results: Three independent variants (rs2740204, rs2770378 and rs4813625) tagging the genomic locus containing the adjacent AVP and OXT genes predicted improvement in ABC Social Withdrawal ($p<0.002$). Individuals homozygous for the C-allele at rs4813625 ($p= 0.0014$) and the A-allele at rs2770378 ($p= 0.0019$) showed greater improvement in social withdrawal than G-carriers. The T-allele at rs2740204 demonstrates an allele dosage-dependent effect on symptom improvement ($p=0.0017$). No effects at either OXTR or AVP receptors was observed. Conclusions: Our results suggest that variants in the OXT/AVP systems influence social withdrawal treatment response to risperidone in children with ASD. If replicated in independent samples, these results may help guide future clinical treatment algorithms.

689S

Genetic variation in dopaminergic and adrenergic receptor targets moderates weight loss during ADHD treatment. *N.A. Nguyen, C.P. Laughlin, G.S. Hellemann, S.K. Loo, J.J. McGough, J.T. McCracken, E.L. Nurmi.* Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA.

Background: Growth effects of ADHD pharmacotherapies are important, treatment-limiting side effects. Previously we reported genetic influences on dexmethylphenidate (d-MPH) and guanfacine treatment of children with ADHD in the UCLA TRECC sample, including variants associated with treatment response and altered height trajectories. The present study focuses BMI changes with stimulant treatment. Due to monoamine and acetylcholine involvement in growth hormone regulation and energy balance, we examined genetic variation in these signaling pathways for association with growth effects. **Methods:** 202 subjects between 7–14 years of age were recruited for the acute phase of a randomized, double-blind, placebo-controlled trial of d-MPH and guanfacine for pediatric ADHD. Three treatment groups included guanfacine monotherapy, d-MPH monotherapy, and combination guanfacine plus d-MPH. Medication responders continued in the trial for approximately 14 months (n=99) and height and weight were tracked regularly in addition to ADHD symptoms. We tested association of genetic variation in monoamine and energy balance candidate systems with height and BMI changes during medication exposure. Due to the large number of markers tested (n=95), we only report results meeting genomewide significance. **Results:** In our sample, guanfacine monotherapy was associated with height and BMI increases over predictions from CDC growth charts (Z-score increase of 0.14 for height and 0.41 for BMI). Both d-MPH monotherapy (Z-score decrease of -0.12 for height and -0.84 for BMI) and combination treatment (Z-score decrease of -0.19 for height and -0.83 for BMI) were associated with growth slowing. Variation in treatment group trajectories for height ($p=6.47\times10^{-15}$) and BMI ($p=5.58\times10^{-34}$) were highly significant. Minor allele (A) carriers at DRD3 rs3732790 showed allele dosage-dependent clinically-significant weight loss (2.6 Z-Score loss) on d-MPH ($p=1.53\times10^{-10}$). BMI change was moderated by ADRA2A rs1800544, with profound weight loss on d-MPH in C-allele carriers and combination treatment in G-allele carriers ($p=2.73\times10^{-9}$). Effects are similar and maintain Bonferroni significance in the Caucasian subset, ruling out population effects. **Conclusions:** The results presented here suggest that genetic factors contribute significantly to stimulant-mediated weight loss pediatric subjects with ADHD and appear to be able to identify patients more likely to be affected.

690M

Differential genetic effects of the melanocortin system in antipsychotic-induced weight gain in children versus adults. *A.K. Subhash, K.S. Mallya, C.P. Laughlin, G.S. Hellemann, J.T. McCracken, E.L. Nurmi.* Semel Institute for Neuroscience, University of California, Los Angeles, 760 Westwood Plaza, 47-376, Los Angeles, CA 90024.

Background: Antipsychotic-induced weight gain (AIWG) is a common, treatment-limiting adverse effect of this widely prescribed drug class. Prior examination of the melanocortin system in adults with AIWG has demonstrated a consistent contribution of the melanocortin 4 receptor (MC4R), which is central to energy balance, growth and body weight regulation. We therefore queried 3 genes in the melanocortin system in our sample of children and adolescents with autism spectrum disorder (ASD) treated with risperidone for aggression and irritability. Methods: 225 youth in the NIMH Autism Risperidone studies were genotyped using Life Technologies' Taqman platform. Complete common variation in key melanocortin signaling receptors was captured with 15 tSNPs spanning the MC3R, MC4R and neuropeptide Y (NPY) loci. Variants were tested for association with BMI and height change (measured weekly across 8 weeks of treatment) using a repeated measures general linear mixed model. Results: In contrast to previous literature, MC4R was not associated with AIWG in our sample. Common allele homozygotes (GG) at MC4R promoter SNPs rs8087522 ($p=7.65\times10^{-7}$) and rs8093815 ($p=6.70\times10^{-9}$) however, showed greater change in height over 8 weeks of treatment in both the complete dataset and the Caucasian subset. On the other hand, we found strong ethnicity-specific association of AIWG with two MC3R gene variants: 3' variant rs6024733 ($p=1.2228\times10^{-5}$) in African Americans and promoter SNP rs6127698 ($p=8.78\times10^{-7}$) in Caucasians. Common allele homozygotes (GG) at rs6127698 and minor allele homozygotes (AA) at rs6024733 were relatively protected from AIWG. While no NPY effects on AIWG were observed, one NPY SNP (rs16141, $p=5.01\times10^{-5}$) predicted height change in Caucasians. These results survive correction for the 120 tests that have been performed in this sample in related studies. Conclusions: Contrary to prior literature in adults showing a substantial contribution of MC4R to AIWG, our data suggest that genetic variation in the peptide hormone receptor MC3R influences AIWG in children. Furthermore, variations in MC4R and NPY show strong height effects in children. Distinct but related genetic effects on AIWG between adults and children may help explain the increased risk of children to this serious adverse event. Thoroughly understanding the pharmacogenomic factors involved in AIWG may guide clinical treatment matching and minimize adverse effects for patients taking anti-psychotic drugs.

Metformin functional pharmacogenomics: STUB1 functions as an E3 ligase for cyclin A and affects metformin sensitivity. *N. Niu, T. Liu, M. Deng, R. Ly, L. Wang.* MPET, Mayo Clinic, Rochester, MN.

Metformin, a widely used anti-diabetic drug, is being considered as a highly promising chemopreventive and therapeutic agent. Although the exact mechanism of action of metformin is unknown, it is thought that metformin could activate AMPK and cause G1 cell cycle arrest. In order to identify biomarkers contributing to metformin response, we took advantage of our Human Variation Panel, a 300 EBV-transformed lymphoblastoid cell line (LCL) model with extensive omic data, and conducted a metformin pharmacogenomic study. The expression of *STUB1*, known as an E3 ubiquitin-protein ligase, was found to be associated with metformin cytotoxicity (IC50 value) with p-value $<10^{-4}$. Functional validation study using siRNA showed that knockdown of *STUB1* significantly altered metformin response in two basal-like breast cancer cell lines, MDA-MB-231 and Hs578T. To further investigate the mechanism by which *STUB1* influences metformin response, we performed mechanistic studies using MDA-MB-231 breast cancer cell line as well as *STUB1* knock-out mouse embryonic fibroblast (MEF) cells. Knockdown of *STUB1* in MDA-MB-231 cell showed an increased proportion of cells in the S phase by flow cytometry and a significant increase in cyclin A protein level by Western Blot. Cyclin A is known to be involved in G1/S transition. In our study, we found that STUB1 interacted with cyclin A. In MEF cells, knockout of *STUB1* caused an increase in cyclin A protein level as well as a decrease in the ubiquitin level of cyclin A. In addition, cyclin A protein was found to be degraded in a proteasome-dependent manner. Thus, we propose that the E3 ubiquitin ligase STUB1 influences metformin response by facilitating proteasome-mediated degradation of cyclin A. In conclusion, genome-wide association study (GWAS) using a genomic data-enriched LCL model system, together with functional validation and mechanistic study using cancer cell line, could help us to identify novel genetic biomarkers involved in metformin response.

692M

Association study of polycystic ovary syndrome with two single nucleotide polymorphism of follicle stimulating hormone receptor in Iranian patients: rs1394205 and rs6166. *B. Dehghan Banadaki[1,2], P. Afsharian[2], M. Shiva[3], SH. Zarei Moradi[2].* 1) Faculty of basic sciences and advanced technologies in biology ,University of science and culture, Tehran, Iran; 2) Department of Genetics at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran; 3) Department of Endocrinology and Female Infertility at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran.

Background: Polycystic ovary syndrome (PCOS) is the most common form of WHO II anovulatory infertility, affecting women in reproductive age. The clinical or biochemical hyperandrogenism, menstrual dysfunction with anovulation and presence of polycystic ovaries are the features for PCOS evaluation. Gonadotropins e.g. Follicle-stimulating hormone (FSH) are fundamental for patients undergoing assisted reproductive technology (ART). Therefore FSH receptor (FSHR) has a critical role in follicular development and ovulation induction. The FSHR gene is highly polymorphic and we have studied two functional polymorphisms (rs6166 (N680S), rs1394205 (-29G>A)) in this gene. Methods: The Genomic DNA was extracted from peripheral blood of candidates. The target zones containing single nucleotide polymorphisms (SNPs) -29 and 680 were amplified by polymerase chain reaction (PCR). The allelic and genotypic distributions of these two SNPs were determined by restriction fragmental length analysis (RFLP) technique. We studied rs1394205 on 102 PCOS patients, 100 drug controls (women with normal ovulation and referred for ART because of husband's infertility disorder) and 90 fertile controls. For evaluating rs6166 we experiment on (73 PCOS patients, 54 drug control, 100 fertile controls). Both PCOS and drug-control groups were undergone same IUI protocols and the clinical, surgical and drug history of all subjects were observed and number of follicles $\geq$ 15, as a feature of drug response, were evaluated. Final data were analyzed by chi-square test in SPSS statistical software. Results: PCOS patients in comparison to other two control groups, showed significantly association with N680S (p=0.0008). Genotype distribution of SS, SN and NN in PCO group was 37%, 42% and 15% respectively. According to drug response (exogenous FSH), 30% of PCOs bearing SS genotype were resistant to drug in comparison to 5% of drug controls with the same genotype. This difference in drug resistance was observed in SN genotype too, 42% in PCOs vs. 20% in drug controls. In SS genotype, 70% of both groups respond to treatment. 29G>A polymorphism did not show any significant difference in three groups. Clinical data shown that Patients with normal BMI (18–25 kg/m2) had a better chance to ovulation induction response. Conclusion: Our observation showed great correlation between rs6166 polymorphism and ovulation induction response in PCOS.

693S

***In Vitro* system to assess functional impact of heterozygous variants and complex combinations of variants in dihydropyrimidine dehydrogenase.** *C.R. Jerde, S.M. Offer, R.B. Diasio.* Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN.

Dihydropyrimidine dehydrogenase (DPD, encoded by *DPYD* [MIM 612779]) is the rate-limiting enzyme of the uracil catabolic pathway and, as such, is additionally responsible for the catabolic degradation of the commonly prescribed chemotherapy drug 5-fluorouracil (5-FU). DPD deficiency [MIM 274270] has been associated with increased incidence of severe adverse toxicity (grade 3 or greater), and in some cases death, following treatment with the standard dose of 5-FU. Clinical studies have established that a 30% reduction in DPD function is adequate to increase the risk for toxicity. While there is growing evidence that certain rare genetic variants in *DPYD* are risk alleles for DPD deficiency, the exact contribution of these variants to the disorder is not well understood, particularly in the heterozygous state. The objective of the present study was to develop a reliable system to rapidly evaluate genetic variants that impair DPD activity by 30% or greater as heterozygous alleles. Previously, our lab has developed and optimized methods for evaluating single variants in vitro that rely upon transient expression of DPD in mammalian cells that have undetectable endogenous levels of the protein (*Cancer Res.* March 15, 2013. 73:1958–1968). In the current study, we describe a method that represents an improvement upon that system and permits the study of heterozygous *DPYD* alleles, as well as complex DPYD genotypes. Using this improved method, twice as many cells were double-positive for both copies of the gene compared to co-transfection with two vectors. Additionally, both copies of the gene were shown to be equally expressed at the mRNA and protein levels in target cells. The modeling of a catalytically-null allele in the heterozygous state resulted in in vitro enzyme activity that was 50% of that for the wildtype positive control. Collectively, these data suggest that this system may be applicable for determining which single variants in the heterozygous state and in complex *DPYD* genotypes contribute to DPD deficiency.

***In silico* gene expression results enhance understanding of association studies.** *L. Li[1], E.R. Gamazon[2], T. Johnson[3], C.F. Xu[4], D.M. Waterworth[5], M.G. Ehm[6], N.J. Cox[2].* 1) StatGen, PCPS, GlaxoSmithKline, RTP, US; 2) Section of Genetic Medicine, Department of Medicine, University of Chicago; 3) StatGen, PCPS, GlaxoSmithKline, UK; 4) Genetics, PCPS, GlaxoSmithKline, UK; 5) Genetics, PCPS, GlaxoSmithKline, Philadelphia, USA; 6) Genetics, PCPS, GlaxoSmithKline, RTP, USA.

With the wealth of publically available gene expression data, there is growing excitement in the genetics field that integrating expression information into analyses of genetic and clinical phenotype data will enable a more informative interpretation of findings, and clearer hypotheses for follow-up studies. When expression, genetic and clinical data are all available for the same individuals, a three-way association analysis can be used to test the hypothesis that a given genetic variant affects the clinical phenotype via gene regulation. However, this approach is limited by the infeasibility of obtaining expression data from relevant tissues in the large sample sizes needed to identify associations between genotypes and clinical phenotypes. As a practical alternative, numerous previous studies have asked whether genetic variants associated with clinical phenotypes are also associated with gene expression in independent convenience samples; so-called expression quantitative trait loci (eQTLs). Here, we further refine this approach by developing a polygenic prediction model for expression levels of genes of interest, which can be constructed using publicly available expression data, and using this to derive in silico expression data of the study sample, enabling further analysis to understand findings. The STabilisation of Atherosclerotic plaque By Initiation of darapLadIb TherapY (STABILITY) trial was a cardiovascular outcomes study involving 15,828 patients which evaluated the efficacy of darapladib (an Lp-PLA2 inhibitor) for stable coronary heart disease (CHD). We conducted genome-wide association study for clinical and biomarker traits to identify genetic variants associated with differential drug response. We identified associated variants ($p < 1e\text{-}5$) that were known eQTLs and therefore sought to determine whether these variants contributed to drug response via gene regulation. To address this question, we used publicly available expression data to construct polygenic prediction models for expression levels of the relevant genes. We then used these models to predict expression levels for individuals in the STABILITY trial. Stronger association of these "in silico gene expression levels" with clinical phenotype than for the single genetic variants would highly suggest the effect of gene regulation, warranting further follow up analysis with clearer hypothesis.

Mapping histone modifications provides novel insights in pharmacogenomic discovery. *C. Liu[1], X. Zhang[1], L. Godley[2], M. Dolan[2], W. Zhang[1].* 1) University of Illinois, Chicago, Illinois, USA; 2) University of Chicago, Chicago, Illinois, USA.

Personalized medicine proposes the customization of healthcare and optimal therapies based on the context of an individual patient's genetic make-up and/or other clinical information. Recent progress in pharmacogenetic and pharmacogenomics studies has indicated that both genetic and epigenetic factors may influence drug response to therapeutic treatments. Our objective was to identify histone modification markers associated with drug toxicities using the Lymphoblastoid cell lines (LCL) model, on which we have access to a variety of genetic, epigenetic, and phenotypic data, including the genetic variants associated with chemotherapeutic agents. Specifically, the ChIP-seq data for four post-translational modifications of histone H3 (H3K4me1, H3K4me3, H3K27ac, and H3K27me3) in ten Yoruba LCLs were collected from a publicly available dataset (GSE47991). Drug response association results for five drugs (carboplatin, cisplatin, etoposide, daunorubicin, and ara-C) in the same cell lines were collected from our previously developed pharmacogenetics-cell line database: PACdb (http://www.pacdb.org/). Association studies revealed a substantial number of genes whose local histone modification associated with cytotoxicities based on Akaike information (AIC) and p-value mixed criteria. For example, local H3K4me1 modification levels in 72 genes were observed to be associated with the IC50 of carboplatin. Group comparisons showed that different histone markers exhibited different strength of association. Overall, H3K4me4, a histone mark known to be associated with active gene expression, outperformed other histone markers as a variable for cytotoxicity. Our previous studies had identified a list of potential genes whose expression levels were associated with these drug response phenotypes. We showed that a subset of those associations could be explained by variations of its local histone modification levels. For example, the expression of ARL4A (encoding ADP-ribosylation factor-like 4A) had been identified to be highly associated with the IC50 of cisplatin ($p < 0.001$). Our results further showed this association could be related to the modification in its local H3K4me3. In summary, our whole genome approach provided a global picture of the contributions of histone modification markers to a series of chemotherapeutic-induced cytotoxicity phenotypes. The mapping of histone modification markers provided novel insights into our previous pharmacogenomic findings.

Gene Expression Based Models for Cancer Drug Sensitivity. *U. Ozbek.* Icahn School of Medicine at Mount Sinai, New York, NY.

Pharmacogenomic studies aim to elucidate the genetic or genomic features contributing to the efficacy of medications. The analysis of these data are challenging due to the large number of genomic features that must be investigated. Shrinkage or regularization techniques can help identify the most important features that can predict sensitivity to drug. This work reviews the properties of several regularization methods, such as ridge regression, lasso, and elastic net, using gene expression data from the Cancer Cell Line Encyclopedia project for predicting the sensitivity of 74 lung cancer cell lines to the drug nilotinib. An empirical illustration of the predictive performance of the regularization methods are provided based on three approaches - the first that directly uses gene expressions, and two methods that use principal components of the gene expressions. In this study, ridge regression models fitted slightly better than lasso and elastic net models.

Statin-induced expression change of *INSIG1* in lymphoblastoid cell lines is correlated with plasma triglyceride statin response in men. *E. Theusch, K. Kim, K. Stevens, D. Naidoo, M. Medina.* Children's Hospital Oakland Research Institute (CHORI), Oakland, CA.

Statins are widely prescribed to reduce cardiovascular disease (CVD) risk. Statins primarily lower plasma low-density lipoprotein cholesterol (LDL-C) levels, but they also cause modest reductions in plasma triglycerides (TG), an independent CVD risk factor, in most people. There is extensive inter-individual variability in statin response, but only a small proportion of this variance has been explained by phenotypic characteristics or by genetic variants identified from association studies. As an alternative approach, we studied statin response variability using RNA-seq data from control and statin-treated lymphoblastoid cell lines (LCLs) derived from 100 Caucasian and 50 African American participants of the Cholesterol and Pharmacogenetics (CAP) simvastatin clinical trial (40 mg/day for 6 weeks). 38% of human genes were statin responsive, and 64% of Epstein-Barr virus genes were upregulated with statin treatment ($q<0.0001$, $N=150$). To identify candidate statin efficacy genes, statin-induced changes in gene expression were correlated to plasma LDL-C response and plasma TG response. Initially, we found 151 genes with expression changes that were significantly correlated with LDL-C response (FDR=5%). Next, we adjusted the gene expression changes for potential confounders using probabilistic estimation of expression residuals (PEER) and found that the first two PEER hidden factors were significantly correlated with LDL-C response ($p<0.05$) but not TG response. Using the PEER-adjusted data, changes in 23 genes were significantly correlated with TG response (FDR=15%). Insulin-induced gene 1 (*INSIG1* [MIM 602055]), a well-known regulator of cholesterol homeostasis, had expression changes strongly correlated with TG response (Spearman's $\rho=0.32$, $q=0.11$, $N=150$), and this correlation was driven by men (sex interaction $p=0.0055$). In Caucasians, we identified a SNP that was associated with *INSIG1* expression changes ($N=99$ LCLs, $p=5.4\times10^{-5}$) as well as with TG response in the combined CAP and PRINCE statin trial populations ($p=0.0048$, $N=1890$), predominantly in men. Statin-induced changes in *INSIG1* alternative splicing were also correlated with TG response in men, and a combined model including *INSIG1* expression level and splicing changes accounted for over 28% of the variance in plasma TG statin response in men ($p<5\times10^{-6}$, $N=86$). In summary, our results strongly suggest that variation in *INSIG1* contributes to statin-induced changes in plasma TG in a sex-specific manner.

Accelerating Drug Development with 23andMe Phenome-Wide Association Studies. *F. Sathirapongsasuti, B.T. Naughton, J.L. Mountain, D.A. Hinds, J.Y. Tung, C.Y. McLean.* 23andMe Inc., Mountain View, CA.

Ninety percent of drugs that are deemed successful in animal models fail human clinical trails, because of adverse drug reactions or lack of efficacy. Human genetics can be a powerful tool in the efforts to increase success of drug development through validation of target genes and prioritization of research programs. 23andMe phenome-wide association studies (PheWAS) leverage extremely large sample sizes and phenotypic breadth to yield valuable insights with direct relevance to potential effects in humans. By mining publicly available drug databases for associations between drug target genes and genes harboring variants significantly associated with one or more 23andMe phenotypes, we found over 2,800 drug-phenotype links. Both positive validation of likely successful drug targets and prediction of adverse drug reactions are seen in the 23andMe data, including a replication of association between rare loss-of-function variants in PCSK9 and LDL cholesterol level. A retrospective look at both successful and unsuccessful drug trials confirms our findings, with substantial increase in specificity of predicting successful trials as well as predicting trail failure based on lack of association. Our results support using PheWAS to inform ongoing target validation and identify new drug targets.

Association of C677T polymorphism of the MTHFR gene with toxicity in breast cancer patients treated with FEC chemotherapy. *A. Ramos-Silva[1 y 2], R. Ramírez'[1 y 3], IA. Gutíerrez[1 y 3], OM. Soto[1 y 2], DI. Carrillo[1 y 3], AM. Puebla[4], AR. Rincón[2 y 5], MP. Gallegos[1].* 1) Lab de Genética Molécular. Div Med Mol, CIBO, IMSS, Guadalajara, Jal,. México; 2) Doctorado en Farmacología. CUCS, U de G; 3) Doctorado en Gentica Humana. CUCS, U de G; 4) Laboratorio de Inmunofarmacología. Departamento de Farmacología. CUCEI, U de G; 5) Departamento de Biología Molecular y Genómica. CUCS. U de G.

Background: The influence of C677T polymorphism in the MTHFR gene involved in metabolism of chemotherapeutic agents has been studied in different cancers. MTHFR plays a major role in folate metabolism and consequently could be an important factor for the efficacy of a treatment with FEC (fluorouracil-epirubicin-cyclophosphamide) in breast cancer patients. Our aim was to evaluate the association of C677T polymorphism with toxicity effects in breast cancer patient's neoadjuvantly treated with FEC chemotherapy. Methods: DNA genomic samples from 525 patients (UMAE gynecology and obstetrician Hospital, CMNO, IMSS), that received FEC neoadjuvant chemotherapy; were included in the study. Protocol was support by FIS/IMSS/PROT/G13/1231. The C677T polymorphism was determinate by polyacrylamide gels electrophoresis, previously PCR and HincIII restriction enzyme analysis. The association was determinate by odds ratio. Results: The genotype 677TT was associated with gastrointestinal toxicity (diarrhea grade III) in breast cancer patient response at FEC chemotherapy [1.9(IC95% 1.06–3.53), p=0.028] and genotype 677CT was associated with hematological toxicity (neutropenia) in breast cancer patients non responder at FEC chemotherapy [1.8(IC95% 1.03–3.41), p=0.046]. Conclusion: The polymorphism C677T could be a good marker of toxicity in breast cancer patients treated with FEC chemotherapy in the analyzed sample.

Integration of Genetics into Clinical Development. *D. Waterworth[1], L. Li[2], L. Warren[2], A. Yeo[3], J. Aponte[4], M. Nelson[2], S. Chissoe[4].* 1) Genetics, PCPS, GlaxoSmithKline, King of Prussia, PA; 2) Statistical Genetics, PCPS, GlaxoSmithKline, RTP, NC; 3) Genetics, PCPS, GlaxoSmithKline ,Stevenage UK; 4) Genetics, PCPS, GlaxoSmithKline, RTP, NC.

Pharmacogenetic analysis is commonly initiated after a clinical trial completes and questions arise around interindividual variation in safety or efficacy. This approach can limit the number of pharmacogenetic studies conducted, but it can also limit the opportunity to identify important genetic predictors and delay their potential impact on drug development. We sought to circumvent these issues in the STABILITY study that tested darapladib, an Lp-PLA2 inhibitor, against standard of care for stable coronary heart disease (CHD). We genotyped 13,557 patients with the Illumina Omniexpress Exome chip prior to study completion. The trial failed to demonstrate efficacy for the primary endpoint of major adverse coronary events (MACE). Despite the large size of this study, no genetic variants reached genome-wide significance for MACE or secondary endpoints. However, we demonstrate that there is little power to detect genetic effects unless they are larger than the drug effect assumed in the design the study. Power was further compromised in this study by the limited effects of darapladib on efficacy outcomes. In spite of the failure to identify pharmacogenetic predictors of darapladib efficacy, the information created through prospective genotyping can be valuable in support of further drug discovery and development efforts. CHD is a particularly heterogeneous condition and having the genetic data along with extensive clinical and biomarker data enables us to try to identify patient subgroups that might benefit future CHD outcome trials. Given the exome content of the genotyping array used, we can determine the proportion of subjects who may have rare conditions leading to CHD, which may be commingled with more common forms. In performing analysis of baseline biomarker data, we identified 24 subjects with a somatic JAK2 mutation (V617F) using platelet count as a trait (causes erythrocytosis) and 37 subjects with dominant familial hypercholesteremia due to an APOB mutation (R3527Q). We are performing a thorough review of such conditions to determine their frequency within the trial population, their effects on intermediate traits and their collective impact on outcomes. This experience, along with improvements in genotyping technology and reduction in costs, has added to our understanding of the value of integrating genetics into clinical development and we are currently transitioning toward a fully integrated approach.

A genome-wide association study on antipsychotic-induced body weight gain dissecting the CATIE sample. *M. Maciukiewicz[1], D. Mueller[1], EJ. Brandl[1], AK. Tiwari[1], CC. Zai[1], NI. Chowdhury[1], T. Arenovich[1], JJ. Chen[2], JL. Kennedy[1].* 1) Pharmacogenetics Research Clinic, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) University of Hong Kong, Department of Pathology,Pokfulam, Hong Kong.

Antipsychotic-induced weight gain (AIWG) is a severe and common side effect often leading to patient non-compliance and increased morbidity and mortality due to metabolic syndrome and cardiovascular events. Genetic predictors would be extremely helpful to identify subjects at risk prior to antipsychotic exposure and first genetic tests are now becoming commercially available. Sample (n=358) consisted of 251 individuals of European and 107 of African-American ancestry with well-documented information on weight changes. Exclusion criteria included a) related individuals, b) available genotype rate of less than 95%, c) mismatch between genetic markers and assigned sex status and d) heterozygosity of more than four standard deviations from the mean. SNPs with MAF < 5%, and genotypes which deviated significantly from HWE were removed. A series of mixed models was used including all potentially relevant covariates and change in BMI over a period of three months as the outcome. In addition, interactions between time and all other predictors were considered. The final model included a random intercept and slope associated with time, study medication group and baseline BMI. Standard quality control workflow was applied to the genotype data and we analyzed 328,733 SNPs. To avoid population stratification, we plotted the MDS components and selected patients within the cluster corresponding to European ancestry as the largest cohort. The GWAS analysis was conducted on 189 individuals. The SNP vs BMI association analysis was carried out using the R package: 'nlme' None of the SNPs was significant at the genome-wide threshold of p = 5×10–8. The top hit of the GWAS was rs12924003 (p=1.06×10–5) located downstream of the SAL-1 gene. The second hit, SNP rs4771655 (p=1.91 ×10–5) is ~194kb upstream of IRS2 gene. The third hit, rs4751427 (p=2.4 ×10–5) is located ~59kb upstream of the Neuropeptide S gene. Our analyses did not detect an association when considering the commonly applied genome-wide correction threshold for multiple testing. Two of our top hits, IRS2 and NPS, were previously shown to be involved in regulation of insulin sensitivity and food intake in other populations.

Genome-wide association study of resistant hypertension in INVEST. *N. El Rouby[1], CW. McDonough[1], Y. Gong[1], CJ. Pepine[2], A. Takahashi[3], T. Tanaka[3], M. Kubo[3], RM. Cooper-DeHoff[1,2], JA. Johnson[1,2].* 1) Pharmacotherapy and Translational Research, University of Florida, Gainesville, FL; 2) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, Gainesville, FL; 3) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan.

Resistant hypertension (RHTN) is defined as a blood pressure (BP) that remains ≥140/90 mm Hg despite the use of ≥ 3 antihypertensive drugs or BP < 140/90 mm Hg requiring ≥ 4 antihypertensive drugs. RHTN is associated with increased risk for adverse cardiovascular outcomes, especially stroke; therefore, we aimed to identify the association between genetic markers and RHTN using a genome wide association study (GWAS) to further characterize those at risk for RHTN. We genotyped 1194 participant samples from the INternational VErapamil-SR trandolapril STudy - GENEtic Substudy (INVEST-GENES) on the Illumina OmniExpressExome chip. INVEST was a clinical trial that compared cardiovascular outcomes in patients with both hypertension and stable coronary artery disease (CAD) after randomization to either a calcium antagonist strategy "CAS" (verapamil-SR ± trandolapril) or non-calcium antagonist strategy "NCAS" (atenolol ± HCTZ). Non-study drugs were used for BP control except for atenolol in CAS and verapamil in NCAS. In this analysis, a case was defined as a BP ≥ 140/90 despite use of ≥ 3 drugs, or use of ≥ 4 drugs regardless of BP. Overall, BP control in both treatment strategies was similar, which allowed for pooling participants. Logistic regression analysis was conducted separately in 657 European Americans and 537 Hispanics using an additive genetic model, adjusting for age, gender, body mass index, diabetes, smoking, left ventricular hypertrophy, congestive heart failure, stroke, percutaneous coronary intervention, principle components, and treatment assignment. Results from both race groups were combined using a meta-analysis. None of the SNPs reached genome wide significance. The meta-analysis identified a missense SNP (rs3732378) in a chemokine receptor gene *CX3CR1* leading to a Threonine to Methionine substitution. The A allele was associated with lower risk of RHTN in Europeans (OR 0.51, $P = 2\times10^{-4}$). This association was replicated in Hispanics (OR 0.47, P=0.005) with a meta-analysis $p = 8\times10^{-6}$. *CX3CR1* is a specific receptor for Fractalkine, a chemoattractant chemokine involved in leukocyte trafficking, inflammation and endothelial dysfunction. The SNP has been reported to alter the ligand-receptor affinity and has been associated in previous studies with reduced risk for atherosclerosis and CAD. In conclusion, we identified a missense SNP in *CX3CR1* that may be associated with reduced risk for RHTN. Additional research is needed to validate our findings.

Identification of nonresponders through the use of EMRs identifies MSRA as a potential controller of response of asthmatics to inhaled corticosteroids. *M.E. March, P.M.A. Sleiman, F. Mentch, E. Hysinger, K. Thomas, C.E. Kim, C. Hou, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Asthma is a chronic inflammatory condition of the lungs, characterized by excessive responsiveness of the lungs to stimuli, in the forms of infections, allergens, and environmental irritants. Currently, 22.9 million Americans suffer from asthma, and the prevalence has increased dramatically since 1980. Asthma is the leading chronic illness in U.S. children, with 6.8 million affected in 2006. Inhaled corticosteroids (ICS) are a common, effective treatment for asthma. ICS act locally in the lungs to reduce the chronic inflammation that characterizes asthma; this reduction in inflammation reduces the frequency and severity of asthma flares that occur in response to acute triggers. Most studies examining the genetic components of the response of patients to ICS treatment focuses on changes in pulmonary function test results that occur following weeks or months of treatment. In the current study, we wished to determine the possibility of identifying responders and nonreponders to ICS therapy through the use of abstracted electronic medical records (EMRs). We developed an approach to score a patient's response to ICS by evaluating changes in the frequencies of hospitalization and emergency room visits, along with changes in ICS dose and the need for additional prescription of stronger therapy in the form of oral steroids. The use of this response score as a quantitative trait in an African American cohort in a genome wide association study revealed a single significant locus, represented by four significant SNPs located within the MSRA gene on chromosome 8. Replication efforts are currently underway.

704M

A genome-wide association study of hepatic toxicity of methotrexate therapy for rheumatoid arthritis. *H. Mo[1], N. Braggs[2], L. Bastarache[1], R.J. Carroll[1], A. Shah[5], D. Roden[2], S. Raychaudhuri[3,4], E.W. Karlson[3,4], J.C. Denny[1,2].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Vanderbilt University, Nashville, TN; 3) Brigham and Women's Hospital, Boston, MA; 4) Harvard Medical School, Harvard University, Boston, MA; 5) Prince of Wales Clinical School, University of New South Wales, Sydney, NSW, Australia.

Low dose methotrexate (MTX) is the first-line disease modifying anti-rheumatic drug (DMARDs) for rheumatoid arthritis (RA) and other inflammatory arthritides. While it is generally well tolerated, hepatic toxicity is among one of the most concerning side effects with a cumulative incidence of 31%. We studied individuals identified from BioVU, a DNA biobank linked to de-identified electronic medical records (EMR) at Vanderbilt, to identify genetic susceptibility of hepatic toxicity of MTX therapy. **Methods:** We identified and genotyped individuals with RA in BioVU using a previously validated algorithm. We evaluated RA individuals for presence of MTX exposure, and then used a combination of algorithms and manual review to ascertained 66 cases and 308 controls with OmniExpress GWAS data and 58 cases and 256 controls with Illumina HumanExome array data. Only individuals of European ancestry were included. MTX hepatic toxicity was defined as liver enzymes (LE, either AST or ALT) greater than 2 times the upper limit of normal (ULN, i.e. 80 IU/L) without other identified causes. Control groups were RA patients who had liver enzyme measurements without abnormal values and who were compliant with MTX treatment. Genotyping was done with Illumina OmniExpress and HumanExome platforms. **Result:** The SNPs with the best P-values in GWAS study was rs913898 (P=9.3e-7, OR=15.51, between *KLF5* and *KLF12*). Other top hits in GWA study include: rs564745 near *EVI5L* with p=4.1e-6 (OR=4.11) and rs12537903 in *NPSR1-AS1* with p=5.0e-6 (OR=4.3). The strongest association on the Exome study is rs7335046 (P=6.6e-5 and OR=4.59, in *MIR548AN* and near *UBAC2*). Among the missense Exome markers with negative PAM30 amino-acid replacement scores, the top hits were *CEBPZ* (P15S, p=0.00041), *LSG1* (L92P, p=0.00063), *ACOXL* (T255M, p=0.00077), *WSB1* (L16S, 0.00082). Previously, *ABCC1*, an efflux transporter involved in MTX metabolism, has been associated with MTX toxicity. In this region, our strongest signal was with rs4781712 with p=0.00026 (OR=0.49). **Conclusion:** In this GWAS of MTX-induced liver injury, we replicated a previously-reported association with *ABCC1* and identified several new potential signals that require further investigation.

705S

A genome-wide association study identified variants in KCNIP4 associated with ACE inhibitor induced cough. *J.D. Mosley[1], C.M. Shaffer[1], S.L Van Driest[2], P.E. Weeke[1], Q.S. Wells[1], J.H. Karnes[1], D.R. Velez Edwards[3], W. Wei[4], P.L. Teixeira[4], L. Bastarache[4], D.C. Crawford[3], J.A. Pacheco[8], T.A. Manolio[5], E.P. Bottinger[6], C.A. McCarty[7], J. Linneman[7], W. Thompson[8], R.L. Chisholm[8], G.P. Jarvik[9], D.R. Crosslin[9], D.S. Carrell[10], E.B. Larson[10], H. Jouni[11], I.J. Kullo[11], G. Tromp[12], K.M. Borthwick[12], H. Kuivaniemi[12], M.D. Ritchie[13], J.C. Denny[1,4], D.M. Roden[1], eMERGE II Network.* 1) Department of Medicine, Vanderbilt University, Nashville, TN; 2) Department of Pediatrics, Vanderbilt University, Nashville, TN; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) Biomedical Informatics, Vanderbilt University, Nashville, TN; 5) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 6) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, NY; 7) Essentia Institute of Rural Health, Duluth, MN; 8) Center for Genetic Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 9) Departments of Medicine (Medical Genetics) and Genome Sciences, University of Washington, Seattle, WA; 10) Group Health Research Institute, Seattle, WA; 11) Division of Cardiovascular Diseases, Mayo Clinic, Rochester MN; 12) The Sigfried and Janet Weis Center for Research, Geisinger Health System, Danville, PA; 13) Department of Biochemistry and Molecular Biology, Penn State University, University Park, PA, USA.

The most common side effect of angiotensin converting enzyme inhibitors (ACEis) is a persistent cough, which effects up to 8% of whites, and often requires a switch to other drug classes. The etiological mechanism of the cough is unknown. We conducted a genome wide association study (GWAS) to identify common SNPs associated with ACEi-induced cough. The discovery cohort comprised 6,007 whites of European ancestry (EAs) from six sites in the electronic MEdical Records & GEnomics (eMERGE) network. The phenotype was defined as a clinically diagnosed cough attributed to an ACEi and recorded in the drug sensitivity/allergy section of the electronic medical record (EMR). Controls were individuals with at least 6 months of ACEi use and no history of an ACEi-associated cough. We performed single SNP tests of association using logistic regression with 3,194,795 SNPs, assuming an additive genetic model, and adjusting for principal components. The most significant SNPs were evaluated in an replication set of 926 eMERGE EA subjects. The GWAS in the discovery set of 1,346 cases and 4,661 controls identified significant associations located in a single region of chromosome 4 within an intron of the gene KCNIP4. The strongest association was in rs145489027 (MAF=0.33, OR=1.3 [95%CI: 1.2–1.4], p=2.4×10–8). Four of the six most significantly associated SNPs in this region with p<1×10–6 were available for analysis in a replication set of 157 cases and 769 controls. The strongest association among these 4 SNPs was in rs7675300, also in KCNIP4, (MAF=0.33, OR=1.3 [1.01–1.70], p=0.04). KCNIP4 is a member of the KChIP family of EF hand-containing calcium-binding proteins and is primarily expressed in neuronal structures where it regulates Kv4 potassium channels. These data suggest that ACEi-induced cough may be mediated, in part, through a neuronally-mediated mechanism involving KCNIP4.

706M

International Clopidogrel Pharmacogenomics Consortium Genome Wide Association Study Identifies Novel Variants for Clopidogrel Response. *A. Shuldiner, International Clopidogrel Pharmacogenomics Consortium.* Prof/Med,Endocr/Diabetes/Nutr, University of Maryland, Baltimore, Baltimore, MD.

Clopidogrel (Plavix) is a commonly used antiplatelet medication in coronary artery disease patients to prevent recurrent thrombotic events. It is a pro-drug that requires activation by CYP2C19, and common loss of function variants of CYP2C19 (e.g., CYP2C19*2) are associated with decreased antiplatelet responsiveness phenotype but explained only a marginal part of this trait. Heritability estimates are high and suggest that there are additional genetic determinants of clopidogrel response. To identify these variants, the International Clopidogrel Pharmacogenomics Consortium (ICPC) amassed clopidogrel response phenotypes (namely on-treatment ADP-induced platelet reactivity and cardiovascular outcomes) and DNA from more than 6,000 clopidogrel-treated patients. A GWAS (Omni Express with exome coverage) was conducted in 2,721 Caucasian patients. We observed strong association between on-treatment platelet reactivity phenotypes and the CYP2C19 locus on chromosome 10 (best SNP rs1926711; $p=6.25\times10^{-32}$). After adjustment for the known CYP2C19*2 loss of function variant (rs4244285; $r^2=0.963$ with rs1926711), there remained residual association just upstream of CYP2C19 (e.g., rs1998591; $p=1.66\times10^{-05}$) suggesting other variants in this region as determinants of clopidogrel response. Other loci nominally associated with platelet response to clopidogrel ($p<10^{-5}$) included rs12651351, intergenic between FHDC1 and TRIM2; rs10505836 in PLEKHA5; and rs2295306 in DHRS1. While we conclude that CYP2C19*2 remains a major genome-wide determinant of clopidogrel response, other loci are likely to exist, but play a lesser role. Replication studies, now in progress, will be required to affirm potentially novel loci for clopidogrel response.

707S

Class II HLA variants are associated with differential antibody response to toxoid vaccinations in a cohort of Ugandan infants. *A.J. Mentzer[1,2], A. Muhwezi[3], T. Carstensen[4], G. Smits[5], A. Rautanen[1,2], D. Gurdasani[4], T. Mills[1,2], C. Pomilla[4], H. Akurut[3], D. Kizito[3], S. Lule[3], K. Mohammed[3], K. Elliott[1,2], F. van der Klis[5], P. Kaleebu[3], A. Elliott[3], M. Sandhu[4], AVS. Hill[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) The Jenner Institute, University of Oxford, Old Road Campus Research Building, Oxford, United Kingdom; 3) MRC/UVRI Uganda, Entebbe, Uganda; 4) The Sanger Institute, University of Cambridge, Hinxton, Cambridge, United Kingdom; 5) National Institute for Public Health and Environment, Bilthoven, The Netherlands.

It is estimated that up to 70% of the variability in response to some vaccines administered in childhood is inherited but the identification of the genetic factors responsible for this variation has not yet been prioritised. We have conducted the first genome-wide association study seeking to identify the genetic variants associated with multiple vaccine responses using 2,181,930 autosomal markers genotyped in 1391 Ugandan children enrolled in the Entebbe Mother and Baby cohort study. Vaccine response was defined as quantitative antibody levels measured against 7 antigens targeting 5 separate pathogens which demonstrated little to moderate correlation within individuals (r=0.02 to 0.58). Strong Class II HLA associations were observed with response to diphtheria toxin (most associated SNP rs2647060 P= 1.70×10^{-26}), pertussis toxin (rs9270894 P=4.14×10^{-27}), pertussis pertactin (rs9275391 P=5.32×10^{-25}), and pertussis filamentous haemagglutinin adhesin (rs3104406 P=1.10×10^{-10}). Little overlap was observed for associated SNPs between each vaccine response measured. No associations of genome-wide significance were observed in HLA with response to tetanus toxin, or against attenuated measles or the conjugated Haemophilus influenzae vaccines. Class II HLA genes are critically involved in the stimulation of the adaptive immune response including antibody production against foreign antigens. Toxoid peptide antigens represent the model on which this mechanism was discovered and this study therefore provides a proof-of-concept for the analytical method employed. We will use the same approach to analyse the data from 10,000 children recruited worldwide as part of the newly developed VaccGene initiative coordinated by the Universities of Oxford and Cambridge, UK. The results from this large-scale analysis will be used to understand why HLA is strongly associated with some, but not all, toxoid vaccine responses and to identify the other elements of the immune system associated with inter-individual variability to response to multiple vaccines. These results may have important implications for future vaccine design.

708M

A genome-wide meta-analysis of corticosteroid response in asthmatics identifies a novel associated haplotype on chromosome 4. *Q.L. Duan[1], B.E. Himes[1,2,3], J. Lasky-Su[1], K.G. Tantisira[1,4], S.T. Weiss[1,2].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Partners Personalized Medicine, Partners Health Care, Boston, MA; 3) Children's Hospital Informatics Program, Boston, MA; 4) Pulmonary Division, Brigham & Women's Hospital, Boston, MA.

Corticosteroids are the most common, anti-inflammatory therapy for controlling asthma, a disease affecting over 300 million people worldwide. However, substantial inter-individual variability in corticosteroid response has been described, with up to 25% non-responsive patients. Multiple loci have been associated with this drug response, but account for only part of the heritability. The current genome-wide association study (GWAS) of corticosteroid response tests nearly five million markers in 723 asthma patients from four independent clinical trials: Childhood Asthma Management Program (CAMP); Leukotriene modifier or Corticosteroid Salmeterol (LOCCS); Childhood Asthma Research and Education (CARE) Network and the Asthma Clinical Research Network (ACRN). All participants had clinically diagnosed mild to moderate asthma. The physiological response to inhaled corticosteroids (ICS) was measured as a percent change in pre-bronchodilator FEV_1 (forced expiratory volume in one second) following four to eight weeks of drug treatment. Genome-wide SNP data was available for all trials, which were previously generated using two genotyping platforms: the Illumina HumanHap550 or 610 BeadChips (CAMP and LOCCS) and the Affymetrix Genome-Wide Human SNP Array 6.0 (ACRN and CARE). Due to the poor overlap among SNPs from the two platforms, however, imputations was performed using the Markov Chain Haplotyping (MaCH) software based on SNPs available in the June 2010 data release of the 1000 Genome Project. Approximately 5 million imputed SNPs (minor allele frequency > 0.05) were tested for association with ICS response using dosage data and an additive, linear regression model in PLINK, with adjustments for covariates (i.e. height, age and gender). Combined P-values were calculated using the Liptak's weighted Z method. While no single SNP achieved genome-wide significance, we identified three SNPs on chromosome 4 that tag a common (35%) haplotype associated with ICS response across our four asthma trials (combined P = 3.13E-11). Replication analysis of this haplotype is underway in an additional asthma drug trial. The current GWAS identifies a common haplotype associated with variable ICS response in asthma, which may have wider health care implications as corticosteroids are prescribed for the treatment various inflammatory diseases.

Additional genetic risk factors for carbamazepine-induced cutaneous adverse drug reactions detected by conditional analysis using HLA-A*31:01 as a covariant in Japanese population. *T. Ozeki[1], T. Mushiroda[1], A. Takahashi[2], M. Kubo[3], Y. Shirakata[4], Z. Ikezawa[5], M. Iijima[6], T. Shiohara[7], K. Hashimoto[4], Y. Nakamura[1].* 1) Laboratory for Pharmacogenomics, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan; 2) Laboratory for Stastical Analysis, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan; 3) Laboratory for Genotyping Development, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan; 4) Department of Dermatology, Ehime University Graduate School of Medicine, Ehime, Japan; 5) Department of Dermatology, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 6) Department of Dermatology, Showa University School of Medicine, Tokyo, Japan; 7) Department of Dermatology, Kyorin University School of Medicine, Tokyo, Japan.

An anticonvulsant, carbamazepine (CBZ), is known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). Previously, to identify a susceptible gene(s) for CBZ-induced cADRs, we conducted a genome-wide association study (GWAS) and subsequent HLA typing in 61 cases and 376 patients who showed no cADRs by administration of CBZ (CBZ-tolerant controls), and found that HLA-A*31:01 was present in 60.7% (37/61) of the patients with CBZ-induced cADRs, but in only 12.5% (47/376) of the CBZ-tolerant controls (odds ratio (OR) = 10.8, 95% confidence interval (CI) = 5.9–19.6, $P = 3.64 \times 10^{-15}$). To detect additional genetic marker for CBZ-induced cADRs, we performed genome-wide imputation using the GWAS data and genotype data from 1000 Genomes Project as reference panels by MaCH-Admix software. For a conditional logistic regression analysis of the imputed genotype data, we selected rs1633021 as the covariant with the firmest association observed in the analyzed GWAS peak of association. After the conditional analysis, there were 22 loci that reached GWAS-level significant association ($P < 5 \times 10^{-8}$). SNPs in 17 loci were validated and 2 SNPs rs4488702 and rs16899783 were replicated (Combined population: *P*-logistic = 4.10×10^{-9} and 2.08×10^{-18}). When 2 SNPs rs4488702 and rs16899783 were included as the risk marker for CBZ-induced cADRs in addition to HLA-A*31:01, the population attributable risk percentage was increased from 57% (A*31:01) to 65% (A*31:01 and 2 SNPs).

A Phenome-Wide Association Study of Numerous Laboratory Phenotypes in AIDS Clinical Trials Group (ACTG) Protocols. *S. Pendergrass[1], A. Verma[1], E. Daar[2], R. Gulick[6], R. Haubrich[4], G. Robbins[3], D. Hass[5], M. Ritchie[1].* 1) Center for Systems Genomics, Department Biochemistry & Molecular Biology, Pennsylvania State University, University Park, PA; 2) Department of Medicine, Los Angeles Biomedical Research Institute, Harbor-UCLA Medical Center, Torrance, CA; 3) Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA; 4) University of California San Diego, San Diego, CA; 5) Vanderbilt University, Nashville, TN; 6) Weill Medical College, Cornell University, New York, NY.

Phenome-Wide Association Studies (PheWAS) have the potential to efficiently discover novel genetic associations across multiple phenotypes. Prospective clinical trials data offer a unique opportunity to apply PheWAS to pharmacogenomics. Here we describe the first PheWAS to explore associations between genotypic data and clinical trial data, both pre-treatment and following initiation of antiretroviral therapy. A "pre-treatment" PheWAS considered 27 laboratory variables from 2807 subjects who had participated in 4 ACTG protocols (ACTG384, A5142, A5095 and A5202), and analyzed ~ 5M imputed SNPs. Lowest p-values were for pre-treatment bilirubin, neutrophil counts, and HDL cholesterol levels. These and multiple other laboratory variables matched associations in the NHGRI GWAS Catalog. An "on-treatment" PheWAS considered data from 1181 subjects from A5202. We considered 838 phenotypes and sub-phenotypes derived from 6 variables: CD4 counts, HIV control, fasting LDL cholesterol levels, fasting triglyceride levels, efavirenz pharmacokinetics (PK), and atazanavir PK. We considered 2,374 annotated drug-related SNPs from PharmGKB. Of 23 associations with the lowest p-values (by phenotype), 21 (91%) were with genes with matching biological plausibility: LDL cholesterol levels with *LPL* and *APOE*; triglycerides with *LPL*; CD4 counts with innate immune response gene *TNF*, HIV control with adaptive immune response gene *HLA-DRQA1*, efavirenz PK with *CYP2B6*; atazanavir PK with drug transporter gene *ABCC4*. This analysis highlights the potential utility of PheWAS to evaluate clinical trials datasets for genetic associations.

711S

Genome-wide association study of warfarin maintenance dose in a Brazilian sample. *G. Suarez-Kurtz[1], A.B. Santoro[1], M.R. Botton[2], M.H. Hutz[2], S. Krithika[3], E.J. Parra[3].* 1) Instituto Nacional de Cncer, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Department of Genetics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 3) Department of Anthropology, University of Toronto at Mississauga, Mississauga, Canada.

The anticoagulant warfarin combines several characteristics that make it a case study for the relevance of pharmacogenomics in personalized drug therapy. We carried out a genome-wide association study of warfarin maintenance dose in a sample from Brazil, comprising 177 individuals receiving low warfarin dose (<20 mg/week) and 188 individuals receiving high warfarin dose (> 40 mg/week). The samples were genotyped with Affymetrix Biobank microarrays. Prior to imputation, SNPs were removed from the initial list of autosomal markers based on the following criteria: 1/ Markers classified as CallRateBelowThreshold, OffTargetVariants or Other by the program SNPolisher, 2/ minor allele frequency <1% , 3/ Hardy-Weinberg p-values < 10-5 in the low dose or high dose sample and 4/ missing genotyping rate per SNP > 5% . The program EIGENSOFT was used to carry out a Principal Component Analysis (PCA), in order to identify the presence of population stratification. Imputation was carried out with the program IMPUTE2, using the combined 1000 Genomes panel as reference samples. Four individuals were eliminated from the statistical analysis due to cryptic relatedness (pi-Hat > 0.2) or evidence of substantial East Asian ancestry, based on the PCA plots. For the statistical analysis, we used the program SNPTEST2 (ml method), including as covariates sex, age, BMI, treatment with Amiodarone and the first two PCA scores. An analysis with the program ADMIXTURE indicates that the average European, African and Native American admixture proportions in this sample are 76.8%, 15.1% and 8.1%, respectively. We identified two genome-wide signals, corresponding to the well-known genes VKORC1 (lead SNP rs749671, p=1.08×10−33) and CYP2C9 (lead SNP rs9332220, p=2.5×10−13), as well as numerous suggestive signals (p<10-5). The lead SNP within the CYP2C9 gene seems to be capturing the effect of two known functional alleles (CYP2C9*2 and CYP2C9*3). The minor allele of rs9332220 is in almost perfect linkage disequilibrium with both CYP2C9*2 and CYP2C9*3.

712M

Swedegene: Genome-wide association study of drug-induced agranulocytosis. *M. Wadelius[1], N. Eriksson[2], Q-Y. Yue[3], P.K. Magnusson[4], E. Eliasson[5], H. Melhus[1], P. Hallberg[1].* 1) Dpt of Medical Sciences, Clinical Pharmacology, Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Uppsala Clinical Research Center and Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Medical Products Agency, Uppsala, Sweden; 4) Swedish Twin Registry, Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 5) Clinical Pharmacology, Department of Laboratory Medicine, Karolinska Institutet, Stockholm, Sweden.

Background: Agranulocytosis is rare, serious and often immune-mediated condition with a case-fatality rate of around 7–10%. It can be caused by a multitude of drugs, for example sulfasalazine, antithyroid agents, antibiotics, clozapine, aspirin, amiodarone and antiplatelet agents. However, few patients develop agranulocytosis after ingesting these drugs, which suggests that genetic factors could play a role in the pathogenesis. The major histocompatibility complex has been the main implicated region, but genetic studies have so far been small and often lacked replication cohorts. The Swedegene (www.swedegene.se) biobank is collecting patients with adverse drug reactions on a nation-wide basis using spontaneous reports sent to the Swedish Medical Products Agency. Blood for DNA extraction is collected and clinical data is obtained from patient interviews, medical and laboratory records. **Objective**: Our aim is to discover genetic and clinical factors that predispose to drug-induced agranulocytosis with the purpose to prevent this reaction in the future. **Method**: A genome-wide association study (GWAS) on 101 agranulocytosis cases was performed with 5 000 unrelated individuals from the Swedish Twin Registry as controls. Cases were genotyped with the Illumina HumanOmni2.5 array at the Uppsala University SciLife SEQ&SNP Technology Platform. Analyses were performed using the R-package GenABEL, imputations were done with Impute v2 (1000 genomes as reference) and HLA-B imputations with the R-package HIBAG. After quality control and imputation, the merged genotype set contained 6 million SNPs. The significance level was set at $p < 2\times10^{-8}$. **Results**: In the pilot study of the first 101 cases of drug-induced agranulocytosis, the majority of the patients were women and the main causative drugs were sulfasalazine, antithyroid agents and antibiotics. Statistical analyses identified significant associations in the HLA-B region on chromosome 6. After HLA-B genotype imputation, the strongest signal came from HLA-B*27 (OR [95% CI] = 3.67 [2.39, 5.63], $p = 2.99 \times 10^{-9}$). The HLA-B locus remained significant when utilizing 233 controls matched for disease or treatment. **Conclusion**: We have found an association between drug-induced agranulocytosis and the HLA-B locus. The results need to be replicated, and we are proceeding with additional cases from Sweden as well as cases and controls obtained through collaboration with other European countries.

713S

DMET platform identifies unique changes in metabolic gene variants in ethnic Arabs. *S. MAJID[1], PN. Muiya[1], S. Hagos[1], E. Andres[1], B. Baz[1], G. Morahan[2], N. Dzimiri[1].* 1) KFSHRC, RIYADH, India; 2) The University of Western Australia, Perth Australia.

Background: The Affymetrix Drug Metabolizing Enzymes and Transporters (DMET) Plus Premier Pack platform has been designed to genotype about 1936 genes/gene variants thought to be essential for screening patients in personalized drug therapy. These variants include among others, the cytochrome P450s (CYP450s), the key metabolic enzymes for several therapeutic agents, many other enzymes involved in phase I and phase II pharmacokinetic reactions as well as signaling mediators commonly associated with variability in clinical response to numerous drugs not only among individuals, but also between ethnic populations. Materials and Methods: We genotyped 600 Saudi individuals for 1936 variants on the DMET platform to evaluate their clinical potential in personalized medicine in the Saudi population. Results: Approximately 49% each of the 437 cytochrome P450 (CYP450) variants, 56% of the 581transporters, 56 % of 419 transferases 48% of the 104 dehydrogenases and 58% of the remaining 390 remaining variants were detected. A great number of these variants exhibited either significantly higher or lower minor allele frequencies (MAFs) than in other ethnic groups, with more than 70 of them, including the CYPs rs7797834 (CYP51A1_c.1359T>C), rs2470890 (CYP1A2_5347T>C), rs7793861 (CYP51A1_c.*251G>C), rs16947 (CYP2D6_2850C>T) and some NAT2, SLC, UGTB and ABC variants exhibiting MAFs of >0.49. Discussion: The distribution of several variations appears to be unique for our study compared to other ethnic populations. The results point to the need to verify and ascertain the importance of a SNP profile in any given population prior to engaging it in pharmacogenetic screening in personalized medicine. Acquiring adequate prevalence data is, therefore, prerequisite for their employment in clinical routine in any given population.

714M

Selection of cancer patients based on tumor *AKT1* or *PIK3CA* mutation status. *J. Fox[1], P. Kirk[1], J. Whiteley[1], H. Ambrose[2].* 1) Personalized Healthcare, AstraZeneca Pharmaceuticals, Macclesfield, Cheshire, United Kingdom; 2) Innovative Medicines, AstraZeneca Pharmaceuticals, Macclesfield, Cheshire, United Kingdom.

The identification of patients who may experience differential benefit from new cancer medicines as a consequence of the presence of a genetic alteration e.g. mutation in their tumour, requires the timely and accurate implementation of appropriate patient selection methods. Both sourcing and validation of assays for use during drug development bring particular challenges and different solutions are required depending on the clinical situation in which assays will be deployed. We have employed a number of approaches to deliver tests for patient selection suitable for implementation during the initial, exploratory, stages of drug development in man. For logistical reasons a PCR based test was developed in house for *AKT1* whereas for *PIK3CA* a commercially available (also PCR based) Research Use Only (RUO) assay was adopted. Both assays underwent preliminary internal validation prior to transfer to external partners for formal validation before their application for patient testing. Identifying acquired mutations, not present in normal patient tissue, in tumour derived material brings additional considerations to DNA testing beyond that necessary for diagnosis of common inherited disorders. First, tests need to have sufficient analytical specificity and sensitivity to allow accurate assignment of mutation status when the mutant sequence exists in only a minority of the DNA sample. Second, the assays need to deliver accurate results when the quantity and/or quality of the DNA for evaluation is less than optimal due, in part, to the tumour tissue preservation steps used in routine pathology practice. Finally, where tumours originating from different anatomical sites are to be examined, the mutation spectrum covered by the test(s) should be sufficient to identify as many suitable patients as possible. The latter element of test selection/development can be challenging where data defining mutation spectra are limited. Here we describe the steps we have followed to successfully deliver PCR based *AKT1* and *PIK3CA* mutation assays to test a patient selection hypothesis.

715S

Impact of regular physical activity on weekly warfarin dose requirement. *P. Shahabi[1,2], E. Rouleau-Mailloux[1,3], S. Dumas[1,4], Y. Feroz Zada[1], S. Provost[1], J. Hu[1], J. Nguyen[1], N. Bouchama[1], I. Mongrain[1], M. Talajic[1,2], J.C. Tardif[1,2], S. Perreault[2,4], M.P. Dubé[1,2].* 1) Beaulieu-Saucier Pharmacogenomics Centre , Montreal Heart Institute, Université de Montréal , Montreal, QC, Canada; 2) Department of Medicine and Social and Preventive Medicine, Université de Montréal, Montreal, Quebec, Canada; 3) Department of Pharmacology, Faculty of Medicine, Université de Montréal, Montréal, Quebec, Canada; 4) Faculty of Pharmacy, Université of Montréal, Montreal, Quebec, Canada.

Background and aim: Warfarin is the most widely prescribed oral anticoagulant worldwide for the treatment and the prevention of thromboembolic disorders. However, there is a marked inter- and intra-individual variability in the warfarin dose requirement. Genetic factors, including the common variants of vitamin K epoxide reductase complex subunit 1 (VKORC1*2) andcytochrome P-450 2C9 (CYP2C9*2 and *3), can predict up to 40 percent of the variability in warfarin dose and the known non-genetic factors, including weight, height, age and drug interaction, are responsible for another 30%. Hence, the sources of 30% of warfarin dose variability are still unknown. We first investigated the association of regular physical activity (RPA) with warfarin dose in a large cohort of warfarin new users, the Quebec Warfarin Cohort (QWC). We then replicated our findings in an independent on-warfarin hospital-based population, the Montreal Heart Institute (MHI) Biobank. Methods: The QWC isan observational, community-based, prospective cohort of new warfarin users who were recruited at 18 anticoagulation clinics in the Quebec province of Canada. The level of RPA was assessed in 1,064 patients of the QWC using the Stanford Brief Activity Survey. A regression model was used to evaluate the association between the baseline level of RPA and the warfarin dose requirement at 3-month time point after the initiation of treatment. The model was adjusted forheight, weight, age as well asCYP2C9*2, *3 and VKORC1*2 variants.For replication, warfarin dose of prevalent users was modeled in 681 patients of the MHI Biobank in whom the level of RPA was assessed with the Global Physical Activity Questionnaire.The model was adjusted for height, weight, age and CYP2C9 variants in the replication population. Results: Higher levels of RPAwere associated with higher doses of warfarin in both cohorts. In the QWC, univariate regression analysis showed that RPA could explain 5.4% of variance in warfarin dose (P value <0.001); the association was replicated in the MHI Biobank (P value =0.0012; R2=1.7%). In the multiple regression model, RPA remained statistically significant and was found to be independently associated with warfarin dose inboth the QWC (P value < 0.001) and the MHI Biobank (P value = 0.0391). Conclusion: RPA was associated with higher warfarin dose requirement. However, the clinical implications of the results of this work require to be directly investigated by further studies.

Comparison of parents' initial intent and reported sharing of their children's *CYP2D6* research results at three month follow up. *C.A. Prows[1,2], B. McLaughlin[1,4], X. Zhang[1], D. Kissell[1], K. Zhang[1,4], J.B. Harley[3,4], M.F. Myers[1,4].* 1) Division of Human Genetics, Children's Hospital Medical Center, Cincinnati, OH; 2) Department Patient Services, Children's Hospital Medical Center, Cincinnati, OH; 3) Division & Center for Autoimmune Genomics and Etiology, Children's Hospital Medical Center, Cincinnati, OH; 4) Department of Pediatrics, College of Medicine, University of Cincinnati, Cincinnati, OH.

The Clinical Pharmacogenetics Implementation Consortium published guidelines in 2012 regarding the use of codeine based on genotype predicted CYP2D6 phenotype. The recommendations refer to other CYP2D6 opioid substrates; tramadol, hydrocodone and oxycodone. However, *CYP2D6* testing to inform opioid therapy is rare in clinical settings. As a component of an eMERGE genomics pilot study, we aimed to determine parents' intent and actual practice of sharing their child's CYP2D6 research result, as it pertained to codeine. Enrolled parents had previously given permission for their child to participate in a genomics study or for their child's leftover clinical samples to be stored in a voluntary bio bank for future genomic research. For our study, children's CYP2D6 research results were returned by an advanced practice nurse to parents by phone. Immediately after results, parents completed a telephone survey that included items about their intent to share their child's result. The questions were asked again at least 3 months after learning results. To date, 136 parents enrolled, *CYP2D6* testing has been performed on 102 banked children's samples and results returned to 62 parents. Initial surveys were completed by 60 mothers, 1 father, of whom 92% reported their race as White, 3% as Black, 5% declined to report. The majority of parents (80%) strongly agreed their child's doctor could use the CYP2D6 result when providing care to their child. Parents reported they were extremely likely to share the result with their child's doctor (66%), pharmacist (23%) and their child (46%) within the year. Of the 31 parents who have completed 3 month follow up telephone surveys, 19 (61%) reported they were extremely likely to share the result with their child's doctor in the initial survey, and 42% of these had actually shared the result by the time of the 3 month call. Two parents had shared their child's results with a pharmacist and only one of these had reported being extremely likely to do so at the initial survey. Although 39% of the parents reached for follow-up had initially reported they were extremely likely to share the result with their child within a year, only 1 had done so at the 3 month follow up. Parents' intent to share and perceived utility of *CYP2D6* testing is high. Enrollment and data collection from 200 participants is planned to determine factors that influence parents' transition from intention to actually sharing their children's CYP2D6 results.

717S

Software for the clinical implementation of pharmacogenomic testing. *R. Ammar[1], I. Cohn[2], T.A. Paton[2], S. Bacopulos[2], J. Vlasblom[2], M. Fiume[3], C.R. Marshall[2], P. Ray[2], R. Cohn[2], S. Ito[2], M. Brudno[1,2], G.D. Bader[1,3].* 1) Donnelly Centre for Cellular and Biomolecular Research, Toronto, ON, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Computer Science, University of Toronto, Toronto, ON, Canada.

In a medical context, a genome can be used to tailor treatment strategies to deliver more precise healthcare with the promise of improved diagnoses and responses to medical intervention. Pharmacogenomics (PGx), the study of how genes influence individual response to drug therapies, has a major direct impact on choice of drug dosing in many medical contexts. We present an open-source software tool, the *Pharmacogenomics app* for *MedSavant*, an open-source system for interpretation of clinical genomes. The app interprets pharmacogenomic variants with medically actionable output based on the guidelines established by the Clinical Pharmacogenetics Implementation Consortium (CPIC). All pharmacogenomic variants are computationally phased using an HMM-based model (BEAGLE) trained on a reference panel from the 1000 Genomes project. Phasing of haplotypes is critical to prevent misinterpretation of mutations. Haplotypes are constructed without imputation to ensure that the diagnostic results are based entirely upon observed genotypes. Patient diplotypes are reported using standard * nomenclature (i.e. *CYP2C19 *1/*17*) along with metabolizer class (*Ultrarapid*, *Extensive*, *Intermediate*, *Poor*), based on haplotype activity scores from the CPIC guidelines. If non-CPIC, rare (allele frequency < 5%) coding variants are discovered, they are reported independently alongside the patient diplotype. Our tool is agnostic to sequencing technologies, and can be used with data generated by targeted PCR-based methods (e.g. Sequenom), whole-exome sequencing (WES) and whole genome sequencing (WGS). The tool can be used with WES or WGS data regardless of why the data was generated. In the event of missing data, our tool will display possible and similar haplotypes. The *Pharmacogenomics app* is currently being piloted as part of a clinical diagnostic exam at The Hospital for Sick Children in Toronto for the evaluation of PGx in paediatric clinical practice.

718M

Implementation of pharmacogenomics into clinical practice: Mayo Clinic experience. *P.J. Caraballo, S. Bielinski, J. Pathak, R. Weinshilboum, G. Farrugia, C. Chute, J. Black, M. Elliott, C. Schultz, C. Rohrer-Vitek, D. Gabrielson, D. Blair, M. Parkulo, I. Kullo.* Mayo Clinic, Rochester, MN.

Background: Pharmacogenomics (PGx) is increasingly gaining acceptance as a guide to prescribing. However, PGx guidelines are complex and human cognition alone is not sufficient to implement them in already busy clinical workflows. Methods: To implement PGx in the clinical setting we developed clinical decision support (CDS) using synchronous and asynchronous rules integrated in two commercially available electronic medical record (EMR) systems supported by clinically driven governance and online education. We leveraged the Mayo Clinic Clinical Decision Support Program which uses multiple applications of the EMR including problem list, allergy module, computerized physician order entry, messaging system, and expert rule system. Advanced interactive functionality and actionable alerts enable busy clinicians to better understand the alerts. Embedded in the alerts and inboxes are web-links to specific online PGx education material including frequently asked questions. We also established a PGx Task Force to seek consensus among knowledge experts and clinical practice groups affected by the implementation of reactive and preemptive PGx. Results: Ten rules (*HLA-B*57:01*-abacavir, *HLA-B*15:02*-carbamazepine, TPMT-thiopurines, *CYP2D6*-codeine/ -tramadol/ -tamoxifen, *SLCO1B1*-simvastatin, *CYP2C19*-clopidogrel, *CYP2C9/VKORC1*-warfarin and *IL28B*-PEG-IFN alfa) have been approved by the PGx Task Force and seven are currently live. One rule (*IL28B*-PEG-IFN alfa) was abandoned as clinical experts felt it was no longer relevant given the availability of new drugs. Two rules (clopidogrel and warfarin) have not yet been implemented as they encountered clinical resistance in view of controversies and uncertainties in clinical guidelines from medical societies. The acquisition of actionable laboratory results has been the main technical challenge, as quality assurance processes require continuous monitoring to ensure appropriate performance. The activation rate of these rules has ranged from 6/year (carbamazepine) to 180/month (thiopurines). In the first quarter of 2014, approximately 390 unique providers and 675 unique patients have been involved in the activation of these rules. Conclusion: Our comprehensive implementation model provides insights into the challenges of incorporating PGx data preemptively in an academic medical center. A coordinated and multidisciplinary effort is needed to facilitate clinical adoption and technical feasibility of EMR-driven PGx-guided therapy.

719S

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Characterization of Clinically-Actionable Pharmacogenetic Alleles in over 100,000 Patients with Biobank-linked Electronic Medical Records. *N. Gonzaludo[1], T.J. Hoffmann[2], P.Y. Kwok[2], N. Risch[2,3], C. Schaefer[3].* 1) Bioengineering & Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

Pharmacogenetic information can be extremely useful in optimizing patient therapy and avoiding adverse clinical outcomes, potentially reducing the cost burden of hospitalizations and treatment of adverse drug events. However, incorporation of pharmacogenetic information into routine clinical practice faces many hurdles, one of which involves the timely availability of accurate genetic information to clinicians when it is needed at point-of-care. With electronic medical record (EMR) systems linked to biorepositories that have generated genotypic information, it is possible to preemptively genotype patients for known drug-gene pairs before these drugs are administered. This information can enable prediction of how patients will respond before they are prescribed a drug, and thus be used to tailor drug therapy for each patient. As part of the Kaiser Permanente Research Program on Genes, Environment, and Health (RPGEH), members in the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort have undergone genome-wide genotyping using Affymetrix Axiom technology. Leveraging genotype data for 103,006 individuals, we phased and imputed a panel of 41 SNPs, which were translated to star allele nomenclature (e.g. CYP2C19*2) in 7 pharmacogenes with established clinical implementation guidelines. Using star allele diplotypes for each GERA cohort member, we assigned metabolizer status phenotypes for several drugs, including clopidogrel, warfarin, and simvastatin. On average, approximately 20–30% of cohort members had actionable metabolizer phentoypes for different drugs, suggesting that a change in drug choice or dose may benefit the patient. Additionally, we performed a similar characterization study using 1000 Genome samples, and compared metabolizer status frequencies across different cohorts, ethnicities, and published frequencies associated with certain drugs. By linking GERA members' metabolizer status to prescription data in the EMR, we were also able to retrospectively assess the impact of this information on prescribing patterns. Our study demonstrates the utility of biobank-linked EMRs for deriving pharmacogenetic information, as well as the potential impact of this information for personalized drug therapy.

720M

Evaluating the Application of Star Allele Nomenclature for Pharmacogenomics in the Era of High-Throughput Sequencing. *A. Gordon[1], Q. Zhu[2], C. Chute[2], D. Nickerson[1], R. Freimuth[2].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Health Sciences Research, Mayo Clinic, Rochester, MN.

As costs for sequencing patient samples within a clinically-relevant timeframe continue to decrease, more and more healthcare institutions are implementing clinical pharmacogenomics tests. Much of the decision support associated with these tests assign a diplotype to each test result, translating that result into a predicted phenotype, and recommending a certain course of action to the provider based on a predicted outcome. The diplotypes are often expressed as a pair of 'Star Alleles,' a nomenclature system that was originally developed to describe variation within the Cytochrome P450 genes and has since spread to many other genes of pharmacogenetic interest. Although this nomenclature system has been useful for pharmacogenomic implementation when individual sites were interrogated, its ability to represent high-throughput sequencing results has not been systematically evaluated. In particular, the ability to distinguish alleles defined by a single variant from those defined by multiple variants and the ability to handle rare variation must be supported. In order to quantitatively analyze these phenomena, we developed an algorithm to assess the strengths and weaknesses of the Star Allele system. The algorithm attempts to assign star allele-based diplotypes using high-throughput sequencing data for pharmacogenomically-relevant genes. We applied this algorithm to phased exome sequence data from 6503 individuals of European-American or African-American ancestry drawn from the NHLBI Exome Sequencing Project. Preliminary analysis of results from CYP2C9 indicate that 25.7% of African-Americans and 14.6% of European-Americans in our dataset carry at least one allele that cannot be named using the canonical star allele definitions, highlighting the need to quantify and understand these nomenclature errors. To that end, we are expanding our analysis to 4 other pharmacogenes of clinical importance that also use this nomenclature system: CYP2C19, CYP3A5, SLCO1B1, and TPMT. We are cataloging the type and frequency of errors encountered, including those due to rare variants, potential phasing errors, and partial or mixed haplotypes. We believe that assessing why and how often such errors occur will help inform a discussion regarding the use of nomenclature to support the clinical implementation of pharmacogenomics in the era of high-throughput sequencing.

A sequence-based pharmacogenomic (PGx) panel: determining CYP2D6 sequence variants and copy number variation. *A.E. Kwitek[1,2], D.L. Kolbe[2], R. Zahr[5], C.A. Campbell[2], K.L. Knudtson[2], K. Popp[5], A.M. Mansilla[2], S.O. Mason[2], E. Snir[2], C.J. Nishimura[2], S.D. Rose[5], S. Gunstream[5], R.J. Smith[2,3,4].* 1) Pharmacology, University of Iowa, Iowa City, IA; 2) Iowa Institute of Human Genetics, University of Iowa, Iowa City, IA; 3) Pediatrics, University of Iowa, Iowa City, IA; 4) Internal Medicine, University of Iowa, Iowa City, IA; 5) Integrated DNA Technologies, Coralville, IA.

Because genetic variation is a major contributor to Adverse Drug Reactions (ADRs), the FDA has incorporated pharmacogenomic (PGx) information for over 100 drugs and recommends genetic testing for nearly 10% of all drugs. Sequence-based pharmacogenetic tests offer tremendous opportunities to transition PGx testing to standard-of-care. However, many sequence-based approaches have difficulties in accurately detecting copy number variants (CNVs) in CYP2D6, a key gene associated with the metabolism of 25% of all drugs, including opioids. We developed a comprehensive PGx test that combines targeted genome enrichment and massive parallel sequencing (TGE+MPS) that can accurately determine CYP2D6 genotypes including SNVs and CNVs. A custom designed xGen® Lockdown® Probe panel (Integrated DNA Technologies) comprised of non-overlapping 120-mer, 5' biotinylated oligonucleotides was used in a 4 hour hybridization reaction to capture over 300 genes and non-coding SNPs (590 kb) associated with drug Absorption, Distribution, Metabolism, and Excretion (ADME). As a pilot study, a validation cohort consisting of 24 CEPH individuals with known CYP2D6 genotype (SNV and CNV) was sequenced in pools of 6 or 8 on the Illumina MiSeq® and subject to both variant calling and copy number analysis. Of the targeted regions, 574 kb were successfully captured. There was over 99.8% coverage at 30x in pools of 6 samples. Variant calling identified, on average, 3000 high-quality variants, and CYP2D6 genotypes were concordant with those determined by multiple methods. CNV analysis was performed on 7 PGx-related genes previously determined to have copy number variation, including known CNVs in CYP2D6. We were able to detect homozygous and heterozygous deletions, duplications, as well as gene-gene and gene-pseudogene fusions involving 10 genes on the panel. The CYP2D6 copy number results were validated by TaqMan® assay and correspond to publically available data. We anticipate the IIHG-PGx panel will provide a cost-effective and rapid test to be used for pre-emptive testing for drug response. PGx test results can assist the clinician in determining the most effective drugs while minimizing ADRs. The utility of this panel spans both clinical testing as well as research studies to determine novel single nucleotide and copy number variants and associations with drug ADME. (*equal contribution).

722M

Prevalence of CYP2C19 * 2 polymorphism in the population with a clopidogrel prescription tertiary Clinic. *J. Martinez, I. briceno, j. Garcia, A. Tellez, P. Galvez, D. Uricoechea.* Bioscience, Univ de La Sabana, Chia, Colombia.

Clopidogrel is an antiplatelet agent used concomitantly with aspirin or as monotherapy in secondary prevention of cardiovascular complications. However, between 5 and 40% of patients develop resistance identified by persistent high platelet reactivity (1). Clopidogrel is metabolized by the hepatic cytochrome P450 (CYP 2C19 enzyme). CYP 2C19 exhibits genetic polymorphisms responsable for the presence of poor metabolizers, intermediate metabolizers and extensive metabolizers. In recent years, research has focused on the CYP2C19 enzyme encoded on chromosome 10. Its polymorphisms may reduce the formation of the active metabolite of clopidogrel and reduce platelet effect. The *2 allele carriers have increased risk of cardiovascular death, myocardial infarction and stent thrombosis compared to non-carriers (2). The defective mutations of the enzyme and their frequencies change between different ethnic groups; however, the polymorphisms of the CYP2C19 gene has not been studied in colombian population. The objective of this study is to determine the prevalence of the polymorphism CYP2C19*2 in a population treated with clopidogrel in a tertiary clinic. Follow up on this population, in order to associate the presence of genetic factors with clinical outcomes will be a second phase of this study. If confirming a significant association, this will contribute significantly so that cardiologists may determine an more appropriate therapeutic strategy for patients. On the other hand, it would be possible to include other antiplatelet agents whose pharmacokinetic and pharmacodynamic parameters are not affected by genetic polymorphisms in the Colombian Health Plan. General objective: Determine the prevalence of CYP2C19 * 2 polymorphism in the population treated with clopidogrel in a tertiary clinic. Specifics: 1.To evaluate the genotype and phenotype status of CYP2C19 in colombian population, in order to contribute to the use of appropriate strategies of drug therapy for this population. 2.To determine the frequency of the polymorphisms associated to variability in response to clopidogrel. 3.To identify the phenotype of patients according to the polymorphisms found. 4.Determining the population at high risk of thrombotic events and cardiovascular death according to genotype / phenotype. 5.To calculate the frequency of demographic variables and non-genetic factors which have been associated with variability in response to clopidogrel in the study population.

Clinician Views about Implementation of Pharmacogenomics into Practice. *J.F. Peterson[1], J.R. Field[2], Y. Shi[3], J.S. Schildcrout[3], J.C. Denny[1], T. McGregor[4], S.L. VanDriest[4], J.M. Pulley[2], I. Lubin[5], M. Laposata[7], D.M. Roden[6], E.W. Clayton[8,4].* 1) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 2) Vanderbilt Institute for Clinical and Translational Research, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Pediatrics, Vanderbilt University Medical Center, Nashville, TN; 5) Genetics, Centers for Disease Control and Prevention, Atlanta, GA; 6) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 7) Department of Pathology, Microbiology, and Immunology, Vanderbilt University Medical Center, Nashville, TN; 8) Center for Biomedical Ethics and Society, Vanderbilt University Medical Center, Nashville, TN.

Attitudes of clinicians participating in pharmacogenomics implementation projects are not well-described but are likely key to the success of translational programs. Using a 54-item online instrument, we surveyed physicians and nurse practitioners in 2013 taking part in a large pharmacogenomics program within a tertiary care academic medical center. Domains surveyed included attitudes towards ordering pharmacogenomics testing, prior pharmacogenomics education, major factors influencing use of the results, expectations of efficacy of genotype-tailored therapy, and responsibility for applying significant results from a multiplexed genetic panel to clinical practice. Of 121 clinicians solicited, 80 (66%) physicians and nurse practitioners gave a complete survey response. Virtually all respondents (99%) agreed that pharmacogenomic variants influence patients' response to drug therapy, and a majority agreed with statements regarding the clinical utility of *CYP2C19* variants to tailor antiplatelet therapy following percutaneous coronary interventions (80%) and *VKORC1* and *CYP2C9* variants to tailor warfarin dosing (86%). Strength of evidence for drug-genome interactions (DGIs) was cited by 88% of respondents as the most important factor influencing the ordering of pharmacogenomic testing; systematic reviews and national standards-setting organizations were the most frequently trusted sources for evidence-based guidance. The majority (92%) of respondents were in favor of immediate notification when a clinically significant drug-genome interaction was present and relevant to the patient's therapeutic course, and most felt specialists were in the best position to apply a pharmacogenomic result to a new prescription (74% agreement). However, survey respondents were divided on whether the provider who originally ordered the test was responsible for acting on a result when a prescription change was indicated (51% agreement). When presented with a scenario where the prescription change was affected by a genetic testing performed 6 months earlier, a majority of respondents (67%) favored assigning responsibility to the implementation program to find and contact the patient's most current providers. Among clinicians practicing within a pharmacogenomics implementation program, genotype results were valued for tailoring prescriptions, but respondents were divided on who is clinically responsible for pharmacogenomic results from a multiplexed panel.

Role of APOE4 genotypes in predicting cardiometabolic outcomes in individuals with metformin and metformin-sulfonylurea combination therapy. *G. Priamvada, B.R. Sapkota, A. Subramanian, P.R. Blackett, D.K. Sanghera.* Department of Pediatrics, College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Genetic polymorphisms in apolipoprotein E (APOE) locus are known to have a significant impact on various inflammatory and metabolic diseases. Apoε4 isoform is a well-known marker associated with increased risk of coronary artery disease (CAD) and late-onset of Alzheimer's disease. Recent evidence suggests improved clinical outcomes with metformin in patients with type 2 diabetes (T2D) and heart failure. However, the role of anti-diabetic medications in response to APOE genotypes is less understood. The objectives of this investigations were: 1) to evaluate the distribution of APOE polymorphisms in a large diabetic case-control cohort of the Asian Indian Diabetic Heart Study, 2) to evaluate the impact of APOE polymorphisms on quantitative risk factors of T2D and CAD, and 3) to examine the role of APOE genotypes in response to anti-diabetic therapy. We assessed the role of APOE genotypes with disease and treatment outcome in a total of 3,569 individuals (2,289 T2D cases and 1,280 controls). No significant difference in the distribution of APOε4 was observed among T2D cases and controls. However, APOε4 carriers had higher fasting glucose (p=0.021), higher diastolic blood pressure, higher LDL cholesterol and lower HDL cholesterol (p=0.031) compared to non-APOε4 carriers. Further stratification of data from diabetic patients by APOE genotypes and anti-diabetic treatments revealed a significant decrease in fasting glucose (p<0.0001), 2 hours glucose (p<0.0001), systolic blood pressure (p=0.007), diastolic blood pressure, and LDL cholesterol (p<0.0001) among the APOε4 carriers compared to non-APOε4 carriers on metformin monotherapy. Similar improved clinical outcomes were observed in patients with metformin-sulfonylurea combination therapy (n=618). Our study suggests APOε4 to be a potential risk factor for cardiometabolic susceptibility in patients with diabetes. Our findings also report significantly improved cardiometabolic outcomes among APOε4 carriers in response to metformin and metformin-sulfonylurea combination therapy. These findings warrant confirmation in a large independent dataset. This study was supported by NIH grants -R01DK082766 (NIDDK) and NOT-HG-11-009 (NHGRI), and VPR Bridge Grant (OUHSC).

Genome Liberty: Direct-to-Consumer Pharmacogenetics. *J.A. Rosenfeld[1,2], C.E. Mason[3].* 1) Department of Medicine, Rutgers Medical School, Newark, NJ; 2) American Museum of Natural History, New York, NY; 3) Department of Department of Physiology and Biophysics, Cornell University, New York, NY.

For many medications, there are genetic markers whose genotype will aid in proper dosing. Certain genotypes will rule out the use of a particular medication, while other genotypes will indicate the use of either a higher or a lower dose. There are a wide range of medications that can be tested in this way including Plavix, codeine, Coumadin and estrogen. While the links between the cytochrome p450 genes and proper dosing of medications are widely known, their clinical use has been extremely limited. The vast majority of doctors refrain from performing this or other genetic tests due to their limited knowledge of genetics and their reticence to order a test they do not completely understand. This extreme restraint by doctors has prevented the widespread adoption of pharmacogentics testing. We have therefore developed a rapid, and low-cost direct-to-consumer test that will empower individuals to help their physicians make proper prescribing decisions. Our test will look at all of the clinically actionable pharmacogentic markers and produce both a physician-friendly and a patient-friendly report that will allow individuals to know which medications they should avoid, and which they should use at a dose different than that recommended for the general public.

CHRNA4 rs1044396 is associated with smoking cessation with varenicline therapy. *P.C.J.L. Santos[1], J.R. Santos[1], P.R.X. Tomaz[1], J.S. Issa[2], T.O. Abe[2], J.E. Krieger[1], A.C. Pereira[1].* 1) Laboratory of Genetics and Molecular Cardiology, Heart Institute, University of Sao Paulo Medical School, Sao Paulo, Brazil; 2) Smoker Assistance Program (PAF), Heart Institute, So Paulo, SP.

Background: Smoking is one of the biggest risk factors for developing cardiovascular disease, and is considered the most preventable cause of premature death worldwide. It is estimated that there are currently over 1.3 billion smokers globally and although there are several therapies for smoking cessation, the most smokers find quitting difficult. Aim: to evaluate the association of CHRNA4 polymorphisms with the success rate of smoking cessation therapy and with the Fagerstrom Test for Nicotine Dependence (FTND) in patients treated with varenicline. Methods: Four hundred eighty-three smoker patients were evaluated by FTND questionary and treated with varenicline and/or bupropion. They were followed for 12 weeks. CHRNA4 rs1044396 and rs2236196 polymorphisms were genotyped by melting curve analysis. Results: We observe that patients with rs1044396 CC genotype had lower frequency of success rate (29.5%) compared with patients with rs1044396 CT or TT genotypes (50.9%), during varenicline therapy (p= 0.007; n=167). We also observed that CHRNA4 rs1044396 was associated with smoking cessation success, even in multivariate model (OR: 2.28; 95% CI: 1.03–5.06). However, we did not observe association of CHRNA4 rs1044396 and rs2236196 genotypes with FTND and with bupropion therapy. Conclusion: Our findings indicate that CHRNA4 rs1044396 might be a pharmacogenetic marker for smoking cessation with varenicline therapy since this gene encodes a subunit of the nicotinic acetylcholine receptors more abundant and higher activity.

Early drug responses that are followed by an acquired drug resistance in non-small cell lung cancer cells exposed to gefitinib. *M. Takahashi[1,2], M. Fukuoka[1], H. Hohjoh[1].* 1) Department of Molecular Pharmacology, National Institute of Neuroscience, NCNP, Kodaira, Tokyo, Japan; 2) Division of RNA Medical Science, The Institute of Medical Science, The University of Tokyo, Minato-ku, Tokyo, Japan.

Acquired drug resistance is a major problem in medication, particularly in cancer treatment. Early drug responses followed by a drug resistance may provide us with a clue for understanding the mechanism of acquired drug resistance and for developing a therapeutic strategy to overcome such a resistance. We attempted to examine early drug responses of cancer cells that were treated with gefitinib [an epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor]. Non-small cell lung cancer (NSCLC) PC-9 cells that bear an oncogenic mutant EGFR and have the potential for acquiring a resistance to gefitinib were used in this study, and we established gefitinib-resistant PC-9 cells (PC-9/GR) by a long-term exposure of a low-dose gefitinib. Comprehensive gene expression analyses against naïve PC-9 cells and PC-9/GR cells were carried out, and the results indicated that fibroblast growth factor 2 (FGF-2) and FGF receptor 1 (FGFR1) were significantly increased in PC-9/GR cells. In addition, while the FGF2 and FGFR1 protein levels were increased in PC-9/GR cells, oncogenic EGFR dimer appeared to be decreased. The findings suggested the possibility that a survival signaling system might have been changed from an EGFR dependent signaling to a FGFR dependent signaling in PC-9/GR cells. To see early responses of naïve PC-9 cells against gefitinib further, we investigated FGFR1 and FGF-2 in naïve PC-9 cells exposed to gefitinib. The analysis revealed that FGFR1 was increased in an exposure time- and gefitinib dose-dependent manner. As for FGF-2, although its apparent gene expression level appeared to remain unchanged, the FGF-2 protein in culture medium was markedly increased by gefitinib treatment in a dose-dependent manner: this may mean FGF-2 that was released from dead cells. Additionally, naïve PC-9 cells that were treated with exogenous FGF-2 appeared to decrease in sensitivity to gefitinib. Taken together, the results suggested that naïve PC-9 cells exposed to gefitinib might be survivable by an up-regulated FGFR1 and by an increase in FGF-2 that was released from neighboring dead cells, and that PC-9/GR cells, after acquisition of gefitinib resistance, would establish a FGF autocrine signaling system. In addition to the above findings, we would like to further discuss about the possibility that thyroid hormone-related factors might contribute to up-regulation of FGFR1 in gefitinib-treated cells.

Modeling the pharmacological response to advance the research in pharmacogenetics. *J. Bertrand[1], M. de Iorio[2], D.J. Balding[1].* 1) Genetics Institute, University College London, LONDON, --., United Kingdom; 2) Statistical Science Dept, University College London, LONDON, --., United Kingdom.

Context: Pharmacogenetics studies the genetic part of interindividual variability in drug response. Its main challenges are: i. the phenotype results from physiological processes (e.g. drug elimination or distribution) not directly observed, ii. genetic variation markers lead to uneven and small sample size subgroups and iii. one has to face the dimensionality curse when dealing with high throughput genetic screening. Nonlinear mixed effect models (NLMEM) handle challenge i. and ii. by capturing the dynamical nature of the phenotype and fitting patients with sparser profiles while borrowing information from more informative ones. Objective: In this work we propose to address challenge iii. with an integrated approach, that combines the strengths of NLMEM with penalised regression, and compare its performance to a classical stepwise procedure through a simulation study. Methods: We simulated pharmacokinetic profiles in association with genotypes for the 1200 single nucleotide polymorphisms (SNP) of the DMET Chip (Daly, 2007). Several scenarios were studied in terms of design: a typical phase II study or a combined design of such a study with additional through concentrations collected in clinical routine and in terms of genetic association: causal variants affecting one or multiple model parameters. Results: Both approaches showed low power estimates on the phase II study design. Adding patients with only a through concentration led to much higher power estimates for both approaches, with the stepwise procedure detecting more false positives. Further, the integrated approach was more powerful at detecting SNP effect on multiple model parameters. Conclusion: Classical phase II study designs are critically under powered to detect realistic PK parameter-SNP associations. The integrated approach showed better performance on a design combining full-profile and sparse sampling which enables the necessary increased in sample size.

"A Tale Of Genetic Variation In The Human SLC22A1 Gene Encoding OCT 1 Among Type 2 Diabetes Mellitus Population Groups Of West Bengal, India". *D. Sur.* C.U., Kolkata, Westbengal, India.

The organic cation transporter 1, OCT 1 (also called SLC22A1-Solute Carrier Family 22 member 1), appears to play a role in the efficacy and disposition of variety of organic cation including drugs. Genetic polymorphisms in the drug transporter have been increasingly recognized as a possible source of variation in drug disposition and response. Genetic variants in OCT1 have been identified largely in European, Asian (Japanese, Chinese and Korean) populations. Interestingly, eight genetic variations were found in the human SLC22A1 gene, which encodes OCT 1, from 50 type 2 diabetes mellitus individuals (T2DM), in West Bengal population. The purpose of this study was to investigate genetic variants of OCT1 in West Bengal populations. The study detected the three previously reported nonsynonymous variations, 480 G>C (L160F); 1022 C>T (P341L); 1222 A>G (M408V) and one synonymous variations 156 T>C (S52S) at a minor allele frequencies (MAF) of 0.63, 0.20, 0.43 and 0.27 respectively. This study also found four previously reported intronic variations: IVS1-43(T>G), IVS2 -99(C>T), IVS5 -61(G>A), IVS9 +43(C>T) with minor allele frequencies of 0.20, 0.17, 0.18, and 0.37 respectively. This is the first report of SLC22A1 variations among Indian, especially West Bengal's type 2 diabetes mellitus patients. The present results would be useful for haplotype analysis and pharmacogenetic studies on OCT1.

A role for B cells in Progressive Multifocal Leukoencephelopathy revealed by comprehensive genomic analysis. *J. Carulli[1], L. Fugger[2], A. Day-Williams[1], A. Haghikia[2,4], C. Sun[1], N. Allaire[1], H. Li[1], C. Dendrou[2], T. Plavina[1], H. McLaughlin[1], P. Cullen[1], M. Liu[1], A. Thai[1], R. Gold[4], R. Martin[3], I. Jelcic[3], T. Compton[1], T. Harris[1].* 1) Translational Medicine, BiogenIdec, Cambridge, MA; 2) The Weatherall Institute of Molecular Medicine, University of Oxford, John Radcliffe Hospital, Oxford, OX3 9DS; 3) Department of Neurology, St Josef-Hospital, Ruhr University Bochum, Bochum, Germany; 4) Department of Neurology University Hospital Zurich Frauenklinikstrasse 26 CH-8091 Zurich.

Progressive multifocal leukoencephalopathy (PML) is a rare and potentially lethal infectious disease caused by JC virus in individuals with compromised immune systems or who take specific immune modulating drugs. JC virus (JCV) has a seroprevalance of 60% in adult populations worldwide, but PML is very rare. Prior to the development of anti-HIV drugs, roughly 5% of AIDS patients developed PML. More recently, PML has been observed at a rate of approximately 1/1000 or lower in patients taking immune-modulating drugs, including natalizumab (anti-VLA4) for multiple sclerosis. To identify novel biomarkers of PML risk, we performed whole exome sequencing, whole genome sequencing, and genome wide transcription profiling of multiple sclerosis patients who developed PML while taking natalizumab with appropriately matched MS patients who did not develop PML while taking natalizumab for two years or more. We also performed whole genome sequencing of two subjects who developed PML while not taking any immune modulating drugs. Single SNV association testing and gene-based collapsing tests of nearly 100 natalizumab PML cases and 100 natalizumab controls did not reveal any significant associations with PML. One of the two "spontaneous" PML subjects had a complete deletion of the Dock8 gene on chromosome 9p. Dock8 deficiency is a primary immune deficiency with pleiotropic effects, including B cell migration defects. Genome-wide transcript profiling of 18 natalizumab PML subjects and 150 natalizumab controls revealed that several transcripts, including IgHM, FcRLA, FcRL3, CD72 and CD22, exhibited lower expression levels in PML compared to non-PML patients. These findings were confirmed by qPCR, and the IgM observation was confirmed at the protein level. Pathway analysis of the transcript data identified B cell pathways significantly deregulated in subjects who got PML. Taken together, the genetic data and the transcript data suggest that variation in maturation and/or migration of B cells plays a role in the development of PML and may provide biomarkers for PML risk.

Association between *CYP2B6* +516 G>T polymorphism and response to first-line therapy in Brazilian HIV-1+ individuals. *T.B. Almeida, M.B. Arruda, R.M. Brindeiro, A. Tanuri, C.C. Cardoso.* Laboratrio de Virologia Molecular, Instituto de Biologia, UFRJ, Rio de Janeiro, Brazil.

According to World Health Organization, 35 million individuals are infected by HIV-1 in the world and about 9.5 million are currently undergoing highly active antiretroviral therapy (HAART). However, 10–20% of these individuals patients do not reach therapeutic success, mainly as a consequence of low adherence to the treatment and emergence of drug resistant viral strains. HAART effectiveness is also influenced by host factors that affect drug absorption, activation and metabolism. Single nucleotide polymorphisms (SNPs) in *CYP2B6* gene can directly influence the expression and function of the enzyme responsible for the metabolism of efavirenz (EFZ) and nevirapine (NVP). The aim of this study was to investigate the association between 14 candidate SNPs in *CYP2B6* gene and HAART failure in EFZ or NVP containing first line regimens. A total of 111 HIV-1+ individuals under HAART selected from the Brazilian cities of Porto Alegre and Curitiba were included in the study. From these, 73 individuals reached therapeutic success, defined by the reduction of viral loads (VL) to undetectable levels (<50 copies/mL). The remaining 38 individuals exhibited HAART failure, with detectable VL after 6 months of treatment. SNP genotyping was performed by SNaPshot® or TaqMan® assays (Life Technologies, USA). Nine SNPs were excluded from the study due to deviations from Hardy-Weinberg Equilibrium or because they were monomorfic in our study population. The frequencies of the remaining 5 SNPs were compared using logistic regression models adjusted for sex and HIV-1 subtype. Our results showed an increased risk of HAART failure (OR=2.21; 95%CI= 0.96–5.04; p=0.048) among carriers of the allele +516T (rs3745274). The same allele has been previously associated to higher EFZ and NVP plasma levels, suggesting that it might favor therapy effectiveness. However, the effect of this SNP may be influenced by additional variations in *CYP2B6* or genes coding for drug transporters. It suggests that the genetic background of each population, including linkage disequilibrium patterns, may influence data interpretation, reinforcing the importance of replicating genetic association results in different populations. To our knowledge, this was the first study to describe the association of CYP2B6 gene to HAART response in Brazilian HIV-1+ individuals. The use of pharmacogenetic markers may be crucial to define personalized regimens, which may be more effective and better tolerated by the patients.

732M

Identifying Differentially Expressed Genes Associated with Extreme Blood Pressure Response to Hydrochlorothiazide monotherapy. *A.C. Costa Sa[1-3], A. Webb[4], Y. Gong[1,2], T. Langaee[1,2], S. Turner[5], A. Chapman[6], J. Gums[1,2,7], S. Scherer[8], R.M. Cooper-DeHoff[1,2,9], W. Sadee[4], J.A. Johnson[1-3,9].* 1) Pharmacotherapy and Translational Research, University of Florida, Gainesville, FL; 2) Center for Pharmacogenomics, University of Florida, Gainesville, FL; 3) Graduate Program in Genetics and Genomics, University of Florida, Gainesville, FL; 4) Department of Pharmacology, College of Medicine, Ohio State University, Columbus, OH; 5) Division of Nephrology and Hypertension, Mayo Clinic, Rochester, MN; 6) The Renal Division, Department of Medicine, Emory University, Atlanta, GA; 7) Department of Community Health and Family Medicine, University of Florida College of Medicine, Gainesville, FL; 8) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 9) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, Gainesville, FL.

Hypertension (HTN) is the most common chronic disease in the world, estimated to affect nearly 1 billion individuals worldwide. Hydrochlorothiazide (HCTZ) is one of the most commonly prescribed antihypertensive (anti-HTN) medications in the US with over 100 million prescriptions annually. Even though HCTZ is one of the preferred options for initial HTN therapy, patient's response varies widely, and less than 50% of them achieve blood pressure (BP) control. We hypothesize that interpreting the functional elements of the genome will help us in identifying candidate biomarkers associated with variability in the efficacy of HCTZ therapy. The present work aims to identify genes with differential expression levels between responders and nonresponders after HCTZ monotherapy in Caucasian hypertensive PEAR (Pharmacogenomic Evaluation of Antihypertensive Responses) participants. Uncomplicated hypertensive patients were recruited and randomized to either HCTZ or atenolol monotherapy. BP and adverse metabolic responses were assessed after 9 weeks of monotherapy. On 50 European American participants, classified as responders and nonresponders to HCTZ, total RNA was isolated from whole blood and used for transcriptomic RNA sequencing with Illumina HiSeq2000®. The generated reads were aligned to the reference genome (Homo Sapiens Hg19) with TopHat2. Cufflinks/Cuffdiff pipeline was used to calculate gene expression levels, reported as fragments per kilobase per million reads (FPKM). Paired t-test was performed to evaluate significance of the change in FPKM. Differential expression analysis revealed that 2 genes may play an important role in BP response to HCTZ: *RHOB* and *CDC42EP2* (FDR adjusted p-value < 0.05). RHOB is a small GTP binding protein, which is known to modulate Ca^{2+}sensitization of vascular smooth muscle cells (VSMCs) and is thought to act by inhibiting myosin phosphatase activity, sustaining muscle contraction. CDC42EP2 is a CDC42 Effector Protein 2. CDC42 is also a GTP binding protein, member of the Rho protein superfamily. It activates serine/threonine kinase MRCK, promoting myosin phosphorylation. Previous studies highlight the convergence of Rho and CDC42 signaling in VSMCs, corroborating our RNA-Seq findings. These results suggest that Rho/Rho-kinase and CDC42/CDC42EP2 pathways may be involved in vascular resistance hypertension and possible reflect in BP response variability associated with thiazide diuretics anti-HTN treatment.

733S

Contribution of rare protein-coding variants to anti-TNF treatment response in rheumatoid arthritis patients. *D. Diogo[1–4], J. Cui[1], R.S. Fulton[5], J.D Greenberg[6,7], D.A. Pappas[7,8], J.M. There are several effective drugs that treat systemic inflammation in rheumatoid arthritis (RA), including the widely used anti-tumor necrosis factor alpha (anti-TNF) biologic therapies. However, a significant number of RA patients fail to enter remission with the drugs currently available. Despite multiple efforts, no confirmed genetic predictor of anti-TNF treatment response in RA patients has been identified from association studies of common variants. Here, we targeted 750 genes for exon-sequencing and investigated the aggregate contribution of rare protein-coding variants to anti-TNF treatment response (improvement in disease activity score) in 1,131 RA patients of European ancestry. Gene-based association tests resulted in a study-wide significant association at *TNF*, driven by two rare missense mutations in three patients predicting good treatment response (Beta = +3.04, $P=4\times10^{-5}$). Interestingly, we observed several additional genes involved in the TNF signaling pathway among the genes with the strongest signals of association ($P<0.05$). We performed a gene set enrichment analysis based on association Pvalues ranking, and observed a nominal enrichment of association at genes involved in the TNF pathway ($P_{enrichment}=0.03$, based on 1,000 phenotype permutations). Our results, if validated in independent collections, would suggest that rare protein-coding variants in genes from the TNF signaling pathway contribute to treatment response in RA patients.

734M

Assessing the clinical utility of massively parallel sequencing for pharmacogenomics research in the ClinSeq® study. *D. Ng[1], L.N. Singh[1], C.S. Hong[1], K.L. Lewis[1], J.C. Mullikin[2,3], L.G. Biesecker[1,2], NIH Intramural Sequencing Center, National Human Genome Research Institute, NIH.* 1) Medical Genomics and Metabolic Genetics Branch, MGMGB/NHGRI/NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Comparative Genomics and Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

ClinSeq® is a medical sequencing project designed to study the clinical application of massively parallel sequencing (MPS) in a cohort of mostly healthy volunteers. One of the goals of personalized medicine is to optimize the efficacy of pharmacologic treatment and to minimize adverse drug reactions. Pilot projects studying the utility of pharmacogenetic (PGx) guided treatment have used Sanger sequencing or genotyping chips to identify a finite number of important PGx variants. To study the utility of MPS for identifying clinically important PGx variants, we compared the accuracy and coverage of whole exome (WES) and genome sequencing (WGS) at 1,934 variant positions interrogated by the Affymetrix Drug Metabolism and Transport (DMET) Plus chip. ClinSeq® cohort is comprised of 973 volunteers age 45–65 from the Washington DC area. Participants received baseline clinical evaluations, WES, consent for return of genetic results and iterative phenotyping to study incidental variants. Five participants had both WES and WGS. Sequence reads were aligned to NCBI assembly GRCh37 with Novoalign v3.02.00 (Novocraft technologies). Genotypes were determined with GATK v3.0-0. Coverage of 1,934 variant positions in 231 DMET genes were analyzed in 973 exomes. High quality reads were defined as GATK score =99 and read depth (RD) ≥10. A variant position had high coverage (HC) if ≥80% (n=779–973) of participants had high quality reads, low coverage (LC) if <80% (1–778) and no coverage (NC) if no one had a high quality read at that variant position. WES had the poorest coverage for intergenic (0/31 HC), promoter (3/91 HC) and 5'UTR variants (10/39 HC). Unsurprisingly, WES coverage was the highest in exonic variants (1,239/1,332 HC, 92/1,332 LC, 1/1,332 NC). WES RD can be used to identify copy number variants (CNVs) affecting drug metabolism (i.e., CYP2D6) with XHMM software. WGS had excellent coverage of coding and noncoding (average RD ≥10) DMET Plus variants ranging from 92% for 5'UTR to 100% for promoter, 3'UTR and intergenic variants. WGS has several advantages over the DMET Plus array for preemptive PGx testing. Any array or other panel test has to be updated as new PGx variants are discovered, necessitating periodic retesting. WGS captures both known and yet to be discovered coding, noncoding and CNV PGx variants in one assay. As the cost of MPS decreases and clinical interpretation improves, WGS will likely be the genomic test of choice for personalized medicine.

Development of a multiplex genotyping method for CYP2C19 specialized to Korean using the single base extension technique. *D. Seo, H. Jeong, J. Seo, J. Ha, I. Hwang, J. Choi, H. Na, J. Kim.* Clinical Research Division, National Institute of Food and Drug Safety Evaluation, MFDS, Cheongju, South Korea.

Most of drugs are xenobiotics for human body and are metabolized mainly in the liver. Drug metabolism was exerted by phase I and II enzymes in the liver and highly dependant on the activity of enzymes. Cytochrome P450s(CYPs) are known to play essential roles in phase I drug metabolism in the liver. Among the CYPs, CYP2D6, CYP2C9 and CYP2C19 are known to play important roles in drug metabolism. According to US FDA's list of pharmacogenomic biomarkers in drug labeling, CYP2C19 is the most common valid biomarker involved in metabolisms of 14 different drugs and a number of genotyping kits are already available in the market after US FDA's approval. National Institute of Food and Drug Safety Evaluation(NIFDS) has put its effort to conduct pharmacogenomic studies since early 2000s for harnessing the new paradigms of drug utilization such as personalized medicine in Korea. As a part of the effort, we developed a genotyping method for CYP2C19 variants using a single base extension technique(SNaPShot) containing Korean specific minor alleles. The kit is capable of genotyping 15 variants of CYP2C19 including common variants, like *2 [A], *3 [A], *4 [G], *5A [T], *8 [C], *17 [T] and also a couples of variants specific to Korean population such as rs11568732, rs3758580, rs3758581, rs4417205 and rs4986894. The validity of the kit was evaluated by triple repetition test on 96 Korean DNA samples. The accuracy of the genotyping was also validated by sequencing of each target variants. The accuracy and precision of the kit ranged from 81.6% to 100% and from 94.8% to 100% on common CYP2C19 alleles, respectively. The accuracy and precision on Korean specific alleles ranged from 80.2% to 90.6% and from 98.3% to 100%, respectively. The overall accuracy and precision of the kit turned out as 85.8% and 99.1% respectively. The results suggested that the newly developed kit was capable of genotyping both common and Korean-specific CYP2C19 alleles with effectiveness. We are expecting that this kit provides a cost-effect mean for genotyping pharmacogenetically important CYP2C19 alleles in Korean population. Acknowledgement : This research was supported by a grant (13181MFDS705) from Ministry of Food And Drug Safety in 2013. And The Korean DNA was supplied by Center for Genome Science National Institute of Health, KCDC. Korean DNA was originated by Ansung-Ansan cohort data.

NAT2 polymorphisms in a Brazilian indigenous group. *V.M. Zembrzuski[1], R.L.F. Teixeira[2], P.H. Cabello[1,2].* 1) UNIGRANRIO, Duque de Caxias, RJ, Brazil; 2) IOC-Oswaldo Cruz Foundation (Fiocruz), Rio de Janeiro, RJ, Brazil.

Tuberculosis is an important disease to public health in Brazil and around the world, especially among indigenous people from Amazonia and Central Brazil. Despite treatment to be effective, adverse drug reactions such as hepatotoxicity can occur, decreasing adherence to medication therapy and may lead to drug resistance. Isoniazid (INH) is the major drug associated with drug-induced hepatotoxicity. INH is metabolized via hepatic N-acetyltransferase2 (NAT2). In subjects with low NAT2 activity there is a higher risk of developing hepatic disorder. On other hand, the high activity shows a correlation between low plasma concentrations of INH and therapeutic failure. The NAT2 protein is encoded by NAT2 gene, and the acetylator status, i.e., related to activity of this protein, is determined by single nucleotide polymorphisms (SNPs) in this gene. Variant NAT2 alleles or haplotypes possessing combinations of SNPs are segregated into clusters possessing a signature SNP either alone or in combination with others. Based in a trimodal classification, individuals homozygous for rapid NAT2 acetylator alleles are deduced as rapid acetylators, individuals homozygous for slow acetylator NAT2 alleles are deduced as slow acetylators, and individuals possessing one rapid and one slow NAT2 allele are deduced as intermediate acetylators. In this study, our objective was to determine the frequency of mutations at the polymorphic gene coding for arylamin N-acetyltransferase 2 (NAT2) and its genotypes associated with acetylation in 94 individuals of a Xavante population, Native American group of Central Brazil. Sequencing analysis showed five polymorphisms already described in other studies, and most frequent in different ethnic groups: 282 C>T, 341 T>C, 481C>T, 803 A>G and 857G>A. It was found three haplotypes: NAT2*4 (wild type), which is a functional allele, was the most frequent (62.2%); NAT2*7B and NAT2*5B accounted for 22.4 and 15.4%, respectively. 55.3% of all individuals had fast acetylation genotypes, while intermediate and slow acetylators comprised 13.9 and 30.8%, respectively. In conclusion, an understanding of genetic diversity of NAT2 has medical relevance for pharmacogenetics and epidemiological applications. Due to major differences in allele frequencies between populations, individuals from different ethnic or geographic origins may respond differently to drugs.

The Ashkenazi Jewish (AJ) population has a history of bottlenecks, expansions and geographical isolation, which has resulted in a unique genetic architecture that includes a high prevalence of founder mutations for autosomal recessive diseases and higher frequencies of some common disease risk alleles. Although recent candidate gene studies also have identified some unique pharmacogenetic variants in the AJ, no pharmacogenomic studies have been reported in this population. To identify novel variants potentially implicated in drug response variability and to characterize the pharmacogenomic profile of the AJ population, 128 whole-genomes of healthy AJ individuals sequenced to high-depth were interrogated across a panel of 320 selected autosomal pharmacogenetic genes representing ~16.9 Mb of the human genome. Of the 73,683 total variants detected, 1,228 (1.7%) were non-synonymous, and 16,449 (22.4%) were previously unreported with 5,547 (33.7%) of these observed in two or more individuals. Of the non-synonymous variants, 373 (30.4%) were novel, with 371 (99.5%) having minor allele frequencies (MAF)<5% and 158 (42.4%) predicted *in-silico* to be functional. AJ individuals had a significantly lower burden of predicted functional variants (mean=23) compared to the European (EUR; 28), African (AFR; 38), and Asian (ASN; 29) populations in the 1000 Genomes Project (p<2e-22), consistent with an isolated population. Over 6% of the AJ and EUR predicted functional variants had significant differences in MAF (p<0.0001), including several predicted to have high functional impact (e.g., *FMO2* p.S195L, *UGT2B11* p.C156R). In addition, after randomly sampling 128 individuals (100X) from the 1000 Genomes Project populations, 149 (non-singleton) non-synonymous variants were unique to the AJ, compared to the EUR (63), AFR (457), and ASN (202) populations. Analysis of clinically actionable pharmacogenetic variants defined by PharmGKB indicated that the AJ harbor most of these variants with comparable frequencies to the EUR; however, ~16% of AJ harbor unique (non-singleton) variants in these clinically relevant pharmacogenes compared to only ~3% of the EUR, the majority predicted to be functional. These data indicate that in addition to common pharmacogenomic variants found in other populations, the AJ harbor many pharmacogenomic variants that are uncommon or absent in other populations and which may play an important role in drug response variability in this unique population.

CYP2D6 allele specific copy number analysis using TaqMan® SNP Genotyping Assays and digital PCR. *T. Hartshorne, S. Patel, D. Keys.* Genetic Analysis, Thermo Fisher Scientific, South San Francisco, CA.

The major drug metabolizing enzyme, CYP2D6, is encoded by a highly polymorphic gene. Over 100 star allele haplotypes are known, which can contain SNP, InDel, and copy number variants (CNVs) and which fall into 3 main functional categories (full, reduced, or none). The diploid star allele content is predictive of CYP2D6 drug metabolizer phenotype (ultrarapid, extensive, intermediate, or poor). We previously described a workflow whereby sample SNP genotype and CNV results, generated using TaqMan® SNP assays and TaqMan® Copy Number assays, respectively, can be translated to star allele diplotypes using AlleleTyper™ software. However, for samples that carry CYP2D6 duplications and are heterozygous for key SNPs, the specific allele that is duplicated cannot always be identified. A phenotype can be assigned if all 3 alleles are of the same functional category, but if alleles are from different functional categories there may be 2 possible phenotypes. To address this issue, we developed a method to detect allele-specific copy number by digital PCR using the QuantStudio™ 3D Digital PCR System. Sample DNA is loaded onto nanofluidic chips at concentrations to give one or no copies of target per dPCR. A count of reactions with and without amplification can be used for target quantification purposes. For the allele-specific dPCR application, TaqMan® SNP assays to CYP2D6 variants that are associated with specific duplicated alleles were run in dPCRs on samples of known SNP genotype and CNV status. Samples were first digested with a restriction enzyme to separate tandem duplicated CYP2D6 alleles and enable their partitioning into distinct dPCRs. Sample input amounts and thermal cycling conditions were optimized to best amplify and resolve each allele in cluster plot analysis. Reactions positive for each allele, detected by allele-specific VIC® or FAM™ dye-labeled probes, were counted and the allele ratios determined. For samples heterozygous for target SNPs, 2-copy samples gave close to 1:1 allele ratios, whereas 3-copy samples gave close to 1:2 ratios and the duplicated allele was readily identified. We have thus shown that allele-specific copy number analysis using dPCR and TaqMan® SNP assays is a simple and effective method for identifying specific duplicated alleles in heterozygous samples. This method facilitates accurate CYP2D6 allele genotyping and better prediction of drug metabolizer phenotype.

Analysis of CYP1A2 gene non-coding region polymorphisms in Roma and Hungarian population samples. *B. Melegh[1,2], P. Matyas[1], B.I. Melegh[1], L. Magyari[1,2], J. Bene[1], B. Duga[1,2], Zs. Banfai[1], A. Szabo[1], R. Szalai[1,2].* 1) Department of Medical Genetics, University of Pecs, Pecs, Hungary; 2) Szentagothai Research Centre, University of Pecs, Pecs, Hungary.

Purpose: CYP1A2 enzyme contributes to biotransformation of wide variety of therapeutically important drugs, including caffeine, clopidogrel, clozapine, warfarin, procarcinogens, and some endogenous substrates. The aim of this study was to determine the pharmacogenetic profile and interethnic differences of variants of CYP1A2 gene in Roma (Gypsy) and Hungarian population.

Methods: A total of 404 Roma and 396 Hungarian healthy subject's biobanked DNA were genotyped for two non-coding variants of CYP1A2: -163C>A (*1F) and -3860G>A (*1C). Polymerase chain reaction - restriction fragment length polymorphism technique was applied.

Results: The minor allele frequency for CYP1A2*1C variant was 2.02% in Hungarians, while was not detectable in the Roma samples; the AA homozygous genotype was also not detectable. For CYP1A2*1F polymorphism we found a marked differences in AA genotype in Roma population compared with the Hungarians (31.9% vs. 49.5%, p<0.001) and in minor allele frequency (56.9% vs. 68.6%, p=0.025). The following CYP1A2 genotypes were identified in Roma and Hungarian samples, respectively: *1A/*1A (18.1% vs. 12.4%), *1A/*1F (50% vs. 36.9%), *1F/*1F (31.9% vs. 46.7%). In Hungarian population we found the *1C/*1F genotype (4.04%), but it was not present in Roma subjects.

Conclusions: Analysis of distribution of CYP1A2 gene variants revealed further pharmacogenetic differences between Roma and Hungarian population samples. Theoretically, as a further consequence, the Hungarians have higher chance for rapid metabolism of CYP1A2 substrates, intensified procarcinogen activation, and perhaps thereby elevated risk for cancers.

Evaluation of DNA extracted from up to 16 years old *post-mortem* blood FTA cards using Quantifiler Human Plus Quantification Kit. *AL. Rahikainen, JU. Palo, A. Sajantila.* Department of Forensic Medicine, Hjelt Institute, P.O.Box 40, FI-00014 University of Helsinki, Helsinki, Finland.

Introduction: The field of pharmacogenetics may significantly benefit from *post-mortem* (PM) studies which often harvest the extreme cases from the population. When combining genetic information to other autopsy data, especially from toxicological analyses, genetic outliers may be revealed. A potential source of DNA is FTA™ Gene Cards (Whatman™, GE Healthcare). In our department, blood samples from all autopsies have been preserved routinely since June 1998 on FTA cards. However, due to the PM changes it is expected that the starting condition of the samples vary prior to sampling and therefore methods used for PM DNA analysis must be compatible with degraded or inhibited DNA samples. The aim of this study was to determine the quality and quantity of DNA on the FTA cards sampled during 1998–2013 and to evaluate their usability in pharmacogenetic studies. *Materials and methods:* Four random samples from eight time points covering sampling years 1998 to 2013 resulting 32 DNA samples in total were extracted in triplicates. Four punches (2.0 mm Harris Micro-Punch™) were used in each extraction. DNA extraction was performed with Automate Express™ System (Applied Biosystems (AB)) according to manufacturer's protocol using PrepFiler Express™ Forensic DNA Extraction Kit (AB). Extracted samples were quantified and qualified by using Quantifiler HP Quantification Kit (AB) and analyzed with 7500 Real-Time PCR system (AB). *Results:* According to the quantification results all samples contained amplifiable DNA, but both quality and quantity were expectedly higher in the more recent samples. There was variation in the DNA quantity between the samples, despite equal amount of input material. Also internal variation was seen among the triplicates. All samples were free of inhibition. *Conclusions:* Blood samples on FTA cards are rather stable over 16 years although the older samples showed more degradation and lower yields compared to the recent ones. This study showed that also in the oldest samples from 1998 the mean DNA yield was 4.9 ng/μl (small target), and 3.4 ng/μl (large target) making them usable in pharmacogenetic studies, but the higher degradation level must be taken account. In Finland the full toxicological analyses are conducted from approximately 70% of the forensic autopsy cases. Therefore the DNA preserved on FTA cards combined with the results of toxicological analyses offers unique opportunity for conducting pharmacogenetic studies.

741S

Utilizing Pharmacometric Modeling in Pharmacogenetic Association Tests to Increase Study Power. *H. Zhou, Z. liu, S. Nayak.* Pfizer, Cambridge, MA.

In parmacogenetic studies, association tests are routinely performed to identify novel genetic markers predictive of treatment response. Traditionally, three approaches can be used to identify genetic markers in clinical trials that are designed to investigate multiple drug doses: (1) to only use data from the placebo arm and the most efficacious arm and test for genotype by treatment interaction in regression models; (2) to use data from all arms and perform an omnibus test for interactions between genotype and treatment with multiple degrees of freedom in regression models; (3) to use data from all arms and test for interaction between genotype and administered dose in regression models. However, all these approaches have drawbacks: ignoring other treatment arms in approach (1) might lead to decreased power due to reduced sample size and loss of information; approach (2) might not be powerful due to the extra degrees of freedom applied to the omnibus test; administered dose in approach (3) might not be the dose at the target site and therefore less correlated with clinical efficacy. In this study we propose an approach that utilizes data from all available treatment arms and incorporates biological mechanisms into genetic association tests in clinical trials. Drug-target binding or dose-response is estimated using pharmacometric modeling and interaction between genotype and estimated drug-target biding or dose-response is tested in regression models. Genetic and treatment-response data are simulated to mimic dose-ranging Phase II trials. Scenarios with a wide range of genetic effect sizes, mutation frequencies, rate constants for drug-target complex formation, and correlations between drug-target complex and efficacy are considered. Power of the proposed approach and conventional approaches to identify genetic markers for treatment response is compared using simulated data. The proposed approach has great potential to increase the power and probability of success of genetic studies to identify biomarkers at early clinical trial stages.

742S

Exome sequencing of multiplex oral clefts families detects recurrent shared rare variants in 9 genes. *E.R. Holzinger[1], Q. Li[1], M. Parker[2], J.B. Hetmanski[2], M.L. Marazita[3], E. Mangold[4], M.M. Nothen[4], J.C. Murray[5], A. Scott[2], T.H. Beatty[2], J.E. Bailey-Wilson[1].* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes Health, Baltimore, MD., Select a Country; 2) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 3) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine; Department of Human Genetics, Graduate School of Public Health; and Clinical and Translational Science Institute and Department of Psychiatry, School of Me; 4) Institute of Human Genetics, Life and Brain Center, University of Bonn, Bonn, Germany; 5) Departments of Biology, Epidemiology, and Pediatrics, University of Iowa, Iowa City.

Non-syndromic oral cleft phenotypes, including cleft lip with or without cleft palate (CL/P), are complex disorders with some known genetic effects. Previous GWAS have identified multiple loci with small effects on risk of CL/P and recently we have identified a novel, potentially damaging variant in CDH1 in one multiplex CL/P family. For this analysis, we used whole exome sequence (WES) data in families with 2 or 3 distantly related (2nd or 3rd degree relationship) affected individuals to identify genes containing within-family shared rare variants. Fifty-five families containing 114 individuals, 4 duplicate subject controls and 2 unrelated CEPH HAPMAP controls were sequenced on the Illumina Hi-Seq 2500 and processed through the GATK pipeline ... The families were from several different populations including 12 of Indian, 11 of Filipino, 19 of German, 10 of Syrian, 1 of European-American and 2 of Asian descent. Ingenuity 'Variant Analysis' was used to identify variants that were shared under a recessive model by all sequenced affected individuals in a family and where such sharing was observed in the same gene in at least two separate multiplex families and thus potentially associated with oral clefts. After filtering based on variant quality and frequency (MAF<0.05 in HapMap), we identified nine genes with variants that are homozygous in all affected individuals in at least two families. The variants were sometimes different across families, allowing for allelic heterogeneity. These rare variants are not present in either of the HapMap controls sequenced here. The genes are: ARHGEF12, CCT4, HSD3B7, MAN1B1, RREB1, SNRPC, STARD9, ZDHHC11, and ZNF835. Some of these genes have known biological functions which may be related to oral cleft. For example, variants in HSD3B7 have been associated with Hardikar syndrome, which sometimes presents with cleft lip and/or palate. Follow-up will include validation of these genes using Sanger sequencing and genotyping of these variants in other individuals in these same families.

Candidate gene analysis of non-syndromic tooth agenesis in Japanese. *J. Machida[1], T. Tatematsu[2], A. Shibata[2], M. Kimura[3], S. Yamaguchi[4], Y. Abe[1], K. Yasui[1], A. Kitagawa[1], S. Makino[1], H. Miyachi[2], K. Shimozato[2], T. Nishiyama[5], Y. Tokita[6].* 1) Oral and Maxillofacial Surgery, Toyota Memorial Hospital, Toyota city, Aichi, Japan; 2) Maxillofacial Surgery, Aichi-Gakuin University, Nagoya, Japan; 3) Oral and Maxillofacial Surgery, Ogaki Municipal Hospital, Ogaki, Japan; 4) Oral and Maxillofacial Surgery, Aichi Children's Health and Medical Center, Obu, Japan; 5) Department of Public Health, Aichi Medical University, Nagakute, Japan; 6) Perinatology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan.

Tooth agenesis is one of the most common congenital anomalies in humans and it is characterized by developmental absence of teeth. According to the number of missing permanent tooth excluding the third molars, tooth agenesis is classified into two categories as follows. Hypodontia is generally defined as agenesis with absence of less than six teeth, and oligodontia is a condition in which six or more teeth are missing. It is well known that both genes including ethnic background and environment play a role in common birth defects. For example, oral cleft is ubiquitous disorder world wide, although its incidence varies widely from highest in Asian populations to lowest in those of African descent. Previously we reported the prevalence of permanent tooth agenesis in Japanese was 7.0%, which is similar to that in other population-based studies.Recent studies revealed that mutations in WNT10A gene are presented in 28 to 56% of tooth agenesis in Caucasian population. In this study, we investigated mutation analysis to determine the contribution of WNT10A and other candidate genes such as MSX1 and PAX9 variants. In total, 38 patients (21 male (55%) and 17 female (45%)) were classified as non-syndromic and included in this study. A mean of 8.4 (range: 5 to 20) teeth were missing. The mean age of these patients was 19.4 years old. In 17 patients (44.7%), there was a positive family history (third degree or more closely related) for tooth agenesis. WNT10A mutations were identified in 16.7% of cases with hypodontia. MSX1 and PAX9 mutations were presented in 21.2%, and 36.4% of cases, respectively. Our findings on the intra oral distribution of agenesis of permanent teeth in children may help us better understand the etiology of agenesis.

744T

Exome sequencing reveals novel genetic cause of hereditary motor Neuropathy. *S. Poornima[1], B. Harika[1], S. Pradeep[2], B. Ravishankar[2], Q. Hasan[1].* 1) Department of Genetics & Molecular Medicine, Kamineni Hospitals, Hyderabad, India; 2) Department of Microbiology, Kamineni Hospitals, Hyderabad, India.

Charcot -Marie -Tooth (CMT), is a genetically and clinically heterozygous group of inherited disorders of the peripheral nervous system characterized by progressive loss of muscle tissue and touch sensation across various parts of the body. A twenty one year old male with hereditary motor neuropathy was referred by an orthopedic surgeon for genetic evaluation. The proband was an only son born to a consanguineous couple. He was full term baby born vaginally, who cried at birth and had a good APGAR score and had no development delay achieving all his milestones at appropriate age. He suffered with high fever at the age of 8 years and developed chicken pox. He subsequently developed gradual weakness of lower limbs followed by wasting of muscles both in the lower and upper limbs. Cytogenetic analysis showed a 46 XY normal karyotype. To rule out that it was not an autoimmune disorder due to the Varicella zoster virus Ig G and IgM antibodies were assessed in the serum and were found to be negative ruling out that the clinical symptoms were part of Vz complications. Elevated levels of CPK and ENMG gave the impression of hereditary motor neuropathy most likely CMT. Detailed pedigree analysis did not indicate any other family member with similar neurological symptoms. NGS analysis for whole genome was carried out from peripheral blood DNA and a panel of 586 neurological targeted genes were evaluated by in silico analysis, which included the genes of the CMT panel. A homozygous missense variation in exon 3 of VRK1 gene (chr14:97321690;G>A) which resulted in the amino acid substitution of Methionine by Valine at codon 236 (p.V236M; NM_003384) was detected. Variations in VRK1 gene were reported as disease causing, in patients with Ponto cerebellar hypoplasia type 1A but this patient doesnot conform to that clinical picture and appears to be unique.

745S

Whole Exome Sequencing Analysis of Severe, Early-Onset COPD in Extended Pedigrees. *D. Qiao[1,2], C. Lange[2], T.H. Beaty[5], J.D. Crapo[4], E.K. Silverman[1,3], M.H. Cho[1,3].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) National Jewish Medical and Research Center; Department of Medicine, Division of Pulmonary, Critical Care and Sleep Medicine, University of Colorado Denver, CO; 5) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

Genomic regions identified by genome-wide association studies explain only a small fraction of heritability to chronic obstructive pulmonary disease (COPD). Alpha-1 antitrypsin deficiency shows that rare coding variants of large effect also influence COPD susceptibility. We hypothesized that exome sequencing in families identified through a proband with severe, early-onset COPD would identify additional rare genetic determinants of large effect.

A total of 351 subjects in 49 extended pedigrees from the Boston Early-Onset COPD Study were ascertained through a proband with severe, early-onset COPD (age < 53, FEV1 < 0.4 predicted, without alpha-1 antitrypsin deficiency). These 351 subjects underwent whole exome sequencing and 347 subjects were analyzed after quality control. 61,695 of 124,288 total variants were defined to be non-synonymous, stop, or splice variants using SNPEff. In addition, exome sequencing data on 200 unrelated subjects with severe COPD and 200 normal controls from the COPDGene study were available as supportive evidence of association. We used two different analytical approaches to identify rare genetic determinants of COPD: 1) association methods for analyzing family-based sequencing data and 2) filtering approaches within individual pedigrees. Because the optimal test for family-based association is not clear, we applied famSKAT, PedGene, FBAT for rare variants, and EMMAX. For the filtering approach, we excluded variants with a minor allele frequency > 0.001 in public datasets and identified a remaining set of functional variants, predicted to be deleterious using Condel and CADD, that segregated with severe COPD within each pedigree.

From the association analysis, all methods except FBAT demonstrated inflation in the association p-values. No genes showed genome-wide significance over all the methods, but suggestive associations were found for *E2F2, MIP, ASAP3*, and *DNAAF2* using famSKAT. With the filtering-based approach, one variant in *ADAMTS1* segregated in two families and had a marginally significant result using SKAT-O test in the case-control dataset. We identified 70 genes containing variants segregated in more than one pedigree, and 5 of these genes showed evidence of association using the case-control dataset, including *BCAR3, ALCAM, EP300, PLD1*, and *POLR1A*. Further network analysis and functional studies are needed to validate the candidate genes discovered.

Nyunoya[2,4].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) COPD Program, Lovelace Respiratory Research Institute, Albuquerque, NM; 3) Department of Biochemistry and Microbiology, Rutgers University, Piscataway, NJ; 4) Department of Internal Medicine, University of New Mexico and New Mexico VA Health Care System, Albuquerque, NM; 5) Department of Medicine, University of Iowa, Iowa City, IA.

Chronic obstructive pulmonary disease (COPD) is characterized by an irreversible airflow limitation in response to inhalation of noxious stimuli, such as cigarette smoke. However, only 15-20% smokers manifest COPD, suggesting a role of genetic predisposition. Although genome-wide association studies have identified common genetic variants that are associated with the susceptibility to COPD, the odds ratios of these variants are much lower than those of familial form of emphysema, such as alpha 1 antitrypsin deficiency. We thus hypothesize that rare genetic variants contribute to the susceptibility to COPD. To test this hypothesis, we performed whole exome sequencing on 62 susceptible smokers with COPD (GOLD stage 3 or 4) and 30 resistant smokers with normal spirometries and without significant comorbidities. Overall we found a significantly higher mutation load in the genic regions of the susceptible smokers than the resistant smokers. However, the difference was mainly accounted for by non-coding regions and the number of loss-of-function mutations is not significantly different between the two groups. We then used the Variant Annotation Analysis Selection Tool (VAAST) to prioritize candidate disease-causing genes in susceptible smokers. We identified several hundred candidate genes that show higher prevalence of deleterious mutations in susceptible smokers. Among these candidates, we selected ~100 candidate genes with relatively high expression in human airway epithelial cells for function analysis using siRNA knockdown experiment. We identified several candidate genes that augment cigarette smoke extract-induced cytotoxicity in vitro. These potentially deleterious mutations of candidate genes may contribute to cigarette smoke-induced cytotoxicity, and potentially COPD.

Autism spectrum disorders and dystrophinopathy in three non-identical twins. *D.P. Moreira[1], M. Lazar[1], K.M. Rocha[1], M. Aguena[1], G. Yamamoto[1], G.S. Kobayashi[1], M.S. Naslavsky[1], M.L. Lebrao[2], Y. Duarte[2], R.C.M. Pavanello[1], M. Zatz[1], M.R. Passos-Bueno[1].* 1) HUG-CELL, Dept of Genetics and Evolutionary Biology, Institute of Biosciences - University of Sao Paulo, São Paulo, SP., Brazil; 2) School of Public Health - University of Sao Paulo, Sao Paulo, SP, Brazil.

Autism spectrum disorders (ASD) are a genetically complex group of neurodevelopmental disorders that have been reported either as an isolated condition or in association with some syndromes. Among them, it has been shown that about 4% of patients with Duchenne/Becker muscular dystrophy (DMD/BMD) have ASD. Here we report three ASD-affected non-identical twins, of which two were also diagnosed with DMD. The ASD diagnosis was made according the DMS-IV-TR criteria. The two ASD-DMD patients harbor a 22-base-pair deletion involving exon 2 (c.64_69del [p.Ser22-Lys23nfs]) in the dystrophin gene, which was maternally inherited. Exome sequencing was performed in the two ASD-DMD patients in order to verify if they harbor other pathogenic mutations that could contribute to the ASD phenotype. To filter for the possible pathogenic variants, we considered only stop codon and frameshift mutations in heterozygosis or homozygosis, with a minor allele frequency (MAF) ≤0.01 in the Exome Variant Server (http://evs.gs.washington.edu/EVS) and 1000 Genomes (http://www.1000genomes.org) databases, and present in ≤5% of a cohort of 136 individuals whose exomes were sequenced at the same laboratory. This filtering led to 10 potential pathogenic mutations. Out of these variants, we highlight two mutations which, in addition to the dystrophin mutation, might contribute to the ASD phenotype: a heterozygous stop codon mutation in *OPALIN* and a frameshift mutation in *DPYSL4*, both of which have not been found in 600 Brazilian controls. *OPALIN* codes for a transmembrane glycoprotein present in oligodendrocytes and is related to myelination. *DPYSL4* plays regulatory roles in neuronal differentiation and death and in neurite outgrowth. Dystrophin is a cytoskeleton protein essential for neuron survival, and has already been associated with neurodevepmental disorders. However, the role of *OPALIN* and *DPYSL4* in these disorders has not been established. These preliminary findings suggest that the ASD phenotype in these boys might depend on at least two hits. We are currently validating these findings in the ASD non-DMD brother as well as in their parents. As the three sibs are twins, we cannot rule out the action of environmental factors contributing to ASD.

748S

Rare variants in high-risk pancreatic cancer susceptibility genes may increase risk for pancreatic cancer in some patients with and without *CDKN2A* mutations. *A.M. Goldstein[1], P. Ghiorzo[2], N. Gruis[3], M. Rotunno[1], M. Malasky[1,4], J. He[1,4], X. Zhang[1,4], L. Pastorino[2], G. Bianchi-Scarra[2], W. Bruno[2], L. Burdett[1,4], B. Hicks[1,4], K. Jones[1,4], S. Bass[1,4], S.J. Chanock[1,4], J. Boland[1,4], A. Hutchinson[1,4], M. Yeager[1,4], X.R. Yang[1], M.A. Tucker[1], Genoa Pancreatic Cancer Study Group.* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 2) University of Genoa, Genoa, Italy; 3) Department of Dermatology, Leiden University Medical Center, Leiden, Netherlands; 4) Cancer Genomics Research Laboratory, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, Maryland, USA.

Germline mutations in *CDKN2A*, the major known high-risk melanoma susceptibility gene, have been described in about 20% of familial melanoma kindreds. Several variables have been shown to be associated with an increased frequency of *CDKN2A* mutations, most notably pancreatic cancer (PC) in a family. The distribution of PC differs according to the specific *CDKN2A* mutation suggesting the importance of other factors in this association. However, the precise relationship between *CDKN2A*, melanoma and PC remains unknown. Only a small subset of individuals with *CDKN2A* mutations develops PC, thus, next-generation sequencing (NGS) may present a critical strategy for uncovering genes related to PC development in these families. Since PC patients with *CDKN2A* mutations have not been systematically assessed for mutations in other known high-risk PC genes, we conducted NGS to examine the known high-risk PC and/or hereditary pancreatitis susceptibility genes (*ATM, BRCA1, BRCA2, CDKN2A, PALB2, PRSS1, STK11, EPCAM, TP53, MLH1, MSH2, MSH6, PMS2, APC, VHL, XRCC2, MEN1, PALLD, FANCC, CTRC, CPA1, CFTR, CASR, SPINK1*). DNA was available for NGS on 29 PC patients from 21 American, Dutch, and Italian families with *CDKN2A* mutations and 12 Italian PC patients without *CDKN2A* mutations who had a personal or family history of melanoma. We interrogated exome data for rare deleterious (co-segregating) mutations in the 24 PC-related genes. Deleterious variants were defined as loss-of function (frameshift, nonsense, indel) variants or substitutions predicted to be damaging by most *in silico* algorithms examined. Rare was defined as frequency <0.01 in publicly available exome databases. As quality control, we confirmed all *CDKN2A* mutations in the 29 *CDKN2A*+ PC patients plus a known *BRCA2* frameshift mutation in a *CDKN2A*- PC patient. Rare, potentially deleterious variants were found in *ATM* (n=3), *EPCAM* (1), *MSH6* (1), *PMS2* (2), *CPA1* (1), and *CFTR* (1). Six of the 9 variants were in *CDKN2A*- PC patients (p=0.028). All *ATM* variants including a novel frameshift were found in *CDKN2A*- PC patients. The variants in the *CDKN2A*+ PC patients included a novel *PMS2* frameshift variant, a *MSH6* substitution (frequency=0.0001) somatically mutated in colon cancer, and a *CFTR* substitution (frequency=0.0003). The findings suggest that rare variants in known high-risk PC-related genes may contribute to PC risk in a subset of patients from melanoma-prone families with and without *CDKN2A* mutations.

749M

Whole Exome Sequencing of 75 Hereditary Prostate Cancer Families. *E. Ostrander[1], D. Karyadi[1], E. Karlins[1], B. Decker[1], L. McIntosh[2], S. McDonnell[3], S. Middha[3], D. Schaid[3], S. Thibodeau[4], J. Stanford[2].* 1) Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Rare inherited mutations are predicted to account for 5% to 10% of all prostate cancer (PCa) cases. However, few causative mutations have been identified. Whole-exome sequencing (WES) of large hereditary PCa (HPC) families offers a new strategy to address genetic heterogeneity in PCa in order to identify rare PCa susceptibility mutations with moderate to high penetrance. Only a small number of families segregating the same rare mutation are needed to highlight genes of potential importance in PCa susceptibility. We performed WES in 75 HPC families from the *PROGRESS* study. In total, 160 affected men were sequenced with one to six affected men sequenced per family. Median read depth was 64.5. GATK UnifiedGenotyper was utilized for SNV and indel detection. All samples were coordinately genotyped and genotype quality was set to 99.9% concordance with the SNP chip. After quality filters, 453,977 variants were identified and genotyped in the 75 HPC families. We searched for rare variants that segregate with prostate cancer in multiple families and are predicted to damage the encoded protein. Rare variants were defined as those with frequencies ≤ 2% in all populations from multiple databases: NHLBI ESP European American and African American, and the five 1000 Genome populations. Protein damaging variants were defined as either high-impact variants (stop gain/loss, start loss, frameshift or splice site acceptor/donor) or missense variants that are SIFT deleterious or PolyPhen probably/possibly damaging. After population frequency and protein impact filters, 22,139 variants including 2,002 high impact variants remained. In order to determine the segregation with PCa, we linked the exome sequencing data to haplotype data from the Omni Express 700K SNP Chip. This approach allowed us to determine how many affected men in each family potentially carried the identified variants and was especially valuable in the 44 families with only one affected sequenced. After comparing the frequency in our dataset to the population frequencies, 861 variants were enriched in our set and present in three or more families, 110 of those variants were in six or more families and 89 were predicted to segregate in at least 50% of the cases on average. We have selected over 350 of the 861 variants for follow up validation and analysis in our population-based, case-control study of approximately 1,300 cases and 1,150 controls.

750T

IDENTIFICATION OF GENETIC VARIANTS IN A CONSANGUINEOUS FAMILY WITH PSYCHOTIC CASES USING AUTOZYGOSITY MAPPING AND WHOLE-EXOME NEXT GENERATION SEQUENCING. *A. Al Amri[1], J. Ivorra[1], M. Ali[2], C. Logan[2], A. Cardno[3], J. Mullins[4], T. Mahmood[5], S. Khan[2], C. Johnson[2], S. Clapcote[1], C. Inglehearn[2].* 1) school of Biological Sciences, St. James's University Hospital, Leeds, West Yorkshire, United Kingdom; 2) Leeds Institute of Biomedical & Clinical Sciences, University of Leeds (UK); 3) Leeds Institute of Health Sciences, University of Leeds (UK); 4) College of Medicine, Swansea University (UK; 5) Leeds and York Partnership NHS Foundation Trust (UK).

Psychosis is a condition in which an individual losses contact with reality. It covers profound forms of psychiatric disorders including schizophrenia, bipolar and schizoaffective disorder. These are complex disorders but have been known to run in families. The biological changes taking place in psychosis are not yet well understood but there is clear evidence of the involvement of both environmental and genetic factors. Here we describe the genetic analysis of a first-cousin consanguineous family of eight offspring, with two psychosis-affected cases, that was recruited from the West Yorkshire Pakistani population. Autozygosity mapping was combined with next generation sequencing to identify putative causative mutations. By using Affymetrix Genome-Wide SNP 6.0 arrays, two homozygous regions shared by the two affected siblings were identified on chromosomes 5q14.3-5q14.5 and 9q22.33-9q33.3. Whole-exome capture was carried out on one affected sibling using the SureSelect All Exon V4 reagent and sequenced on an Illumina HiSeq 2500 platform. The sequence reads were aligned against the human reference genome (hg19) and processed in SAM/BAM format using Picard and GATK. Annovar was used to annotate the variants before filtering according to depth of coverage, minor allele frequency, zygosity, mapping information and pathogenicity profile. Four variants, located in the genes DFNB31, MUSK1, OR1J1 and NUP188, passed the filtering criteria and were identified as the best candidates in this family. Work to assess the implications of these mutations in psychosis is currently ongoing. Keywords: Psychosis, Autozygosity mapping, Schizophrenia.

751S

Haploinsufficiency for DLX4 is Associated With Abnormal Craniofacial Development and Upregulated BMP4. *A.L. Choi[1], S. Mandal[1], J. Talbot[2], D. Wu[1], M. Prochazkova[3], H. Perry[3], V.L. Gil-da-Silva-Lopes[4], R. Lao[5], E. Wan[5], P. Tang[5], P-Y. Kwok[5], O. Klein[3], B. Zhuan[6], A. Slavotinek[1].* 1) Dept Pediatrics, Division Genetics, Univ California, San Francisco, San Francisco, CA; 2) Department of Molecular Genetics, Ohio State University; 3) Department of Orofacial Sciences, University of California, San Francisco, San Francisco; 4) Department of Medical Genetics, University of Campinas, São Paulo Paulo, Brazil; 5) Cardiovascular Research Institute, University of California, San Francisco, San Francisco; 6) School of Stomatology, Wuhan University, China.

Cleft lip and/or palate (CL/P) is found in 1 in 600 to 1 in 900 live births and is the commonest structural birth defect in humans. We used exome sequencing in a female and her son who had bilateral CL/P, euryblepharon and lagophthalmos, but no other features of blepharocheilodontic syndrome (BCDS). We identified a single nucleotide deletion in the mother, c.546_546delG, predicting p.Gln183Argfs*57 and replacement of the terminal 57 amino acids of the protein in the Distal-less 4 (DLX4) gene. The sequence variant was absent from public databases, predicted to be deleterious and was verified in mother and son by Sanger sequencing. There are three Dlx homeobox clusters with closely located gene pairs (Dlx1/Dlx2, Dlx3/Dlx4, Dlx5/Dlx6) and DLX4 has not been previously associated with disease. Both wildtype and mutant DLX4 localized to the cell nucleus and transfection studies with Western blotting did not show that the mutant DNA was significantly degraded. We used antisense morpholinos (MOs) to reduce expression of the orthologous Danio rerio genes, Dlx4a and Dlx4b, and found that morphant larvae injected with Dlx4b alone and Dlx4b together with Dlx4a had severe jaw malformations and cyclopia that were dose dependent. We also injected human wildtype DLX4 mRNA and did not observe a phenotype, implying that haploinsufficiency, rather than gain of function, was likely. We used siRNA to knockdown DLX4 in human cells and found a consistent increase in BMP4 expression. Co-injection of Dlx4b MO with an antisense MO targeting Bmp4 was able to prevent, but not rescue the Dlx4b phenotype, as there was substantial toxicity from the dual injections. We sequenced DLX4 in three unrelated patients with BCDS, but could not demonstrate any sequence variants. We then sequenced DLX4 in 155 patients of Chinese ethnicity with non-syndromic CL/P and CP, but no sequence variants (not even synonymous) were observed. From the published literature, Dlx1/Dlx2 double homozygous null mice and Dlx5 homozygous null mice both have a cleft of the secondary palate and a girl with cleft palate had a de novo chromosome deletion with the proximal breakpoint just 88 kb downstream from DLX5, leading to the hypothesis that dysregulation of DLX5 caused the cleft. Despite the fact that we have only one family, we consider that the clefts are likely to be due to haploinsufficiency for DLX4 and our findings thus have significance for craniofacial morphogenesis and for human CL/P.

752M

EXOME SEQUENCING REVEALS A NOVEL *CUBILIN* MISSENSE VARIANT ASSOCIATED WITH ALBUMINURIA IN AMERICAN INDIANS. *N. Franceschini[1], P.E. Melton[2], K. Haack[3], C. Bizon[4], E.T. Lee[5], L.G. Best[6], L.A. Almasy[3], J.A. Umans[7], S.A. Cole[3].* 1) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Centre for Genetic Origins of Health and Disease, University of Western Australia, Crawley, Australia; 3) Texas Biomedical Research Institute, San Antonio, TX; 4) Renaissance Computing Institute, University of North Carolina, Chapel Hill, NC; 5) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 6) Missouri Breaks Research Industries, Inc, Timber Lake, SD; 7) MedStar Health Research Institute, Hyattsville, MD.

Cubilin mediates the uptake of albumin in kidney proximal tubules, and a missense variant in the gene *CUBN* was associated with albuminuria in individuals of European ancestry. We previously were unable to replicate these associations (rs1801239, minor allele frequency [MAF]=0.17) with urine albumin-to-creatinine ratio (UACR) in American Indians. To identify coding variants in *CUBN* associated with UACR, we sequenced it's coding regions in 94 unrelated participants of the Strong Heart Family Study (SHFS), a large family study of American Indians recruited without phenotype ascertainment. We tested associations of log-UACR with each variant annotated to *CUBN* using linear regression methods, and additive genetic models adjusted for age, sex and its interactions. In a secondary analysis, we additionally adjusted for diabetes, and performed associations with clinically defined albuminuria (UACR≥ 30 mg/g) using logistic regression methods. Linkage disequilibrium (LD) was estimated from the data. The mean participant age was 57 years, 43% were men, and 55% had diabetes. The median UACR was 13 mg/g and 37% had UACR≥ 30 mg/g. Whole exome sequencing (mean call rate=0.98, Ti/Tv =2.50 and average variant read depth = 37x) identified 73 *CUBN* variants, 15 not previously described in publicly available databases, and 6 missense variants. In analysis of variants with MAF ≥ 0.03, a missense variant (rs1276712, MAF= 0.09 in American Indians) was significantly associated with UACR (beta 0.81, SE= 0.28, p=0.0048) when accounting for multiple testing. This variant explained 8.8% of the inter-individual variance of the trait, and it was associated with clinical albuminuria (odds ratio 4.4, p=0.02). The association was attenuated when adjusting for diabetes (p=0.02). rs1276712 is not in LD with the European ancestry rs1801239 (r^2=0.003 in American Indians), which was not significant in our data (p=0.55). rs1276712 C allele results in an amino-acid change (C2162Y) at cubilin domain 15, a site of direct interaction of cubilin with megalin, and required for albumin update at the proximal tubule. In conclusion, this study identified a novel and independent association of a *CUBN* missense variant with UACR and increased albuminuria in American Indians, suggesting allelic heterogeneity at this locus. Future studies will examine the impact of this variant in changes in albuminuria over time, and other clinically relevant chronic kidney disease outcomes.

753T

Examining Associations Between Multiple Sclerosis Cognitive Impairment and Genes Previously Associated with Cognitive Decline in Other Disease. *C. Holingue[1], M. George[1], C. Schaefer[2], A. Bernstein[3], R. Whitmer[2], L. Barcellos[1,2].* 1) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, CA, USA; 2) Kaiser Permanente Division of Research, Oakland, CA, USA; 3) Palm Drive Hospital, Sebastopol, CA, USA.

Cognitive impairment due to multiple sclerosis (MS) affects over half of individuals with the disease. Cognitive deficits can range from impairments in memory to diminished visual/spatial processing. These symptoms can affect social/emotional function, employment status, and quality of life. Yet, there is great variability in the severity and type of impairment that individuals with MS experience. The current evidence regarding the risk factors for cognitive impairment is limited. A recent finding shows evidence for association between the ε4 variant of the *APOE* gene and exacerbated cognitive decline in MS cases (Shi et al. 2011), which is also implicated in Alzheimer's Disease. This suggests there may be associations between MS cognitive decline and polymorphisms in genes previously associated with neurodegeneration. The current study investigated the association between cognitive score in MS cases and polymorphisms in genes related to cognitive impairment. Cases were identified from Kaiser Permanente, Northern California Region (KPNC). A cognitive score was calculated using the TICS-M (Modified Telephone Interview for Cognitive Status) at study entry. All participants provided biospecimens for DNA extraction; DNA samples were genotyped using Illumina's Human 660K BeadChip with imputation based on the 1000 Genome Reference and utilizing the IMPUTE2 software. To choose candidate genes, the NCBI gene database was used to search for genes associated with "cognitive impairment" in humans and then genes associated with Alzheimer Disease, Parkinson's Disease, Depression, Learning and Memory were extracted from the "Genes to Cognition Online" website (www.g2conline.org). This resulted in a total of 51 candidate genes. A sample of 954 individuals were analyzed using PLINK. Linear regression was performed with each SNP in the one of the above genes as the independent variable and cognitive score as the dependent variable. The top two principal components, derived from EIGENSTRAT SMARTPCA were included as covariates in the model, in order to account for possible confounding by ancestry. No evidence for association was observed for SNPs in these genes. This is the first study to investigate cognitive impairment in MS in relation to a broad set of genes previously associated with neurodegeneration or depression.

754S

Genetic contribution to cerebral palsy. *G. McMichael[1], M.N. Bainbridge[2], E. Haan[3], M. Corbett[1,4], A. Gardner[1,4], S. Thompson[5], B.W.M. van Bon[6], C.L. van Eyk[1], J. Broadbent[1], C. Reynolds[1], M.E. O'Callaghan[1], L.S. Nguyen[4], D.L. Adelson[7], R. Russo[8], S. Jhangiani[2], H. Doddapanein[2], D.M. Muzny[2], R.A. Gibbs[2], A.H. MacLennan[1], J. Gecz[1,4].* 1) The Robinson Institute, University of Adelaide, Adelaide, Australia; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, USA; 3) South Australian Clinical Genetics Service, SA Pathology (at Women's and Children's Hospital), North Adelaide, Australia; 4) School of Pediatrics and Reproductive Health, The University of Adelaide, Adelaide, Australia; 5) Department of Pediatric Neurology, Women's and Children's Hospital, North Adelaide, Australia; 6) Department of Human Genetics, Radboud University Medical Center, Nijmegen, the Netherlands; 7) School of Molecular and Biomedical Science, The University of Adelaide, Adelaide, Australia; 8) Department of Pediatric Rehabilitation, Women's and Children's Hospital, North Adelaide, Australia.

Cerebral palsy (CP) is the most frequent cause of physical disability in childhood with a prevalence of 2-2.5 per 100 live births. It is largely sporadic and causally heterogeneous. Evidence of intrapartum fetal compromise is found at birth in <10% of cases. Several known epidemiological risk factors have been identified for CP including preterm delivery, intrauterine growth restriction and intrauterine infection. The contribution of genetic causes to CP is frequently overlooked. We performed whole exome sequencing of 183 cases with CP and their parents when available (98 trio and 67 duo cases). We used multiple prioritization criteria to identify potentially causative variants including the type of mutation (eg. protein truncating), involvement of a known disease gene, haploinsufficiency index, brain expression, Residual Variation Intolerance Score and Combined Annotation-Dependent Depletion. Based on these strict prioritization criteria, 10 de novo mutations were predicted to be causative for CP; three in known disease genes: TUBA1A (n=2), SCN8A (n=1) and KDM5C (n=1) and six in novel candidate CP genes: AGAP1, JHDM1D, MAST1, NAA35, RFX2 and WIPI2. Additionally, we found four inherited from an unaffected mother to affected son X-chromosome variants, in two known disease genes L1CAM and PAK3 and two novel candidate CP genes CD99L2 and ODZ1 respectively. In summary, 14% of CP cases have a predicted pathogenic disease variant with 8 occurring in novel candidates for CP. The genetic heterogeneity of CP revealed by these results reflects the complex and clinically variable nature of this disorder. These results highlight a previously unappreciated role for the contribution of genetics to CP causation, which will influence future management, especially genetic counselling.

755M

Testing the effect of compound heterozygosity on anthropometric traits in the general population. *S. Lessard[1], P.L. Auer[2], A. Giri[3], C. Schurmann[4], T. Karaderi[5], H. Yaghootkar[7], C. Lindgren[5,6], T. Edwards[3], T. Frayling[7], R.J.F. Loos[4], G. Lettre[1], GIANT ExomeChip Consortium.* 1) Montreal Heart Institute and Université de Montréal, Montreal, Quebec, Canada; 2) University of Wisconsin, Milwaukee, Milwaukee, USA; 3) Vanderbilt University, Nashville, USA; 4) Icahn School of Medicine at Mount Sinai Hospital, New York, USA; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK; 6) Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge 02142, MA, USA; 7) Genetics of Complex Traits, University of Exeter Medical School, University of Exeter, Exeter, UK.

Background: In Mendelian genetics, a recessive disease can result when two different recessive alleles in the same gene are inherited in trans, that is on each copy of the gene. This genetic mechanism - termed compound heterozygosity - is observed for several monogenic disorders, such as phenylketonuria and sickle cell disease. However, the role of compound heterozygosity in human complex diseases and traits has not been explored extensively. **Method:** We analyzed height, body mass index (BMI) and waist-to-hip ratio (WHR) in up to 68,000 individuals from 9 studies included in the GIANT ExomeChip Consortium. We applied inverse normal transformation on phenotypes after adjusting for sex and age. All participants were genotyped using the Illumina ExomeChip. We defined compound heterozygotes as individuals that carry at least two loss-of-function variants in the same gene, assuming that such variants are rare and not inherited in cis. We compared the phenotypic mean in compound heterozygotes to the mean in the remaining individuals, and assess statistical significance using phenotype permutations. We combined results across studies using a weighted Z-score meta-analysis method, where the weight is the sample size of the corresponding study. **Results:** By considering 5,624 nonsense and 10,578 splice site variants genotyped on the ExomeChip, we identified at least one compound heterozygote for 2,911 genes for height, 2,664 genes for BMI and 1,795 genes for WHR. No genes reached a Bonferroni-corrected threshold for statistical significance ($P<6\times10^{-6}$). However, there was a strong signal for the cyclin D1 gene with height (*CCND1* $P=1.9\times10^{-5}$) and the parathyroid hormone-like hormone gene with WHR (*PTHLH*, $P=9.9\times10^{-5}$). In both cases, however, the signal was due to a common variant and reflects a "true" recessive signal. The strongest compound heterozygosity signal observed is for BMI with the taste receptor gene *TAS1R1* ($P=5.1\times10^{-4}$, five nonsense variants included). The BMI of the 137 *TAS1R1* compound heterozygotes is on average 0.74 kg/m2 higher than the BMI of the remaining 40,210 participants. **Conclusion:** The role of compound heterozygosity has rarely been tested in the context of complex human diseases and traits. Here, we successfully developed a method of analysing this model in large meta-analysis data. As with other studies of predominantly low-frequency and rare variants, our data suggest that very large sample sizes will be needed to detect robust associations.

756T

Locating new genes which may be involved in the development of Primary Congenital Glaucoma. *D. Bercovich[1], A. Wolf[2], O. Geyer[2].* 1) Human Molec Gen & Pharm, Tel Hai College, Galile Elyon, Israel; 2) Department of Ophthalmology, Carmel Medical Center, Israel.

Since there are Primary Congenital Glaucoma patients (PCG) who do not contain mutations in genes known to be involved in this disease (like the CYP1B1, MYOC & FOXC1 genes), prenatal screening and diagnosis in fetuses suspected with this disease is not viable. Furthermore, after birth, it is difficult to accurately identify primary Congenital Glaucoma, in many cases it is miss-diagnosed as another syndrome associated with eye diseases. The main problem is the Jewish population, in which individuals with significant mutations in these genes is rare. In order to locate the gene (or genes), which may be involved in this disease, Full sequencing of the whole Exom was preform by next generation sequencing (NGS) method to identify new loci with point mutations or possible copy number variations. 6 PCG Jewish patients from different ethnic groups (Ashkenazi, Sfaradi, Balkan and Ethiopia) and two parents pairs, to combine this data with their patients NGS (a total of 10 DNAs) were screened. 87 different genes were found be possible candidates in the recessive model. All DNA alterations were found to be in the same way in the parents as well which exclude them as been the pathogenic DNA alterations. One locus with CMA was found to be varied among Congenital Glaucoma patients and family members. This indicated that copy number around this gene could contribute somehow to the Congenital Glaucoma phenotype and more investigation may be done and this possible connection of this gene.

757S

Genome-wide Copy Number Variants in Chronic Obstructive Pulmonary Disease (COPD). *F. Begum[1], I. Ruczinski[2], S. Li[3], M. Parker[1], J. Hetmanski[1], T. Beaty[1], E. Silverman[4], J. Crapo[5], COPDGene Investigators.* 1) Department of Epidemiology, Johns Hopkins University, Baltimore, MA., USA; 2) Department of Biostatistics, Johns Hopkins University, Baltimore, MA, USA; 3) Cancer Genomics Research Laboratory (CGR), Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 4) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA; 5) Department of Medicine, National Jewish Health, Denver, USA.

Chronic Obstructive Pulmonary Disease (COPD), a common lung disease, is the third leading cause of death in the United States. This chronic and progressive disease has both environmental (mainly cigarette smoking) and genetic risk factors. Several genome-wide association studies (GWAS) have identified multiple genes influencing risk to COPD including *CHRNA3*, *FAM13A*, *HHIP*, *RIN3*, *MMP12*, and *TBFB2*. To properly understand the genetic etiology of COPD, it is also important to explore the role of copy number variants (CNVs) since the presence of CNVs can alter gene expression and may be causal for disease. We delineated CNVs using PennCNV on 9076 COPDGene study subjects using genome-wide marker data generated using Illumina's Omni-Express array. COPDGene subjects are comprised of one-third African-American and two-thirds Non-Hispanic white adult smokers, with or without COPD After employing rigorous quality control procedures to reduce the false positive CNV calls, we tested for association between CNV components (defined as disjoint intervals of copy number regions within race) and several COPD related phenotypes. We detected hemizygous deletions that achieved genome-wide significance on chromosome 5q35.2, near the gene *FAM153B*, in tests of association with total lung capacity assessed by chest CT among African-Americans. This region includes multiple reported CNVs, and we are currently following up on this signal.

758M

Investigating the role of salivary amylase copy number in obesity using low-pass whole genome sequencing. *M.A. Tuke[1], A.R. Wood[1], L. Harries[6], L. Boquete-Vilarino[1], M. Nalls[2], D. Hernandez[2,3], S. Bandinelli[4,5], A. Singleton[2], D. Melzer[6], L. Ferrucci[7], M.N. Weedon[1], T.M. Frayling[1].* 1) Genetics of Complex Traits, University of Exeter Medical School, Exeter, UK; 2) Laboratory of Neurogenetics, National Institute of Aging, Bethesda, Maryland, USA; 3) Department of Molecular Neuroscience and Reta Lila Laboratories, Institute of Neurology, UCL, London, United Kingdom; 4) Tuscany Regional Health Agency, Florence, Italy, I.O.T. and Department of Medical and Surgical Critical Care, University of Florence, Florence, Italy; 5) Geriatric Unit, Azienda Sanitaria di Firenze, Florence, Italy; 6) Institute of Biomedical and Clinical Sciences, University of Exeter Medical School, Barrack Road, Exeter, UK; 7) Longitudinal Studies Section, Clinical Research Branch, Gerontology Research Center, National Institute on Aging, Baltimore, Maryland, USA.

Copy number variation at the salivary amylase gene (AMY1) has recently been strongly associated with body mass index (BMI) and obesity (Falchi et al. Nature Genetics, 2014). Each additional copy of the AMY1 gene was associated with an odds ratio of 1.19 for obesity compared to normal weight individuals and the variant was reported as explaining a larger proportion of the variance in BMI than the variant at the FTO/IRX3 locus. Here, we aimed to further replicate and characterise this association in the InCHIANTI study. We performed whole genome sequencing on 657 samples to an average depth of 7x. We aligned the reads to a repeat masked GRC build 37 reference genome using the mrsFAST alignment algorithm that can align single reads to multiple positions in the genome and so is optimal for regions of variable copy number. We derived an absolute copy number value for the full amylase region using mrCaNaVaR. We then regressed the resulting copy number against body mass index corrected for age and sex. We had between 88% to >99.9 power to detect association when assuming the published variance explained of between 1.73% and 7.94%. The preliminary analysis did not provide any evidence of an association between salivary Amylase copy number and BMI (P = 0.457). However, our work is ongoing and we are validating the association using quantitative PCR and expanding the analysis to several thousand individuals. In conclusion, our preliminary results do not support the association between BMI and salivary amylase gene copy number.

759T

Novel Missense Mutations in ABCC8 and Type 2 Diabetes in Pima Indians. *L.J. Baier, Y.L. Muller, K. Huang, A. Nair, B. Gene, A. Stacy, V. Ossowski, C. Wiedrich, E.J. Weil, R.G. Nelson, W.C Knowler, P.H. Bennett, R.L. Hanson, C. Bogardus.* PECRB, NIDDK/NIH, Phoenix, AZ.

To identify novel mutations that affect risk for type 2 diabetes in American Indians, we obtained whole genome sequence data on 335 Pima Indians. One initial analysis focused on identifying novel variants predicted to be damaging in genes previously implicated with type 2 diabetes. These variants are currently being genotyped in additional samples (N=7,355) for association analysis with type 2 diabetes. Using this approach, we identified 6 novel missense variants and one known variant (rs757110; predicts an Ala1369Ser) in the ABCC8 gene that encodes the sulfonylurea receptor 1 protein (SUR1). SUR1, together with inward-rectifier potassium ion channel encoded by the KCNJ11 gene, regulate insulin secretion by ATP/ADP-sensing. Rare activating mutations in SUR1 cause neonatal diabetes while rare inactivating mutations cause hyperinsulinemia of infancy. The common SNP rs757110 has been associated with type 2 diabetes in some studies, but in our sample had no association (minor allele frequency 0.39; odds ratio (OR)= 0.99 [95% confidence interval 0.88-1.11]; P= 0.9 adjusted for age, sex, birth year, fraction of Pima heritage). Of the 6 novel variants, 4 have been genotyped in follow-up samples to date (Arg1420His, Gly1316Gln, Met801Ile, and Ser165Leu) while 2 are pending genotyping (Asp691Glu and Lys1565Glu). Among the variants with follow-up genotypic data, Arg1420His provided the most compelling evidence for having a role in type 2 diabetes. Individuals with a His allele (243 heterozygotes and 1 homozygote; overall frequency = 0.02 in Pima Indians) were at higher risk for type 2 diabetes (OR= 1.96, 95%CI=1.4 -2.7; P= 6×10^{-5} adjusted as above) despite being leaner (BMI = 33.4 vs. 35.3 kg/m^2, respectively for Arg/His vs Arg/Arg; P= 0.002 adjusted for sex, age, birth year, and fraction of Pima). The one individual homozygous for the risk allele (His/His) had been diagnosed with hyperinsulemia and hypoglycemia at 4 months of age, and was diagnosed with type 2 diabetes at 3.5 years of age, suggesting a very profound phenotype for this variant in homozygosity. Arg1420 is located in the second nucleotide binding domain of SUR1 and therefore a substitution at this position is predicted to have a functional impact. In conclusion, whole genome sequencing identified potentially functional variation in ABCC8 that appears to contribute to type 2 diabetes in Pima Indians.

760S

Targeted sequencing of genes associated with type 2 diabetes in 6800 individuals. *V. Bansal[1,2], J. Gassenhuber[5], T. Phillips[1], G. Oliviera[1], N. Villarasa[1], R. Tisch[1], E.J. Topol[1], B.O. Boehm[3,4].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Department of Pediatrics, University of California San Diego, La Jolla, CA; 3) Department of Internal Medicine, Division of Endocrinology and Diabetes, University Medical Centre Ulm, Ulm, Germany; 4) Lee Kong Chian (LKC) School of Medicine, Nanyang Technological University, Singapore and Imperial College London, London, UK; 5) Sanofi-Aventis Germany GmbH, Frankfurt am Main, Germany.

Advances in high-throughput sequencing technologies present unprecedented opportunities for understanding the role of rare variants in complex diseases. For type 2 diabetes, more than 70 common genetic variants have been identified by extensive genome-wide association studies. We utilized a candidate gene approach to search for rare variants associated with type 2 diabetes and focused on genes within loci identified by GWAS for T2D and related traits, genes involved in monogenic forms of diabetes and additional genes linked to diabetes. The coding and 5' and 3' untranslated regions of 130 genes (1.2 megabases in total) were sequenced in 1880 cases (including 600 patients with age of onset < 40 years) and 1840 controls. To increase efficiency, sequencing was done in pools (20 individuals per pool) and library preparation for each pool was done using the Agilent SureSelect target enrichment method. To process the pooled sequence data generated in this study, we developed computational methods for variant calling, assessment of population stratification, and rare variant association analysis. Single variant association analysis and gene-based association analysis of rare variants using a number of statistical methods (CAST, Calpha, and SKAT) did not identify any new statistically significant associations. To increase power, we sequenced an additional 2100 type 2 diabetes cases and 1050 controls using the same approach. Joint analysis of rare variants in the two cohorts identified 10 variants (minor allele frequency in the 0.1-0.5% range) that were moderately associated with T2D with effects on the phenotype in the same direction. This list included a rare non-synonymous variant in the MTNR1B gene that was recently associated with T2D (Bonnefond et al, Nature Genetics 2012). In addition, we observed a significant excess of rare non-synonymous variants in the glucokinase (GCK) gene in T2D patients with an early age of onset. Our analysis suggests that rare variants that have a moderate to strong effect on the risk for type 2 diabetes are likely to have very low minor allele frequencies and sequencing of tens of thousands of individuals is needed to identify such variants. Ongoing work includes (1) genotyping of select rare variants in additional cohorts and (2) further phenotype analysis of individuals with specific variants of interest.

761M

Characterizing variation under linkage peaks in families. *K.L. Edwards[1], J.Y. Wan[1], C. Johnson[1], S. Santorico[2].* 1) Epidemiology, University of California Irvine, Irvine, CA; 2) University of Colorado, Denver Denver, CO.

Background: The Metabolic Syndrome (MetS) is a complex condition characterized by a cluster of CVD risk factors, including obesity, lipid abnormalities, hypertension and glucose intolerance. In our previous work using extended pedigrees with MetS and linkage analysis we identified three chromosomal regions with evidence for linkage to multivariate traits defined by clusters of MetS risk factors. Methods: Whole exome deep sequencing was performed (50x) using the library and exome capture with 62Mb target from Roche/Nimblegen SeqCap EZ v2.0 (~300,000 exons and flanking regions), the HiSeq sequencer, and GATK read processing. Whole exome sequencing was performed in a subset of linked families of European, Mexican, African and Japanese-American descent. Results: We provide a descriptive summary of rare and common variation found under one of the linkage peaks on chromosome 2. Results are based on sequencing 5 European American families consisting of two families (n=11 individuals) with linkage to the region and three families (n=17 individuals) with no evidence of linkage to the same region. Among the 267 biallelic variants in the linked families, 34 (12.7%) were possibly damaging (PolyPhen>0.80) and 72 had a CADD score >10. In the unlinked families 332 biallelic variants were identified, with 48 variants (14.5%) having a PolyPhen >0.80 and 92 variants with a CADD >10. The minor allele frequency of deleterious variants appears to be higher in our linked families, with 25% having an alternate allele frequency (AF) of 0.127 or below compared to 25% with an AF of 0.078 or below in the unlinked families. Among the linked families 6 variants (2.2%) were private and were not found in the unlinked families or 1000 Genomes. We also describe the distribution of variants in this same linkage region in Mexican, Japanese and African American families sequenced under the same project and compared to 1000 Genomes. Summary: Overall it appears that the frequency of rare and private mutations is higher in regions under linkage peaks.

762T

An exome-wide sequencing study for type 2 diabetes-associated kidney disease in African Americans. *M. Guan[1,2], P. Mudgal[2], J.G. Wilson[3], B.I. Freedman[4], D.W. Bowden[2,5,6], M.C.Y. Ng[2,5].* 1) Integrative Physiology and Pharmacology Program, Wake Forest University, Winston-Salem, NC., USA; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 3) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS, USA; 4) Department of Internal Medicine, Wake Forest School of Medicine, Winston-Salem, NC, USA; 5) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 6) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC, USA.

End-stage kidney disease (ESKD) is a significant worldwide public health concern; diabetes accounts for 44% of incident ESKD cases in the U.S. Previous GWAS from our group have identified several strongly associated SNPs for type 2 diabetic (T2D)-ESKD. However, the common SNPs identified in GWAS have modest effects and cumulatively explain only a small proportion of disease variance. Therefore, we evaluated the contribution of low frequency coding variants in T2D patients on dialysis or with high risk for T2D-ESKD (eGFR<30 ml/min/1.73 m^2) since these variants may harbor stronger effects. Exome sequencing data in 1,565 African Americans including 537 T2D-ESKD cases and 1,028 non-T2D, non-ESKD controls from the T2D-GENES Consortium exome sequencing study were examined. Single variant association was performed for an additive effect with a mixed linear model that corrects for sample structure and hidden relatedness (EMMAX). Sequencing Kernel Association Test (SKAT) was used for gene-based analyses with stronger weighting for rare SNPs. Nine rare variants from nine different genes were significantly associated with T2D-ESKD at exome-wide significance level (p<5E-7). The top signal was located in MRPL12 (rs62077220, p=2.25E-18, MAF=0.037) which encodes a 39S subunit protein for mammalian mitochondrial ribosomal proteins. Only two of nine T2D-ESKD associated genes from single variant analyses demonstrated modest significance in gene-based analyses. Interestingly, several regions achieved nominal significance in both tests. One of the novel genes was VPS33A, with single variant association at p=1.41E-5 (rs2271411, MAF=0.3) and gene-based p-value at 4.4E-4, respectively. VPS33A plays a vital role in segregation of intracellular molecules into distinct organelles. A mutation in VPS33B, which is an important paralog of VPS33A, was reported to be associated with arc syndrome (Arthrogryposis-renal dysfunction-cholestasis syndrome). Overall, these findings may partially explain the genetic predisposition to T2D-ESKD in African Americans. Replication in independent African American populations remains necessary.

763S

Exome chip meta-analysis identifies novel loci and low-frequency variants contributing to central body fat distribution. *A.E. Justice[1], H.M. Highland[2], K.L. Young[1], M. Graff[1], T. Increased central fat is a leading predictor of greater cardiometabolic risk. Recent work shows that genetic factors contribute to the distribution of central fat, measured here as waist to hip ratio adjusted for BMI (WHR^a), which is correlated with visceral adiposity (r=0.56). Also, among the loci with known association with WHR^a, more than half show marked sexual dimorphism. The genetic underpinnings of WHR^a may include rare and protein-coding variants with high penetrance and large effect sizes; however, the majority of genetic studies focus on common variants in European-descent populations. Thus, we set out to identify coding and low-frequency variants (LFVs) (MAF<5%) associated with central fat distribution across the human exome using exome array data from 90,224 women and 75,759 men of European (90%), African (8%), and Asian (2%) ancestries. We performed a two-stage meta-analysis using an inverse variance weighted approach: 1) ancestry-specific meta-analysis of the study-specific summary results for WHR^a; and 2) meta-analysis of ethnic-specific results. Analyses included up to 236,047 exome array single nucleotide variants (SNVs) (201,126 with MAF<5%). Four SNVs reached genome-wide significance (GWS) (P<5E-8) in men only, with one novel SNP in *RREB1* (MAF=40%, P=4.4E-9, β=0.03). A total of 16 SNVs reached GWS for women, including two novel loci in *RAPGEF3* (MAF=1.8%, P=7.6E-9, β=0.139) and *DNAJA3* (MAF=29%, P=3.4E-8, β=0.03). The non-synonymous LFV within *RAPGEF3* exhibited a much greater effect on WHR^a compared to common variants (β=0.026 to 0.062). Similar to previously identified WHR^a loci, *RAPGEF3* is involved in angiogenesis and the regulation of insulin secretion. Interestingly, RAPGEF3 activity is decreased in presence of progesterone, an ovulatory sex steroid present in high levels in women of reproductive age, potentially helping to explain the GWS for this locus in women, but not men. These observations highlight the importance of large-scale genomic studies for identifying central fat distribution susceptibility LFVs. We plan to extend our analyses to include a greater number of individuals from diverse ancestries, and to conduct gene-based association and pathway analyses to identify genes and pathways influencing central fat distribution. Such efforts will provide insights into the etiology of central fat distribution and may highlight population-specific variants that pose increased susceptibility among individuals at greater risk.

Thyroid hormones are essential for health and maintenance of metabolic balance. Work here aimed to identify genetic variants, including rare variants, associated with the heritable traits: thyrotropin (TSH) and free thyroxine (FT4) using whole genome sequencing (WGS) data from the UK10K Consortium. TSH and FT4 levels were standardized adjusting for age, age2 and sex. We analyzed data from the two UK10K cohorts (ALSPAC and TwinsUK N=2,287) and used an additional collection with WGS data (SardiNIA) and deeply imputed datasets (imputed to a joint 1000g and UK10K reference panel) to perform a meta-analysis for common variants (MAF >1%) associated with TSH and FT4 (N=16,335). We then undertook analysis of rare variants (MAF <1%) using sequence kernel association testing (SKAT) in 40 candidate genes and performed genome-wide complex trait analyses (GCTA) to explore the extent that common SNPs (MAF >1%) explained the variance in TSH and FT4. For TSH we report a novel variant at 3p25 (MAF= 23.5%, P=6.15×10-09) and a new independent variant in established locus (MAF=10.4%, P=5.94×10-14). Expression quantitative trait locus analysis revealed our variant at 3p25 modulates gene transcription in adipose, skin and whole blood cells. Methylation profiles also revealed evidence for methylation quantitative trait locus effects for our novel variant in an established locus (P=4.38×10-07). For FT4 we identified a low frequency variant in 18q11 (MAF=3.2%, P=1.27×10-09) tagging a rare functional variant (MAF= 0.4%, P=2.14×10-11) known to be associated with substantially raised FT4 levels through altered thyroxine binding in transthyretin. SKAT analysis also revealed a novel association with FT4 in chromosome 8p12 (P=2.53×10-06). GCTA analysis estimated that common SNPs (MAF>1%) explained 24% (95%CI 19, 29) and 20% (95%CI 14, 26) of TSH and FT4 variance, respectively (P=<0.0001). Our results demonstrate that the increased coverage in WGS population association studies allows novel association detection of both common and rare variants in thyroid function. Common variants collectively account for over 20% of the variance in TSH and FT4; a substantial advance on estimates from earlier genome-wide association studies.

765T

Gene-variants associated with familial mesial temporal lobe epilepsy identified by whole exome sequencing. *R. Secolin[1], P.A.O. Ribeiro[1], F.R. Torres[1], M.G. Borges[1], A.C. Coan[2], M.E. Morita[2], C.V. Soler[1], M.L. Santos[1], C.V. Maurer-Morelli[1], B.S. Carvalho[1], F. Cendes[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Department of Neurology, University of Campinas - UNICAMP, Campinas, SP, Brazil.

Background: Epilepsy is a common chronic neurological disorder that affects approximately 1% of the population worldwide. Familial mesial temporal lobe epilepsy (FMTLE) is a clinically well characterized syndrome with an autosomal dominant inheritance. **Objective:** To identify genes associated with FMTLE in two large families. **Methods:** Whole exome sequencing was performed in eight individuals from two FMTLE families (F-10 and F-26), including six patients and two unaffected parents. Exome was targeted with Nextera Rapid Capture Expanded Exome kit (Illumina™) and sequenced in a high-performance Hiseq Illumina 2500 sequencing machine (Illumina™) to obtain more than 50X average coverage per sample. A bioinformatics analysis was performed using the GATK software package. Sequences were aligned using BWA algorithm. Variant calling and functional prediction was performed using VariantAnnotator and SnpEff tools. We prioritized nonsynonymous, frameshift, splicing, and indel variants according to novelty, quality score, and putative pathogenicity. **Results:** We found a total 1,955,506 and 2,134,863 variants in F-10 and F-26 families, respectively. After bioinformatics processing, we identified 184 functional variants in F-10 and 193 in F-26, which are shared only by patients and absent in unaffected individuals. Among them, we observed three genes as potential candidates for FMTLE in the families studied. **Conclusions:** Putative roles related to formation of axon connections, protein-protein interaction, phosphorylation-dependent ubiquitination pathway make the three candidate genes identified relevant for FMTLE. **Supported by:** CEPID-BRAINN FAPESP, São Paulo, Brazil.

Mutations in Human Capicua Gene Found in Patients with CFD and NTDs. *Y. Lei[1], H. Zhu[1], M. Parker[1], W. Yang[3], G. Shaw[3], R. Finnell[1,2].* 1) Dell Pediatric Research Institute, Department of Nutritional Sciences, The University of Texas at Austin, Austin, Texas; 2) Department of Chemistry, College of Natural Sciences, The University of Texas at Austin, Austin, Texas; 3) Department of Pediatrics, Division of Neonatology, Stanford University School of Medicine, Stanford, CA.

Cerebral folate deficiency (CFD) syndrome is characterized by very low concentration of 5-methyltetrahydrofolate (5-MTHF) in cerebrospinal fluid, while folate levels in plasma and red blood cells are normal. Previously, mutations in several folate pathway genes, including hFRα (folate receptor alpha), DHFR (dihydrofolate reductase), and PCFT (proton coupled folate transporter) have been identified in CFD patients. In an effort to identify causal mutations for CFD, we performed whole exome sequencing analysis of DNA samples collected from a CFD patient, her healthy sibling, and her biological parents. A de novo mutation in human Capicua gene (CIC), c.1057C>T (p.R353X), was identified in the patient. The results were confirmed using Sanger sequencing. In addition, a missense mutation predicted to be damaging, c.1738G>GT (p.G580GC) was identified in another CFD patient. The CIC protein is a HMG-box transcriptional repressor. The DNA binding domain located at amino acid residues 200-268 binds the octomer sequence T(G/C)AATG(A/G)A. The mutation identified in the CFD patient, p.R353X, yields a truncated protein which still contains the DNA binding domain (HMG box), therefore it is still able to bind to its targets. CIC target binding octomer sequence has been found in the promoter regions of folate transport genes FOLR1, PCFT, RFC1, and DHFR, which is involved in folate metabolism. In the patient's induced pluripotent stem (iPS) cell, the p.R353X mutation down regulated FOLR1, PCFT and RFC1 gene expression compared with H9 stem cells and an iPS cell line from an individual with wildtype CIC. Chromatin immunoprecipitation assays demonstrated that CIC bound to the FOLR1, PCFT and RFC1 promoter in vitro. In dual-luciferase assay, the CIC protein repressed FOLR1 promoter transcription. CIC coding regions were also sequenced in 190 patients with spina bifida, a common form of neural tube defects (NTDs), from California. Four missense mutations (p.S68P, p.M379L, p.P484S, p.P896A) were identified. Three of the mutations (p.M379L, p.P484S, p.P896A) were predicted to be damaging by MutationTaster and FATHMM. When compared to the rare (<1%) missense mutation frequency (38/6464) based on NHBLI exome sequencing database, there is significant difference between the spina bifida cohort and the NHBLI cohort. Our findings suggest that human Capicua gene regulates folate transporter gene expression, and may play a role in the etiology of CFD and NTDs.

767M

Combining linkage analysis and whole-exome sequencing for the identification of novel ADHD-related variants in multi-generation pedigrees. *J. Corominas-Galbany[1], M. Klein[1], M. Onnink[1,2], S. Gross-Lesch[3], C. Jacob[3], A. Reif[3], M. Romanos[4], B. Franke[1,2], K.P. Lesch[3].* 1) Department of Human Genetics, Radboud university medical center, Nijmegen, The Netherlands; 2) Department of Psychiatry, Donders Institute for Brain, Cognition and Behaviour, Radboud university medical center, Nijmegen, The Netherlands; 3) Department of Psychiatry, Psychosomatics and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany; 4) Department of Child Psychiatry, Psychosomatics and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany.

Attention-Deficit/Hyperactivity Disorder (ADHD) is a highly heritable and multifactorial disorder characterized by inattention, and/or motor hyperactivity and impulsivity. Susceptibility loci for ADHD have been investigated in the recent years and valuable candidate genes have been suggested. Nevertheless, the understanding of the genetic basis of ADHD is still a challenge. Large multi-generation pedigrees with affected individuals allowed the identification of haplotype blocks shared among all ADHD-affected family members. The characterization of these region is essential for the identification of genes and variants that may be related to the ADHD phenotype. Hence, the main goal of this study is to combine linkage analysis with whole-exome sequencing (WES) in order to identify novel genetic ADHD risk factors. This study was performed with nine ADHD families of German descent, for which WES data was obtained from 3 or more affected individuals to detect rare and common genetic variants shared among all sequenced members of a family. WES was carried out using Agilent SureSelect All Exon 50Mb Target Enrichment kit and single-end sequencing on the 5500xl SOLiDTM System. All individuals were genotyped on GeneChip Human Mapping 50K Array Hind240 and SNP data was used to fine-map the ADHD-associated loci previously described. Rare and common candidate variants to be associated with ADHD were validated using Sanger sequencing. ADHD phenotype and haplotype co-segregation in large pedigrees points towards a dominant inheritance pattern of the disease. An initial genome-wide approach focused on one family allowed the identification of 7 rare variants, but none of them segregated with phenotype through the family. This result made us move to the inclusion of linkage analysis data, because segregation of ADHD does not have to be due to rare variants only. In fact the combination of several common and rare variants, each with small or intermediate effect, may underlie co-segregating haplotype blocks. Linkage analyses performed showed an haplotype co-segregating with ADHD-affected individuals at 9q31-9q32 that lead to the detection of several common and rare variants of interest in distinct genes. Validation of these variants and segregation analysis through the family are ongoing. This study uses a complementary strategy in addition to GWAS approaches to detect variants that may shed new light on our understanding of ADHD's genetic basis.

Targeted exome sequencing in extended pedigrees with type 2 diabetes identifies a novel diabetic nephropathy susceptibility gene. *M.G. Pezzolesi[1,2], A.M. Smiles[1], J. Skupien[1], J.C. Mychaleckyj[3], S.S. Rich[3], J.H. Warram[1], A.S. Krolewski[1,2].* 1) Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA.

Genome-wide linkage analysis in extended pedigrees from the Joslin Study of Genetics of Nephropathy in Type 2 Diabetes Family Collection (Joslin T2DN Family collection) previously identified several genomic regions with evidence of linkage for urinary albumin excretion levels or variation in renal function in individuals with type 2 diabetes (T2D). Several in independent studies have reported evidence of linkage to many of these same regions, however, to date no gene located within or near these loci that contributes to these diabetic nephropathy (DN) sub-phenotypes has been established. To advance these efforts, we recently performed targeted exome sequencing of all protein-coding genes across 6 loci (f4 genomic regions with evidence for linkage with urinary albumin excretion levels: chromosomes 5q, 7q, 21p, and 22q; and 2 genomic regions linked to variation in renal function: chromosomes 2q and 7p) using a custom target enrichment library followed by Next-Generation sequencing. A total of 662 members from 49 extended pedigrees in the Joslin T2DN Family collection were resequenced for the coding region of the 361 genes across the 6 linkage regions. Following quality control analyses, multi-sample variant calling was performed for 603 samples that exceeded 35X on-target read depth and with greater than 15-fold sequence coverage across 70% of the target regions. In total, more than 6,000 non-reference variants were identified, including > 1,200 missense and nonsense variants. Using data from the NHLBI's Exome Sequencing Project reference panel, rare functional variants were selected from among these variants and segregation analysis was performed in families contributing evidence of linkage to each of the 6 linked genomic regions. Analyses performed to date have identified 3 rare variants in the proline rich 14-like (*PRR14L*) gene that segregate in DN cases from 4 families with evidence of linkage on chromosome 22. These data suggest that rare variants in *PRR14L* account for the linkage peak identified at this locus and that this gene contributes to variation in urinary albumin excretion in individuals with type 2 diabetes.

769S

Mis-matches between adiposity and metabolic traits: A replicated genomewide association study for metabolic disparity. *L.J. Corbin[1], K. Burrows[1], M. Mangino[2], SM. Ring[3], NJ. Timpson[1].* 1) MRC Integrative Epidemiology Unit, University of Bristol, Oakfield House, Oakfield Grove, Bristol, United Kingdom; 2) DTR Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 3) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

Whilst increased Body Mass Index (BMI) is correlated with a range of cardio-metabolic risk factors two sub-phenotypes of obesity have been characterised that contradict this. Metabolically obese normal-weight (MNOW) individuals present with a normal BMI but have a poor metabolic profile. In contrast, metabolically healthy obese (MHO) individuals have high BMI, but do not suffer the metabolic disturbances expected. By developing a novel phenotypic outcome acting as an indicator of metabolic disparity, we explore the biological pathways underlying these sub-phenotypes using genomewide association analyses in two independent collections. Analyses were performed in a collection from the Avon Longitudinal Study of Parents and Children (ALSPAC, mean age 15.5yrs) and in a replication cohort of adults from the UK Adult Twin Registry (TwinsUK, mean age 50.9yrs). A compound phenotype was generated by subtracting standardised BMI from standardised fasting plasma glucose to yield a continuously distributed variable where positive values were indicative of "healthier" adiposity status relative to glucose, zero was indicative of matching adiposity/glucose status and negative values were indicative of "healthier" glucose status relative to adiposity. Genomewide analysis of this trait in ALSPAC (n=2584) gave evidence of association at the G6PC2 locus where each additional T allele at the well-known variant rs560887 was related to a -0.25(SE 0.04, p=3.9e-10) change in standardised disparity score. This was replicated in TwinsUK (n=2599)(-0.11(SE 0.04, p=0.003)) and a meta-analysis gave a joint p-value 6.1e-11. This signal was also seen when using DXA derived fat mass in place of BMI (meta-analysis p=4.4e-10) and, as anticipated, with an inverted beta coefficient when replacing glucose status with HOMA_b. This work illustrates how derived phenotypes can be used as indicators of disparity between adiposity and glycaemic traits. Using a standardised disparity score allows a powerful analysis of metabolic features avoiding the costly procedure of defining MONW and MHO by threshold. Results are in line with the carriage of additional T alleles at G6PC2(rs560887) being associated with improved glycaemic profile. Work here did not yield signals of variants showing independent contributions to adiposity; this likely the result of genetic architecture and the causal effect that BMI has on many downstream, causal effects.

770M

Association analysis of exome chip data of Polycystic Ovary Syndrome in Estonian Biobank. *R. Magi[1], A.P. Morris[1,2,3], T. Karaderi[2], T. Laisk-Podar[4], T. Tammiste[4], A. Metspalu[1], A. Salumets[4,5], C.M. Lindgren[2,6].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Department of Biostatistics, University of Liverpool, Liverpool, UK; 4) Department of Obstetrics and Gynaecology, University of Tartu, Tartu, Estonia; 5) Institute of Bio- and Translational Medicine, University of Tartu, Tartu, Estonia; 6) Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge, MA, USA.

Polycystic ovary syndrome (PCOS) is a common multifactorial disease affecting up to 10% of women of reproductive age, therefore being their most frequent endocrine problem. It is one of the leading causes of female subfertility as ~40% of women with PCOS are infertile. Genome-wide association studies (GWAS) have revealed several candidate genes, but most of the heritability of PCOS is unexplained. To investigate the contribution of potentially causal coding variants to PCOS, we have genotyped 167 cases and 711 population controls (363 females) from the Estonian Biobank with the Illumina exome array.

We conducted single variant and burden tests of association using SKAT-O within genes for (i) loss of function (LOF) and (ii) rare non-synonomous (NS) variants with minor allele frequency (MAF) <1%). The association analyses were adjusted for first two principal components to account for the population stratification. In the autosomal analysis, both male and female samples were used in the control group but in the X chromosome analysis, only female samples were used.

Altogether 55,345 polymorphic variants were successfully tested in single variant analysis. It revealed one missense variant which was showing exome-wide evidence of association ($p<5\times10^{-7}$, Bonferroni correction for 100,000 variants): exm233350 in the nebulin coding *NEB* gene ($p=4.9 \times 10^{-9}$, MAF=0.05%). Mutations in *NEB* have previously been associated with myopathy and muscle structure. None of the associations were statistically significant in the gene-based tests after multiple testing correction for 20,000 genes ($p<2.5\times10^{-6}$). The strongest associations came from aggregating non-synonymous rare variants within *POLK* ($p=4.3 \times 10^{-5}$) and *PELI3* (7.3×10^{-5}) gene, which are DNA replication and immune response related genes.

Our study suggests that rare variants can contribute to the genetic component of PCOS, but cannot explain previously reported association signals in established GWAS loci.

771T

Large-scale exome chip genotyping reveals novel coding variation associated with endometriosis. *A.P. Morris[1,2,3], R. Mägi[2], N. Rahmioglu[3], A. Mahajan[3], N. Robertson[3], M. Peters[4], M. Saare[4], A. Salumets[4,5], K.T. Zondervan[3], UK Exome Chip Consortium.* 1) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom; 2) Estonian Genome Centre, University of Tartu, Tartu, Estonia; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) Department of Obstetrics and Gynaecology, University of Tartu, Tartu, Estonia; 5) Institute of Bio- and Translational Medicine, University of Tartu, Tartu, Estonia.

Genome-wide association studies (GWAS) have identified nine loci harbouring common variants associated with endometriosis. However, these variants typically map to non-coding genomic regions, and together explain only ~3% of the estimated 52% heritability of the condition. To investigate the contribution of coding variation to endometriosis pathogenesis, we undertook genotyping with the Illumina Exome Chip of two studies of European ancestry: (i) 910 cases from the Oxford Endometriosis Gene (OXEGENE) study and 13,334 population controls (6,828 females) from the UK Exome Chip Consortium; and (ii) 326 cases and 711 population controls (363 females) from the Estonian Biobank. Within each study, we evaluated the association of endometriosis with: (i) individual coding variants; and (ii) burden/over-dispersion of loss of function (all frequencies) and rare non-synonymous (minor allele frequency [MAF] less than 1%) variants within genes using SKAT-O. Analyses were adjusted for principal components to account for population structure. Association summary statistics were combined across studies by meta-analysis (fixed-effect sample size weighted *Z*-score method for single variants and Fisher's method for gene-based tests). We conducted pathway analysis on the basis of single variant meta-analysis summary statistics using the most up to date curated pathway gene-sets from the molecular signatures database as implemented in MAGENTA. No individual coding variants achieved exome-wide significant evidence of association ($p<5\times10^{-7}$, Bonferroni correction for 100,000 variants). The strongest signals include deleterious missense variants in *TAF1L* (D141N, $p=1.5\times10^{-5}$, MAF= 0.077%) and *BMP3* (Y67N, $p=3.2\times10^{-5}$, MAF=2.7%). We observed exome-wide significant evidence of association ($p<2.5\times10^{-6}$, Bonferroni correction for 20,000 genes) with burden/over-dispersion of loss of function variants in *C16orf89* ($p=1.1\times10^{-6)}$ and rare non-synonymous changes in *NECAB3* ($p=1.7\times10^{-7}$), *ZNF485* ($p=1.1\times10^{-6}$), and *RSAD2* ($p=2.1\times10^{-6}$). MAGENTA analyses highlighted potential involvement of cell adhesion/structure, immune function and cancer-related pathways in endometriosis. Our study provides preliminary novel insight into the contribution of coding variation to the genetic component of endometriosis. None of the identified genes from these analyses map to established endometriosis loci, providing no support for the hypothesis that rare coding variation can explain common GWAS association signals.

772S

Association of Rare Variants with Cerebral Palsy by Whole Exome Sequencing. *JJ. Connolly[1], Y. Guo[1], D. Abrams[1], M. Oskui[4], M. Shevell[4], L. Tian[1], H. Hakonarson[1,2,3].* 1) Ctr Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA, USA; 2) Division of Human Genetics Dept of Pediatrics, Perelman School of Medicine, Philadelphia, PA, USA; 3) Pulmonary Medicine, CHOP, Philadelphia, PA, USA; 4) Departments of Pediatrics and Neurology/Neurosurgery, McGill University, Montreal, Canada.

Despite the fact that cerebral palsy (CP) is the most common motor disability of childhood, with a prevalence of 0.2-0.3% of live births, the basis of the majority of CP disorders is still unknown. Arguably the most widely-researched cause of CP is birth asphyxia, resulting primarily from adverse events during labor. However, several recent studies have suggested that this phenomenon only accounts for ~10% of CP cases. The pediatric biorepository at Center for Applied Genomics (CAG) includes 814 individuals diagnosed with CP. Of these, we selected 65 patients for whom evidence of a genetic cause is strongest (or evidence of environmental causes are weakest). Relevant exclusion factors include premature birth (<37 weeks), complications of pregnancy, complications of labor, and co-morbidity with known Mendelian disorders. Here, we present results from all 65 cases, who underwent whole exome sequencing (WES) at an average coverage of 65X, which was compared against a control set from the 1000 Genomes Project. Due to excessive rare variants in WES results, a burden test was applied. The total number of rare variants across a gene was tabulated in each individual and these totals were compared between cases and controls. Top associations (per SNP-set (Sequence) Kernel Association Test SKAT) included signals detected in *KANK3*, *RNF135*, *ADAP2*, and *SMURF1*.

773M

Whole Genome Sequencing for Discovery of Variants associated with Neuromyelitis Optica. *A. Day-Williams[1], K. Estrada[2,3], F. Zhao[2,3], T. Harris[1], B. Greenberg[4,5], D. MacArthur[2,3], J. Carulli[1].* 1) Computational Biology and Genomics, Translational Sciences and Technology, Biogen Idec, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, USA; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Neurology and Neurotherapeutics, University of Texas Southwestern Medical Center, Dallas, TX; 5) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX.

Neuromyelitis optica (NMO) is an autoimmune disorder of the central nervous system that affects the optic nerves and spinal cord. Auto-antibodies against Aquaporin 4 (AQP4) are found in ≈70 percent of NMO patients yet no association to AQP4 has been identified in small genome-wide association studies (GWAS), but associations to the HLA have been reported. We have performed the first whole-genome sequencing analysis of NMO by deep sequencing (>30X) 143 NMO patients and 658 population controls. We have performed joint variant calling of single-nucleotide variants (SNVs) and insertions/deletions (indels) using the GATK HaplotypeCaller yielding 42 million SNVs and 6.3 million indels. In addition, large deletions have been identified in the same cohort using GenomeSTRiP and to further investigate the role of the HLA we have also called classical HLA alleles from the sequencing data using the Omixon method. Quality control of the SNVs and indels includes concordance of non-reference alleles with whole-genome array genotypes, mean depth of coverage, Ti/Tv ratio, call rate, number of alternative alleles, number of singletons, number of indels, allelic balance, heterozygosity and heterozygote/homozygote ratio. We have performed single-variant association analysis using the Efficient Mixed-Model Association eXpedited (EMMAX) software which adjusts for ancestry and relatedness via a variance-component matrix and performs a 2-sided test. Gene-level association analysis was performed using the Sequence Kernel Association Test (SKAT) and collapsing methods to test for an aggregation or burden of rare variants per gene (or group of genes) based on different minor allele frequency and functional characterizations. We will present the results of the association analyses from the first whole-genome sequencing analysis of NMO as well as the HLA analysis and a detailed investigation of AQP4.

774T

Whole exome sequencing in a patient with multiple miscarriages identifies a novel candidate gene. *C. DEMETRIOU[1,3], N. SETO-SALVIA[1], A.C. THOMAS[1], E. CHANUDET[2], H. WILLIAMS[2], R. SHAHNI[1], M. BITNER-GLINDZICZ[1], P. STANIER[1], L. REGAN[3], G.E. MOORE[1].* 1) Genetics and Genomic Medicine, Institute of Child Health - University College London, London, UK; 2) Centre for Translational Genomics-GOSgene, UCL Institute of Child Health, London, UK; 3) Department of Obstetrics and Gynaecology, St. Mary's Campus, Imperial College London, London, UK.

Miscarriage is the most common pregnancy complication with up to 50% of women experiencing one or more early miscarriages (<10 weeks). Recurrent miscarriage (RM) is defined as 3 or more consecutive pregnancy losses and it affects about 1-2% of couples trying to conceive. The etiology of RM has been attributed to genetic defects, uterine anomalies, thrombophilia and endocrine defects.

This study involves a family of Bangladeshi origin in which the female proband has suffered a total of 29 early miscarriages and no successful pregnancies (17 occurred with her first partner, 5 with her second partner and 7 with her current partner). Her mother had 3 successful pregnancies but also 3 late miscarriages, and her two brothers both have two children. The patient was negative for all known RM risk factors tested.

Whole exome sequencing was performed on available samples including the patient, current partner and both brothers. Based on variant changes that were present in the patient but not present in the other family members or 4 Asian female controls, a list of genes was prioritized using the Ingenuity variant analysis program.

Four candidate genes were identified, *FKBP4*, *SERPINB2*, *MIRLET7D* and *CD46*, all with previously reported data linking the genes to infertility or other processes involved in pregnancy. We confirmed the variant changes found in these 4 genes in the family by Sanger sequencing and then sequenced these genes in our control and RM cohorts. These cohorts consisted of 120 White-European and 100 Asian female patients that had RMs and no live births as well as 100 Bangladeshi controls.

Four novel or rare missense variants (not reported in 1000 Genomes, dbSNP or exome variant server) were identified in one of these genes, which were present only in Asian patients but not those of white-European origin. All four were predicted to be damaging by several pathogenicity prediction programs. Functional analysis is being performed to investigate protein localisation and protein-protein interactions using cell transfection with constructs containing the 4 variants and 3 common SNPs (as controls) created by site-directed mutagenesis.

775S

The use of exome sequencing to identify single nucleotide variants associated with necrotizing enterocolitis in premature infants. *J.M. Devaney, A.L. Franklin, M. Said, Z. Tatari-Calderone, S. Vukmanovic, K. Rais-Bahrami, N.L.C. Luban, H. Gordish-Dressman, A.D. Sandler.* Children's National Medical Center, Washington, DC, United States.

Necrotizing enterocolitis (NEC) and spontaneous intestinal perforation are gastrointestinal emergencies in premature neonates. NEC is a common in neonates affecting approximately 11% of premature infants with a mortality rate of from 20% to 40%. Recent studies have suggested that genetic polymorphisms, specifically variants in genes affecting inflammation, may contribute to susceptibility for neonatal bowel inflammation and NEC. We utilized whole exome sequencing (WES) to search for variants that may increase the risk of developing NEC. Buccal swabs were collected for DNA extraction from infants ≤ 32 weeks gestation with and without a diagnosis of NEC. Infants with congenital heart disease, congenital anomalies, and inherited blood/metabolic were excluded. We performed exome sequencing using an Illumina TruSeq Exome Enrichment Kit on an Illumina HiScanSQ system for 54 samples (n = 27 without NEC; n = 27 diagnosed with NEC). We aligned the resulting reads to the hg19 reference genome with BWA, applied GATK base quality score recalibration, indel realignment, duplicate removal, and performed SNP and INDEL discovery. Variants were annotated using ANNOVAR. We analyzed 11 genes (*IL17A*, *IL17B*, *IL17D*, *IL17F*, *NFKB1*, *NFKB2*, *IL1A*, *IL1B*, *IL6*, *PTAFR*, and *TLR4*) for non-synonymous or missense variants generated by WES and selected 26 variants that we tested for an association with development of NEC. None of the variants tested were associated with the development of NEC. However, we uncovered 26 candidate variants in inflammatory genes. None of the discovered variants were associated with the development of NEC. In this limited, candidate gene approach to the analysis of WES data, we did not discover a causal variant for NEC; however, we will be expanding the search for variants to the entire exome.

776M

Whole-exome imputation of sequence variants identified two novel alleles associated with adult body height in African Americans. *M. Du[1,10], P.L. Auer[2], S. Jiao[1], J. Haessler[1], D. Altshuler[3], E. Boerwinkle[4], C.S. Carlson[1], C.L. Carty[1], Y.I. Chen[5], K. Curtis[1], N. Franceschini[6], L. Hsu[1], R. Jackson[7], L.A. Lange[8], G. Lettre[9], K.L. Monda[6], D.A. NIckerson[10], A.P. Reiner[1], S.S. Rich[11], S.A. Rosse[1], J.I. Rotter[3], C.J. Willer[12], J.G. Wilson[13], K. North[6], C. Kooperberg[1], N. Heard-Costa[14], U. Peters[1], National Heart, Lung, and Blood Institute (NHLBI) Go Exome Sequencing Project.* 1) Fred Hutchinson Cancer Research Center, Seattle, WA., USA; 2) University of Wisconsin-Milwaukee Joseph J. Zilber School of Public Health, Milwaukee, WI; 3) Broad Institute, Cambridge, MA; 4) The University of Texas Health Science Center at Houston, Houston, TX; 5) LABioMed at Harbor-UCLA Medical Center, Torrance, CA; 6) University of North Carolina Gillings School of Global Public Health, Chapel Hill, NC; 7) The Ohio State University Wexner Medical Center, Columbus, OH; 8) University of North Carolina School of Medicine, Chapel Hill, NC; 9) Montreal Heart Institute and Université de Montréal, Montreal, Quebec; 10) University of Washington, Seattle, WA; 11) University of Virginia School of Medicine, Charlottesville, VA; 12) University of Michigan Medical School, Ann Arbor, MI; 13) University of Mississippi Medical Center, Jackson, MS; 14) Boston University School of Medicine, Boston, MA.

Adult human body height is a quantitative trait for which genome-wide association studies (GWAS) have identified numerous loci, primarily in European populations. These loci, composed of common variants, explain less than 10 percent of the phenotypic variance in height. Here, we searched for novel associations between height and common (minor allele frequency, MAF≥5 percent) or less frequent (0.5 percent<MAF<5 percent) variants across the exome in African Americans. Using a reference panel of 1,692 African Americans and 471 Europeans from the National Heart, Lung, and Blood Institute's (NHLBI) Exome Sequencing Project (ESP), we imputed whole-exome sequence data into 13,719 African Americans with existing array-based GWAS data (discovery set). Variants achieving a height-association threshold of P<5E-06 in the imputed dataset were followed up in an independent sample of 1,989 African Americans with whole-exome sequence data (replication set). We used a Bonferroni-corrected P<2.5E-07 (=0.05/196,779 whole-exome sequence variants) to define statistically significant associations in meta-analyses combining the discovery and replication sets (N=15,708 participants). We discovered and replicated 3 independent loci for association following Bonferroni-correction: 5p13.3/*C5orf22*/rs17410035 (MAF=0.10, β=0.64 cm, P=8.3E-08), 13q14.2/*SPRYD7*/rs114089985 (MAF=0.03, β=1.46 cm, P=4.8E-10), and 17q23.3/*GH2*/rs2006123 (MAF=0.30; β=0.47 cm; P=4.7E-09). Conditional analyses revealed that 5p13.3 (*C5orf22*/rs17410035) and 13q14.2 (*SPRYD7*/rs114089985) harbored novel height alleles independent of previous GWAS-identified variants in all populations (r2<0.01 with GWAS loci); in contrast, 17q23.3/*GH2*/rs2006123 was correlated with GWAS-identified variants in European and African populations. Notably, 13q14.2/rs114089985 is uncommon in African Americans (MAF=0.03) and is monomorphic in European and Asian populations, suggesting it is an African American-specific height allele. In summary, our findings demonstrate that whole-exome imputation of sequence variants can identify low frequency variants as well as discover novel variants in non-European populations.

777T

Next steps for whole exome sequenced cases: imputing non-coding regions and incorporating whole genome sequenced controls. *A.E. Hendricks[1,2], S.A. McCarthy[2], I.S. Farooqi[2], E. Zeggini[2], I. Barroso[2], UK10K Obesity Group.* 1) Mathematical and Statistical Sciences University of Colorado -- Denver, CO; 2) Wellcome Trust Sanger Instititute, Cambridge, CB10 1HH.

The number of whole-exome sequenced (WES) case, or case-control, sets has recently increased substantially. After researchers complete an initial family or case-control exome based analysis, one might ask what else can be done. Two possible ways to proceed are to impute non-sequenced regions or to use external data sets to increase the number of samples in the control set and subsequently the power to detect association. Here, we do both.

Others have shown that imputation of non-coding regions and association tests of simulated quantitative phenotypes is possible given the <1x off target reads produced by high-depth WES. Here, we investigate the imputation and association of non-coding regions using real data from the UK10K project (www.uk10k.org). Specifically, we use high depth (50x) WES case (N=926) and control (N=1233) samples as well as low depth (6x) whole-genome sequenced (WGS) control samples (N=3621). The case patients are from the Severe Childhood Onset Obesity Project consisting of UK white patients, with an age of onset below 10, and with a body mass index (BMI) Standard Deviation Score (SDS) > 3, a design that is enriched for rare, highly penetrant causes of obesity.

We focus on case-control analysis, which is particularly susceptible to bias, and add WGS controls to an existing WES control set as well as use the WGS separately. Using IMPUTE2, we impute the WES cases and controls genome-wide with both the 1000Genomes only and 1000Genomes plus the UK10K WGS as the imputing backbone. As a true positive, we look for the FTO signal, a signal that is not in high LD with variants in the coding region and was thus notably missing when we performed our case-control analysis on the WES coding regions. We also work to show that, after sufficient quality control and filtering, we attain results without inflated test statistics despite imputation into non-coding regions and the use of WGS controls.

We believe this work is vital to getting the most information and benefit out of WES data. Successful research in this area will enable groups to increase power to replicate signals and find new genetic associations using WES case or case-control data regardless of whether the association is inside or outside of a coding region.

778S

Whole-exome DNA sequencing to find new variants associated with fetal hemoglobin levels. *K.S. Lo[1], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Faculté de Médecine, Université de Montréal, Montreal, Quebec, Canada.

The most promising strategy to treat patients with the commonest Mendelian diseases in the World - sickle cell disease (SCD) and beta-thalassemia - is to increase the endogenous production of fetal hemoglobin (HbF). HbF is a highly heritable trait (h2~0.6-0.8) and genetic studies have identified SNPs at the *BCL11A*, *HBS1L-MYB* and *beta-globin* loci that are associated with its levels. To find new HbF-associated loci, and test the role of rare coding genetic variation, we sequenced the exome of 189 African-American patients with SCD selected from the lower and upper 10% tails of the HbF distribution. We achieved a mean coverage of 76X and identified 164,038 novel variants. Because a subset of these patients (N=164) is also genotyped on the Illumina ExomeChip, we estimated that 67% of the coding genetic variation in this African-American population is missed by the ExomeChip. More specifically, we identified 795 nonsense, 261 splice site and 45,966 missense variants that are not genotyped on the ExomeChip. As expected, these variants are mostly rare in SCD patients (mean minor allele frequency (MAF) =4.6%). Most of the variants polymorphic in the ExomeChip dataset were also identified by whole-exome sequencing (WES) (96%), confirming the high-sensitivity of our experiment. We carried out single variant- and gene-based analyses but did not identify new significant association with HbF level variation. The strongest novel association is in *LINC00908* (P= 2.3×10-5, MAF=5.8%), a long intergenic non-protein gene coding RNA. To increase statistical power, we imputed the coding variants identified by WES into 1279 SCD patients genotyped on the Illumina 610-quad array. We imputed successfully (RSQR>0.5) 906, 5,478 and 28,091 variants with MAF<1%, 1%≤MAF<5% and MAF≥5%, respectively. In testing this imputed dataset for association with HbF levels, we identified a strong signal with several missense variants in olfactory receptor genes on chromosome 11. However, these coding variants are in linkage disequilibrium with the HbF-associated *XmnI* polymorphism at the *beta-globin* locus. No other novel variants reached statistical significance in these analyses. In conclusion, although the initial 3 HbF-associated loci were identified in modest size populations, the remaining common and rare variants associated with HbF have small phenotypic effect sizes and we will need large cohorts to find them.

779M

Whole-Exome Sequencing Identifies Rare, Functional CFH Variants in Families with Macular Degeneration. *J. Seddon[1], Y. Yu[1], M. Triebwasser[2], E. Wong[3], E. Schramm[2], B. Thomas[4], E. Mardis[2], J. Atkinson[2], M. Daly[4], S. Raychaudhuri[5], D. Kavanagh[3].* 1) Tufts Medical Center, Department of Ophthalmology and Ophthalmic Epidemiology and Genetics Service, 800 Washington St. #450, Boston, MA 02111; 2) Washington University School of Medicine, St. Louis, MO; 3) Newcastle University, UK; 4) Mass. General Hospital, Boston, MA; 5) Brigham and Women's Hospital, Boston, MA.

We sequenced the whole exome of 35 cases and 7 controls from 9 age-related macular degeneration (AMD) families in whom known common genetic risk alleles could not explain their high disease burden and/or their early-onset advanced disease. Two families harbored novel rare mutations in CFH (R53C and D90G). R53C segregates perfectly with AMD in 11 cases (heterozygous) and 1 elderly control (reference allele) (LOD = 5.07, P= 6.7×10-7). In an independent cohort, 4 out of 1,676 cases but none of the 745 examined controls or 4300 NHBLI Exome Sequencing Project (ESP) samples carried the R53C mutation (P=0.0039). In another family of 6 siblings, D90G similarly segregated with AMD in 5 cases and 1 control (LOD= 1.22, P=0.009). No other sample in our large cohort or the ESP had this mutation. Functional studies demonstrated that R53C decreased the ability of FH to perform decay accelerating activity. D90G exhibited a decrease in cofactor-mediated inactivation. Both of these changes would lead to a loss of regulatory activity, resulting in excessive alternative pathway activation. This study represents an initial application of the whole-exome strategy to families with early-onset AMD. It successfully identified high impact alleles leading to clearer functional insight into AMD etiopathogenesis.

780T

Whole genome sequencing of 3,514 individuals from the founder population of Sardinia. *C. Sidore[1,2,3], F. Busonero[1,2,4], A. Maschio[1,2,4], M. Zoledziewska[1], A. Mulas[1,3], E. Porcu[1,2,3], G. Pistis[1,2,3], M. Steri[1], F. Danjou[1], A. Kwong[2], C.W. Chiang[7], R. Lyons[4], A. Angius[1,5], H.M. Kang[2], J. Novembre[6], S. Sanna[1], D. Schlessinger[8], F. Cucca[1,3], G. Abecasis[2].* 1) Istituto di Ricerca Genetica e Biomedica, CNR, Monserrato, Cagliari, Italy; 2) Center for Statistical Genetics, Ann Arbor, University of Michigan, MI, USA; 3) Università degli Studi di Sassari, Sassari, Italy; 4) University of Michigan, DNA Sequencing Core, Ann Arbor, MI, USA;; 5) Center for Advanced Studies, Research, and Development in Sardinia (CRS4), AGCT Program, Parco Scientifico e tecnologico della Sardegna, Pula,Italy; 6) Department of Human Genetics, University of Chicago, IL, USA; 7) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA, USA; 8) Laboratory of Genetics, National Institute on Aging, National Institutes of Health, Baltimore, MD, USA.

Recently, the combination of genome wide association studies with reference panels based on next generation sequencing has profoundly improved the resolution of genome analysis and the ability to identify causal variants associated with complex traits or diseases. The commonly used sequencing-based reference panels are usually based on diverse populations and do not allow imputation of population-specific variants, particularly those present in isolated populations. Here we substantiate the increased informativeness that is recoverable by further analysis of population-specific variation present in genetically distant populations, and especially in isolated founder populations whose genetic distance from more cosmopolitan groups is most marked. To investigate the Sardinian specific genetic variation we used whole genome sequencing (coverage ~4x) of 3,514 Sardinian individuals, identified >23M single nucleotide polymorphisms (SNPs) and generated a reference panel for imputation. Strikingly, for Sardinian individuals, imputation using our Sardinian reference panel was much improved for low frequency variants (MAF 0.5-5%) compared to imputation based on 1000 Genomes Project haplotypes (increasing r2 with directly measured genotypes from 0.59 to 0.90). We will show how relative isolation affects haplotype length, enrichment of deleterious variants, and genetic differentiation with Europeans. Next, we used this reference panel to study the genetics of LDL-cholesterol in the island by first imputing missing variants in 6,602 individuals from an isolated population in the Lanusei Valley genotyped with >800,000 SNPs. Variants detected by our sequencing explained >90% of the genetic heritability of LDL-cholesterol and point to many interesting association signals. Particularly interesting is the Q39X mutation in the HBB gene, common in Sardinia (MAF>5%) and very rare in Europe, not previously identified by any GWAS analysis. The variant results in a decrease of 14.4 mg/dl in blood among carriers (p < 10-21). Our results illustrate the benefits of large-scale sequencing efforts in founder populations and their ability to uncover functionally relevant variants that may be very rare elsewhere.

781S

Insights into the genetic architecture of anthropometric traits using whole genome sequence data. *I. Tachmazidou[1], G. Ritchie[1,2], J. Min[3], K. Walter[1], J. Huang[1], J. Perry[4], T. Keane[1], S. McCarthy[1], Y. Memari[1], UK10K consortium.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) European Molecular Biology Laboratory, European Bioinformatics Institute, Cambridge, United Kingdom; 3) MRC Integrative Epidemiology Unit, University of Bristol; 4) MRC Epidemiology Unit, University of Cambridge.

Body weight and fat distribution measures are associated with increased risk of cardiometabolic disease. As part of the UK10K study, we have investigated the genetic architecture of 12 anthropometric traits in 3,538 individuals with ~7x whole genome sequence (WGS) data from the ALSPAC and TwinsUK cohorts. Variants discovered through WGS, along with those from the 1000 Genomes Project (1KG), were imputed into additional individuals from the ALSPAC and TwinsUK cohorts with GWAS data, increasing the total sample size to 11,178. We investigated association between anthropometric traits and ~9 million variants with MAF≥0.01 and ~5 million variants with MAF 0.001-0.01. *In silico* replication was sought in 16 external cohorts for a total sample size of 15,000-40,000 depending on trait. To determine novelty of signals, we performed conditional analyses on all established variants within a 1MB window. We observe a significant excess of independent (r2<0.2) previously not reported variants with MAF>0.01 and p<10-5 in the UK10K discovery set in all anthropometric traits. We find significant enrichment of variants associated with BMI in UK10K and established monogenic obesity genes (binomial p=4.8×10-5). Further replication is ongoing, but interim analyses identify replicating signals, for example, variant chr5:105105444 (EAF 0.0084; UK10K p=4.69×10-5; replication p=2.53×10-4; overall p=5.53×10-8, beta -0.37, SE 0.07, sample size=27,687) is a novel signal associated with waist circumference adjusted for BMI, a measure of central adiposity. Waist to hip ratio is associated with variants at chr9:23016057 (EAF 0.003; UK10K p=6.11×10-5; replication p=2.92×10-04; overall p=5.98×10-8, beta 0.55, SE 0.10, sample size=25,373) and chr14:100931682 (EAF 0.001; UK10K p=5.18×10-2; replication p=2.88×10-07; overall p=8.11×10-8, beta 0.97, SE 0.18, sample size=18,212). These replicating signals are at variants with MAF<0.01, have modest effect sizes and are not present in HapMap. Imputation based on the combined UK10K and 1KG panel has helped identify these loci. Larger sample sizes are required for the identification and replication of further rare variant associations with anthropometric traits.

782M

Next generation association studies in isolated populations. *E. Zeggini[1], L. Southam[1,2], K. Panoutsopoulou[1], K. Hatzikotoulas[1], G.R.S. Ritchie[1], A-E. Farmaki[3], I. Tachmazidou[1], A. Matchan[1], N.W. Rayner[1,2], J. Schwartzentruber[1], I. Ntalla[3], E. Tsafantakis[4], M. Karaleftheri[5], G. Dedoussis[3], A. Gilly[1].* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 3) Harokopio University Athens, Athens, Greece; 4) Anogia Medical Centre, Anogia, Greece; 5) Echinos Medical Centre, Echinos, Greece.

Isolated populations have unique characteristics that can be leveraged to increase power in genetic association studies. In founder populations genetic drift can drive trait-associated alleles to higher frequency and thus enable the identification of rare variant associations with smaller discovery sets. We have collected samples from two isolated populations in Greece (HELlenic Isolated Cohorts study): the Pomak villages (HELIC-Pomak) in the North of Greece; and the Mylopotamos villages (HELIC-MANOLIS) on Crete. All samples (n~3000) have information on a wide array of anthropometric, cardiometabolic, biochemical, haematological and diet-related traits, genotypes from the Illumina OmniExpress and exome-chip platforms, and are being whole-genome sequenced at low depth. Using 1x WGS data from 995 (HELIC-MANOLIS) individuals, we demonstrate that over 80% of true low-frequency (0.01<MAF<0.05) variants are found, compared to an average 60% for 0.001<MAF<0.01 and 40% for MAF<0.001. Genotype concordance reaches >95% and minor allele concordance >90% across the whole MAF spectrum. We replicate known association hits, thereby providing a proof of concept for a robust processing pipeline for low-depth WGS variant calls. Using genotype data, we find that 80% of subjects have at least one "surrogate parent" in the isolates, compared to 1% in the outbred Greek population. In the MANOLIS cohort we observe an enrichment of missense variants amongst the variants that have drifted up in frequency by >5 fold. We have previously reported a lipid traits association with a functional variant in the APOC3 gene in 1267 individuals in MANOLIS. The equivalent sample size needed to detect this in the general European population would be 67,000. In the Pomak cohort we find novel associations at variants on chr11p15.4 showing large allele frequency increases (from 0.2% in the general Greek population to 4.6% in the isolate) with haematological traits, for example with mean corpuscular volume (at rs11035019, beta=-1.249, p= 3.45×10^{-29}). Their detection in cosmopolitan populations would necessitate thirteen times as many samples. We demonstrate the significant power gains that can be afforded by studying well-characterised founder populations.

783T

When nature meets science: longevity blueprint. *D. Ben-Avraham[1], S. Carmi[2], Y. Freudenberg-Hua[3,4], J. Freudenberg[5], K.Y. Hui[6], E. Kochav[2], X. Liu[7], J. Xue[2], F. Grady[2], S. Longevity has emerged as a proof of concept for a healthy lifespan. While life expectancy almost doubled during the last century, suggesting tremendous progress in medical treatment and life style improvement, the outcome (i.e. living longer) had resulted with increase prevalence of age-associated diseases, complex morbidities and frailty. Understanding the physiology of aging had placed its mark on a pallet of treatments resulting in partially enhancement of quality of life, setting the stage for genetic studies. However, a decade of research and numerous efforts attempting to decipher the genetic component of longevity have resulted in limited success. Here, we report of an effort to detect the genetic signature of longevity by using the most advance technology (Whole genome sequencing-WGS) as well as a population well fitted for such a genetic study (Ashkenazi Jews-AJ). We obtained whole genome sequences of 148 AJs (74 centenarian (By Illumina) and 74 elderly unrelated controls (By Complete Genomics-CGI)). Following structured filtration pipeline, we merged the two data sets guided by 5 samples that were sequenced on both platforms. Our genome-wide analysis identified ~6M SNVs that were concordant between both platforms and were further used for merging. We also applied additional quality control filters, resulting in filtering out 30% of the selected SNVs and leaving ~4.2M SNVs that were used for the case control analysis in the entire cohort. We evaluated the association with longevity using linear regression model of the ~4.2M SNVs in parallel (PLINK). Variants in 4 loci (rs78563403, rs67505584, rs8010307and rs59010232) reached p<10-7. Those loci were validated in imputed Human OmniExpress genotyping in 639 AJ cases and 473 AJ control. We further applied meta-analysis of the two datasets, revealing 2 segments on chromosomes 1 (rs1765725, rs1698975, rs1765724) and 13 (rs2182054, rs7319950, rs9550998) and 2 SNPs on chromosome12 (rs2710278, rs7961171) with p<10-7. This study highlights the utility of the Ashkenazi Jewish population in genetic research, where a small sample size was required to detect significant variant association in a complex polygenic trait.

784S

Quantitative trail loci for plasma proteins in current and former smokers with and without chronic obstructive pulmonary disease (COPD). *R.P. Bowler[1], W. O'Neal[2], K. Kechris[3], W. Sun[2], S. Jacobson[1], T.H. Chen[2], M.B. Drummond[4], R.E. Kanner[5], P.G. Woodruff[6], D. Couper[2], G.A. Hawkins[7], COPDGene and SPIROMICS.* 1) Department of Medicine, National Jewish Health, Denver, CO; 2) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Biostatistics and Informatics, School of Public Health, University of Colorado Denver, CO; 4) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Department of Medicine, University of Utah School of Medicine, Salt Lake City, Utah; 6) 5Department of Medicine and Cardiovascular Research Institute, University of California San Francisco, CA; 7) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston Salem, NC.

Background: Chronic obstructive pulmonary disease (COPD) occurs most commonly in current and former smokers and is the third leading cause of death in the United States. Genetic association studies have identified multiple genetic loci associated with COPD phenotypes such as airflow obstruction and emphysema. Similarly protein biomarker studies have identified blood biomarkers associated with these COPD phenotypes. The relationship between genetic markers and protein levels has not been explored in at risk subjects. **Methods**: Using two similar cohorts of older smokers (COPDGene and SPIROMICS), we explored the relationship between genome wide genetic markers and 96 candidate blood biomarkers for COPD in 750 (SPIROMICS) and 602 (COPDGene) non-Hispanic Whites. Genotyping was performed on Illumina platforms. Candidate COPD blood biomarkers were assessed in fresh frozen serum and plasma using 13 Myriad-RBM single and multiplex panels. *cis* and *trans* protein quantitative trait loci (pQTL) were identified using an additive regression model adjusted for covariates (age, gender, BMI, smoking status, pack-years), as well as genetic principal components, and correction for multiple comparisons. The Stouffer-Liptak test was used for the meta-analysis to combine the p-values from the two studies. **Results**: We identified 539 significant pQTL SNPs (69% *cis*; 31% *trans*) in 36 proteins. The top *cis*- association was for GC (rs7041; Vitamin D binding protein; P= 5 X 10^{-394}). This SNP leads to an Asp to Glu amino acid change at position 432 of the protein and is associated with more severe COPD. The top trans association was rs507666 (chromosome 9) for SELE (chromosome 1; E - selectin; P = 7 X 10^{-103}). This SNP is an intron variant in ABO (alpha 1-3-N-acetylgalactosaminyltransferase) and has also been associated with blood group and altered glycosyltransferase activities. Other notable pQTLs include rs2070600, a non-synonymous *cis*-SNP (P = 4 X 10^{-22}) located in exon 3 of AGER (advanced glycation end product receptor), which leads to a glycine to serine amino acid change at position 82 and is associated with emphysema. **Conclusions**: This is the largest integration of genetics and protein biomarkers in two highly phenotyped cohorts. It demonstrates how genetic variation influences intermediate phenotypes of disease (e.g. protein biomarkers) and may allow us to begin to unravel the mechanisms through which genotype influences disease risk.

785M

Low-frequency coding variants associated with female reproductive ageing. *K.S. Ruth, ReproGen consortium (www.reprogen.org).* Genetics of Complex Traits, University of Exeter Medical School, Exeter, United Kingdom.

Background: Genome-wide association studies (GWAS) have identified over 100 loci associated with age at menarche and 18 for age at natural menopause. The majority of these variants are common (minor allele frequency (MAF) > 5%), have small effect sizes, and in aggregate explain a small fraction of the population variation in these reproductive ageing traits. It is predicted that functional genetic variants with lower MAF, but larger effects on phenotype, may contribute substantially to the genetic variance underlying these traits.

Aim: To identify low-frequency coding variants contributing to the genetic variation in age at menarche and age at natural menopause.

Methods: Exome chip genotyping data were collected from 17 studies of European populations. Single marker and burden testing meta-analyses were carried out in 67,628 women for age at menarche and 35,605 women for age at natural menopause.

Results: New low frequency signals were identified for both age at menarche and age at natural menopause. For age at menarche, a nonsynonymous variant with MAF 1.1% was identified in *ALMS1* (2p13) ($p=4.95\times10^{-9}$), which increased age at menarche by approximately 3 months per allele. Burden testing identified the gene *PRKAG1* (12q13.12, containing 4 variants with MAF <3.5%) as associated with age at menarche ($p=2.2\times10^{-6}$). For age at natural menopause, two low frequency nonsynonymous variants were identified in *HELB* (12q14.3) (MAF 2.5% $p=3.87\times10^{-28}$ and MAF 3.5% $p=1.37\times10^{-29}$); these variants are 49 bp apart and are in linkage disequilibrium ($r^2=0.7$), each increasing age at natural menopause by approximately 1 year. Two-directional burden testing identified the gene *SLCO4A1* (20q13.33, containing 18 variants) as associated with age at natural menopause ($p=4.54\times10^{-7}$).

Conclusions: We report the first large-scale exome chip genotyping project for reproductive ageing. Two genes containing low frequency or rare variants were associated with age at menarche and a further two genes were associated with age at natural menopause. None of these genes have been previously implicated in genetic associations for reproductive traits in humans and the effect sizes were large compared to GWAS findings.

786T

Redefining the contiguous gene syndrome in the era of high-throughput sequencing. *L. COLLEAUX[1], M. LANGOUET[1], K. SIQUIER-PERNET[1], S. SANQUER[3], C. BOLE-FEYSOT[4], P. NITSCHKE[5], A. MUNNICH[1], R. BAROUKI[3], J. AMIEL[1,2].* 1) Imagine Institute, Necker-enfants malades hospital, Paris, France; 2) Genetic Service, Necker-enfants malades hospital, AP-HP, Paris, France; 3) Metabolic and proteomic biochemistry service, Necker-enfants malades hospital, AP-HP, Paris, France; 4) Genomic platform, Imagine Institute, Necker-enfants malades hospital, Paris, France; 5) Bioinformatic platform, Imagine Institute, Necker-enfants malades hospital, Paris, France.

We ascertained an Algerian consanguineous family in which two sibs presented with psychomotor delay, progressive microcephaly, spasticity, thin corpus callosum, and severe and early onset obesity. Exome sequencing identified two homozygous substitutions cosegregating with the phenotype and locating 170 kb apart on 7q22.1: a c.1137+1G>T splice mutation in *AP4M1* previously described in a Moroccan family and a c.595A>T misense variation in *AZGP1* which encodes zinc-alpha2-glycoprotein (ZAG). Haplotyping analysis indicated that the AP4M1 mutation was a founder mutation shared between both families, whereas the *AZGP1* mutation occurs secondarily and is unique in our family. Mutations in *AP4M1* cause AP4-deficiency syndrome, a condition characterized by severe intellectual disability, progressive microcephaly and spasticity. Notably, none of the 25 previously reported cases with AP4-deficiency syndrome exhibited obesity. On the other hand, ZAG is an adipokine stimulating lipolysis in adipocytes; ZAG likely regulates body weight since administration of human ZAG to ob/ob mice resulted in progressive weight loss. We propose that the phenotype of our patients resulted from the additional effects of the two mutations in *AP4M1* and *AZGP1* accounting for the neurological signs and the precocious morbid obesity, respectively. The contiguous gene syndrome was proposed in 1986 to explain the association of multiple and unrelated clinical features due to the deletion of multiple adjacent genes: the phenotype results from the combination of the endophenotypes of each contiguous gene sensitive to haploinsufficiency. Today, high-throughput sequencing allows us to enlarge this concept to describe simultaneous transmission of independent mutations that are genetically linked.

787S

Sequencing of genes expressed in podocytes uncovers FSGS risk alleles in European-American population. *M. Artomov[1,2,3], H. Yu[4], C. Winkler[6], J. Kopp[5], A.S. Shaw[4], M.J. Daly[2,3].* 1) Chemistry and Chemical Biology Dept, Harvard University, Cambridge, MA; 2) Broad Institute, Cambridge, MA; 3) Analytic and Translation Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Department of Pathology and Immunology, HHMI, Washington University School of Medicine, St. Louis, MO; 5) Kidney Disease Section, NIDDK, National Institutes of Health, Bethesda, MD; 6) Molecular Genetic Epidemiology Studies Section, NCI, Frederick, MD.

Focal segmental glomerulosclerosis (FSGS [MIM 607832, 603965, 613237, 614131, 603278, 612551]) is one of the major causes of nephrotic syndrome in adults and children. Over the last 10 years, various genetic approaches have identified at least eight genes: ARHGAP24, TRPC6, MYH9, INF2, APOL1, NPHS2, ACTN4, and CD2AP as FSGS susceptibility genes. Since mutations in these genes explain only a small fraction of FSGS cases, it seems very likely that other genes await discovery. The FSGS phenotype is known to be specific to podocytes, thus we focused only on sequencing 2500 genes that are highly expressed in the podocyte. Here we present our analysis of 214 European FSGS cases aiming to search for novel germline mutations in Europeans predisposing to the disease. We used expression studies in both human and mouse to assemble a list of approximately 2500 genes representing about 7 Mb and sequenced these genes in about 200 patients and we have used 378 full exome sequences of European ancestry controls for the case/control study. Most of the genes so far reported to be associated with FSGS have been found in studies involving individuals of African-American descent. Here we focused on genetic factors driving disease in European individuals. We found damaging rare mutations in several genes that have previously been reported as risk genes in Africans. We then performed unique to cases mutations anlaysis and found that top hits are ARHGAP24, which is a known risk gene in Africans, APOL3, which is in a close linkage with known APOL1 risk gene and KANK1 which is associated with renal cell carcinoma, MPRIP, which directly interacts with MYH9 at the protein level and potentially could be a new risk gene for FSGS. We have used allelic association test to search for associated variants. Our two top hits were the known FSGS allele - G1 APOL1 variant and a stop codon mutation in APOL3. Interestingly, we saw a perfect co-inheritance of these SNPs within our cases. Our results suggest that the genetic nature of FSGS in Europeans is similar to Africans and mostly is driven by the same alleles and risk genes. We find several new genes that seem to increase risk of FSGS in Europeans and were not previously reported.

788M

Evaluating rare variants in *ZNF469* and other GWAS identified candidate genes in keratoconus. *K.P. Burdon[1, 2], S.E.M. Lucas[1], R.A. Mills[2], E. Souzeau[2], J.E. Craig[2].* 1) Menzies Research Institute Tasmania, University of Tasmania, Hobart, TAS, Australia; 2) Department of Ophthalmology, Flinders University, Adelaide, SA, Australia.

Keratoconus [OMIM148300] is a complex disease characterised by progressive thinning and conical protrusion of the cornea, resulting in major visual impairment. Rare mutations in *VSX1* and *MIR184* have been reported. Recent genome-wide association studies have implicated genetic variation near the *HGF* and *RAB3GAP1* genes and GWAS for central corneal thickness followed by analysis in multiple keratoconus cohorts have highlighted *FOXO1* and *ZNF469* as candidate genes. The role of *ZNF469* is controversial with the risk allele for keratoconus being associated with thicker corneas. To evaluate coding variants in these genes in keratoconus, following ethics approval and informed consent of the participants, we undertook exome sequencing in 51 patients with severe keratoconus and 51 examined normal controls with the SureSelect V4 exome capture (Agilent), sequenced on HiSeq2000 (Illumina). Reads were aligned to human genome hg19, variants called with Samtools and annotated with Annovar. The rate of rare (MAF<0.01 in 1000genomes) and novel (not present in dbSNP135) nonsynonymous variants was compared between cases and controls. The potential functionality of variants was assessed with SIFT. Variants are undergoing validation by Sanger sequencing. In *RAB3GAP1* (NM_012233), 3 variants were found in cases; p.Q860H, p.I305V (rs116775947) and p.R336C (rs150478342) and 2 in controls; p.N718S and p.R530C. All five are predicted to be tolerated. In *HGF* (NM_000601) p.R328H was detected in 1 case and p.A46V (rs150267054) in 2 cases. Both are predicted to be tolerated. In *FOXO1* (NM_002015), 1 variant, p.S390L, was detected in a single case. This variant is predicted to be deleterious by SIFT and may play a role in disease susceptibility. In *ZNF469* (NM_001127464), 9 novel and 7 rare nonsynonymous variants were detected in 18 cases including 9 deleterious in 12 cases. In controls 15 novel and 5 rare variants were detected in 20 samples including 11 controls with deleterious or deletion mutations. The proportion of samples with novel or rare nonsynonymous variants was not different between cases and controls (χ^2 p=0.838) nor was the rate of predicted deleterious nonsynonymous variants (p=0.810). Despite strong association signals at these loci, rare coding variants in these genes do not account for disease, although a larger cohort may be required to test *FOXO1*. *ZNF469* is a highly variable gene and the burden of rare variants does not appear to contribute to keratoconus.

789T

Whole genome sequencing of two trios identifies mutations in *ADNP2* and *ZNFP2*, candidate genetic modifiers for 22q11DS cognitive and cardiac phenotypes. *J. Chung[1], J. Cai[2], B.G. Suskin[1,3], K. Coleman[4], B.E. Morrow[1].* 1) Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Obstetrics & Gynecology and Women's Health, Montefiore Medical Center, Bronx, NY; 4) Childrens Healthcare of Atlanta at Egleston, Atlanta, GA.

The 22q11.2 Deletion Syndrome (22q11DS) is characterized by highly variable expressivity, ranging from mild craniofacial defects to severe congenital heart disease and/or psychiatric illness. Genetic modifiers may account for variable expressivity through a multi-hit model where the 22q11.2 deletion acts as the primary hit and genetic variants act as second hits to modify the phenotype. To identify candidate genetic modifiers for physical and behavioral phenotypes, we used whole genome sequencing (WGS) of two trios with normal parents and probands (C1 and C2) with 22q11DS, who have similar *de novo* 3 Mb deletions but discordant phenotypes. On the remaining 22q11.2 allele in each case, we found 30 coding variants in each case and 1,038 and 940 noncoding variants in C1 and C2 respectively. For C1, we found 349,978 rare (MAF < 0.05), 57,319 novel, and 48 *de novo* variants elsewhere in the genome. For C2, we found 371,778 rare, 61,367 novel, and 35 *de novo* variants. C1, a male, recruited at 14 years old, had tetralogy of Fallot (TOF), cognitive deficits, and attention deficit hyperactivity disorder. He was later diagnosed with schizophrenia (SCZD) at age 28. C2, a female, age 14, had juvenile rheumatoid arthritis that has resolved, no heart anomalies, and no major cognitive deficits or psychiatric illness. Our first goal was to determine if there was an enrichment of potentially pathogenic DNA variants in candidate genes for TOF or cognitive/SCZD in C1 vs C2. We identified 62 genes in C1 and 65 genes in C2 with potentially pathogenic novel, rare compound heterozygous, or *de novo* variants using ANNOVAR. We used ToppGene to prioritize these target genes against known TOF and cognitive/SCZD genes from OMIM. In C1, we did not identify an enrichment of candidate genes for TOF, but we did find enrichment of candidate genes for cognitive/SCZD, compared to C2 (Fisher's p-value = 9.72E-05). Among the interesting variants in C1, were common variants in *COMT* (rs4680) and *PRODH* (rs450046) on the remaining 22q11.2 allele, and a heterozygous *de novo* mutation in *ADNP2* (c.2243G>C), encoding a protein that may be neuroprotective. In C2, we identified a novel nonsynonymous mutation in *ZFPM2* (*FOG2*; c.1576C>T), a known TOF disease gene, which may act as a protective variant when combined with haploinsufficiency of *TBX1* on 22q11.2. Overall, this analysis reveals the utility and challenges of WGS for identifying potential modifier genes (*ZFPM2* and *ADNP2*) for this complex disorder.

790S

Whole exome sequencing of Cold Medicine-Related Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis (CM-SJS/TEN) with Severe Mucosal Involvement. *Y. Hitomi[1], S. Khor[1], M. Ueta[2,3], C. Sotozono[2], S. Kinoshita[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 3) Research Center for Inflammation and Regenerative Medicine, Faculty of Life and Medical Sciences, Doshisha University, Kyoto, Japan.

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are acute inflammatory vesiculobullous reactions of the skin and mucous membranes, and these reactions are reported to be caused by inciting drugs, viral infections, or malignant tumor. Although the occurance of SJS/TEN is rare at about 1-6 cases per million, mortality rates are higher than other drug rush (SJS: 3%, TEN: 27%). In addition, Quality-of-life (QOL) of the most survivors is often low, as severe ocular surface complications are often developed as the aftereffect. Over 1,000 drugs have been reported as the so-called "causal medicine" of SJS/TEN, and susceptibility to SJS/TEN caused by some of them the medicines have been reported to be associated with *HLA* genes. As examples, *HLA-A*31:01* and *HLA-B*15:02* have been reported to be associated with carbamazepine-induced severe cutaneous adverse reactions (SCARs). Besides, *HLA-B*58:01* have been reported as susceptible allele of Allopurinol related SJS/TEN. Recently, *HLA-A* and other genes have been reported to be susceptible for Cold Medicine-Related Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis (CM-SJS/TEN) in Asian populations by genome-wide association study (GWAS). However, remaining genetic susceptibility of CM-SJS/TEN including rare variants and structural variants remains to be discovered. To identify the functional variants for CM-SJS/TEN with severe mucosal involvement, whole-exome sequencing was performed in about 50 Japanese CM-SJS/TEN patients with severe mucosal involvement using next generation sequencer (NGS) - ion Proton (Thermo-Fisher Scientific). Whole-exome sequencing data were then analyzed using CLC Genomics Workbench (CLC bio) software. Here we will show the provisional results of Whole-exome sequencing for CM-SJS/TEN. This study illustrates novel diagnostic and therapeutic methods for CM-SJS/TEN. (Hitomi Y. and Khor S. are contributed equally to this work.).

791M

Identification of putatively causative variants in three anorexia nervosa multiplex families by whole exome sequencing. *D. Li[1], R.D. Cone[2], B. Li[3], H. Hakonarson[1,4,5].* 1) The Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN 37270, USA; 3) Center for Quantitative Sciences, Vanderbilt University, Nashville, TN 37270, USA; 4) Division of Human Genetics Department of Pediatrics, The Children's Hospital of Philadelphia and The Perelman School of Medicine, Philadelphia, PA 19104, USA; 5) Division of Pulmonary Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

Anorexia nervosa (AN) is a perplexing illness characterized by low body weight and persistent fear of weight gain during period of growth, resulting in extreme emaciation. Family studies have consistently demonstrated that AN occurs in families and twin studies have revealed the contribution of additive genetic factors to the observed familial aggregation, but so far just few genetic factors have been found to be specific to AN and no single gene has been shown to be necessary or sufficient to express the phenotype. While GWAS relies on proxy association of genetic variants with unknown disease causality, in which it only focuses on one affected child from multiplex families, the published studies don't specifically analyze inherited mutations despite the fact that AN is highly heritable. Familial AN with young age of onset, extremely low body weight, extended course of illness or male affected constitutes a unique and extreme form of the disease. Here we report the discovery of 5 ultra rare (MAF=0.000077 in ESP6500SI) or novel variants in *COMT, DRD4, KCNN3, GRPR and ESR1*, in 3 AN multiplex kindreds as strong biological candidates. Polymorphisms in these genes have been associated with several psychological disorders, including but not limited to AN, Attention Deficit Hyperactivity Disorder (ADHD), schizophrenia, depression and bipolar disorder. We are currently recruiting additional family members to further validate the cosegregation pattern and conducting follow-up functional assessment to elucidate the roles these genes play in AN and potentially other eating disorders. The resulting variants will be presented together with detailed phenotypic characterization of the families examined.

792T

Whole exome sequencing implicates novel rare genetic variants in susceptibility to Legionella pneumonia. *A. Ndungu[1], KS. Elliott[1], TC. Mills[1], A. Rautanen[1], P. Hutton[2], C. Garrard[3], AC. Gordon[4], CJ. Hinds[5], AVS. Hill[1], SJ. Chapman[1,6], GAinS Investigators.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) John Radcliffe Hospital, Oxford, UK; 3) Intensive Care Unit, John Radcliffe Hospital, Oxford, UK; 4) Section of Anaesthetics, Pain Medicine & Intensive Care, Imperial College, London, UK; 5) William Harvey Research Institute, Barts & The London School of Medicine, London UK; 6) Respiratory Medicine, Churchill Hospital Site, Oxford Radcliffe Hospital, Oxford, UK.

Community acquired pneumonia (CAP) is associated with considerable mortality and morbidity worldwide. 2-9 % of all CAP cases are attributable to the flagellated bacteria *Legionella pneumophila*. Exposure through contaminated water supplies may be relatively common, yet there is great interindividual variation in susceptibility to disease. Host genetic variation is increasingly recognised as playing an important role in determining susceptibility to infectious agents, however, the role of host genetics in susceptibility to Legionella pneumonia has not been fully characterised. Few candidate gene studies have mainly focused on genes in the Toll-like receptor pathway of the innate immune system. The role of these genes in pathogenesis has further been studied in mice with *NAIP, TLR4, 5* and *6* being implicated in susceptibility to Legionella. We use a whole exome sequencing approach in an attempt to identify novel genes and large effect genetic variants associating with Legionnaires' disease in humans. We performed whole exome sequencing of 16 Caucasian individuals from the UK presenting to hospital with microbiologically proven CAP due to *Legionella pneumophila*. Individuals were recruited as part of the Genetics of Sepsis and Septic Shock (GenOSept) study. We obtained whole genome sequence data of 1,927 healthy individuals from the UK10K ALSPAC cohort for use as controls. Over 63,000 mutations were identified as missense, nonsense, splice site variants or variants occurring in untranslated regions. We performed Fisher's exact test to compare frequencies of non-synonymous variants between cases and controls. Two rare single nucleotide variants in *LAMA5* and *SLC22A18* genes were identified with suggestive evidence of association at $P = 1.43 \times 10^{-5}$ and $P = 5.40 \times 10^{-5}$ respectively. We further performed gene-based testing by collapsing variants with allele frequency less than 5% predicted to be deleterious to protein function. Two genes *FAM71E2* and *RFX8* had suggestive evidence of association at $P = 2.99 \times 10^{-5}$ and $P = 5.38 \times 10^{-5}$ respectively. Plans to sequence additional samples are under way. Legionella infection has a mortality rate of between 16-30% if untreated. A comprehensive understanding of genetic predisposition is greatly needed for better prevention, diagnostic and treatment strategies.

793S

Exome sequencing of multiplex pedigrees for the identification of novel rare susceptibility variants for CD. *B.-S. Petersen[1], S. Nikolaus[2], S. Schreiber[2], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Germany; 2) Department of Internal Medicine, University Hospital Schleswig Holstein, Kiel, Germany.

Crohn's disease (CD) is a complex, chronic inflammatory bowel disease (IBD). A variety of genetic and environmental factors likely play a role in causing CD. Genome-wide association studies (GWAS) and meta-analyses have so far identified 163 genetic susceptibility loci for IBD. These, however, explain less than 30% of the heritability so far. Apart from the mostly common variants included in classical GWAS, further sources of heritability include rare and novel variants with possibly higher penetrance which can be identified through systematic resequencing studies. We have therefore carried out exome sequencing for 50 affected individuals from 17 pedigrees with at least three individuals affected by CD for finding rare high penetrance variants and novel candidate genes involved in disease etiology. The results were analyzed pedigree-wise and filtered for rare and novel coding variants shared by the patients. In several cases this led to the identification of candidates likely to play an important role for disease development in the underlying pedigree. A total of 300 variants were selected and are currently being genotyped in a large patient control cohort to test for recurrence and for proving that the identified variants are not common in healthy individuals. Our preliminary results have revealed novel rare candidate variants in known and novel CD genes shared by the affected individuals of a pedigree which may have an important impact on the development of the disease, also in other patients.

794M

Mutations in LRP2 and NUP205 in Patients with Non-Syndromic Autosomal Recessive Intellectual Disability Using Exome Sequencing. *N. Vasli[1], I. Ahmed[1,2], K. Mittal[1], M. Ohadi[1], A. Mikhailov[1], MA. Rafiq[1], A. Bhatti[2], M. Carter[3], DM. Andrade[4,5], M. Ayub[6], P. John[2], JB. Vincent[1,7,8].* 1) Molecular Neuropsychiatry and Development Lab, The Campbell Family Brain Research Institute, The Centre for Addiction & Mental Health (CAMH), Toronto, Ontario, Canada; 2) Atta-ur-Rehman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), Islamabad-Pakistan; 3) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto ON Canada; 4) Division of Neurology, Department of Medicine, University of Toronto, Toronto, Ontario, Canada; 5) Krembil Neuroscience Centre, Toronto Western Research Institute, Toronto, Canada; 6) Division of Developmental Disabilities, Dept. of Psychiatry, Queen's University, Kingston, ON, Canada; 7) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 8) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada.

Intellectual disability (ID) is a genetically heterogeneous disorder with more than 50 mutated genes to date. ID is characterized by deficits in memory skills and language development with difficulty in learning and problem solving. It affects ~2% of population with difference in severity based on the Intelligence quotient (IQ) scores from mild forms with IQ range from 50 to 70, to profound forms with IQ below 20-25. For detection of disease-causing mutation in such a heterogeneous disorder, exome sequencing is a powerful tool as almost all known gene can be assessed simultaneously in a high-throughput manner.

In this study, we performed exome-sequencing for several families with non-syndromic autosomal recessive ID (NS-ARID). After genotyping and exome sequencing, several interesting genes were detected. For example, a homozygous missense mutation was detected in *LRP2* gene in a Pakistani patient with mild ID from a marriage between second cousins. The variation was absent in 400 ethnically matched healthy control chromosomes and is not listed in SNP databases. The *LRP2* mutation identified here is located in one of the LDL-receptor class Adomains which is a cysteine-rich repeat that plays a central role in mammalian cholesterol metabolism suggesting that alteration of cholesterol processing pathway can lead to intellectual disability. In another Pakistani family, a homozygous missense mutation in *NUP205* gene was detected in a female patient with mild ID. Sanger sequencing analysis showed complete segregation within the family. Functional studies are ongoing to verify the pathogenicity of variants detected.

Here we describe the use of autozygosity mapping and whole exome sequencing to identify new genes for NS-ARID in several families. Due to the widely use of exome sequencing where all the genes are assessed at once, more genes for ID are identified leading to identification of underlying pathways.

795T

Low-frequency coding variation in PRF1 and GALC mediate multiple sclerosis risk. *C. Cotsapas[1,2], M. Mitrovic[1], International MS Genetics Consortium.* 1) Neurology, Yale School of Medicine, New Haven, CT; 2) Broad Institute of MIT and Harvard, Boston MA.

Multiple sclerosis (MS) is an autoimmune disease in which the myelin sheath surrounding brain neurons is destroyed by the immune system, leading to progressive physical and cognitive morbidity, brain atrophy and death. Over the last decade we have conducted a series of genome-wide association studies showing that the genetic architecture of MS is complex and likely involves hundreds of risk loci. We have identified almost 100 such loci explaining over 50% of the heritability and our ongoing common variant mapping efforts in ~36,000 cases and ~44,000 controls will substantially increase this number. To complement these efforts we have interrogated 250,000 low-frequency non-synonymous (NS) coding variants across all exons in the genome using Illumina's exome chip in a total of ~40,000 cases and ~60,000 controls of European descent. In our interim analysis, we have analyzed 26,231 cases and 24,031 controls in 14 country-level strata following stringent quality control to eliminate technical artefacts and population stratification. We tested >80,000 NS polymorphic variants for association to MS risk and find that two low-frequency variants (MAF < 0.05) show convincing evidence of association ($p < 6.25 \times 10^{-7}$, Bonferroni-adjusted p < 0.05 for number of variants tested). These variants are in genes PRF1 (preforin 1, OR = 1.2) and GALC (galactosylceramidase, OR = 0.77). A further variant in HDAC7, a histone deacetylase, has suggestive evidence of association ($p = 1.97 \times 10^{-5}$, OR = 0.77). We are currently analyzing our remaining samples to perform a joint analysis across approximately 100,000 cases and controls. Recognizing that even in a cohort of this size, individual variant tests are underpowered to detect small effects on risk, we are performing gene burden tests to identify genes harboring more low-frequency MS risk variants than expected by chance. As not all genes tolerate substitutions equally, we shall also look for genes with strong mutational constraint and association to MS risk. Overall, our results suggest that low-frequency variation identifies a number of MS risk genes in both known risk loci and elsewhere in the genome. These effects account for a small but significant proportion of disease risk heritability and reveal novel risk genes and aspects of MS susceptibility biology.

796S

Genomic Insights into Innate immunity against Viral Respiratory Infections in Pediatric Population. *S. Asgari[1], C. Hammer[1], I. Bartha[1], P. McLaren[1], L. Schlapbach[2], J. Fellay[1].* 1) School of Life Sciences, Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland; 2) Paediatric Critical Care Research Group, Mater Research, University of Queensland, Brisbane, Australia.

Background: Respiratory viruses are the most common pathogens leading to non-elective admission to Pediatric Intensive Care Unit. Human genetic variation plays a key role in determining individual responses after exposure to infectious agents. Current knowledge on the genetic basis of susceptibility to common respiratory infections is very limited. Study objectives: This project aims at identifying and functionally characterizing rare human genetic variants conferring unusual susceptibility to viral respiratory infections in the pediatric population. Methods: Previously healthy children below 4 years of age that required respiratory support for a viral respiratory disease were prospectively recruited in Switzerland and Australia between 2011 and 2014. Exome capture was done using Agilent SureSelect capture kits, and prepared libraries were sequenced on Illumina HiSeq2000. Short sequencing reads were mapped to hg19. Variant calling was carried out using GATK3.2 Haplotypecaller. After read mapping to hg19, variant calling and annotation, and filtration for potentially high-impact changes, we compared allelic frequencies between our cases and controls from the Exome Variant Server and the 1000 Genomes Project, both at single variant and at gene levels. In addition, we tested all genes for potential enrichment in rare (MAF <1%) loss-of-function variants (LoFs) using a binomial test. Results: A total of 120 patients were recruited and sequenced. Single variant and gene-based association testing did not show any significant difference between cases and controls. We observed a significant enrichment (p<2.5E-06) for LoFs in 128 genes; two of those were found in homozygous form, including IFIH1, which encodes a virus-specific pattern recognition receptor. A total of 9 patients carried a LoF in this gene. We studied by RNA sequencing a variant mapping to an essential splice site, which was found both in homozygous and heterozygous form in our study population (N=1 and 3, respectively); the analysis showed that the rare allele leads to the skipping of an exon coding for a protein domain involved in viral RNA recognition. Conclusions: This study provides proof-of-concept that rare genetic variations can be responsible for severe presentations of common viral infections in previously healthy children. Using exome sequencing, we successfully identified potentially deleterious mutations. Further studies are needed to explore the functional impact of these variants.

797M

Evaluating the impact of rare functional polymorphisms in pediatric sepsis. *A. Bittencourt Piccini[1,2], L. Schlapbach[4], I. Bartha[1,2,3], P. J. McLaren[1,2,3], J. Fellay[1,2,3], Swiss Pediatric Sepsis Study.* 1) School of Life Science, EPFL, Lausanne, VD, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne Switzerland; 3))Institute of Microbiology, University Hospital of Lausanne, (CHUV), Lausanne, Switzerland; 4) Paediatric Critical Care Research Group, Mater Children's Hospital, Brisbane, Australia.

Sepsis is defined as a systemic inflammatory response syndrome (SIRS) in response to an infectious process. It is one of the leading causes of infant mortality with over 1 million neonatal deaths worldwide every year. Up to 50% of lethal infections occur in apparently healthy children. A number of genetic variants have been identified through candidate gene studies, but they have not been confirmed independently. Through a non-biased exome sequencing approach, we scanned 43 samples from the Swiss Pediatric Sepsis Study for genetic variants that may underlie their susceptibility to sepsis. After sequencing, read alignment and quality control, we identified an average of 42,473 variants per individual, for a total of 277,625 variant loci. The majority of these variants are single nucleotide changes. Individuals that did not cluster with European ancestry population were filtered out. Using Snpeff software for functional annotation, we found that 1395 genes harbored at least one loss of function variant. We also ran a gene-based analysis of variant burden using VAAST software, which identified 9 genes that were significantly enriched for potentially deleterious variants in our cases vs. population controls. These preliminary findings require confirmation in additional samples. Although no causal gene or variant has been identified in this first analysis, candidate genes were identified that could be implicated in unusual susceptibility to pediatric sepsis. Ongoing recruitment, sequencing and bioinformatic analyses will permit further exploration of human genetic variation that might play a role in the pathogenesis of sepsis.

798T

Exome sequencing of 487 Community Acquired Pneumonia patients. *K.S. Elliott[1], A. Ndungu[1], T.C. Mills[1], A.L. Rautanen[1], P. Hutton[2], C. Garrard[2], A. Gordon[3], C.M. Hinds[4], M. Lathrop[5], A.V.S. Hill[1], S.J. Chapman[1].* 1) Wellcome Trust Centre Human Genetics, University of Oxford, Oxford, UK; 2) Intensive Care Unit, John Radcliffe Hospital, Oxford, UK; 3) Anaesthetics, Pain Medicine and Intensive care, Imperial College, London, UK; 4) William Harvey Research Institute, Queen Mary University of London, London EC1M 6BQ, UK; 5) McGill University-Génome Québec Innovation Centre, Montreal, Canada.

Respiratory infection is the largest contributor to global disease burden and pneumonia kills over one million children each year. A major genetic component of the infectious disease was demonstrated by a study of Danish adoptee children where a 5.8-fold increased risk of death from infectious disease was observed if one of their biological parents had died prematurely from infection. Severe bacterial disease may exert enormous selective pressure leading to the finding of rare susceptibility variants of relatively recent origin. In order to identify such variants an exome sequencing study was undertaken. DNA samples from 487 adult UK individuals admitted to an intensive care unit with severe community-acquired pneumonia (CAP) were collected as part of a study of genetic predictors of death from sepsis in critically ill patients (Genomic Advances in Sepsis [GAinS]). Analysis of sepsis susceptibility was performed on a discovery cohort of 270 CAP samples compared to the UK10K ALSPAC control dataset. After stringent QC criteria were applied, 135,392 variants were identified. Of these, 43 reached ExWAS significant threshold for association ($p < 3.6 \times 10^{-7}$) and an additional 63 variants were suggestive ($p < 1 \times 10^{-4}$). The exomes from the remaining 217 CAP patients are being analysed as a replication dataset against the UK10K TWINSUK control dataset. The sepsis outcome phenotype was also analysed, measured as 28 day mortality post-ICU admission within the 487 combined CAP cohorts (deaths n=237, survivors n =237, unknown n=13). In single variant analysis of - sepsis outcome, seven variants were identified reaching the ExWAS significance threshold including variants in two related genes known to be involved in thrombosis. Collapsing methods with rare deleterious variants are being performed to detect gene centric associations. Identification of novel, large-effect genetic variants has the potential to significantly expand current understanding of sepsis biology and may have clinical applications.

799S

Genome-wide exome array analyses reveal novel rare variants for refractive error in Asia populations. *Q. Fan[1], J. Liao[2], CC. Khor[3], YY. Teo[1,4], SM. SAW[1,2], TY. Wong[1,2,5], CY. Cheng[1,2,5].* 1) SSH School of Public Health, National University of Singapore, Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore, Singapore; 3) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; 4) Department of Statistics and Applied Probability, National University of Singapore, Singapore, Singapore; 5) Department of Ophthalmology, National University of Singapore, Singapore, Singapore.

As one of the leading causes of visual impairment, myopia poses a significant burden to public health in Chinese population. Genome-wide association studies have identified genetic loci contributing to refractive error, however, a substantial portion of the heritability remains unknown. We conducted exom array analysis for low-frequency (MAF 1-5%) and rare variants (MAF < 1%) on spherical equivalent in 2,253 Chinese and 2,091 Malay adults residing in Singapore. We genotyped the whole genome exome variants using the Illumina HumanExome Beadchip. Among 274,00 variants passing quality control, 84,000 (31%) were polymorphic variants. We conducted the regression-based association test for single-variant (MAF > 0.1%) and burden test (SKAT) for 53,991 nonsynomous variants (MAF < 5 %) within 14,130 genes. One gene harboring 4 rare/low frequency nonsynomous variants (cumulative MAF = 3.6%) on chromosome 1 was identified to be associated with SE variation after Bonferroni correction for the number of genes ($P = 2.25 \times 10^{-7}$, respectively). Conditional analysis suggested the signal of the top gene was mainly driven by the single low frequency variant within this gene. This protein coding gene is a part of the epidermal growth factor receptor (EGFR) pathway, whereas EGFR signaling has been implicated in the myopia development in animal models. Six genes containing at least two rare nonsynomous variants also exhibited suggestive association with SE ($P < 5.0 \times 10^{-5}$). Our data suggest the likely role of rare genetic variants in influencing refractive error. The interpretation of the gene-based tests needs carefully considering the effects of single rare variants where the large sample size is required.

800M

Analysis of the rare variant burden in the exomes of candidate HIV-target genes in relation to HIV-acquisition and AIDS-progression. *M.C. Turchin[1], S. Penugonda[2], E-Y. Kim[2], K. Kunstman[2], M. Stephens[1,3], S.M. Wolinsky[2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) The Feinberg School of Medicine, Northwestern University, Division of Infectious Diseases, Chicago, IL; 3) Department of Statistics, University of Chicago, Chicago, IL.

Multiple genome-wide association studies (GWAS) have been conducted attempting to link common human genetic variation (minor allele frequency, MAF, >5%) to various aspects of HIV and AIDS pathology. Despite using large sample sizes (up to 6,000s) and samples representing ancestries beyond Western Europeans (Fellay et al. 2009, Pelak et al. 2010, McLaren et al. 2013), the majority of associations have only been found within the human leukocyte antigen (HLA) region. Here, we present the results of a more focused gene-exome sequencing study utilizing ~550 genes whose protein-products have previously been implicated as significantly associating with the 18 HIV-1 proteins (Jäger et al. 2012). These ~550 genes were sequenced in over 900 individuals, the majority of which are of Western European descent. Individuals in this sample were classified as either sero-positive or sero-negative for associations involving HIV-acquisition, with HIV-positive individuals further being classified as slow/very-slow progressors or rapid/very-rapid progressors (where applicable), thus allowing us to look at associations regarding AIDS-progression as well. Analyses were conducted focusing on both the rare variant burden (MAF <5%) in the exomes of these genes as well as variants that are classified as 'damaging' as designated by multiple functional-prediction algorithms. Overall, we find a handful of genes outside the HLA region that appear to contain an excess of rare, 'damaging' variants in one class of individuals versus another for both HIV-acquisition and AIDS- progression. These results provide further insight into the biology of HIV-human interactions, and with proper functional follow-up and validation, may provide future directions for the development of HIV-drug targets.

The application of the new D5000 ScreenTape assay in larger NGS library quality control. *A. Inche[1], L. Prieto-Lafuente[1], C. McDonald[1], E. Brown[1], B. McHoull[1], M. Liu[2], R. Salowsky[3].* 1) Agilent Technologies Ltd, Edinburgh, United Kingdom; 2) Agilent Technologies, La Jolla, CA, USA; 3) Agilent Technologies GmbH, Waldbronn, Germany.

The current winners of the next generation sequencing (NGS) race are the short read sequencers. As this technology continues to be rapidly adopted, smarter strategies are being developed by manufacturers and in the wider NGS community to address some of the short comings of these short reads. Some of the solutions currently available have increased the overall library size up to and above 2000bp. The Agilent 2200 TapeStation is now a very well accepted QC tool within the NGS library preparation workflow. However, it has been somewhat tricky to QC these larger libraries on the current assay portfolio for this system. Here we present data from some of these larger libraries as analysed on the new D5000 ScreenTape assay for the 2200 TapeStation, which should help streamline sample QC of these libraries. The data shown includes samples from the Illumina Nextera Tagmentation kit which typically generates libraries up to and over 2000bp. We also present an overview of the performance characteristics of the D5000 ScreenTape assay.

802S

Using Exome Sequencing Followed By Genotyping To Identify Susceptibility Gene For Morbid Obesity. *H. Jiao[1], P. Arner[2], P. Gerdhem[3,4], R.J. Strawbridge[5], E. Näslund[6], A. Thorell[7], A. Hamsten[5], J. Kere[1], I. Dahlman[2].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, SE-141 57 Stockholm, Sweden; 2) Department of Medicine (H7), Huddinge, Karolinska Institutet, SE-141 86 Stockholm, Sweden; 3) Department of Orthopaedics, Karolinska University Hospital, SE-141 86 Stockholm; 4) CLINTEC, Karolinska Institutet, SE-141 86 Stockholm, Sweden; 5) Cardiovascular Genetics and Genomics Group, Atherosclerosis Research Unit, Department of Medicine, Solna, Karolinska Institutet, SE-171 76 Stockholm; 6) Department of Clinical Sciences, Danderyd Hospital, Karolinska Institutet, 182 88 Stockholm, Sweden; 7) Department of Clinical Science at Danderyds Hospital and Department of Surgery, Ersta Hospital, Stockholm, Karolinska Institutet, Sweden.

We used exome sequencing to identify variants associated with morbid obesity. DNA from 100 morbidly obese adult subjects and 100 controls were pooled (n=10/pool), subjected to exome capture, and subsequent sequencing. At least 100 million sequencing reads were obtained from each pool. After several filtering steps and comparisons of observed frequencies of variants between obese and non-obese control pools, we systematically selected 144 obesity-enriched non-synonymous, splicing site or 5'upstream single nucleotide variants for validation. We first genotyped 494 adult subjects with morbid obesity and 496 controls. Five obesity-associated variants (nominal p-value < 0.05) were subsequently genotyped in 1,425 morbidly obese and 782 controls. Out of the five variants only one was confirmed. The variant showed strong association with body mass index ($p=6.28\times10-5$) in joint analysis of all 3,197 genotyped subjects, and had an odds ratio of 1.32 for obesity association. In conclusion, using exome sequencing we identified a low-frequency coding variant that was associated with morbid obesity. The corresponding gene display reduced body weight in mice. It may be involved in the development of excess body fat.

Identification of genes involved in functional recovery after stroke through exome sequencing of extreme phenotypes. *R. Rabionet[1], M. Mola[2], G. Escaramís[1], H. Susak[1], C. Soriano[2], C. Carrera[3], S. Ossowski[1], I. Fernandez-Cadenas[3], J. Roquer[2], J. Jimenez-Conde[2], X. Estivill[1].* 1) Bioinformatics and Genomics, Center for Genomic Regulation, Barcelona, Spain; 2) Neurovascular Research Group (NEUVAS), IMIM, Barcelona, Spain; 3) Fundació Docencia i Recerca Mutuaterrassa, Terrassa, Barcelona, Spain.

Cerebrovascular diseases are the second most important cause of death in Spain, and together with other neurodegenerative diseases, they are the leading cause of disability in adults. Variability in functional outcome after a stroke can be influenced by many factors. Irrespective of clinical factors such as age, stroke etiological subtype, vascular stenoses, location of the injury and the size of the affected area, inter-individual variation in capacity of neuronal recovery is considerable. A number of systems and metabolic pathways are important for response to cerebral ischemic damage, and their activity may be modulated by variation in the genes that encode their various components. We aim to identify genetic variants, genes and pathways influencing the functional recovery process. With this aim, we have selected 81 patients with extreme phenotypes (36 bad vs 45 good outcome), suffering an anterior territorial ischemic stroke, with similar stroke severity, and matched for basal functional level, age and gender, from a cohort of over 4000 stroke cases. These patients underwent exome sequencing (Nimblegen v3 and Illumina sequencing). Downstream analysis was performed using a mixed-model association test, with variants collapsed by gene and weighted by their frequency and condel scores, with the aim of identifying genes with an accumulation of variants in either set of samples. This provided a set of aprox. 400 nominally significant genes (although none passed multiple testing correction), which includes some relevant genes for stroke risk and stroke outcome. Further analysis including CNV analysis and integration with GWAS results from this and other cohorts of stroke cases is underway. These findings will be validated in the extended cohort.

804T

Lessons Learned From the Sequencing of Severe Insulin Resistance Exomes. *F. Payne[1], W. Bottomley[1], I. Isaac[2], S. O'Rahilly[2], D.B. Savage[2], R.K. Semple[2], I. Barroso[1], The UK10K Consortium.* 1) Metabolic Disease Group, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) University of Cambridge Metabolic Research Laboratories, Institute of Metabolic Science, Cambridge, United Kingdom.

The UK10K Consortium (http://www.uk10k.org/) is a collaboration between multiple research centres, mainly in the UK, aiming to uncover genetic variants contributing to disease and health status by sequencing 10,000 people. As part of the Rare Disease Group, the exomes of a 1,000 individuals with rare, extreme conditions have been sequenced to an average read depth of 72x using next generation sequencing technology (NGS), with an aim to detect novel causal variants. Amongst these, we focused our analysis on patients with disorders of insulin action of unknown aetiology. These are a group of highly heterogeneous conditions encompassing both severe insulin resistance (SIR) syndrome (a collection of rare disorders of extreme resistance to the glucose-lowering effects of insulin) and unrestrained metabolic or mitogenic insulin-like activity in the absence of insulin. In the discovery phase, 60 probands and their family members (125 samples in total) were whole-exome sequenced, with follow-up in a further 250 index cases by targeted sequencing of 76 genes selected either as good candidates for disease from previous NGS or GWAS studies, or already known to be disrupted in individuals with disorders of insulin action (e.g. *INSR, LMNA, PPARG, AGPAT2* and *AKT2*). After sample quality control, 117 discovery and 248 follow-up samples were carried through for further analysis. To prioritise putative causative variants after removing those with low sequencing depth and quality, we filtered using the 1000 Genomes (http://www.1000genomes.org/), NHLBI Exome Sequencing Project (ESP: http://evs.gs.washington.edu/EVS/) and the remaining UK10K exomes and genomes to exclude common variants and focused on those predicted to alter protein sequence (potentially functional). Family trios were also assessed to detect variants with a high probability of being de novo using DeNovoGear (https://sourceforge.net/projects/denovogear/). Possible candidates were confirmed by Sanger sequencing and co-segregation with available family members was examined wherever possible. Combined analysis of discovery and replication samples has provided possible diagnosis to 5.6% of the index cases to date. These include mutations within genes known to be disrupted in syndromes of SIR (*INSR, PPARG, AGPAT2, ALMS1*) and in strong candidates either with a role in insulin action (*MTOR, RICTOR, SNAP23, TBC1D4*) or those within pathways relevant to phenotypic features (*POC1A*).

805S

Disease associated variants in healthy centenarian exomes. *L.C. Tindale[1,2], S. Leach[1], A.R. Brooks-Wilson[1,2].* 1) Genome Sciences Centre, BC Cancer Research Centre, Vancouver, BC, Canada; 2) Simon Fraser University, Burnaby, BC, Canada.

Many people strive to live to 100, but very few attain this goal. The genetic component to longevity has been established through twin and family studies, but the search for specific variants and mechanisms to explain this rare and complex phenotype is ongoing.

We resequenced the exomes of four healthy centenarians who had never been diagnosed with cancer, cardiovascular disease, diabetes, Alzheimer disease, or major pulmonary disease, as well as four mid-life individuals. The objective of this pilot study was to gain insight into whether the centenarians' exceptional health and longevity were a result of carrying fewer deleterious variants than typical individuals. We hypothesized that the centenarians would have 1) fewer common disease associated genome-wide association study (GWAS) variants, 2) on average fewer variants predicted to be damaging, and 3) few or no high penetrance variants in known disease genes.

The NHGRI Catalog of Published GWAS was filtered for exonic variants associated with common chronic diseases. The proportion of disease associated alleles of GWAS SNPs was compared between the centenarians and controls, as well as to published populations from HapMap and the NHLBI Exome Sequencing Project; however, no difference was detected between the centenarians and comparison groups. Analysis of predicted deleterious variants also showed no evidence of a difference in the burden of SNPs and insertions or deletions predicted to have a high functional impact, between centenarians and controls. Lastly, we are in the process of screening for variants in the 57 genes classified by the American College of Medical Genetics and Genomics as carrying clinically relevant variants.

Our findings support the interpretation that attaining extreme longevity does not appear to be a result of carrying fewer common disease variants, or having a lower burden of predicted damaging variants. We suggest that future studies should focus on seeking rare longevity-promoting variants that contribute to long term good health.

806M

Genetic variation among Multiple Sclerosis in Saudi Patients. *M. Albalwi[1, 2, 3], I. Alabdulkareem[2, 3], W. Alharbi[2], M. Balow[2], Z. Rabhan[2], M. Aljumah[2,3].* 1) Department of Pathology and Laboratory Medicine, King Abdulaziz Medical City, National Guard Health Affairs, Riyadh, Saudi Arabia; 2) King Abdullah International Medical Research Center, Medical Genomic Research Department, Riyadh, Saudi Arabia; 3) King Saud Bin Abdulaziz University for Health Sciences, College of Medicine, Riyadh, Saudi Arabia.

Multiple Sclerosis (MS) is an immune-mediated, inflammatory and demyelinating disorder of the central nervous system (CNS), which includes damage to axons, oligodendrocytes and neurons. After trauma, MS is the most common acquired neurological disorder of young adults. The disease shows a spectrum of severity, ranging from an asymptomatic pathological process, to mildly symptomatic, to severely disabling disease. Although the pathogenesis of MS is poorly understood, available evidence suggests that both genetic and environmental components play important roles in disease development, both independently and interactively. The contribution of genetics to MS is supported by many reports showing familial aggregation of the disease, high concordance rates among twins, and an increased risk among relatives of patients with MS. The role of genetics in MS and its interaction with environmental triggers are currently being extensively studied. However, the purpose of the study is to identify the genetic variation and the risk factors that may be associated with Multiple Sclerosis in the affected patients from Saudi Arabia. Using HLA high-resolution genotype sequencing and whole exom sequencing approch on FLX+ Titanium chemistry and solid 5500 next generation sequencing revealed presence of scientific variation evidence shared among our MS patients. Further more, our analysis suggesting that some of these variations findings may contribute to drugs effect and pathogenesis of MS and others autoimmune diseases in Saudi population.

Admixture mapping of exome genotyping data implicates region 15q21.2-22.3 with keloid risk in African Americans. *K.S. Tsosie[1,2], D.R. Velez Edwards[1,3,4,5], S.M. Williams[6], T.L. Edwards[1,2,3,4], S.B. Russell[1,7].* 1) Center for Human Genetics, Vanderbilt University, Nashville, TN; 2) Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, TN; 3) Vanderbilt Epidemiology Center; 4) Institute for Medicine and Public Health; 5) Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 6) Department of Genetics, Geisel School of Medicine, Dartmouth University, Hanover, NH; 7) Division of Dermatology, Department of Medicine, Vanderbilt University, Nashville, TN.

Keloids (MIM 148100) are benign dermal fibrotic tumors with no effective clinical remedy that affect people of recent African ancestry approximately 20 times more than individuals of Caucasian descent. Possible related fibroproliferative diseases with increased prevalence in African populations include hypertension, nephrosclerosis, allergic disease, and uterine fibroma. Familial aggregation and ancestral differences in risk among geographic subpopulations strongly suggests a genetic association between African ancestry, keloids and fibroproliferative disease risk. There are no published genome-wide studies of keloid risk in African ancestry subjects. We conducted admixture mapping (AM) and whole exome association in 478 African Americans (AAs: 122 cases, 356 controls) with exome arrays to identify regions of local ancestry and SNP genotypes under AM peaks associated with keloid risk. **Results:** The most significant association with keloids discovered by AM was observed on chr15q21.2-22.3. This 5Mb region includes *NEDD4*, which was previously implicated in keloid formation by GWAS in Japanese and later validated in Chinese. Though our study nominally replicated this finding by AM and genotype association, the most significant SNP genotype association under the AM peak was observed at *MYO1E* (rs747722, odds ratio [OR]=4.41, 95% confidence interval [CI]=2.29-8.50, p=9.07×10^{-6}). A scan of all common genotype associations also identified associations at *MYO7A* (rs35641839, OR=4.71, 95% CI=2.38-9.32, p= 8.34×10^{-6}) at chr11q13.5. GWAS have linked the chr15q21.2-22.3 region with hypertension in AAs, asthma in Europeans, and atherosclerosis in a Finnish cohort, providing evidence for common genetic elements. Examination of earlier microarray data of fibroblasts from keloids and normal scars that included some subjects from this study also implicated chr15q21.2-22.3 as a causal region for keloids, with increased expression of *MYO1E* in keloids compared to normal scars. Notably, *MYO1E* has been shown to be a crucial component of the invadosome, a structure involved in matrix degradation and invasion and thus may have a functional role in the keloid phenotype. **Conclusion:** This study is the first to use AM and exome array association analysis to explore the genetics of keloids in AAs. Our findings, strengthened by support from expression data, further elucidate a potential region on chr15q21.2-22.3 for a role in risk of keloids in AAs, Japanese, and Chinese populations.

808S

Exome sequencing in pooled DNA samples identifies a potential candidate variant for preeclampsia. *T. Kaartokallio[1], J. Wang[2,3], H. Jiao[2,3,4], J. Kere[1,2,3,4,5], H. Laivuori[1,6,7].* 1) Haartman Institute, Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden; 3) Science for Life Laboratory, Karolinska Institutet, Stockholm, Sweden; 4) Clinical Research Centre, Karolinska Institutet, Stockholm, Sweden; 5) Folkhälsan Institute of Genetics, Helsinki, Finland; 6) Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Helsinki, Finland; 7) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland.

Preeclampsia (PE), a common vascular pregnancy disorder, increases the risk for mortality and morbidity for both mother and child. As PE is a placental disease that reduces reproductive success, it is plausible that variants predisposing to this disease are under negative evolutionary selection and do not reach high frequencies in a population. In this study, our aim was to identify low-frequency variants that predispose to PE in a Finnish population by utilizing exome sequencing in pooled DNA samples. The exonic regions of a 100 preeclamptic women were sequenced in pools of ten using Illumina platform. The reads were aligned to the human reference genome with the BWA software package, and variants were called with SAMtools and annotated with ANNOVAR. In the filtering step, we selected missense, nonsense and splice site variants that were present in at least two PE pools and had minor allele frequency (MAF) ≤ 0.05 in the 1000G_EUR data. MAFs of the variants in our data were estimated by pooling all the reads at each position together and calculating the percentage of the reads supporting the minor allele. Estimated MAFs were then compared to MAFs in the 1000G_EUR data, in the SISu (Sequencing Initiative Suomi) data (a data set currently containing exome data from ~3300 Finns), and in scoliosis exome seq data, which was produced with a strategy similar to ours. Fifty-nine variants that fulfilled the above filtering criteria and were enriched in our data compared to the reference data (PE_MAF/reference_MAF ≥ 1.5) were selected for validation. Forty-eight of these variants were successfully Sequenom genotyped in 180 pregnant controls and in 180 PE cases, including the original cases, to confirm the presence of the variants in the original samples and to validate the MAF difference between the cases and controls/general population. Next, twenty-eight of the variants with OR ≥ 1.3 or ≤ 0.67 were selected for genotyping in 1456 PE cases and in 704 pregnant controls to test the association of the variants with PE. To increase the power, genotypes from the SISu data were included in the analysis. With this approach, we identified a nominal association of four variants with PE. The strongest association was seen for a variant in the *TP53BP* gene (uncorrected p 0.006). Replication genotyping of this variant is currently underway in a Scandinavian PE case-control cohort.

809M

High burden of deleterious variants and the genetic basis of speech sound disorders. *H.A. Voss-Hoynes[1], C.M. Stein[1], W.S. Bush[1], B. Truitt[1], L. Freebarin[2], B.A. Lewis[2], S.K. Iyengar[1]*. 1) Department of Epidemiology and Biostatistics and; 2) Communication Sciences, Case Western Reserve University, Cleveland, Ohio.

Speech sound disorders (SSD) are communication disorders occurring in 16% of 3 year olds and cost an estimated $30 - $154 billion annually in lost productivity, special education, and medical care. SSD exhibits high heritability, and for childhood apraxia of speech (CAS), a severe subtype of SSD, there are a few candidate genes such as FOXP2. However, apart from this knowledge, a comprehensive understanding of SSD genetics remains to be developed. We hypothesize that SSD is similar to neurodevelopmental disorders such as autism and intellectual disability and occurs not due to a single variant, but rather as the result of a high burden of multiple variants. The present study to test this hypothesis is a 26-year longitudinal cohort study based in Cleveland, OH, involving 135 cases with SSD, 34 (35%) of whom are affected with CAS, and 213 unaffected parental controls. To examine the genetic component of SSD, we used both exome sequencing and HumanOmni2.5Exome genotyping. Analysis of FOXP2 in exome sequenced (n=11 CAS) and genotyped (n=135 SSD and CAS) samples did not identify any single variant or CNVs that could be considered causative mutations. We expanded our analysis to examine overall variant burden using a single measure of deleteriousness, Combined Annotation Dependent Depletion scores (C-scores), which allows for comparison of the distribution of deleterious variants between groups. Preliminary results on a subset of 7,000 variants indicate that while there is no significant difference between the total number of rare (<1%) variants per individual (mean # case=3.43 vs control=3.26, p=0.5), there are distinctions in the deleteriousness of the variants present. Compared to controls (mean RawC=4.39), the CAS cases alone (mean RawC=6.07), but not all cases, trend toward a higher burden of deleterious variants (p=0.08). Additionally, compared to cases without CAS (mean RawC=4.16), apraxic individuals have a significantly higher burden of deleterious rare variants (p=0.05). Finally, a missense variant in BTBD8, a gene expressed prominently in the fetal, but not the adult brain, exhibited the most extreme frequency difference between apraxic cases vs controls (14% vs 5%). Our results suggest that the genetic etiology of SSD is best examined in an integrative, whole genome manner and imply that human speech evolved through changes in many genes and interactions between them rather than as a single event. To explore the role of coding single nucleotide variants (SNVs) on fasting glucose (FG) levels, we performed exome-wide association analysis in up to 60,564 non-diabetic individuals of European (84%) and African (16%) ancestry from 23 studies with Illumina Exome chip data. We performed single variant analyses for all coding and non-coding SNVs with MAF>0.02%. Gene-based tests included rare (MAF<1%) SNVs predicted to be protein-altering. Single variant analyses revealed two novel FG-associated loci: *GLP1R* (SNV A316T) and *ABO* (four non-coding SNVs, lead rs651007). Follow-up of *GLP1R* in exome sequencing data from up to 14,118 individuals, performed to investigate association of sequence variation not captured by the exome chip, identified an intronic SNV 100 bp from A316T (rs761386, MAF=3%, β=0.09, $p=7.6\times10^{-6}$) that was more strongly associated with FG than A316T (p=0.01). rs761386 was close to a splice site, suggesting a possible effect on *GLP1R* pre-mRNA splicing. Follow-up of the four *ABO* SNVs using GTEx and ENCODE Consortium resources identified that rs507666 resides near the transcription start site of a long non-coding RNA that is antisense to exon 1 of *ABO* and expressed in pancreatic islets. rs507666 is also an eQTL for the glucose transporter *SLC2A6* ($p=1.1\times10^{-4}$). Gene-based analyses identified a set of 15 SNVs associated with FG in the previously established *G6PC2* locus. To further investigate the combined effect of these SNVs, we performed haplotype meta-analysis showing significant association ($p=1.1\times10^{-17}$) for haplotypes with the 15 SNVs. Haplotypes carrying the single rare allele at R283X (MAF=0.26%, $p=2.8\times10^{-10}$), P324S (MAF=0.19%, $p=1.4\times10^{-7}$) or S207Y (MAF=0.59%, $p=1.5\times10^{-6}$) were most strongly associated with FG compared to the most common haplotype. The association at the three SNVs was not explained by the known common intronic *G6PC2* SNV rs560887, which is close to the splice acceptor of intron 3 and may be implicated in *G6PC2* pre-mRNA splicing. rs560887 is also near the transcription start site of expressed sequence tag DB031634, a potential cryptic minor isoform of *G6PC2* mRNA. Together, these findings suggest that both coding and non-coding SNVs in *G6PC2* affect glucose homeostasis. In conclusion, further follow-up of exome chip results with exome sequencing, functional annotation and haplotype meta-analysis offers new insight into the functionality of observed associations and reveals novel variants implicated in regulation of FG levels.

811S

Exome Array Analysis of Quantitative Traits related to Glaucoma. *A.I. Iglesias Gonzalez[1], H. Springelkamp[1,2], S. van der Lee[1], N. Amin[1], C.C. Klaver[1,2], C.M. van Duijn[1].* 1) Department of Epidemiology, Erasmus MC, Rotterdam, The Netherlands; 2) Department of Ophthalmology, Erasmus MC, Rotterdam, The Netherlands.

Purpose: Intraocular Pressure (IOP) and Vertical Cup to Disc Ratio (VCDR) are extensively studied endophenotypes of glaucoma. Although there has been major progress identifying common variants with small effect, there has been limited progress identifying rare variants. To evaluate the association of exonic variants to IOP and VCDR in Caucasians, we analysed exome-array and exome-sequencing data in both a population-based and a family-based study. **Methods**: The Illumina HumanExome BeadChip containing ~ 250,000 variants was used to genotype 3,163 subjects from the Rotterdam Study I (RS-I), a population-based cohort, and 1,512 subjects from the Erasmus Rucphen Family (ERF) Study, a family-based cohort. In addition, overlapping variants of ~1,879 individuals from RS-I (~600) and ERF (~1,279) with exome-sequencing data available were included in the analysis. In total, 5,781 individuals with IOP data and 3,758 individuals with VCDR data were analysed. Rare variants were analysed for an association with IOP and VCDR using both single variant analysis and burden test implemented in SeqMeta; an additive genetic model was assumed adjusting for age, sex and the first five principal components (RS-I) or family structure (ERF). Variants with p-values $<2.0E^{-4}$ were selected for replication in RS-II and RS-III imputed with the Genome of the Netherlands (GoNL). **Results**: Single variant analysis for IOP identified a novel common missense variant rs11541353 (p-value = $2.33E^{-8}$) located in the *NPAS2* gene, involved in a circadian mechanism known as contrast sensitivity which is regulated by retinal ganglion cells. This finding was replicated using GoNL imputations. Gene-based analysis showed significant association (p-value $<1.85E^{-6}$) between IOP and three genes: *RNASEH2B*, *SPOPL* and *IVL* when using a minor allele frequency (MAF) upper bound of 5%. Gene-based analysis for VCDR identified one novel significant association (p-value $<1.85E^{-6}$) with *CDK13* which belongs to the family of cyclin-dependent kinases and interact with *CDKN2B*, a key gene involved in glaucoma. **Conclusions**: We have identified multiple genes associated with IOP. *NPAS2* is involved in the circadian clock mechanism. Changes in circadian rhythm have been found in glaucoma patients. *RNASEH2B* is involved in DNA replication, *SPOPL* belongs to the ubiquitin ligase complex, and *IVL* is important for keratinocyte differentiation. In addition, in the VCDR analysis we found a new gene involved in the cell cycle pathway.

812M

Relationship between neutrophil count, white blood count and *TCIRG1* variation. *E.A. Rosenthal[1], V. Makaryan[2], D.C. Dale[2], D.R. Crosslin[1,3], D.A. Nickerson[3], A.P. Reiner[4,5], G.P. Jarvik[1], NHLBI GO ESP.* 1) Dept Med Gen, Univ of Washington School of Medicine, Seattle, WA; 2) Div of GIM, Univ of Washington School of Medicine, Seattle, WA; 3) Dept Genome Sciences, Univ of Washington, Seattle, WA; 4) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Dept of Epidemiology, Univ of Washington School of Public Health, Seattle, WA.

Congenital neutropenia is a hematological condition characterized by low neutrophil counts and recurrent bacterial infections. Recently, we reported linkage and association between congenital neutropenia and a novel *TCIRG1* missense mutation (NG_007878.1:c.2206C>A) in a five generation pedigree (PMID:24753205). We investigated the role of *TCIRG1* SNVs in neutrophil count (NPC) and total white blood count (WBC), of which neutrophils are the major component, using data from the exome sequence project (N=3560, WBC range 2×10^9 to 11×10^9 cells/Liter). After quality control, only 934 individuals (367 European ancestry (EA), 563 African ancestry (AA), 4 other ancestry) had measured NPC (NPC range 10-87% of total WBC, correlation with WBC = 0.40), reducing power to detect an association. We tested association with *TCIRG1* SNVs that were predicted to cause a coding or splicing change, using single SNV, burden and Kernel (SKAT) association tests, prioritizing evolutionarily conserved and predicted damaging SNVs. We detected suggestive evidence for association between NPC and the common missense SNV rs36027301 (1-tail p=0.02, β=-2.4), adjusting for age, sex, cohort, race, and *DARC* (rs2814778 and rs12075). For WBC, we analyzed EA (N=1957) and AA (N=1603) individuals separately. In the analysis of EA individuals, WBC was adjusted for age, sex and cohort. In the analysis of AA individuals, WBC was additionally adjusted for the known effects of *DARC*. In all tests, there were no statistically significant association of WBC and *TCIRG1* variants (p>0.2). These results could be due to difficulty in choosing SNVs with a true functional effect versus those that are benign, or low statistical power if variation in *TCIRG1* is associated only with NPC, but not with other WBC components, given the low correlation of WBC and NPC in these data. Further investigations in larger cohorts are underway.

813T

Identification of COPD causal variants by combining GWAS associated SNPs, lung eQTLs, and pathogenicity prediction tools. *M. Lamontagne[1], C. Couture[1], DS. Postma[2], W. Timens[2], K. Hao[3], D. Nickle[3], DD. Sin[4], PD. Pare[4], M. Laviolette[1], Y. Bosse[1,5].* 1) Centre de recherche de l'Institut universitaire de cardiologie et de pneumologie de Québec, Québec, Canada; 2) University of Groningen, University Medical Center Groningen, GRIAC research institute, Groningen, The Netherlands; 3) Merck & Co. Inc., Rahway, New Jersey, USA; 4) University of British Columbia James Hogg Research Center, Center for Heart and Lung Health, St. Paul's Hospital, Vancouver, BC, Canada; 5) Department of Molecular Medicine, Laval University, Québec, Canada.

Introduction: Chronic obstructive pulmonary disease (COPD) is the fourth most common cause of death worldwide and is predicted to be the third leading cause of mortality by the year 2030. COPD is a complex disease characterized by a progressive airflow obstruction that is not fully reversible. Genome-wide association studies (GWAS) have identified polymorphisms associated with COPD and lung function. However, most of these SNPs are located in non-coding regions (intron and intergenic) and their mechanisms of action are unknown. The aim of the present study is to identify GWAS-associated SNPs that are also associated with gene expression levels in the lung and to verify whether these SNPs are in LD with possible pathogenic variants. **Methods:** Genome-wide association studies on COPD and lung function were reviewed to extract significant SNPs. GWAS-associated SNPs were analyzed to identify expression Quantitative Trait Loci (eQTLs) in a large-scale lung eQTL mapping study including 1,111 patients that underwent lung surgery at three participating sites. eQTLs analyses were performed independently in the three datasets and meta-analyzed using the Fisher's method. Missing genotypes were imputed with MACH and association tests between adjusted expression traits (n = 38,820 probe sets) and GWAS-associated SNPs were performed in PLINK. The Combined Annotation-Dependent Depletion (CADD) method was used to determine the potential pathogenicity of selected SNPs. **Results:** After imputation, 243 SNPs associated with COPD or lung function from previous GWAS were available in the three cohorts. Thirty-three GWAS-associated SNPs were significantly regulating the expression levels of 30 genes (43 probe sets) after correction for multiple testing (Bonferroni P-value $\leq 5.30 \times 10^{-9}$). The average CADD score among the 243 GWAS variants was 4.51 and 26 of them had a score greater than 10. Most of the significant eQTL-SNPs (29/33) were in strong LD ($r2 \geq 0.8$) with SNPs having possible pathogenic effect (CADD score $\geq$ 10). One SNP, rs4846480, was in strong LD with seven SNPs with a CADD score greater than 10. **Conclusion:** By combining genotypes from GWAS-associated SNPs and genome-wide gene expression in the lung, we identified genes that are likely to play a role in the pathogenesis of COPD. We also identified possible functional SNPs by combining GWAS-associated SNPs, lung eQTLs, and the latest tool to predict the pathogenicity of genetic variants.

814S

Association of *IRS2* gene polymorphism G1057D with obesity in young. *M. Martinez Lopez[1], C. Rodriguez-Perez[1], J.M Magaña-Cerino[1], R. Diaz-Martinez[2].* 1) Division Academica Ciencias de la Salud, Universidad Juarez Autonoma de Tabasco, Villahermosa, Tabasco, Mexico; 2) Hospital Civil de Guadalajara, Guadalajara, Mexico.

Obesity is a public health problem in the country and is associated with insulin resistance (IR). The substrate insulin receptor 2 (IRS2) in the signaling pathway of insulin is considered essential in the development and/or survival of β cells. The polymorphic variant of the G1057D IRS2 gene is associated with the pathogenesis of obesity and an increased risk of developing type 2 diabetes (T2D) in adulthood. Objective was to determine whether the IRS2 G1057D polymorphism gene is associated with obesity in young people. Materials and Methods a descriptive study was conducted on students of the Universidad Juarez Autonomy de Tabasco. the control group (n = 94) a group of cases was divided into obese with a history of diabetes (OCAD) (n = 94) and obese with no history of diabetes (OSAD) (n = 94). Peripheral blood samples for biochemical determination and for the extraction of genomic DNA were taken. Genotyping was performed by real time PCR with HRM and direct DNA sequencing. Statistical analysis One-way ANOVA was used, and the post hoc Dunnett t-test for metabolic characterization, for the association of the polymorphism with obesity, the X2 test was used and the OR was calculated on the significant value of $p<0.05$. Results obese youth had alterations in the lipid profile observed lower concentrations of HDL cholesterol and increased triglycerides $p < 0.05$. The allele frequency of IRS2 gene (G = 0.74 and D = 0.26) was found in Hardy Weinberg equilibrium in the population. The GD allele frequency was 43.1% in obese and 22.3% in the control. The wild-type GG, which has 45.2% of obese and 76.6% of the control. The DD homozygote was identified in 11.7% of cases and 1.1% of the control group. The G1057D variant was associated with obesity with an OR = 2.41 (95% CI 1.29-4.50). Conclusion metabolism between groups of young normal weight and obese is different. The G1057D IRS2 gene polymorphism is very common among young obese is statistically associated with it. This mutation is in equilibrium between the study populations. Therefore we can say that this mutation may be responsible for cases of obesity in young people having a unhealthy lifestyle.

Revealing the detailed MHC implication in seven common diseases from the WTCCC by HLA imputation. *N. Vince[1,2], A. Bashirova[1,2], G. Nelson[1], M. Carrington[1,2].* 1) Cancer and Inflammation Program, Laboratory of Experimental Immunology, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Ragon Institute of MGH, MIT and Harvard, Cambridge, MA.

The Wellcome Trust Case Control Consortium (WTCCC) comprise a study of 7 complex human diseases each of which comprise approximately 2000 individuals: bipolar disorder (BD), coronary artery disease (CAD), Crohn's disease (CD), hypertension (HT), rheumatoid arthritis (RA), type 1 diabetes (T1D), type 2 diabetes (T2D). The genome wide association study (GWAS) published in 2007 showed various associations across the genome, and particularly strong associations within the MHC for RA and T1D. Most HLA alleles are not efficiently tagged by any GWAS SNPs, and therefore, HLA allelic effects can be missed in SNP analyses. To test for allelic effects, imputation approaches have been recently developed. We used the SNP2HLA software to impute the HLA class I and class II alleles in the 7 disease cohorts. Imputed HLA class I data was further applied to predict HLA-C level of expression. Each of the 7 disease cohorts were compared to 3000 controls from the WTCCC, all with UK ancestry. Logistic regression with stepwise selection as a statistical model was used to ascertain the independency of each association. As expected RA and T1D show the strongest association with HLA: HLA-DQA1*0501 (P=7.1E-15, OR=0.43) and HLA-DQB1*0301 (P=7.2E-26, OR=0.18), respectively. In addition, HLA-DRB1*0103 shows a strong association with CD (P=9.0E-13, OR=3.51). The other 4 studied diseases have less significant associations with HLA, which need to be replicated elsewhere for confirmation: HT, HLA-DRB1*1101 (P=0.002, OR=1.55); BD, HLA-DPB1*0101 (P=0.002, OR= 0.72); T2D, HLA-B*3701 (P=0.003, OR=0.54); CAD, HLA-A*0205 (P=0.005, OR=0.44). Apart from the HLA alleles, the HLA-C expression level associates with CD: P=4.3E-6, OR=1.39. Thus, available GWAS data can be used for imputing HLA alleles and exploring the HLA allelic effects on human diseases.

816T

A polymorphism in the peptidyl arginine deiminase type IV gene (*PADI4*) is associated with radiographic joint destruction in patients with rheumatoid arthritis who are negative for anti-citrullinated peptide antibody (ACPA). *K. Ikari, S. Yoshida, K. Yano, A. Taniguchi, H. Yamanaka, S. Momohara.* Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan.

Rheumatoid arthritis (RA) is a complex polygenic disease of unknown etiology and is characterized by progressive joint damage. Anti-citrullinated peptide antibodies (ACPA) are the most specific autoantibody for RA. Genetic polymorphisms in the *PADI4* gene, encoding the citrullinating enzyme peptidyl arginine deiminase 4, have been associated with susceptibility to RA in several populations. *PADI4* polymorphisms have also been reported to be associated with joint damage in patients with RA. In the present study, we investigated whether a polymorphism in *PADI4* is associated with radiographic joint destruction in ACPA-negative patients with RA.

This study used DNA samples from 122 Japanese ACPA-negative patients with RA who satisfied the American College of Rheumatology 1987 revised criteria for RA. Most of patients were female (81.1%), 51.6% were rheumatoid factor (RF) positive, and the mean age was 55 years. We used the Sharp/ van der Heijde score (SHS) of the hands at a 5-year disease duration to measure joint damage. Single nucleotide polymorphism (SNP) rs2240340 was selected for the study because it has the best evidence of association with RA in the Japanese population. Genotyping was performed by using a TaqMan assay. The genetic risk of joint damage associated with rs2240340 was assessed by multiple regression analysis adjusted for the possible genetic risk associated with the shared epitope (SE) alleles of the class II, DR beta 1 major histocompatibility complex gene (HLA-DRB1). These alleles are thought to be associated with joint damage in RA patients.

The *PADI4* SNP was significantly associated with radiographic joint destruction in the Japanese population (P = 0.0395). The result remains significant when the analysis was adjusted by RF status (cutoff = 15.0 IU/ml) with HLA-DRB1 SE alleles (P = 0.0287). A SNP in *PADI4* may contribute to joint destruction in ACPA-negative patients with RA. The *PADI4* gene is likely to play a role in the disease progression of RA in addition to its role in the formation of ACPA. The results of this study provide important information about the risks of progressive joint damage in patients with RA.

817S

Risk for nonsyndromic cleft lip and palate from rare coding variants. *K. Asrani[1], W. Yang[2], J. Rine[1], E. Lammer[3], G. Shaw[2], N. Marini[1].* 1) California Institute for Quantitative Biosciences, University of California, Berkeley, CA; 2) Department of Pediatrics, Stanford University Medical Center, Stanford, CA; 3) Childrens Hospital Oakland Research Institute, Oakland, CA.

Cleft lip and/or cleft palate are common craniofacial malformations with complex and heterogeneous etiologies, reflecting both genetic and environmental factors. Both linkage and association studies have shown multiple genes influence risk for clefts. Murine models of clefts as well as studies on normal lip/palate development suggest additional genetic loci. However, causal variants have yet to be identified. Association studies, whether case-control or family-based, have little power to detect unknown rare variants that may be causal. Thus, our goal was to identify rare, potentially causal variants among a list of rationally chosen candidate genes. To this end, we sequenced the exons of 51 candidate genes in 322 ethnically diverse cases and 150 non-malformed controls. 31 target genes are involved in folate metabolism and comprise nearly all cellular enzymes that utilize a folate cofactor. 20 additional genes have been implicated in disease risk by murine models of clefting (e.g. WNT9B), studies of normal craniofacial development (e.g. BMPR1B), or by multiple association studies (e.g. IRF6). Our findings indicate that rare, protein-altering variants (missense, nonsense, frame-shift) confer risk for nonsyndromic clefts. First, the aggregate burden of rare, coding alleles was considerably higher in cases than controls. Overall, cases were 33% more likely to harbor a rare, protein-altering change in 51 genes (case mean = 1.52 mutations/individual: control mean = 1.15 mutations/individual). Second, mutations that are likely to result in functional impairment (nonsense, frame-shift) were significantly enriched among cases. 15 of 322 cases (~5%) harbored one such change within this set of 51 genes, whereas no such changes were found in controls (0 of 150; P-value = 0.01). Third, in gene-level analyses, the burden of rare alleles showed a strong case bias for several genes/gene regions previously implicated in cleft risk. For example, within the BHMT/BHMT2/DMGDH gene cluster on chromosome 5, 41 rare alleles were found in the case population versus 9 in controls (OR=2.3/ 95% CI = 1.1-4.9). Other loci with stronger allele burdens in cases were WNT9B, BMP4 and BMPR1B. Thus, we conclude that rare coding variants may confer risk for isolated clefts. Additional rare and common variant association analyses on this dataset will be discussed.

Screening of CDH1 mutations in a Brazilian sample of nonsyndromic cleft lip / palate individuals. *L.A. Brito, C. Malcher, G. Yamamoto, S.G. Ferreira, M. Naslavsky, M. Aguena, M. Zatz, M.R. Passos-Bueno.* Human Genome Research Center, Institute of Biosciences, University of São Paulo, Brazil.

The epithelial cadherin is a calcium-dependent cell adhesion molecule, essential to the formation of adherens junction. Mutations in its encoding gene, CDH1, have been largely associated with different types of cancer, including gastric, lobular breast, endometrial, ovarian and prostate cancer. Recent studies have suggested a potential involvement of mutations in this gene with cleft lip with or without palate (CL/P) in individuals without known history of cancer in the family. Nonsyndromic CL/P is a complex trait, and, although many associations with common variants have been reported, they confer small risk and do not explain the whole heritability of the disease. To investigate the role of rare (<1%) CDH1 variants in susceptibility to nonsyndromic CL/P in the Brazilian population, we analyzed the coding regions and exon-intron boundaries of CDH1 in 199 affected individuals (sequenced by Sanger method) and 609 controls (from our in-house control exome database - sequenced with HiScan SQ - Illumina Inc; mean coverage of 100x). We found a total of 15 non-described variants in our affected group, 11 of those were not present in our control sample: 2 missense, 1 sinonymous, 6 intronic (near exon boundaries), 1 upstream and 1 in 3'UTR. The missense variants (p.D254N and p.R784H) were found in familial cases of CL/P, and are potentially causal, since they are segregating in the remaining affected family affected members and are predicted to damage the protein function, according to in silico analyses (scores for both variants: Polyphen-2 = 1.0, Probably damaging; SIFT <0.023, Damaging; PROVEAN <-4.36, Deleterious). Kernel association test (SKAT), performed only with rare variants in the CDH1 regions covered by both methods (Sanger and exome), did not detect statistical difference between affected and unaffected groups (p=0.07). Our results support the involvement of rare CDH1 variants in nonsyndromic CL/P etiology; however, collectively, CDH1 variants do not seem to be a common cause of CL/P in the Brazilian population, since no association was detected. In addition, since the carriers of the two missense mutations belong to familial cases of CL/P, we encourage the mutational screening of CDH1 mutations only in families segregating nonsyndromic CL/P. FAPESP, CNPq.

819T

Microsatellite (AT)n in the 3' UTR of the CTLA4 gene is associated with coronary artery aneurysm of Kawasaki disease. *H. Chi[1,2,3,4], MR. Chen[1,3], NC. Chiu[1,3], FY. Huang[1,7], TN. Huang[1,2], WF. Chen[5], CL. Lin[5], YJ. Lee[1,5,6,7].* 1) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 2) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine; 3) Department of Nursing, Mackay Junior College of Medicine, Nursing, and Management; 4) Department of Medicine, Mackay Medical College; 5) Department of Medical Research, Mackay Memorial Hospital Tamsui District; 6) Institute of Biomedical Sciences, Mackay Medical College; 7) School of Medicine, Taipei Medical University.

Background Kawasaki disease (KD) is a febrile disease of children complicated with vasculitis of large coronary arteries and potential aneurysm formation. The *CTLA4* gene encodes a T-cell receptor, cytotoxic T-lymphocyte-associated protein 4 (CTLA4), which involved in controlling the proliferation and apoptosis of T lymphocytes. A microsatellite (AT)n repeat in the 3' untranslated region has been reported to be associated with the organ-specific autoimmune disorders in several racial groups. CTLA4 expression is increased during the acute stage of KD and significantly higher than at the convalescent stage. This suggests that CTLA4 may be important in pathogenesis of KD or CALs. We investigated whether the *CTLA4* gene was associated with CALs in Han Chinese children with KD. **Material and methods** The patients were 576 unrelated children (339 boys, 237 girls) with KD. Their age at diagnosis was 1.9 ± 1.7 years (range 0.1 - 10.2 years). We typed 3'UTR (AT)n microsatellite using fluorescence-based methods. Polymerase chain reaction (PCR) primers were 5'-GCCAGTGATGC-TAAAGGTTG -3' (forward) and 5'-ACACAAAAACATACGTGGCTC- 3' (reverse). The forward primer was labeled with fluorescent dyes. PCR products were electrophoresed on an ABI 3730 DNA analyzer and their size was analyzed with GENESCAN 4.0. We designate the alleles according to the number of repeat units. **Statistical analysis** Statistical difference in allele distribution between patients with CALs and those without CALs were assessed by the chi-square test. Odds ratios and 95% confidence intervals were also calculated. Only those alleles of >2.0% in frequency in either patients or control were compared. The Bonferroni correction, $Pc = 1 - (1-P)n$, was used for multiple comparisons where *Pc* is the corrected *P* value, *P* the uncorrected value and n is the number of comparisons. In this study, n is 8 for each allele. A *Pc* value of less than 0.05 was considered statistically significant. **Results** The PCR products were 95-141 base pair (bp) in length corresponding to alleles 8-31. Alleles 16, 8, 15, and 17 were major alleles with a frequency of >10%. Allele 8 was 79/400 (19.8%) in patients with CALs and significantly less frequent compared to that in patients without CALs which was 210/752 (27.9%); OR= 0.64 (0.47-0.85), $P = 0.0023$, $Pc = 0.018$. **Conclusions** The microsatellite (AT)n in the 3'UTR of the CTLA4 gene is associated with CALs in KD. Allele 8 conferred protection against the formation of CALs in patients with KD.

820S

Interaction between *PTPN2* and HLA-DRB1 SE alleles in rheumatoid arthritis. *M. Houtman, K. Shchetynsky, L. Padyukov.* Rheumatology Unit, Department of Medicine Solna, Karolinska Institutet and Karolinska University Hospital, Stockholm, Sweden.

Background: One of the most common chronic autoimmune disorders worldwide is rheumatoid arthritis (RA). It has a strong genetic component and over 100 risk loci have been discovered in genome-wide association studies (GWAS). The major risk factor for RA is HLA-DRB1 shared epitope (SE) alleles. Outside of this region, a recently identified candidate gene for RA is protein tyrosine phosphatase non-receptor type 2 (*PTPN2*), a suggested phosphatase in cytokine receptor signaling. However, the functional consequences of genetic variations in the *PTPN2* region remain undefined. We therefore aimed to identify additional susceptibility SNPs in *PTPN2* through the analysis of statistical interactions between SNPs in *PTPN2* and HLA-DRB1 SE alleles in development of RA. **Methods:** Genotypes from two independent cohorts were used in this study, the Swedish EIRA study (3151 patients with RA and 2247 matched healthy controls) and NARAC (873 patients with RA and 1196 controls). Interactions were investigated by calculating the attributable proportion due to interaction (AP) between 11 SNPS in the *PTPN2* region and HLA-DRB1 SE alleles. **Results:** We found *PTPN2* SNPs rs657555 and rs11080606 in statistical interaction with HLA-DRB1 SE alleles in autoantibody positive RA in the two independent cohorts EIRA and NARAC (AP = 0.208 [0.071-0.345] and AP = 0.209 [0.019-0.399], respectively). When individuals from the EIRA study were analyzed only *PTPN2* SNP rs657555 demonstrated association with RA ($p = 6.13\times10^{-5}$; OR = 1.23 [1.11-1.37]). This is an intronic SNP in region between exons 2 and 3 that does not influence directly known splicing elements. **Conclusion:** Through the analysis of statistical gene-gene interactions between SNPs in *PTPN2* and HLA-DRB1 SE alleles, we identified a new candidate SNP in the *PTPN2* region that distinguish a subgroup of RA cases from healthy controls. The potential link between *PTPN2* and SE in RA should be further investigated in functional studies in relation to different autoimmune diseases.

821M

Genetic variants of SMADs in the TGF-β/SMAD signal pathway are related specifically to susceptibility to ulcerative colitis in Japanese patients. *T. Inamine[1], S. Suzuki[1], A. Yamashita[1], S. Fukuda[1], S. Kondo[1], H. Isomoto[2], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch, Nagasaki, Japan; 2) Dept Gastroenterol and Hepatol, Nagasaki Univ Grad Sch, Nagasaki, Japan.

PURPOSE Inflammatory bowel diseases (IBD), comprised of Crohn's disease (CD) and ulcerative colitis (UC), is attributed to inappropriate inflammatory response in the intestinal epithelia of patients. TGF-β/SMAD signals play a key role in differentiation of naive CD4+ T cells to Th17 cells or regulatory T (Treg) cells. In order to identify genetic determinants of IBD, we investigated an association between susceptibility to IBD and SMADs polymorphisms in the Japanese population. METHODS The study subjects consisted of 108 patients with UC, 81 patients with CD, and 199 unrelated healthy control subjects. A total of 21 tag single nucleotide polymorphisms (SNPs) in four genes (*SMAD2, SMAD3, SMAD4,* and *SMAD7*), which are involved in the TGF-β/SMAD signal pathway, were genotyped by PCR-restriction fragment length polymorphism, -direct DNA sequencing, or -high resolution melting curve analysis. The frequencies of alleles and genotypes were compared between control subjects and UC patients or CD patients by chi-square test or Fisher's exact test in three inheritance models: the allele, the minor allele dominant, the minor allele recessive models. RESULTS Five SNPs (rs13381619, rs9955626, rs1792658, rs1792684, and rs1792671) of *SMAD2*, rs4147358 of *SMAD3*, two SNPs (rs7229678 and rs9304407) of *SMAD4*, and rs12956924 of *SMAD7* showed the significant association with susceptibility only to UC. In each gene, rs13381619 of *SMAD2*, rs4147358 of *SMAD3*, rs9304407 of *SMAD4*, and rs12956924 of *SMAD7* showed the strongest association ($P = 0.0007$ in the minor allele dominant model, 0.0205 in the minor allele dominant model, 0.0050 in the minor allele recessive model, and 0.0011 in the minor allele recessive model, respectively). In addition to UC, rs1792658 of *SMAD2* also showed the significant association with susceptibility to CD ($P = 0.0409$ in the minor allele recessive model). CONCLUSION Genetic variants of SMAD signaling molecules in the TGF-β/SMAD pathway may disturb the signal transduction and alter the balance of differentiation to Th17 and Treg, leading to dysregulation of immune response and eventually resulting in the development of IBD, especially UC. However, a genome-wide association study in European ancestry has shown the association of SMAD3 with susceptibility to CD. Although the TGF-β/SMAD signal pathway is crucial in the etiology of IBD, genetic variants of the key SMAD molecules in this pathway may be different between Caucasian and Japanese patients.

822T

Associations of BST2 Polymorphisms with HIV-1 Acquisition in African American and European American People who Inject Drugs. *E.O. Johnson[1], D.B. Hancock[1], N.C. Gaddis[2], N.L. Saccone[4], L.J. Bierut[3], A.H. Karl[5].* 1) Behavioral Hlth Epidemiology, RTI International, Research Triangle Park, NC; 2) Research Computing Division, RTI International, Research Triangle Park, NC; 3) Dept of Psychiatry, Washington University School of Medicine in St. Louis, MO; 4) Dept of Genetics, Washington University School of Medicine in St. Louis, MO; 5) Urban Health Program, RTI International, San Francisco, CA.

An estimated 50% of the variability in acquiring human immunodeficiency virus type I (HIV-1) upon exposure is attributable to host genetic factors. The only genetic polymorphism conclusively associated with risk of acquiring HIV-1, a low frequency 32-base pair deletion in the chemokine (C-C motif) receptor 5 (CCR5) gene, accounts for little of the population variability. Identification of other genetic polymorphisms underlying HIV-1 susceptibility is needed to better understand disease pathogenesis. The BST2 gene encodes a host restriction factor that suppresses the release of HIV-1 particles by tethering them to the cell surface based on in vitro studies. However, little is known about the influence of BST2 polymorphisms on HIV-1 acquisition and disease progression in vivo. In this study, we tested a dense set of polymorphisms spanning BST2 for association with HIV acquisition and viral load using 955 HIV antibody negative cases and 2,181 HIV antibody positive controls from the Urban Health Study of European American and African American people who inject drugs. We tested 470 single nucleotide polymorphisms (SNPs) and insertions/deletions (indels), genotyped or imputed from 1000 Genomes across BST2 and its flanking regions. The novel SNP rs113189798 was associated with HIV acquisition, exceeding the corrected P value threshold for multiple testing. The rs113189798-G allele, which occurred at frequencies of 16% in AAs and 4% in EAs, was associated with reduced risk of HIV-1 acquisition across both ancestry groups (meta-analysis $P=1.43\times10^{-4}$): odds ratio (95% confidence interval) of 1.22 (1.01-1.49) in AAs and 2.17 (1.43-3.33) in EAs. This SNP is located 17.8 kb downstream of BST2. The SNP rs12609479, which was previously reported for affecting BST2 expression but not previously linked to HIV acquisition, was nominally associated with HIV-1 acquisition in the UHS (meta-analysis P=0.036 across the ancestry groups). The rs12609479-A allele is predicted to increase BST2 expression and subsequently decrease risk of acquiring HIV-1. Rs113189798 and rs12609479 are only weakly correlated (r^2=0.2-0.4), and represent distinct association signals. No significant associations were found for HIV viral load. Our findings provide support to BST2 as a genetic susceptibility factor for HIV-1 acquisition: identifying a novel SNP association for rs13189798 and linking the previously reported regulatory SNP rs12609479 to risk of acquiring HIV-1.

823S

Assessing genetic association between RASGRP3 and SLE susceptibility. *X. Kim-Howard[1], C. Sun[1], A. Adler[1], H. Zhang[2], L.H. Lian[3], K.H. Chua[4], S.-C. Bae[5], S. Nath[1].* 1) Oklahoma Med Res Foundation, Oklahoma City, OK; 2) Peking University First Hospital, Beijing, China; 3) Department of Molecular Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia; 4) Department of Biomedical Science, University of Malaya, 50603 Kuala Lumpur, Malaysia; 5) Hanyang University Hospital for Rheumatic Diseases, Seoul 133-791, Korea.

Systemic lupus erythematosus (SLE) is a chronic, multisystem autoimmune disease with diverse clinical manifestations. Despite evidence for a distinct genetic architecture of SLE in Asians, little research has investigate the full spectrum of genetic variants that influence Asian SLE. Recent GWAS in Han Chinese identified association between SLE and RASGRP3 (rs13385731). RASGRP3 is responsible for Ras-ERK signaling mediated by B-cell receptor ligation in B cells and is involved in immunoglobulin production. It is not known whether rs13385731 is the primary variant responsible for SLE association with RASGRP3, or if it is in linkage disequilibrium with another causal variant. Objectives of this study were to: (a) perform comprehensive analysis using dense fine-mapping in 3 Asian populations, (b) identify robust, independent SLE-predisposing variants, and (c) test whether these variants are associated in ethnically diverse populations. Genotype data from 125 SNPs within RASGRP3 (chr2: 33,656,416-33,794,798 bp) were extracted from the ImmunoChip array, on 2487 cases and 3958 controls from Korean (KR), Han Chinese (CH), and Malaysian Chinese (MC) cohorts. To increase statistical power we performed ethnicity-specific imputation-based association analysis. For replication in other ancestries the most significant SNPs were confirmed by TaqMan assay in European-Americans (EA), African-Americans (AA), and Hispanics (HS). We also assessed association between significant SNPs and SLE clinical sub-phenotypes. After imputation we analyzed 162 SNPs from RASGRP3. The most significant association was at rs13425999 (P(META)=7.5E-8; P(KR)=9.8E-5; P(CH)=1.0E-3; P(MC)=0.03). SLE association with rs13385731 was confirmed (P(KR)=3.2E-4; P(CH)=1.7E-3; P(MC)=0.03; P(META)=4.5E-7). Published rs13385731 was significantly associated in EA and AA (P(EA)=2.1E-3; P(AA)=2.2E-3) but not HS (P(HS)=0.06); rs13425999 was significant in (P(EA)=1.0E-4) but not AA or HS. In KR rs13425999 was collinear with rs13385731 (313 bp apart), either SNP explained association between SLE and RASGRP3. Thus, we replicated RASGRP3 association with SLE in KR, HC, MC and EA,. Preliminary bioinformatic analysis indicate that rs1342599 is located in an open chromatin, attached with several histone marks (H3K27Ac, H3K4Me1), suggesting that it is a likely functional SNP.

824M

Polymorphism in MEN-1 gene is associated with increased risk and earlier age of pituitary adenoma development. *J. Klovins[1], R. Peculis[1], I. Balcere[2], V. Pirags[1,2].* 1) Genome Centre, Latvian Biomedical Research and Study Centre, Riga, Latvia; 2) University of Latvia.

Clinically significant pituitary adenomas affect one individual out of approximately 1000 to 1300 people in general population. So far mutations in number of genes responsible for familial cases of PA contributing up to 5% of all tumors have been described. Genetics of cases not clearly attributed to familial adenoma is unclear with multiple genes potentially involved. In this study, we analyzed 96 tag-SNPs from seven genes known for their involvement in familial PA cases and 3 receptor genes (AIP, SSTR2, SSTR5, DRD2, GNAS, MEN1 and PRKar1a) including their neighboring regions in 143pituitary adenoma patients and 354 age and sex matched controls (1:2.5) in order to investigate potential involvement of these genes in determination of the risk for non-familial pituitary adenomas. We identified one rare SNP in MEN1 locus strongly associated (P=2.1e-4; OR =17.8; CI95[2.18-145.5]) with increased risk of PA development. The same SNP was also associated with younger age at diagnosis of PA (beta=-17.4). We also confirmed previously found association of SNP in SSTR5 gene and two nominal associations of SNPs in DRD2 gene with either risk of PA development or clinical characteristics of the disease. We thus have showed that SNP in MEN1, the gene known to be responsible for familial pituitary tumors also plays role in sporadic cases.

825T

Targeted resequencing of CFH-CFHR genes identifies new putative functional common and rare variants conferring susceptibility to Meningococcal disease. *V. Kumar[1], Z.Y. Phua[1], T.W. Kuijpers[3], F. Martinon-Torres[4,5], A. Salas[6,7], M.L. Hibberd[8], E.D. Carrol[9], W. Zenz[10], M. Levin[2], S. Davila[1].* 1) Human Genetics, Genome Institute of Singapore, Singapore; 2) Division of Infectious Diseases, Department of Medicine, Imperial College London; 3) Division of Pediatric Hematology, Immunology and Infectious diseases, Emma Children's Hospital Academic Medical Center, Amsterdam, The Netherlands; 4) Pediatric Emergency and Critical Care Division, Department of Pediatrics, Hospital Clínico Universitario de Santiago, Santiago de Compostela, Spain; 5) Grupo Gallego de Genética, Vacunas e Investigación Pediátrica, Instituto de Investigación Sanitaria de Santiago, Galicia, Spain; 6) Unidade de Xenética, Departamento de Anatomía Patolóxica e Ciencias Forenses Facultade de Medicina, Universidade de Santiago de Compostela, Santiago de Compostela, Galicia, Spain; 7) Instituto de Medicina Legal, Facultade de Medicina, Universidade de Santiago de Compostela, Santiago de Compostela, Galicia, Spain; 8) Infectious Diseases, Genome Institute of Singapore, Singapore; 9) Institute of Child Health, University of Liverpool, Alder Hey Children's National Health Service Foundation Trust, Liverpool, UK; 10) Department of General Pediatrics, Medical University of Graz, Graz, Austria.

Meningococcal disease (MD) is an infection caused by *Neisseria meningitidis*. In recent years, genome wide association studies (GWAS) have suggested the involvement of a number of genes in determining host susceptibility and progression to disease. For instance, variants within the CFH-CFHR region have been robustly shown to be associated with susceptibility to disease. Yet the putative functional variants within this genomic region remain to be elucidated. Moreover, this reported association accounts for a small fraction of heritability and it is plausible that rare variants with moderate penetrance could contribute to disease susceptibility as well. CFH and CFHR genes share sequences of high homology within chromosome 1 that has made extremely challenging its analysis. Using a Nimblegen capture design we have been able to cover more than 92% of the targeted region (~300 kilobases). We sequence 238 MD cases and 237 controls from Western Europe and perform a case-control analysis. Calling of 3,032 high-quality single nucleotide polymorphism (SNP) with less than 10% sample missingness rate was obtained. Within the CFH region we have identified a SNP (in linkage disequilibrium with the top GWAS SNP, rs1065489) exceeding original GWAS P value. In addition we have identified a rare variant with P value $< 10^{-5}$ showing a genetic effect on the opposite direction to that of GWAS SNP. We are currently genotyping these SNPs in 1,300 MD cases and 3,000 controls to validate our results.

826S

Candidate-gene association study of sciatica. *S. Lemmelä[1], S. Solovieva[1], R. Shiri[1], M. Heliövaara[2], J. Viikari[3], O.T. Raitakari[4,5], T. Lehtimäki[6], E. Viikari-Juntura[1], K. Husgafvel-Pursiainen[1].* 1) Health and Work Ability, Finnish Institute of Occupational Health, Helsinki, Finland; 2) Population Health Unit, National Institute for Health and Welfare, Helsinki, Finland; 3) Department of Medicine, University of Turku, and Division of Medicine, Turku University Hospital, Turku, Finland; 4) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Turku, Finland; 5) Department of Clinical Physiology and Nuclear Medicine, Turku University Hospital, Turku, Finland; 6) Department of Clinical Chemistry, Fimlab Laboratories, University of Tampere School of Medicine, Tampere, Finland.

Sciatica is a common and often disabling low back disorder (LBD) in working-age populations. It presents as pain radiating from the back to the leg, usually caused by compression or irritation of one of the lumbosacral nerve roots. It is a complex disorder with relatively high heritability (35-75%) but poorly understood molecular mechanisms. Candidate gene studies have mostly focused on genes associated with LBD, such as those related to cartilage structure and stability, pain signaling, obesity or inflammation[1]. We investigated 11 SNPs in genes previously associated with LBDs (sciatica, lumbar disc degeneration [LDD] or low back pain), osteoarthritis or nicotine addiction (smoking is a known risk factor for LBD). The study comprised two large Finnish population cohorts; Young Finns Study (YFS; 171 sciatica cases, 1777 controls) and Health 2000 (H2000; 294 sciatica cases, 5296 controls). Four candidate gene SNPs were genotyped in both populations; rs1107946 of COL1A1, rs2294995 of COL9A3, rs7775 of FRZB and rs1317286 of CHRNA3. Seven additional SNPs were genotyped in YFS; rs61734651 of COL9A3, rs1799907 of COL11A2, rs1800587 of IL1A, rs1800796 of IL6, rs731236 of VDR, rs288326 of FRZB, rs16969968 of CHRNA5 as well as rs2187689 in HLA gene region in H2000. Genotyping was done by qPCR using Taqman assays or OpenArray system. Allele and genotype frequency differences between cases and controls were estimated by Pearson's X2-test with Yates' continuity correction in R program. Odds ratios with 95% confidence intervals were estimated using R. We found an association between rs2187689 on HLA region (6p21.32) and sciatica in H2000 (p=0.04; OR=1.31, 95%CI 1.02-1.69). This SNP was selected due to its previous association with LDD in a GWAS of Northern Europeans[2]. None of the other SNPs were significantly associated with sciatica. Further analysis taking into account work-related and lifestyle factors will be carried out. Current findings, based on relatively large population cohorts, are in line with earlier studies in suggesting that common candidate genes may have a more limited role alone but a wider range of genes each with a subtle effect as well as gene-environment interaction are likely involved. GWA studies and exome/whole-genome sequencing approaches may aid in identifying novel candidate loci for low back disorders, including sciatica. [1]Eskola, Lemmelä et al., PLoSOne 7(11):e49995, 2012. [2]Williams et al., Ann Rheum Dis 72(7):1141-8, 2013.

827M

Association study between NOD2 and CCDC122-LACC1 genes and leprosy in Brazilians. *C.S. Marques[1], H. Salomão[2], V.M. Fava[2], L.E.A. Arnez[1], E.P. Amaral[3], C.C. Cardoso[1,4], I.M.F. Dias-Batista[5], W.L. Silva[5], P. Medeiros[5], M.C.L. Virmond[5], F.C.F. Lana[3], A.G. Pacheco[6], M.O. Moraes[1], M.T. Mira[2], A.C. Pereira[5].* 1) Leprosy Laboratory, Instituto Oswaldo Cruz, FIOCRUZ, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Core for Advanced Molecular Investigation, Graduate Program in Health Sciences, School of Medicine, PUCPR, Curitiba, Brazil; 3) Departamento de Enfermagem Materno-Infantil e Saúde Pública Federal de Minas Gerais, UFMG, Brazil; 4) Laboratório de Virologia Molecular, Departamento de Genética, UFRJ, Rio de Janeiro, Brazil; 5) Instituto Lauro de Souza Lima, Bauru, Brazil; 6) Programa de Computação Científica, FIOCRUZ, Rio de Janeiro, Brazil.

Leprosy is a complex disease with phenotypes strongly influenced by genetic variations. Previously, a Chinese genome-wide association study (GWAS) identified novel genes and pathways associated with leprosy susceptibility, which was only partially replicated by independent studies in different ethnicities. The aim of our study was to perform a validation and replication study of the Chinese GWAS in Brazilians, using a stepwise strategy that involved two family-based and three independent case-control samples, totalizing 3,614 individuals enrolled. We selected 36 tag SNPs at five candidate genes from the Chinese study (CCDC122-LACC1, NOD2, TNFSF15 and RIPK2) which were tested in the discovery sample from Prata Village, a former leprosy colony. The DNA samples were genotyped using allelic discrimination Real Time PCR (TaqMan assay, Applied Biosystems). The family-based association analysis was performed using Transmission Disequilibrium Test (TDT) in the FBAT software, version 2.0.2. In case-control studies, comparative analyses for allelic, genotype and carrier frequencies were performed using an unconditional logistic regression model in R environment. Also, overall analysis combining the case-control samples was performed controlling for geographic region, gender and ethnicity. Linkage disequilibrium was estimated by Haploview software, version 4.2. In the discovery sample we observed an association between leprosy and tag SNPs at NOD2 (rs8057431-A) and CCDC122-LACC1 (rs4942254-C) alleles, both under-transmitted to affected offspring, indicating protection to leprosy. After, these associations were consistently detected in all replication populations from Brazil. The combined analysis showed the following Odds Ratios towards leprosy: rs8057431-AA (OR= 0.49, P= 1.39e-06) and rs4942254-CC (OR= 0.72, P = 0.003). These results indicate an association between NOD2 and CCDC122-LACC1 genes with leprosy protection in Brazilians, and suggest them as important markers to this disease across diverse populations.

828T

The role of SIRT2 in human longevity: converging evidence from gene expression, epigenetics and genetic variation. *D.R. Mazzotti[1], C. Guindalini[1], W.A.S. Moraes[1], M.L. Andersen[1], R. Pellegrino[1,6,7], L.R.A. Bittencourt[1], B. Borsatto-Galera[2], M.A.C. Smith[3], M.S. Cendoroglo[4], L.R. Ramos[5], S. Tufik[1].* 1) Deparamento dePsicobiologia, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Departamento de Ciências Básicas em Saúde, Faculdade de Ciências Médicas, Universidade Federal do Mato Grosso Cuiabá, Brazil; 3) Departamento de Morfologia e Genética, Universidade Federal de São Paulo, São Paulo, Brazil; 4) Disciplina de Geriatria e Gerontologia, Universidade Federal de São Paulo, São Paulo, Brazil; 5) Departamento de Medicina Preventiva, Universidade Federal de São Paulo, São Paulo, Brazil; 6) Center for Applied Genomics - The Children's Hospital of Philadelphia, Philadelphia, United States; 7) Center for Sleep and Circadian Neurobiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, United States.

The increase in life expectancy indicates that aging at the population level is unavoidable. The identification of factors that may help the development of actions to promote healthy aging is fundamental. Using an integrative approach, we aimed to identify whole blood oxidative stress gene expression changes and associated epigenetic mechanisms as well as genetic variants associated with human longevity. For the gene expression and epigenetic study, oldest old individuals (N=10, 85 to 105 years old), older adults (N= 13, 60-70 years old) and young adults (N=15, 20-30 years old) had oxidative stress and antioxidant defense related gene expression and microRNA expression evaluated by qRT-PCR, and DNA methylation by bisulfite sequencing. For the association study, 2025 individuals (20-105 years) were genotyped for 9 polymorphisms within differentially expressed genes. We found significant up-regulation of SIRT2 expression in the oldest old individuals (fold-change=1.438), accompanied by lower DNA methylation rate in specific CpG sites and down-regulation of miR-1275, a microRNA predicted to regulate SIRT2 expression. Strong and significant associations between two SIRT2 polymorphisms (rs10410544 and rs4802998) and longevity (individuals >90 years-old) were found (OR=2.577; 95%CI=1.472-4.510 and OR=2.365; 95%CI=1.281-4.366, respectively and adjusted for gender and genetic ancestry proportions). We described SIRT2 as a novel marker whose fully characterization is essential for understanding the mechanisms behind molecular regulation of healthy aging and longevity in humans.

829S

Association of IL10 variants with visceral leishmaniasis in Indian population. *A. Mishra[1,2], S. Nizammuddin[1], G. Arekatla[1], S. Prakash[1], N. Tupperwar[1], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, Andhra Pradesh, India; 2) (DBT-RA scheme) Department of Biotechnology, Govt. of India.

Visceral leishmaniasis (VL) is a multi-factorial disease in which host genetics play a significant role in determining the disease outcome. T cells generate specific and memory T cells, in response to intracellular parasitic infections. The immunological role of anti-inflammatory IL10 cytokine, which is secreted by Th2 and group of cells, is well documented in several studies in parasite infections but its genetic role has not been attempted in Indian VL. VL patients display high level of IL10 in blood serum and elevated levels of mRNA. Therefore the aim of this study is to evaluate the role of IL10 gene in Indian VL and look for the distribution of disease associated allele / haplotype in diverse Indian populations. We sequenced all the exons and exon-intron boundaries of IL10 gene in 184 VL patients along with 172 ethinically matched control from VL endemic region of India. Our analysis revealed four variations namely rs1518111 (2195 A>G, intron), rs1554286 (2607 C>T, intron), rs3024496 (4976 T>C, 3' UTR) and rs3024498 (5311 A>G, 3' UTR), of these, rs3024498 is significantly associated with VL for genotype frequencies (AG, $\chi 2$ =15.18; p =0.00010, OR =0.376 and for GG, $\chi 2$ =12.97; p =0.00032, OR =0.369) and for allelic frequency ($\chi 2$ =18.87; p =0.00001, OR = 0.515). Further analysis of the above four variations in 1138 individuals from 34 ethnic populations of India, representing different social and linguistic group, showed variable frequency. Interestingly, we found less representation of VL (rs3024498) and high representation of leprosy (rs1554286) associated alleles in tribes compared to castes. Haploview analysis also showed strong to moderate LD variation in 29 Indian populations. Overall, our population data of rs3024498 and rs1554286 suggest, that tribal and lower caste population of India have protected genotype and allele from VL while, more susceptible allele for leprosy. This study has potential medical implication in pharmacogenomics and vaccination programs.

830M

SVEP1 c.2080A>C (p. Gln581His) gene is associated with altered mortality of septic shock. *T. Nakada[1,2], J. Russell[2], J. Boyd[2], S. Thair[2], E. Nakada[2], K. Walley[2].* 1) Department of Emergency and Critical Care Medicine, Chiba University Graduate School of Medicine, Chiba, Japan; 2) University of British Columbia, Critical Care Research Laboratories, Heart + Lung Institute, St. Paul's Hospital, Vancouver, BC, Canada.

Background: Septic shock is a leading cause of death in intensive care units. Genetic factors are associated with altered mortality of septic shock. However the key genetic variations have not been fully elucidated. To identify the key variations, we first identified non-synonymous single nucleotide polymorphisms (SNPs) in conserved genomic regions that are predicted to have significant effects on protein function. We then test the hypothesis that these variants across genome alter clinical outcome of septic shock. **Methods:** Septic shock patients (n=520, European ancestry) were genotyped for 843 non-synonymous SNPs, which we identified in conserved regions of the genome and are predicted to have damaging effects from the protein sequence using PolyPhen-2 and phastCons. The primary outcome variable was 28-day mortality. Productions of adhesion molecules including IL-8 GRO-alpha, MCP-1 and MCP-3 were measured in human umbilical vein endothelial cells (HUVECs) after SVEP1 gene silencing by RNA interference. We measured IL-8 levels in the plasma obtained on admission from the septic shock patients. **Results:** Of 843 non-synonymous SNPs, SVEP1 c.2080A>C (p. Gln581His, rs10817033) was significantly associated with altered 28-day mortality (Armitage trend test, uncorrected $P=3.8 \times 10^{-5}$, Bonferroni corrected P = 0.032). Patients with septic shock having the SVEP1 C allele of SVEP1 c.2080A>C had a significant increase in the hazard of death over the 28-day (hazard ratio 1.72, 95% confidence interval, 1.31 - 2.26, $P=9.7 \times 10^{-5}$) and increased organ dysfunction, and needed more organ support ($P < 0.05$). SVEP1 gene silencing increased IL-8, GRO-alpha, MCP-1 and MCP-3 in HUVECs under LPS stimulation ($P<0.01$). Non-survivors of the septic shock cohort had significantly increased IL-8 levels ($P=0.0005$). There was a trend toward increased plasma IL-8 with increasing C alleles of SVEP1 c.2080A>C, most notably among homozygous carriers, though this was not statistically significant (CC vs. AC vs. AA, P=0.22). SVEP1 c.2080A>C polymorphism alters amino acids in a conserved region in protein sequence and is predicted to be damaging. **Conclusions:** C allele of SVEP1 c.2080A>C (p. Gln581His), a non-synonymous SNP in conserved regions and predicted to have damaging effects on protein structure, was associated with increased 28-day mortality of septic shock. SVEP1 may involve the leukocyte adhesion pathway.

831T

Generalization and fine-mapping of CDKN2B-AS1 for primary open-angle glaucoma in African Americans from the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study. *N. Restrepo[1], R. Goodloe[1], E. Farber-Eger[1], D. Crawford[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville TN.

Primary open-angle glaucoma (POAG) is the second leading cause of permanent vision loss and blindness in the U.S. Genome-wide and candidate gene association studies have identified several loci associated with POAG risk in populations of European-descent. African Americans are ~15 times as likely to develop permanent vision impairment from glaucoma vs. European Americans, yet few studies have been performed in this population. To begin to fill these gaps in knowledge, we have performed a generalization and fine-mapping study for one POAG-associated region, CDKN2B-AS1, in African Americans from the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study as part of the larger Population Architecture using Genomics and Epidemiology study. A total of 242 CDKN2B-AS1 SNPs were targeted for genotyping using the Metabochip. African American POAG cases (n=135) and controls (n=1,739) were identified in BioVU, the Vanderbilt University Medical Center DNA repository. Cases and controls were identified via a combination of International Classification of Diseases diagnostic codes, Current Procedural Terminology billing codes, and manual review of clinical records. We performed single SNP tests of association for common variants (MAF>0.05) using logistic regression assuming an additive genetic model adjusted for age and sex. We did not replicate associations previously described in European Americans for rs523096, rs564398, rs2157719, rs1412829, rs1063192 at a corrected threshold of 2.06×10-4. These SNPs have minor allele frequencies (MAF) ranging from 0.37-0.45 in HapMap CEU populations compared to 7-9% among EAGLE BioVU African Americans. In addition to striking MAF differences, we observed differences in linkage disequilibrium (LD) for this gene between HapMap CEU and ASW data, and mostly low levels of LD in EAGLE BioVU African Americans when plotted using LocusZoom. Although none of the associations tested survived multiple correction testing, several were nominally associated with POAG including six variants in a 37kbp region (Chr 9: 22,105,026-22,068,305) that were associated at p<0.01 with ORs ranging 1.40-1.44. An exception was a SNP at Chr. 9 (bp 22105026; MAF=0.42) that was associated with an OR of 0.70 (95% CI: 0.54-0.92). Although underpowered, this study highlights the need for further studies among African Americans to determine if lack of generalization is due to differences in LD or differences in the genetic risk factors for POAG.

832S

Associations between variants in motilin genes and infantile hypertrophic pyloric stenosis. *PA. Romitti[1,2], Y. Zhu[2], Y. Cao[2], DM. Kay[3], RJ. Sicko[3], S. Richardson[4], R. Fan[5], A. Liu[5], ML. Browne[4,6], CM. Druschel[4,6], T. Carter[5], M. Caggana[3], LC. Brody[7], JL. Mills[5].*1) Iowa Registry for Congenital and Inherited Disorders; 2) Department of Epidemiology, College of Public Health, The University of Iowa, Iowa City, IA; 3) Division of Genetics, Wadsworth Center, New York State Department of Health, Albany, NY; 4) Congenital Malformations Registry, New York State Department of Health, Albany, NY; 5) Division of Intramural Population Health Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, DHHS, Bethesda, MD; 6) Department of Epidemiology and Biostatistics, School of Public Health, University at Albany, Rensselaer, NY; 7) Genome Technology Branch, National Human Genome Research Institute, NIH, DHHS, Bethesda, MD.

The onset (days to weeks following birth) and descriptive epidemiology (male and non-Hispanic White excess) of infantile hypertrophic pyloric stenosis (IHPS) suggest its etiology may comprise environmental and genetic factors. Maternal and infant use of erythromycin, a motilin agonist, has been associated with IHPS. We examined associations between variants in the motilin (*MLN*) and motilin receptor (*MLNR*) genes and IHPS. Given the predominance of IHPS among non-Hispanic Whites, we used the population-based New York State (NYS) Congenital Malformations Registry to identify non-Hispanic White cases with IHPS born 1998-2005. A sample of sex- and racial/ethnic-matched controls born during the same time period was randomly selected from unaffected NYS live births. Case and control data were linked with NYS Newborn Screening Program data to obtain residual newborn blood spots. DNA was purified from de-identified blood spots for cases (n=656) and controls (n=656) and genotyped for single nucleotide polymorphisms (SNPs), identified by haplotype tagging, in the *MLN* (12 SNPs) and *MLNR* (1 SNP) genes. Using unconditional logistic regression, we estimated odds ratios (ORs) and 95% confidence intervals (CIs), corrected for multiple comparisons (P<0.0038), between each SNP genotype (heterozygous or homozygous minor vs. homozygous major) and IHPS. Statistically significant increased associations were observed between both *MLN* rs1547668 (homozygous minor: OR=2.78; 95% CI=1.51-5.12, uncorrected P=0.0011) and *MLN* rs4713685 (homozygous minor: OR=2.10; 95% CI=1.38-3.21, uncorrected P=0.0006) and IHPS. Significantly reduced associations were observed between *MLN* rs1547669 (heterozygous: OR=0.69; 95% CI=0.54-0.89, uncorrected P=0.0037; homozygous minor: OR=0.56; 95% CI=0.41-0.76; uncorrected P=0.0003) and IHPS. No significantly increased or decreased associations were observed for the *MLNR* SNP and IHPS. Using this large population-based sample of European ancestry, we observed significantly increased associations in two *MLN* SNPs and significantly decreased associations in another *MLN* SNP and IHPS. The hormone encoded by the *MLN* gene is secreted by cells of the small intestine to regulate gastrointestinal contractions and motility. The associations identified for *MLN* SNPs provide insights into potential genetic susceptibilities for IHPS and support for the observed associations between maternal and infant erythromycin use and this defect.

Intracranial Aneurysm Genetics: A south India perspective. *S. Sathyan[1], L. Koshy[1], H.V. Easwer[2], S. Premkumar[3], J. Alapatt[3], S. Nair[2], R.N. Bhattacharya[2], M. Banerjee[1].* 1) Human Molecular Genetics, Rajiv Gandhi centre for biotechnology, Thiruvananthapuram, KERALA, India; 2) Department of Neurosurgery, SCTIMST, Thiruvananthapuram; 3) Department of Neurosurgery, Calicut Medical College, Calicut, India.

Intracranial aneurysm (IA) is a fairly common condition that is often asymptomatic until the time of rupture. Rupture of cerebral aneurysm is the foremost cause for spontaneous Subarachnoid hemorrhage (SAH). In general population 2-3% of the individuals are likely to harbour intracranial aneurysm. Autopsy studies from India have shown the prevalence of IA ranges from 0.2% to 10.3% with a mean prevalence of 5.3 %. Aneurysmal SAH(aSAH) is associated with mortality rate as high as 40% to 50%. Genetic and environmental factors are reported to influence development of IA.The genes involved in vascular remodelling, endothelial dysfunction and immune response converge in addressing various hypothesis that has been put forward for pathogenesis of IA. Till date five genome wide association studies have been carried pointing out involvement of 4q31.23, 8q21.3, 9p21.3 and 13q.13.1.9p21 genomic loci for IA. The objective of this study is to screen these hypothesis driven candidate genes and validate the positional regions in the GWAS studies in the pathogenesis of intracranial aneurysm in south Indian population. The study populations consisted of 225 radiologically confirmed aneurismal cases and 235 ethnically and age matched controls from Dravidian Malayalam speaking population of Kerala. Genotyping was carried out based on allelic discrimination and Sequencing chemistry. In silico validation of functional effect was carried out. While evaluating the environmental factors our study show that history of hypertension (P-value<0.001,OR= 2.98) and cigarette smoking (P-value<0.001,OR=3.59) where associated with intracranial aneurysm while diabetes showed an protective effect on intracranial aneurysm(P-value=0.009,OR=0.34 (0.15-0.76). While evaluating the pathway focused genetic associations for possible endophenotyping we observe that *MMP2, COL1A2* and *VCAN* genes of extracellular matrix remodeling and proinflammatory cytokines of TNFalpha and IFN gamma of immune response are associated with IA in South Indian population. Their functional implication and interaction in developing a precise ECM/proinflammatory endophenotype would be interesting.Among positional GWAS hits located in 4q31.23, 8q21.3, 9p21.3 and 13q.13.1.9p21 harbouring *EDNRA, SOX17, CDKN2BAS* and *STARD13* respectively we could not replicate any of these regions with exception to 9p21.3 to be associated for IA in South Indian population. This is the first study on genetics of IA in any Indian population.

834T

Association between IRF6 polymorphisms and 8q24region in non-syndromic cleft lip with or without cleft palate in Brazilian population. *L.T. Souza[1,2], T.K. Kowalski[2], J. Ferrari[2], I.L. Monlleo[3], E.M. Ribeiro[3], J. Souza[3], G.F. Leal[3], A.C. Fett-Conte[3], V.G. Silva-Lopes[3], A.K.C. Ribeiro-dos-Santos[4], S.E.B. Santos[4], T.M. Félix[1,2,3,5].* 1) Programa de pós-graduação em Saúde da Criança e do Adolescente-Uinersidade federal do Rio Grande do Sul, UFRGS, Brazil; 2) Laboratório de Medicina Genômica, Hospital de Clínicas de Porto Alegre, HCPA, Brazil; 3) Projeto Crânio-Face Brazil, Brazil; 4) Laboratório de Genética Humana e Médica, Universidade Federal do Pará, UFP, Brazil; 5) Serviço de Genética Médica, Hospital de Clínicas de Porto Alegre, HCPA, Brazil.

Cleft lip and palate (CL/P) has a multifactorial inheritance. Identification of genetic risk factors has been the subject of intensive research. Three polymorphisms, rs2235371 and rs642961 in IRF6 and rs987525 in 8q24, have been associated with CL/P risk in several studies. Variants in IRF6 gene are responsible for 12% of clefts, the first variant associated was rs2235371 (V274I) and it is in linkage disequilibrium with rs642961. The rs642961 was suggested to cause disruption of the binding site of transcription factor AP-2α. The function of 8q24 is still unknown. A variant rs987525 (C>A) have involved in the pathogenesis of CL/P in Caucasians and admixed populations. The aim of this study was to evaluate the association between three polymorphisms and CL/P in the Brazilian admixture population. In this study were included subjects with non-syndromic CL/P and their parents that from three different geographical regions of Brazil. This research was approved by the Research Ethics Committee of Hospital de Clínicas de Porto Alegre and all the individuals signed an Informed Consent. For ancestry analysis, a panel of 48 INDELs was selected to measure the proportions of three different ancestries in the probands with CL/P. All selected markers were analyzed by multiplex. The SNPs were analyzed using TaqMan assay (Applied Biosystem). Statistical analysis was performed with FBAT and Haplin softwares. Acestry was analyzed in 228 probands. We select triads whose probands had European ancestry >=0.6 to further genetic analysis of the polymorphisms. We analyzed 151 nuclear families totalizing 390 individuals. MAF for rs2235371 A allele was 0.08, 0.19 for rs642961A allele and 0.41 for rs987525 A allele. TDT analysis showed an overtransmission of G allele rs2235371 (p=0.004) and of A allele for rs987525 (p=0. 048). Haplotype analysis in IRF6 showed association for the children haplotype (rs2235371G and rs642961A) in single and double dose and mother haplotype (rs2235371G and rs642961A) for single dose. This data confirms association of rs2235371 G allele in IRF6 and rs987525 A allele in 8q24 region with non-syndromic CL/P, similar to the previous studies in Caucasian and Mixed populations. The association between these polymorphisms and CL/P is due to European ancestry. We found association with the haplotype (rs2235371 G and rs642961 A) for non-syndromic cleft lip and/or palate.This is the first study that was able to show this association in Brazil.

***MC4R, TMEM18, SH2B1, SEC16B* and *ADIPOQ* gene variants: associations with anthropometric and dietary variables in young children.** *M.R. ZANDONA[1], M.R. VITOLO[1, 2], S. ALMEIDA[1], V.S. MATTEVI[1].* 1) Federal University of Health Sciences of Porto Alegre, PORTO ALEGRE, RIO GRANDE DO SUL, Brazil; 2) Departament of Nutrition, Federal University of Health Sciences of Porto Alegre, Porto Alegre, RS, Brazil.

Background: The prevalence of childhood obesity is increasing worldwide and has become a major health problem. Identification of susceptibility genes in early life could provide the foundations for interventions in lifestyle to avoid obese children to become obese adults. Genome-wide association studies (GWAS) have led to the identification of several loci in the human genome containing genetic variants conferring an increased risk of developing overweight and obesity. Furthermore, association studies in children and adolescents remain useful in the investigation of candidate genes for obesity, in which rare variants might be identified and responsible for unexplained phenotypic variation. In this study we evaluated the influence of genetic variants related to obesity identified by GWAS (*MC4R, TMEM18, SH2B1* and *SEC16B*) and association studies (*ADIPOQ, PPARG* and *LEPR*) on anthropometric phenotypes and food intake in a cohort of 424 children followed-up since birth until 3 years old. Methods: The polymorphisms were genotyped using real-time polymerase chain reaction and the dependent variables were compared among genotypes at the ages of 1 and 3 years old by t-tests and analysis of variance. Multilevel mixed models were also used to analyze genotype effects on the patterns of individual change in anthropometric and dietary variables over time. Results: In this sample 52.6% were boys. At 3 years, overweight prevalence was 43.1%. *TMEM18* rs6548238 was associated with BMI Z-score at 3 years and over the years (P=0.029, P=0.011; respectively). We also found associations with intake of lipid dense foods at 1 year (P=0.045) and total energy intake over the years (P=0.017). *MC4R* rs17782313 was associated with intake of sugar dense foods at 1 year and intake of lipid dense foods over the years (P= 0.023, P=0.020; respectively). *SH2B1* rs7498665 was associated with intake of sugar dense foods at 3 years (P=0.029). *SEC16B* rs10913469 was associated with sum of skinfolds at 1 year in girls (p=0.028). Association between *ADIPOQ* rs17300539 and BMI-Z score was observed at 1 year (P=0.022) and *ADIPOQ* rs266729 was associated with sum of skinfolds over the years (P=0.027). Conclusions: This study provides indications that genetic variants in *TMEM18, MC4R, SH2B1, SEC16B* and *ADIPOQ* genes might be associated with anthropometric phenotypes and food intake in young children.

Aim/hypothesis: Mutations that cause functional changes in an ion channel may result in different diseases, such as cardiac arrhythmias and beta cell dysfunction, depending on which tissue the channel is expressed in. *KCNE1* is expressed in both cardiomyocytes and in pancreatic islets and a low frequent functional variant in this gene, *KCNE1* p.D85N (CEU MAF 0.02), has been shown to affect the QT-interval. We aimed to test for associations between the QT-interval-associated allele of *KCNE1* p.D85N and insulin release from pancreatic beta cells. **Methods:** Associations of the *KCNE1* p.D85N variant with QT-interval and insulin levels were studied in 5,738 Danish individuals from the Inter99 study without known diabetes. An association with 2-h insulin was taken forward for replication in a total of 1,662 Danish and Finnish non-diabetic individuals and the results were combined in a meta-analysis. The beta cell response to an intravenous load of glucose and tolbutamide was examined in 303 individuals from the Danish Family study. **Results:** The QT-interval-prolonging allele of *KCNE1* p.D85N associated with increased QT-interval (β=0.023, p=1.4×10^{-13}) and decreased 2-h insulin (β=-0.149, p=0.013) in Inter99. The association with decreased 2-h insulin stayed significant in the combined meta-analysis (β=-0.174, p= 7.6×10^{-4}). This variant was also associated with decreased intravenous tolbutamide-induced insulin secretion (incremental AUC (mean±SD) 1,574±1,744 vs. 2,398±1,625, p=0.036) in the Danish Family study. **Conclusion/interpretation:** We found that heterozygote carriers of the low frequent QT-interval-prolonging allele of *KCNE1* p.D85N have lower insulin levels after an oral glucose tolerance test and intravenous tolbutamide injection suggesting that these carriers have both impaired glucose and tolbutamide-stimulated insulin secretion.

Ion channels play an important role in regulating and maintaining the calcium and pH homeostasis that is critical for tooth development. Mutations in genes encoding for ion channels can be related to a heterogeneous group of diseases called “channelopathies.” One common channelopathy is Timothy Syndrome, a Mendelian disease that affects many parts of the body including the heart, fingers and toes, the nervous system and causes small, misplaced teeth and frequent cavities in children. As part of a larger candidate gene study we investigated 480 single-nucleotide polymorphisms (SNPs) in several ion channel genes, including CACNA1C, CACNA2D1, CACNB2, CACNG2, KCNH1, KCNK5, and KCNK17, several of which are known to play a role in Timothy syndrome or other channelopathies. We tested association of these genes with dental caries in 13 race and age-stratified cohorts from six independent studies of Caucasians and African Americans. We performed analyses independently for each cohort and synthesized results by meta-analysis. After gene-wise adjustment for multiple testing, two SNPs for CACNA2D1 were significantly associated with dental cares via meta-analysis across the five childhood cohorts and in one individual childhood cohort (p-values<0.0007). In adults, genetic association was observed in three individual cohorts for potassium channel genes KCNH1 and KCNK5 (p-values<0.001), but no single SNP was significant via meta-analysis across all eight adult cohorts. These findings strengthen the hypothesis that ion channel genes, particularly those involved in channelopathies, may affect the risk of dental caries. Grants:R01-DE014899, U01-DE018903.

Analysis of Haptoglobin Duplication with Type 2 Diabetes and Diabetic End Stage Kidney Disease. *JN. Adams[1,2,3], LM. Raffield[1,2,3], AJ. Cox[2,3,4], ET. Barton[4], CD. Langefeld[5], BI. Freedman[2,3,6], MCY. Ng[2,3], ND. Palmer[2,3,4], DW. Bowden[2,3,4].* 1) Molecular Genetics and Genomics, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Division of Public Health Sciences, Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC, 27157.

Haptoglobin (HP) is an acute phase protein that binds to freely circulating hemoglobin. HP assists in the removal of hemoglobin from the circulatory system, thus preventing its accumulation in the kidney. This accumulation could lead to kidney damage and oxidative damage caused by the heme iron. The HP protein exists as two distinct forms, HP1 and HP2. The longer HP2 form arose from a duplication of exons 3 and 4 and has been associated with cardiovascular disease (CVD) events and mortality in individuals with type 2 diabetes (T2D). HP has also been reported to be associated with T2D in multiple ethnicities, and with end stage kidney disease (ESRD) in individuals with type 1 diabetes. This novel duplication is not tagged or genotyped on conventional genotyping arrays and thus requires direct genotyping of the locus or Western blot. In this study we investigated the association of the *HP* duplication with T2D and diabetic end stage kidney disease (DMESKD) in African-Americans. *HP* genotyping was performed by PCR amplification using two sets of allele-specific primers, followed by resolving the products by agarose gel electrophoresis. Genotyping was performed in 4560 African American individuals: 2022 with T2D and DMESKD, 891 with T2D only, and 1647 controls with neither disease. The *HP* duplication was then analyzed for association with T2D and DMESKD. The *HP* duplication was not associated with T2D in this population (p=0.25). However, analyses revealed that the *HP*2 allele was associated with increased DMESKD risk with an odds ratio (OR) of 1.18 (95% confidence interval (CI) 1.06-1.28, p= 0.0012) when comparing individuals with DMESKD to control individuals. When comparing individuals with DMESKD to individuals with T2D and controls, the *HP*2 allele remained associated with DMESKD with an OR of 1.15 (95% CI 1.05-1.25, p=0.00183). This study suggests an association between the *HP* duplication and susceptibility to DMESKD in the African-American population. HP is a strong biological candidate for kidney disease. HP has been shown to decrease oxidative damage of the kidney. However, the HP2-2 protein has been shown to have decreased antioxidant properties compared to HP1-1. In addition the HP2-2-hemoglobin (Hb) complex is cleared much slower than the HP1-1-Hb complex. This leads to an accumulation of iron in the proximal tubule cells of the kidney. This accumulation leads to increased oxidative stress and damage to the tubule, and increased kidney disease.

839M

Assessment of Common and Rare Variants at Established Type 2 Diabetes and Glucose Homeostasis Loci for Type 2 Diabetes Risk in African Americans. *J.M. Keaton[1,2,3], P. Mudgal[3], B.I. Freedman[4], D.W. Bowden[2,3,5,6], M.C.Y. Ng[2,3].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 6) Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) is a metabolic disease characterized by both insulin resistance and impaired insulin secretion. African Americans (AAs) have higher disease prevalence of T2D (12.6%) compared to European Americans (7.1%). Although GWAS of primarily European populations have identified ~70 loci associated with T2D, these loci are usually represented by a common index variant spanning a large region of linkage disequilibrium (LD). GWAS in a single population may not have sufficient resolution to identify causal SNPs, address the impact of rare variants, or assess genetic architecture underlying ethnic disparities in disease prevalence. With these considerations, we examined SNP- and locus-wide association of 44 T2D loci reported in Europeans ($P \leq 5\times10\text{-}8$, odds ratio [OR] 1.07-1.39) for association in an AA cohort consisting of 1617 T2D cases and 676 healthy controls. Considering the pathophysiology of T2D, we also examined 29 reported European glucose homeostasis (GH) loci ($P \leq 5\times10\text{-}8$). Individuals were genotyped using an Affymetrix BioBank array customized for fine-mapping of T2D and GH candidate genes/loci. Our results show that 16 T2D index SNPs, or their proxies ($r^2 \geq 0.5$ in CEU), at the *THADA*, *GRB14*, *IRS1*, *WFS1*, *ANKRD55*, *JAZF1*, *CDKN2A/B*, *TCF7L2*, *KCNQ1*, *MTNR1B*, *KLHDC5*, *HMGA2*, *TSPAN8/LGR5*, *FTO*, *MC4R*, and *CILP2* loci were significantly associated with T2D ($P<0.05$, OR 1.17-1.55) in AAs. Additionally, 6 GH index SNPs or proxies at the *DGKB/TMEM195*, *GLIS3*, *ADRA2A*, *MADD*, *FADS1*, and *VPS13C/C2CD4A/B* loci were significantly associated with T2D ($P<0.05$, OR 1.19-1.35). The strongest association was *TCF7L2* rs7903146 ($P=2.22\times10\text{-}5$, OR=1.35), consistent with current literature. Of the 22 associated loci, the most strongly associated SNP in AAs was identical to or in LD ($r^2 \geq 0.5$) with the European index SNP at 10 loci: *GRB14*, *IRS1*, *ANKRD55*, *JAZF1*, *KCNQ1*, *FTO*, *TCF7L2*, *MADD*, *FADS1*, and *VPS13C/C2CD4A/B*. Gene-based analysis including both common and rare coding variants in SKAT revealed significant association at the IRS1 ($P=0.025$) and TSPAN8 ($P=0.020$) loci, but these associations were lost when only SNPs with predicted functional consequences were included in the model. These findings suggest that loci discovered in European GWAS influence T2D risk in AAs with similar effect sizes, that the lesser degree of LD in AAs may facilitate identification of the causal variants, and that rare coding variants at established T2D loci do not significantly contribute to T2D risk in AAs.

840T

Detailed phenotypic analysis of lipid SNPs reveals divergent effects of *SORT1* on circulating LDL cholesterol, plasma glucose and their respective cardio-metabolic complications. *L.A. Lotta, R.A. Scott, N.J. Wareham.* MRC Epidemiology Unit, School of Clinical Medicine, University of Cambridge, Box 285, Institute of Metabolic Science, Cambridge Biomedical Campus, Cambridge, CB2 0QQ, United Kingdom.

Epidemiologic and genetic evidence suggest that the genetic background of blood lipids may be largely shared with that of glycaemic and anthropometric traits. Recent GWAS have identified >100 SNPs associated with lipid levels, but knowledge of their relevance to other metabolic traits is incomplete. We sought to assess the association of lipid SNPs with metabolic traits in 4,202 participants of the Fenland cohort study. We genotyped or imputed a total of 137 SNPs identified in a recent large-scale GWAS. Using linear regression models, we studied the association of individual SNPs and genetic risk scores of lipid traits (i.e. triglycerides, total-, HDL- and LDL-cholesterol) with detailed glycaemic and anthropometric phenotypes. These included fasting and post-challenge plasma glucose, insulin, HbA1c as well as anthropometric measurements from ultrasound and dual-energy X-ray absorptiometry (DEXA). Quantile-quantile plots of the association of SNPs with metabolic traits were systematically inflated, highlighting considerable pleiotropy. A 63-SNP HDL-increasing genetic score was associated with multiple measures of reduced glycaemia, insulin resistance and adiposity. Individual SNPs with evidence of pleiotropic effects included those at known metabolic-trait or type 2 diabetes (T2D) loci (e.g. *FTO*, *MC4R*, *FADS1-2-3*, *FAM13A* and *GCKR*). The SNPs with the strongest effect across multiple phenotypes were rs1121980 at *FTO* and rs629301 at *SORT1* - a known LDL and coronary artery disease (CAD) gene encoding an insulin-sensitive intracellular sorting protein. The LDL-reducing allele of rs629301 was associated with increased fasting insulin (beta [SE] in SD per allele, 0.07 [0.03]), HOMA-insulin resistance index (0.07 [0.03]) and body fat mass (0.06 [0.03]). DEXA-scan analyses also revealed increased fat mass in each body compartment - in particular the trunk (0.07 [0.03]) - while bone or lean masses were unaffected. In the publicly-available CARDIoGRAM and DIAGRAMv3 datasets, the SNP was associated with CAD (OR [95% CI], 0.90 [0.87-0.93]) and T2D (1.04 [1.00-1.08]) in opposite directions, consistent with the association observed with the corresponding intermediate traits - LDL cholesterol (beta [SE], -0.13 [0.03]) and fasting glucose (0.05 [0.03]). Our study highlights opposite effects of *SORT1* on cholesterol levels and glycaemic traits. This finding is relevant to discussions on the development of lipid-lowering drugs targeting sortilin.

841S

Candidate Genes for Non-syndromic Orofacial Clefts Identified by GWAS Were Assessed in Two African Populations. *A. Butali[1], P.A Mossey[2], W.L Adeyemo[3], E.A Mekonen[4], L. Gaines[1], T. Busch[1], R.O Braimah[5], S.B Aregbesola[5], J. Rigdon[1], C. Emeka[3], O. James[3], O. Ogunlewe[3], A.L Ladeinde[3], F. Abate[4], T. Hailu[4], M. Ibrahim[4], P. Gravem[4], M. Deribew[4], M. Gesses[4], A. Adeyemo[6], M.L Marazita[7], J.C Murray[1].* 1) University of Iowa, Iowa City, IA. U.S.A; 2) University of Dundee, UK; 3) University of Lagos, Nigeria; 4) Addis Ababa University, Ethiopia; 5) Obafemi Awolowo University, Nigeria; 6) National Institutes for Health, Bethesda, MD, U.S.A; 7) University of Pittsburgh, Pittsburgh Pennsylvania, U.S.A.

Genome-wide association studies (GWAS) for non-syndromic cleft lip with or without cleft palate (NSCL/P) have identified 14 new loci. These loci have been replicated in several studies confirming the role of common variants in increasing risk to NSCL/P. Rare variants in these candidate genes have also been reported in resequencing studies. Here, we present analysis of common variants reported in the GWAS studies and rare variants identified following genotyping and Sanger sequencing in two sub-Saharan African populations from Nigeria and Ethiopia. Genotyping of 24 common variants in these 14 loci was done using Fluidigm technology which allows multiplexing of samples. Genotyping of 228 pedigrees was completed with a 95% genotyping call rate. Transmission disequilibrium tests and parent of origin analyses were conducted using PLINK. We sequenced the coding regions of the following genes: MAFB, PAX7, VAX1, ARHGAP29, and IRF6 in 220 probands from Africa [140 Nigerians and 80 Ethiopians] in order to identify rare functional variants. The TDT results for the 24 common variants were not significant ($p>0.05$). However, we observed significant paternal effects for SPRTY2 rs9574565 ($X2=4.5$; $p=0.03$). We also found new rare variants— p.His165Asn in the MAFB gene, p.Asp428Asn in the PAX7, a splice-site variant that creates a new donor splice-site in PAX7 following sequencing. All these variants segregate in parents. It is important to conduct an unbiased genome-wide association and sequencing studies using samples from this understudied African population in order to identify new candidate genes and loci for NSCL/P. Grants: R00-DE022378 (AB) R37-DE008559 (JCM), R01-DE016148 (MLM).

Interaction of immune-related genetic polymorphisms and breastfeeding duration with *Helicobacter pylori* prevalence: the Pasitos Cohort Study. *M.L. Grove[1], K.A. Volcik[2], E.A. Brown[3].* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Biochemistry and Molecular Biology, University of Texas Medical School at Houston, Houston, TX; 3) Center for Infectious Disease, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX.

Helicobacter pylori (*H. pylori*) is a bacteria that colonizes in the mucosal layers of the gastric and sometimes duoadenal or esophageal epithelium in up to 50% of the human population. In 3% of individuals, *H. pylori* contributes to the progression of gastric cancer which is the second leading cause of cancer mortality worldwide. Numerous risk factors have been associated with *H. pylori* infection risk, including genetic variation and environmental contributors such as breastfeeding. Therefore, we investigated the associations of immunological candidate gene loci with *H. pylori* prevalence within the context of breastfeeding (BF) status. We examined 87 SNPs in 27 immune-related genes in 239 Hispanic infants from the Pasitos Cohort Study which were ascertained from two populations residing on the United States (US) and Mexico border at El Paso, Texas and Juarez, respectively. *H. pylori* infection prevalence was ascertained using serum measures, breastfeeding status was categorized as <6 months or ≥6 months duration, and genetic variation was captured with the Sequenom MassARRAY® system using established genotyping methods. Additive logistic regression models were used to test each single nucleotide polymorphism (SNP) by country of origin which included gender, BF status, and a SNPxBF multiplicative interaction term. Models with statistically significant interactions were further stratified by BF categories and the genotypes assessed for additive effects including gender as a covariate. We observed significant SNPxBF interactions for three variants in the US population (*CCR6* *P*=0.003, *IL15* *P*=0.004, and *SFTPD* *P*=0.042), and *IL6R* (*P*=0.037) in the Mexico population. After stratification of these loci by BF status, variants in *CCR6* and *SFTPD* were shown to be associated with 25% and 26% lower prevalence in infants BF≥6 months (rs2022001, odds ratio [OR]=0.25, 95% confidence interval [CI]=0.10-0.67, *P*=0.006; and rs721917, OR=0.26, 95% CI=0.08-0.80, *P*=0.019), respectively. Homozygote infants BF<6 months with the risk-raising allele in *IL15* in the US population and *IL6R* in the Mexico population were 2.6 and 2.1 times more likely to be infected with *H. pylori* (rs10519613, OR=2.66, 95% CI=1.49-4.77, *P*=0.001; and rs6427641, OR=2.12, 95% CI=1.09-4.14, *P*=0.028), respectively. To our knowledge, we are the first to report variations in immune-related genes may interact with BF status to influence *H. pylori* prevalence in Hispanic infants.

843T

Why do some athletes with sickle cell trait suffer from heat illness? *A.C. Stone[1], R. Grieger[1], J. Lund[1], M. Ciambella[1], C. Flansburg[2], L. Madrigal[2].* 1) Human Evolution & Social Chg, Arizona State Univ, Tempe, AZ; 2) Department of Anthropology, University of South Florida, Tampa, FL.

The NCAA recently declared sickle cell trait (SCT) to be a risk factor for sudden illness and death among student athletes. Although its effect on SCT is not fully understood, fetal hemoglobin (HbF) concentration in adults is negatively correlated with disease severity in sickle cell anemia, and the concentration of HbF in adults is found to be highly variable across populations. In order to test whether lower HbF levels in some SCT athletes increases their risk for illness during exercise, we conducted preliminary analysis of five single nucleotide polymorphisms (SNPs) located in the human beta globin gene cluster (rs7482144 and rs10128556), the HBS1L-MYB intergenic interval (rs9402686), and the BCL11a gene (rs10189857 and rs4671393). These SNPs contribute to the heritable variation in HbF levels and are associated with increased HbF concentrations in adults. A sample (n= 22) of NCAA football student athletes was genotyped at these SNPs, and their allele frequencies were compared to those of other populations. For rs7482144 and rs10128556 in the beta globin gene cluster, the minor allele frequencies of both were 0.091 in the sample population. The minor allele frequencies for rs9402686, rs10189857, and rs4671393 were 0.07, 0.34, and 0.41, respectively. These results compared closely with other populations of recent African heritage. The results of this study will be combined with data from medical records to assess whether these polymorphisms can be used to predict susceptibility to exercise related illness in NCAA student athletes with SCT.

Genetic determinants of benign prostatic hyperplasia: associations with prostate volume. *A. Giri[1], J.H. Fowke[1,2], S.S. Motley[1], S. Byerly[1], T.L. Edwards[1,3].* 1) Division of Epidemiology, Institute for Medicine and Public Health, Vanderbilt University, Nashville, TN; 2) Vanderbilt-Ingram Cancer Center, Vanderbilt University School of Medicine, Nashville, TN; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

A highly prevalent condition among men over the age of 50, benign prostatic hyperplasia (BPH) is the non-malignant proliferation of the epithelial and stromal cells in the prostate gland. It is usually diagnosed in the presence of enlarged prostate. Components of metabolic disorders such as obesity, elevated lipid profiles, and fasting glucose/insulin levels have been positively associated with BPH. However, whether there is a genetic basis to these associations has not been investigated in detail. Using the Metabochip platform we evaluated over 100,000 common single nucleotide polymorphisms (SNPs) from 257 loci implicated with metabolic disorders throughout the genome in relation to prostate volume (PV). Participants for this study were derived from the Nashville Men's Health Study, a rapid-recruitment protocol targeting men seeking a diagnostic prostate biopsy. Consenting participants provided information regarding individual characteristics, measurement of anthropomorphic traits and blood samples prior to prostate biopsy. PV (ml) was measured using ultrasound. Data from 876 prostate cancer free men and 442 men with low-grade prostate cancer (Gleason Score < 7) served as discovery and validation samples, respectively. We used linear regression in PLINK to evaluate the associations between SNPs (additive coding) and natural-log transformed (ln) PV while adjusting for age, body mass index, height, and 10 genetic ancestry principal components derived using Eigensoft. Inverse variance weighted fixed-effect meta-analysis of beta-coefficients from the discovery and validation sample suggested SNP rs11736129 (near *LOC100131429*) to be significantly associated with ln-PV (beta: 0.16, p-value 1.16×10^{-8}). Other SNPs that were nominally associated ($p < 1\times10^{-4}$) with ln-PV included rs9583484 (intronic SNP in *COL4A2*), rs10146527 (intronic SNP in *NRXN3*), rs9909466 (SNP near *RPL32P31*), and rs2241606 (synonymous SNP in the *SLC12A7* exon). *LOC100131429* is an unprocessed pseudogene that bears sequence resemblance with the *ARMC1* gene, which has been reported to be nominally associated with childhood obesity in Hispanics. Similarly, the *NRXN3* locus has been previously associated with waist-to-hip ratio in the GIANT consortium. *COL4A2* is a component of type IV collagens which provide major structural support to basement membranes of several organs including the prostate. In conclusion, we found several metabolic loci that may be important to the etiology of BPH.

IDENTIFICATION OF SIGNIFICANT ASSOCIATION AND GENE-GENE INTERACTIONS OF POLYMORPHISMS IN THREE INFLAMMATORY GENES CRP, TNF-α, AND LTA FOR LOWER EXTREMITY PERFORMANCE IN COMMUNITY-DWELLING ELDERS IN TAIWAN-TAICHUNG COMMUNITY HEALTH STUDY FOR ELDERS (TCHS-E). *T.C. Li[1,2], C.C. Lin[3,4], C.I. Li[4,5], N.H. Meng[4,6], W.Y. Lin[3,4], C.S. Liu[3,4], C.H. Lin[3,4,7], C.W. Yang[5,7], C.K. Chang[4,6], F.Y. Wu[8], L.N. Liao[8].* 1) Graduate Institute of Biostatistics, China Medical University, Taichung, Taiwan; 2) Department of Healthcare Administration, College of Health Science, Asia University, Taichung, Taiwan; 3) Department of Family Medicine, China Medical University Hospital, Taichung, Taiwan; 4) School of Medicine, College of Medicine, China Medical University, Taichung, Taiwan; 5) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 6) Department of Physical Medicine and Rehabilitation, China Medical University Hospital, Taichung, Taiwan; 7) Ph.D. Program for Aging, College of Medicine, China Medical University, Taichung, Taiwan; 8) Department of Public Health, College of Public Health, China Medical University, Taichung, Taiwan.

Purpose: We conducted a cross-sectional study to assess the main effects and possible gene-gene interaction of three inflammatory cytokine gene polymorphisms C-reactive protein (CRP), tumor necrosis factor α (TNF-α), and lymphotoxin α (LTA) on lower extremity performance by investigating eleven single-nucleotide polymorphisms (SNPs) of these three genes in community-dwelling elders in Taiwan. Methods: Five SNPs (rs2794520, rs1205, rs1130864, rs1800947, rs3093059) of CRP gene, three SNPs (rs2239704, rs909253, and rs1041981) of LTA gene, and three SNPs (rs1799964, rs1800629, and rs3093662) of TNF-α gene were genotyped for 472 unrelated elderly subjects (221 women and 251 men; mean age, 73.8±6.1 years). Lower extremity performance measurements were administered to all participants including timed up and go test (TUG, sec), walking speed (m/sec), weight-adjusted leg press (waLP, %), and time to rise from a chair three times (Chair3, sec). Results: Significant genotypic association was found for SNPs rs2794520 and rs1205 (in CRP; P <0.05) on walking speed and SNP rs1800947 (in CRP; P <0.05) on waLP in women; and for SNP rs2239704 (in LTA; P <0.05) on waLP in both men and women. We also identified significant two-locus gene-gene effects involving rs2794520 in CRP gene and rs1799964 in TNF-α gene, and rs1205 in CRP gene and rs1799964 in TNF-α gene for walking speed and Chair3; rs2239704 in LTA gene and rs1799964 in TNF-α gene for TUG; rs1130864 in CRP gene and rs2239704 in LTA gene for walking speed; rs909253 in LTA gene and rs1799964 in TNF-α gene, and rs1041981 in LTA gene and rs1799964 in TNF-α gene for waLP; and rs3093059 in CRP gene and rs1799964 in TNF-α gene for Chair3 in women; rs1800947 in CRP gene and rs1800629 in TNF-α gene for TUG in men. Conclusions: These results support the hypothesis that inflammatory genes are involved in lower extremity performance, most likely via complex gene-gene interactions. In addition, there exists gender difference in the association between inflammatory genes and lower extremity performance.

846T

IDENTIFICATION OF SIGNIFICANT ASSOCIATION AND GENE-GENE INTERACTIONS OF POLYMORPHISMS IN THREE INFLAMMATORY GENES TNF-α, LTA AND IL-6 FOR MARKERS OF APPENDICULAR SKELETAL MUSCLE MASS IN COMMUNITY-DWELLING ELDERS IN TAIWAN-TAICHUNG COMMUNITY HEALTH STUDY FOR ELDERS (TCHS-E). *L.N. Liao[1], C.C. Lin[2,3], C.H. Lin[2,3,4], C.W. Yang[4,5], C.S. Liu[2,3], C.I. Li[3,5], N.H. Meng[3,6], C.K. Chang[3,6], W.Y. Lin[2,3], F.Y. Wu[1], T.C. Li[7,8].* 1) Department of Public Health, China Medical University, Taichung, Taiwan; 2) Department of Family Medicine, China Medical University Hospital, Taichung, Taiwan; 3) School of Medicine, College of Medicine, China Medical University, Taichung, Taiwan; 4) Ph.D. Program for Aging, College of Medicine, China Medical University, Taichung, Taiwan; 5) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 6) Department of Physical Medicine and Rehabilitation, China Medical University Hospital, Taichung, Taiwan; 7) Graduate Institute of Biostatistics, China Medical University, Taichung, Taiwan; 8) Department of Healthcare Administration, College of Health Science, Asia University, Taichung, Taiwan.

Purpose: We undertook a cross-sectional study to assess the main effects and possible gene-gene interaction of three inflammatory cytokine gene polymorphisms tumor necrosis factor α (TNF-α), lymphotoxin α (LTA) and interleukin-6 (IL-6) on markers of appendicular skeletal muscle mass by investigating nine single-nucleotide polymorphisms (SNPs) of these three genes in community-dwelling elders in Taiwan. **Methods:** Arm and leg lean muscle mass (LMS, kg) and appendicular skeletal muscle mass (ASM; kg), were measured by Dual-energy X-ray absorptiometry. Height-adjusted skeletal muscle index (hSMI; kg/m^2) was defined as ASM divided by height squared. Weight-adjusted skeletal muscle index (wSMI; %) was tallied as ASM divided by weight. Three SNPs (rs2239704, rs909253, and rs1041981) of LTA gene, three SNPs (rs1799964, rs1800629, and rs3093662) of TNF-α gene, and three SNPs (rs1880243, rs1800796, and rs1554606) of IL-6 gene were utilized to genotype 472 unrelated elderly subjects (221 women and 251 men; mean age, 73.8±6.1 years). **Results:** Significant genotypic association was found for SNP rs2239704 (in LTA; P <0.05) on leg LMS, ASM, hSMI, and wSMI and SNP rs1799964 (in TNF-α; P <0.05) on arm LMS and ASM in women; and for SNP rs1880243 (in IL-6; P <0.05) on leg LMS and ASM in men. We also identified significant two-locus gene-gene effects involving rs909253 in LTA gene and rs1799964 in TNF-α gene for leg LSM and ASM in both men and women and for hSMI and wSMI in women; and rs1041981 in LTA gene and rs1799964 in TNF-α gene for leg LSM, ASM, hSMI and wSMI in women; rs909253 in LTA gene and rs1800796 in IL-6 gene for leg LSM, ASM, hSMI, and wSMI in men; and rs1041981 in LTA gene and rs1800796 in IL-6 gene for arm and leg LMS, ASM, hSMI and wSMI in men. **Conclusions:** These results support the hypothesis that inflammatory genes are involved in lean muscle mass markers, most likely via complex gene-gene interactions. In addition, there exists gender difference in the association between inflammatory genes and lean muscle mass markers.

Genetic risk of rheumatoid arthritis conferred by *HLA-DRB1* in African Americans stratified by local ancestry. *R.J. Reynolds[1], N.M. Pajewski[2], S. Raychaudhuri[3,4], R.M. Plenge[5], S.L. Bridges[1].* 1) University of Alabama at Birmingham, Birmingham, AL; 2) Wake Forest University, Winston Salem, NC; 3) Brigham and Women's Hospital, Boston, MA; 4) Broad Institute, Cambridge, MA; 5) Merck & Co.

HLA-DRB1 Val11 is the residue with highest risk for rheumatoid arthritis in Caucasians. We sought to validate the rheumatoid arthritis (RA) risk of *HLA-DRB1* exon 2 amino acid positions and residue substitutions in African Americans. We inferred local ancestry (copies of ancestral alleles) flanking *HLA-DRB1* to test the hypothesis that RA risk from residues at amino acid position 11 is independent of European ancestry at this locus. 579 seropositive RA patients and 893 healthy controls were four digit *HLA-DRB1* genotyped and all samples were genotyped on the immunochip. Ancestral population reference panels of Africans (Zambia) and Europeans (1200 haplotypes each) were genotyped on the immunochip, and for all samples, the extended major histocompatibility complex of chromosome six was phased using BEAGLE. Local ancestry was estimated with HAPMIX. Association analysis was performed using PLINK. Binomial regression models were fit in R to test the hypothesis that the Val11 and Asp11 residues had equivalent risk with local ancestry. Local European ancestry (P-value = 9.02E-04), but not global European admixture (P-value = 0.07) was associated with increased RA risk. Amino acid 11 was the most strongly associated position (Permutation P-value <1E-05), but positions 71 and 74 were not significantly associated. Within position 11 the valine, OR(CI) = 3.0 (2.3, 4.0), and aspartic acid, OR(CI) = 1.9 (1.3, 2.7), residues conferred RA risk. The aspartic acid residue is specific for *HLA-DRB1* *09:01. There was no joint effect of local European ancestry and Val11 on RA risk (P-value = 0.69). In contrast, there was an interaction effect of local ancestry and Asp11 on RA risk (P-value = 8.59E-03). Stratified by two copies of African ancestry, the observed Asp11 risk increased from OR 1.9 to 2.6 (1.7, 4.1). Asp11 was not a significant risk residue for individuals with either 1 or 2 copies of local European ancestry. These results demonstrate that the major source of RA risk comes from *HLA-DRB1* amino acid position 11 and the valine residue, which does not vary by African or European ancestry. However we also found evidence of heterogeneity in RA risk between Caucasians and African Americans for both *HLA-DRB1* amino acid positions 71 and 74 and the Asp11 residue. Importantly, we document that local ancestry of class II HLA genes may mediate the individual genetic risk for immune system related diseases.

848M

THE MAIN EFFECTS AND GENE-GENE INTERACTIONS AMONG CRP, TNF-α AND LTA IS ASSOCIATED WITH HANDGRIP STRENGTH IN COMMUNITY-DWELLING ELDERS IN TAIWAN-TAICHUNG COMMUNITY HEALTH STUDY FOR ELDERS (TCHS-E). *F.Y. Wu[1], C.S. Liu[2,3], C.C. Lin[2,3], C.H. Lin[2,3,4], W.Y. Lin[2,3], C.I. Li[3,5], C.W. Yang[4,5], N.H. Meng[3,6], C.K. Chang[3,6], T.C. Li[7,8], L.N. Liao[1].* 1) Department of Public Health, China Medical University, Taichung, Taiwan; 2) Department of Family Medicine, China Medical University Hospital, Taichung, Taiwan; 3) School of Medicine, College of Medicine, China Medical University, Taichung, Taiwan; 4) Ph.D. Program for Aging, College of Medicine, China Medical University, Taichung, Taiwan; 5) Department of Medical Research, China Medical University Hospital, Taichung, Taiwan; 6) Department of Physical Medicine and Rehabilitation, China Medical University Hospital, Taichung, Taiwan; 7) Graduate Institute of Biostatistics, China Medical University, Taichung, Taiwan; 8) Department of Healthcare Administration, College of Health Science, Asia University, Taichung, Taiwan.

Purpose: We undertook a cross-sectional study to assess the main effects and possible gene-gene interactions of inflammatory gene polymorphisms C-reactive protein (CRP), tumor necrosis factor α (TNF-α) and lymphotoxin α (LTA) on handgrip strength, by investigating eleven single-nucleotide polymorphisms (SNPs) of three genes in community-dwelling elders in Taiwan. Methods: Eleven SNPs (rs2794520, rs1205, rs1130864, rs1800947, and rs3093059 in CRP gene; rs1799964, rs1800629, and rs3093662 in TNF-α gene; rs2239704, rs909253, and rs1041981 in LTA gene) were utilized to genotype 472 unrelated elderly subjects (221 women and 251 men; mean age, 73.8±6.1 years). Handgrip strength was measured by handgrip dynamometer (TTM-110D, TTM Co. Japan). We systematically explained the main effects and possible gene-gene interactions using linear regression to adjust for potential confounders. Results: All SNPs were consistent with Hardy-Weinberg equilibrium (P >0.05). For the comparison of handgrip strength among the genotype, dominant and recessive models, the linear regression models were adjusted for age, BMI, smoking and physical activity. In the genotype and dominant models, there were significant differences in handgrip strength in the G allele of CRP rs3093059 in woman (P <0.05). In women, CRP rs2794520 and LTA rs2239704 were significant markers for handgrip strength in the genotype and recessive models (P <0.05). We also found that men carrying the AA or AG genotypes of TNF-α rs1800629 had greater handgrip strength; women carrying the GG genotype of CRP rs1205 had lower handgrip strength. We identified significant gene-gene interaction of LTA (rs2239704, rs909253, and rs1041981) and TNF-α (rs1799964) polymorphisms on handgrip strength in women; CRP (rs3093059) and TNF-α (rs1799964) polymorphisms in men. Furthermore, CRP rs2794520 & TNF-α rs1800629, CRP rs1205 & TNF-α rs1800629, and CRP rs1800947& LTA rs2239704 in women, as well as CRP rs3093059 & LTA rs2239704 in men, were significant interactions on handgrip strength. Conclusion: Our study show that an observed main effect and interaction between CRP, TNF-α and LTA polymorphisms on handgrip strength in elders.

849T

A gene-gene interaction in a shared Alzheimer disease/age-related macular degeneration pathway. *M.W. Logue[1,2,3], M. Schu[1], J. Farrell[1], K.L. Lunetta[2], G. Jun[1,2,4], C.T. Baldwin[1], M.M. DeAngelis[5], L.A. Farrer[1,2,4,6,7].* 1) Biomedical Genetics, Boston University School of Medicine, Boston, MA; 2) Biostatistics, Boston University School of Public Health, Boston, MA; 3) Research Service, VA Boston Healthcare System, Boston, MA; 4) Ophthalmology, Boston University School of Medicine, Boston, MA; 5) John A. Moran Eye Center, University of Utah, Salt Lake City, UT; 6) Neurology, Boston University School of Medicine, Boston, MA; 7) Epidemiology, Boston University School of Public Health, Boston, MA.

There is a growing body of biochemical and epidemiological evidence that Alzheimer disease (AD) and age-related macular degeneration (AMD) share pathogenic mechanisms. Recently, we found that risk genes for both disorders are enriched in clathrin-mediated endocytosis (CME), LXR/RXR activation, and atherosclerosis signaling pathways (Logue et al, 2014). Examining these pathways in summary GWAS data, we identified several novel AMD loci including *HGS* and *TNF*. Here, we explored the possibility that AD risk variants modify the effect of AMD risk variants within these three pathways by testing gene-gene interaction models in HapMap 2 imputed GWAS data for 1,336 AMD cases and 1,121 controls of European ancestry from the MMAP Study cohort (Chen, et al., 2010,Fritsche, et al., 2013). We analyzed the peak AD variants (or LD proxies) in *PICALM*, *CD2AP*, *APOE*, and *CLU* for interaction with the peak AMD risk loci in *APOM*, *CSNK2B*, *HGS*, *TNF*, *CETP*, *C3*, *C4A*, and *COL10A1*, restricting AD and AMD risk variant interactions to genes within one of the 3 pathways (22 independent tests; significance determined using robust SE estimates). Using a logistic-GEE model of AMD risk which included an AMD risk variant and AD risk variant, a GxG interaction, and age as a covariate, we found significant interaction (p= 0.00019; exceeding a Bonferroni-corrected threshold) within the CME pathway between the known AMD risk variant rs805262 in *CSNK2B* and the known AD risk variant rs10948363 in *CD2AP*. The rs10948363 G allele (MAF=27%), which is an AD risk allele, mitigates (heterozygous state) and even reverses (rare homozygous state) the risk of AMD conferred by the *CSNK2B* risk variant. In the MMAP dataset, the odds ratio (OR) associated with each minor allele T of rs805262 (MAF=46% in 1000 Genomes EUR) is 1.36 for those with the rs10948363 AA genotype (53% of EUR) and 1.05 among rs10948363 heterozygotes (41% of EUR), whereas rs805262 has an apparent protective effect (OR=0.65) for those who have the uncommon GG rs10948363 genotype (6.1% of EUR). Three other interactions, all of which involved genes in the CME pathway (*APOM* x *CD2AP*, *CSNK2B* X *CLU*, and *APOM* x *CLU*) were nominally significant (p<0.01). These findings reinforce the idea that AD and AMD share genetic mechanisms and that the clathrin-mediated endocytosis pathway may also play an important role in AMD pathogenesis.

850S

Targeted regulome sequencing reveals common, rare, and private regulatory variants associated with fetal adiposity. *C. Guo[1], I. McDowell[1], AA. Pai[2], DM. Scholtens[3], GE. Crawford[1,4], BE. Engelhardt[1,5], MG. Hayes[6], WL. Lowe[6], TE. Reddy[1,4].* 1) Institute for Genome Science and Policy, Duke University, Durham, NC; 2) Department of Biology, Massachusetts Institute of Technology, Cambridge, MA; 3) Department of Preventive Medicine, Division of Biostatistics, Northwestern University Feinberg School of Medicine, Chicago, IL; 4) Department of Pediatrics, Division of Medical Genetics, Duke University, Durham, NC; 5) Department of Biostatistics & Bioinformatics, Duke University Medical School, Durham, NC; 6) Division of Endocrinology, Metabolism and Molecular Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL.

Fetal growth has immediate and long-term effects for the health of the newborn. In particular, small and large for gestational age babies are at risk for later life obesity and type-2 diabetes. In our previous genome-wide association study of 4281 newborns, we demonstrated association of variation between CCNL1 and LEKR1 in 3q25.31 with fetal adiposity. As the associated variants were not in protein coding exons, we hypothesized that they alter the expression of nearby genes. To test this hypothesis, we sequenced regulatory elements within 250kb of the lead GWAS SNP, encompassing all variants in strong LD (r2 >0.8) with rs900400, across 760 babies in the upper and lower deciles of fetal adiposity in the Hyperglycemia and Adverse Pregnancy Outcome study. The babies represented four ancestry groups: European, Afro Caribbean, Mexican-American, and Thai. To define regulatory elements for sequencing, we used genome-wide measurements of open chromatin across ~50 different cell types including pre-adipocytes, liver, and islet β cells. Open chromatin regions are a general indicator of transcription factor binding and gene regulation, and several studies now demonstrate that a substantial fraction of complex phenotypes involve genetic variation in those regions. In total, we sequenced ~100 regulatory elements at a median coverage of 1100x for each sample. We found 995 variants (921 SNPs and 74 indels), 560 of which are not found in dbSNP or the 1,000 Genomes Project. To assess the regulatory function of the identified variants, we mapped eQTLs for protein coding genes and long-noncoding RNAs in four different cell types using data from the GTEx project, and in lymphoblastoid cell lines from the gEUVADIS dataset. Several variants in our sequencing are eQTLs for nearby genes, including two long-noncoding RNAs. Together, by combining targeted regulome sequencing and genome-wide eQTL analyses, these results suggest a potential role for novel genes including long-noncoding RNAs in fetal adiposity.

Genome-wide Sequencing to Identify Novel Variants for Obesity in Pima Indians. *K. Huang, P. Piaggi, S. Kobes, R. Hanson, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

To identify genetic variation that increases risk for type 2 diabetes (T2D) or obesity, we obtained whole genome sequence data on 335 Pima Indians (51%; male, age: 25.1±5.8 years, BMI: 33.5±7.3 kg/m2). Sequencing was performed by Illumina (N=301) and Complete Genomics, Inc (N=34). ~13 million variants were found, including ~11 million SNPs, ~1.6 million Indels and 255,802 substitutions. Among all SNPs, 2.7 million were novel. Individuals who were sequenced were part of a study of health among Pima Indians living in the Gila River Indian Community, and were informative for longitudinal measures of BMI and type 2 diabetes status. As a preliminary screen for selecting variants for follow-up genotyping, we performed association analyses between all novel common SNPs (N=71,021 with a MAF≥0.05 and a genotype calling rate≥0.85) and maximum BMI childhood z-score (age 5-20 years; N=287) and maximum BMI in adulthood (after age 15 years from an exam where the individual was non-diabetic, N=289). The most significant preliminary association with childhood z-score was a novel exonic SNP in ZNF595 (chr4:86248, A/C, MAF=0.15; $p=3.2\times10^{-12}$ after adjusted for birth year, β=1.2 units per copy of the risk allele). In addition, variants in CHRNA4 and OR4A15/OR4C15 showed genome-wide significant association with childhood z-score (smallest $p=1.7\times10^{-10}$ after adjusted for birth year, β=1.1 units per copy of the risk allele) and adulthood BMI (chr11:55226415, G/A, MAF=0.15; $p=2.0\times10^{-9}$ after adjusted for age, sex and birth year, β=1.0kg/m^2 per copy of the risk allele), respectively. These novel variants and others selected for having the lowest p values or being positioned within excellent biologic candidates will be genotyped in 5,880 American Indians for validation of the preliminary associations with z-score during childhood and BMI during adulthood.

Fine-mapping eGFR susceptibility loci through trans-ethnic meta-analysis. *A. Mahajan[1], J. Haessler[2], N. Franceschini[3], A. Morris[1,4,5].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 3) University of North Carolina, Chapel Hill, NC, USA; 4) Department of Biostatistics, University of Liverpool, Liverpool, UK; 5) Estonian Genome Center, University of Tartu, Tartu, Estonia.

Chronic kidney disease (CKD) is a major public health problem and affects nearly 10% of the global population. Reduced estimated glomerular filtration rate (eGFR), a measure of kidney function used to define CKD, is associated with cardiovascular disease morbidity and mortality, acute kidney injury, and progression to end stage renal disease. Genome-wide association studies (GWAS) have been successful in identifying loci for eGFR. However, these loci are typically characterised by common lead SNPs with association signals extending over large genomic intervals containing multiple transcripts. As a result, limited progress has been made in identifying causal variants for eGFR and understanding the downstream pathogenesis of CKD. To address these drawbacks, we performed trans-ethnic meta-analysis to fine-map known eGFR loci by leveraging differences in distribution of linkage disequilibrium between diverse populations. We considered six GWAS comprising of 23,568 individuals of European, African American, and Hispanic ancestry, each supplemented by imputation up to the 1000 Genomes Project reference panel (March 2012 release). Within each study, association with eGFR (MDRD equation) was tested under an additive model. We then combined association summary statistics across studies with MANTRA, 500kb up and down of the lead SNP at known eGFR loci, and constructed "credible sets" of SNPs that encompass 99% of the posterior probability of being causal. We resolved fine-mapping of potential causal variants to less than 20 variants at three loci: *GCKR* (3 SNPs, 144.5kb), *UMOD/PDILT* (4 SNPs, 39.3kb), and *SHROOM3* (19 SNPs, 74kb). At *GCKR*, the credible set covers three SNPs including *GCKR* P446L, which is predicted to be the functional variant at this locus. Variants in the 99% credible set for *SHROOM3*, include intronic variants in the gene and overlap regulatory elements from ENCODE, thereby highlighting a potential mechanism for the action of this locus on eGFR. These findings provide evidence that trans-ethnic GWAS can be used to fine-map potentially causal variants at complex traits loci that can be taken forward for experimental validation and could help to further our understanding of the biological mechanisms underlying disease.

853S

Fine-mapping major histocompatibility complex associations in psoriasis and its clinical subtypes by HLA/MICA variant imputation. *Y. Okada[1-5], B. Han[3-5], L.C. Tsoi[6], P.E. Stuart[7], E. Backgrounds: Psoriasis vulgaris (PsV) risk is strongly associated with genetic variation within the major histocompatibility complex (MHC) region, although its fine genetic architecture has not been elucidated. **Methods:** To fully characterize and fine-map the MHC associations of PsV, we conducted a large-scale fine-mapping study of PsV risk in the MHC region in 9,247 PsV cases and 13,589 controls of European descent. We also evaluated risk of two major clinical subtypes of PsV, psoriatic arthritis (PsA; n = 3,038) and purely cutaneous psoriasis (PsC, defined as 10 years of psoriasis without developing PsA; n = 3,098). We imputed class I and II HLA genes variants by applying SNP2HLA software to the SNP genotype data. In addition, we newly constructed an imputation reference panel of sequence variants for *MICA*, an HLA-like gene within the MHC region that has been implicated for PsA risk. We applied *MICA* variant imputation to the SNP genotype data and evaluated their risk as well. **Results:** As previously described, we observed that *HLA-C*06:02* demonstrated the most significant impact on overall PsV risk (odds ratio [OR] = 3.38, 95% confidence interval [95%CI]: 3.18-3.60, $P = 1.7\times10^{-364}$). Stepwise conditional analysis revealed multiple independent risk variants of both class I and class II HLA genes for PsV susceptibility independent of *HLA-C*06:02* (*HLA-C*12:03*, HLA-B amino acid positions 67 and 9, HLA-A amino acid position 95, and HLA-DQα1 amino acid position 53; $P < 5.0\times10^{-8}$), but no apparent independent risk conferred by *MICA*. Strikingly, we found that risk heterogeneity between PsA and PsC may be driven by one amino acid position at HLA-B (Glu at HLA-B amino acid position 45; OR = 1.46, 95%CI: 1.31-1.62, $P = 2.9\times10^{-12}$), which demonstrated much more significant association signals compared to classical *HLA-B* alleles including *HLA-B*27* and *HLA-B*39:01* ($P > 1.0\times10^{-4}$). **Conclusion:** These results indicate that multiple class I and II HLA genes (*HLA-C*, *HLA-B*, *HLA-A*, and *HLA-DQA1*) contribute to development of PsV, and suggest that different genetic factors, most evident at *HLA-B*, underlie for the differential risk for of specific PsV sub-phenotypes. Our study illustrates the value of high-resolution HLA and *MICA* imputation for fine-mapping causal variants in the MHC.

Meta-analysis on the 22q11.21 region identifies an autoimmune disease risk allele as associated with systemic lupus erythematosus. *Y. Zhang[1], Y. Wang[1], J. Yang[1], N. Hirankarn[2], XJ. Zhang[3], YL. Lau[1], W. Yang[1,4].* 1) Paediatrics, The University of Hong Kong, Hong Kong, Hong Kong; 2) 2.Lupus Research Unit, Department of Microbiology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 3) State Key Laboratory Incubation Base of Dermatology, Key Laboratory of Dermatology, Anhui Medical University, Ministry of Education, China, Hefei, Anhui, 230032, China; 4) Centre for Genomic Sciences, LKS Faculty of Medicine, The University of Hong Kong, Hong Kong.

Systemic lupus erythematosus (SLE) is an autoimmune disease with unclear etiology. It usually presents with a diverse spectrum of clinical manifestations. Genetic predisposition is responsible for 50 to 60 percent of the likelihood of developing the disease. Genome-wide association studies (GWASs) on SLE have identified more than 40 loci with genome-wide significance. The 22q11.21 genomic region is a shared locus for several autoimmune diseases including SLE, systemic sclerosis (SSc), Crohn's disease (CD), celiac Disease (CeD), Rheumatoid Arthritis (RA), Psoriasis(PS) and Inflammatory bowel disease(IBD). Here we examined the association for SLE in this region, and emphasized on the relationship of all the reported variants with various autoimmune diseases. Through meta-analysis of two existing GWASs on Chinese Han populations with a total of 1,659 cases and 3,398 controls matched geographically, we have identified SNP rs2298428 as the most significant SNP for SLE in the 22q11.21 region (P= 2.17E-09). The association of rs2298428, a missense mutation in YDJC gene, was further replicated in three cohorts from Hong Kong, Anhui and Thailand, independent of the GWAS samples used (P=1.31E-11, OR=1.23). This SNP also showed consistent correlation with the expression of UBE2L3 in multiple cell types, highlighting the functional mechanism of the abnormal expression of UBE2L3 to SLE.

855T

Involvement of GTF2IRD1 in the complex hearing phenotype of Williams-Beuren Syndrome. *C.P. Canales[1], A.C.Y. Wong[2], G.D. Housley[2], E.C. Hardeman[1], S.J. Palmer[1].* 1) Cellular and Genetic Medicine Unit, School of Medical Sciences (SOMS), UNSW Australia, Sydney, Australia; 2) Translational Neuroscience Facility & Department of Physiology, School of Medical Sciences (SOMS), UNSW Australia, Sydney, Australia.

Amongst the spectrum of physical and neurological defects in Williams Beuren Syndrome (WBS), it is common to find a distinctive response to sound stimuli that includes extreme adverse reactions to loud or sudden sounds (usually called 'hyperacusis'), and a fascination with certain sounds that may manifest as strengths in musical ability. However, hearing tests have indicated that sensorineural hearing loss (SNHL) is frequently found in WBS patients and the genetic origins of this unusual auditory phenotype are currently unknown. However, the use of the term 'hyperacusis' is inaccurate since hyperacuity implies increased functional sensitivity leading to detectably lower hearing thresholds, and 'auditory allodynia', meaning aversion to, or fear of certain sounds that are usually acceptable to others, is a more accurate description of this condition. Here, we investigated the involvement of *GTF2IRD1*, a gene located within the WBS deletion that has been implicated as a contributor to the WBS neurocognitive profile and craniofacial abnormalities. Using knockout mice, we analysed the expression of the gene in the inner ear and examined hearing capacity. Rather than using acoustic tests in mice that rely on behavioural responses, which could be confounded by the altered anxiety responses previously reported in *Gtf2ird1* knockouts, we used objective physiological assays under general anaesthesia to evaluate hearing capacity, minimizing the behavioural component. Using auditory brainstem response (ABR), which measures sound-evoked auditory neurotransmission from the cochlear nerve to the auditory midbrain, and distortion product of otoacoustic emissions (DPOAE), which measures sound-evoked electromechanical amplification via the outer hair cell 'cochlear amplifier', we demonstrated that *Gtf2ird1* null mice have hypoacusis (higher hearing thresholds) in both assessments. These data, together with the *Gtf2ird1* expression pattern in diverse cell types within the inner ear, indicate that the principal hearing deficit in the mice can be traced to impairments in cochlear amplifier, suggesting that similar mechanisms may underpin the SNHL experienced by WBS patients. The origin of the auditory allodynia remains unexplained but may form part of a central defect in the processing of sensory input and/or emotional control mechanisms, which *GTF2IRD1* may also contribute to.

856S

Genetic variant at ETS1 locus increases lupus risk and affects Stat1 binding. *L. Kottyan[1,2], X. Lu[1,3], E. Zoller[1], M. Weirauch[1,3], B. Namjou[1], K. Greis[4], N. Shen[1,5], K. Kaufman[1,2], J. Harley[1,2,3], The International Consortium on the Genetics of Systemic Lupus Erythematosus (SLEGEN).* 1) Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) United States Department of Veterans Affairs Medical Center, Cincinnati, Ohio, USA; 3) Immunology Graduate Program, University of Cincinnati College of Medicine, Cincinnati, OH; 4) Cancer Cell Biology, University of Cincinnati Medical Center, Cincinnati, OH; 5) Institute of Rheumatology, Shanghai Jiao Tong University School of Medicine, Shanghai, China.

Over the past 10 years, genetic association studies have identified over 55 systemic lupus erythematous (SLE)-risk loci. Genetic variants in ETS1 have been associated with SLE in several independent studies in populations of Asian ancestry. Several recent studies have implicated ETS1 as a critical driver of immune cell function; indeed, mice deficient in ETS1 develop an SLE-like autoimmunity. rs1128334, in the 3' UTR of ETS1, has been associated with the decreased expression of ETS1. We performed a fine-mapping study of over 20,000 subjects of two multi-ancestral cohorts using genotyped and imputed variants spanning the ETS1 locus. By constructing genetic models using frequentist and Bayesian association methods, we identified a set of variants that are most likely to be causal. Of the three variants that we tested, only rs6590330 differentially binds lysate from B cell lines as assessed by electrophoretic mobility shift assays and DNA affinity precipitation assays. We found that the active form of the transcription factor STAT1 binds the risk allele of rs6590330 but not the non-risk allele using mass spectrometry, a finding confirmed by Western blot analysis. rs6590330 is in strong linkage disequilibrium with rs1128334 and is predicted to also be associated with decreased ETS1 expression. We propose a model in which the risk allele of rs6590330 increases SLE risk by binding pSTAT1 and depressing the expression of ETS1.

Rs738409 Polymorphism in PNPLA3 Gene is Associated with Lower Insulin Resistance in Korean Men. *JH. Park[1], JM. Yun[1], HT. Kwon[2].* 1) Family medicine, Seoul National University Hospital, Seoul, South Korea, MD; 2) Family Medicine, Healthcare Research Institute, Seoul National University Hospital Healthcare System Gangnam Center, Seoul, South Korea, MD.

Background & Aims: The rs738409 polymorphism in adiponutrin is a well-known genetic risk factor for nonalcoholic fatty liver disease (NAFLD) development. When we consider that NAFLD is closely associated with insulin resistance, the association between rs738409 variant and insulin resistance is highly suspected. Methods: We enrolled 1,189 Korean men who visited the Health Promotion Center of Seoul National University in Seoul, South Korea from December 2009 to June 2012 and 1,189. Hepatic steatosis was evaluated by abdominal ultrasound and subjects with secondary causes of NAFLD or alcohol consumption of more than 30g/day were excluded from NAFLD classification. Serum glucose and insulin levels were measured using overnight fasting blood sample. The homeostasis model assessment estimated insulin resistance (HOMA-IR) index was calculated by multiplying glucose in mg/dl by insulin in μU/ml/405. The cutoff value of 2.56 was used for insulin resistance diagnosis as previously reported in Korean men. Rs738409 genotyping was performed using TaqMan assay on a ViiATM 7 Real-Time PCR System. Results: The participants were predominantly middle-aged men (49.1 ±7.0 years; range, 30-60 years), and the frequencies of NAFLD and insulin resistance were 43.7% and 17.5%. The minor allele frequency of the rs738409 G allele was 0.43.The rs738409 G allele was not associated with insulin resistance status (Fisher's exact P = 0.653) and HOMA-IR index level (one-way ANOVA P = 0.068) in the analysis without adjustment for NAFLD status by genotypes. We performed multivariate regression analysis after adjustment for NAFLD status. The rs738409 CG and GG genotype showed lower mean levels of HOMA-IR index compared to the CC genotype (P = 0.031 and < 0.001, respectively. Then, we checked the effect of the rs738409 G allele on HOMA-IR index levels in each NAFLD and non-NAFLD subgroup stratified by NAFLD status using one-way ANOVA. In the non-NAFLD group, the CG and GG genotypes compared to the CC genotype showed significantly lower mean levels of HOMA-IR index in an additive manner (Sidak-corrected P = 0.018 and < 0.001, respectively); however, in the NAFLD group, those inverse associations were not shown. Conclusion: The adiponutrin polymorphism rs738409 known as a NAFLD genetic risk factor was also associated with decreased levels of insulin resistance assessed by HOMA-IR index, and the inverse association was prominent in subjects without NAFLD.

858T

Extended Haplotypes of controls regions of the HLA-G are associated with type 1 diabetes mellitus. *R. De Albuquerque[1, 2, 3], N. Lucena-Silva[2], D. Meire Rassi[4], E. Cruz Castelli[5], S. Gregori[3], E. Donadi[4], C. Teixeira Mendes-Junior[1].* 1) Faculty of Medicine of Ribeirão Preto, University of São Paulo, Departament of Genetic, Ribeirão Preto-SP, Brazil; 2) Aggeu Magalhães Research Center, Department of Immunology, Oswaldo Cruz Fundation (Fiocruz), Recife-PE, Brazil; 3) Division of Regenerative Medicine, Stem Cells and Gene Therapy, San Raffaele Telethon Institute for Gene Therapy (HSR-TIGET), San Raffaele Scientific Institute, Milan, Italy; 4) Faculty of Medicine of Ribeirão Preto, University of São Paulo, Department of Medicine, Ribeirão Preto-SP, Brazil; 5) Departamento de Patologia, Faculdade de Medicina de Botucatu, Universidade Estadual Paulista Júlio de Mesquita Filho, Botucatu, Brazil.

The TD1 (Type 1 Diabetes) is a multifactorial disease in which the autoimmune destruction of pancreatic cells is mediated by humoral and cellular mechanisms. Various subpopulations of lymphocytes are involved in this process, however, the CD8 + T lymphocytes appear to be the cells responsible for early insulitis. Genetic susceptibility to TD1 has been primarily attributed to MHC genes: a study mapping the MHC region identified the HLA-G region as an independent susceptibility gene for the disease. A major function of HLA-G is the inhibition of Natural Killer cells (NK) and cytotoxic T cells (CTL), by interaction with inhibitory receptors found in these cells. The HLA-G gene presents a 3' untranslated region (3'UTR) that contains some polymorphisms, in this study, we analyzed the 9 most studied, 3 of them related with several posttranscriptional regulatory elements. On the other hand, the transcription level is driven by the 5' regulatory region through of the transcription factor, which are target for some of the 28 SNPs that we studied. We analized extended Haplotypes of those both controls regions of the HLA-G in 120 patients with TD1 and 100 controls from the same geographical region of the patients. DNA was extracted by the salting out. The 5' regulatory region and 3'UTR fragments were amplified using the polymerase chain reaction (PCR) and were directly sequenced in an ABI310 Genetic Analyzer. The presence of significant associations between the SNPs detected of the HLA-G gene was evaluated by means of a likelihood ratio test of linkage disequilibrium (LD), using the ARLEQUIN. The PHASE method and expectation-maximization (EM) algorithm were used to infer the haplotypes. Regarding 3'UTR haplotypes, we observed two significant haplotypes, a conferring susceptibility to TD1 (UTR17), and another suggesting a protective role to TD1 (UTR-3). On 5' URR, we found four significant haplotypes, two for susceptibility (G0104a, G010101a) and two for protective role(G0104a, G010101c). Thus, with relation extended haplotypes, suggesting a balance between these regions, which were according to the previous papers, but we found two new haplotypes (PG0104b + UTR-13, G0103f + UTR-17), on the total two conferring protection (G010101c + UTR-4, G0104a + UTR-3), and one of the new (G0103f + UTR-17) conferring susceptibility. The present study revealed significant associations between and haplotypes of controls regions of the HLA-G with TD1 susceptibility.

859S

Sequencing of the *TBX6* Gene in Families with Familial Idiopathic Scoliosis. *E.E. Baschal[1], K. Swindle[1], C.M. Justice[2], A. Perera[3], R.M. Baschal[1], A. Poole[1], O. Pourquié[4], O. Tassy[4], N.H. Miller[1].* 1) Department of Orthopedics, University of Colorado Denver Anschutz Medical Campus, Aurora, CO; 2) Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, Maryland, USA; 3) Molecular Biology Facility, Stowers Institute, Kansas City, USA; 4) d)Department of Cell Biology and Development, Institut de Génétique et de Biologie Moléculaire et Cellulaire (IGBMC), Strasbourg, France.

Idiopathic scoliosis, which affects 3% of the population, is a structural curvature of the spine whose underlying genetic etiology has not been established. Congenital scoliosis is the presence of vertebral malformations as identified on radiographs. Idiopathic scoliosis has been reported to occur at a higher rate than expected by chance alone in family members of individuals with congenital scoliosis, indicating that the two diseases might have a shared etiology. The *TBX6* gene on chromosome 16p, essential to somite development, has been associated with congenital scoliosis in a Chinese population. The 16p11.2 locus encompasses several unique genomic structural variants and several reports identify an increased incidence of scoliosis and vertebral anomalies in patients with 16p11.2 rearrangements. Previous studies have identified linkage to this locus on 16p in a sample of families with familial idiopathic scoliosis (FIS) segregating with an autosomal dominant pattern of inheritance. Given these factors, we sequenced the *TBX6* gene in a sample of families with FIS to determine the potential association between *TBX6* variants and FIS. We selected parent-offspring trios from 13 families (42 individuals) with FIS for Sanger sequencing of the *TBX6* exons. The trios were selected from a large population of families with FIS in which a genome-wide scan had resulted in linkage to 16p. Selection criteria required that each trio contain both an affected proband and an affected parent, each with a scoliotic curvature of ≥25°. Sequencing analyses of this familial subset resulted in the identification of five coding variants. All 13 families had at least one variant. Three of the five variants were novel; the remaining two variants were previously characterized and accounted for 90% of the observed variants in these families. In all cases, there was no correlation between transmission of the *TBX6* variant allele and FIS phenotype. Transmission of sequence variants within the *TBX6* gene was not correlated with the FIS phenotype in this select study population. However, these findings do not rule out the *TBX6* gene as a whole, as a causative variant could be located in a region of the gene that was not sequenced in this study. There are also several other candidate genes in the region. Further investigation of the *TBX6* gene and additional genes within this region is required in order to delineate their potential roles in the etiology of FIS and axial skeletal development.

860M

Association of variants in *GALNT10* and related pathway genes with body mass index in African Americans. *M. Stromberg[1, 2, 3], P. Mudgal[3], B.I. Freedman[4], D.W. Bowden[2, 3, 5, 6], M.C.Y. Ng[2, 3].* 1) Molecular Genetics & Genomics, Wake Forest University, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 6) Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC.

Obesity is a chronic health problem which has a higher prevalence in African Americans (AAs) (35.7%) compared to non-Hispanic whites (23.7%) in the United States. Genetic contributors to obesity in AAs remain poorly understood, although recent genome-wide association studies (GWAS) identified several regions including the *GALNT10* locus as being associated with body mass index (BMI) in AAs. *GALNT10* is a member of the N-acetylgalactosaminyltransferase family which is located in the Golgi apparatus and is expressed in the hypothalamus of the brain, which regulates hunger. There are 20 members in the GALNT family, each with a unique expression pattern. Previous studies have not identified the causal variant(s)at *GALNT10* and have not examined biological candidate genes from the relevant pathways in detail. As such, this study assessed 71 candidate genes for association with BMI in 2,293 African American subjects. Genotyping was performed using an Affymetrix Biobank array customized for fine-mapping of GWAS and candidate loci related to metabolic traits. Single SNP association was performed in two cohorts using linear regression under an additive model with adjustment for age, sex and the first principal component followed by meta-analysis. Nominal significance (P<0.0005) was observed at *ATF4* (p=0.000337), *GALNT18* (p=7.91E-06), *ST3GAL1* (p= 0.000191), *WBSCR17* (p=0.000215), with the strongest association at *GALNT18*. *GALNT18*, or *GALNTL4*, has been previously associated with Type 2 Diabetes in AAs. The most significant association observed at the *GALNT10* locus is rs1346482 (p=0.001015). Previously associated SNPs in this locus (rs815611, rs2033195, rs7708584) are shown to have pairwise r^2 values ranging from 0.32-0.84 (0.84, 0.68, 0.32 respectively) in the YRI population. These findings suggest that several members of the GALNT family and related pathway members may play roles in modulating adiposity in AAs, although further replication is needed.

Targeted Sequencing of an Admixture Mapping Peak in Latinos Implicates Rare Non-coding Variation in Asthma Susceptibility. *D.G. Torgerson[1], M. Pino-Yanes[1], C.R. Gignoux[1], C. Eng[1], E.G. Burchard[1,2] on behalf of the GALA II Investigators.* 1) Department of Medicine, University of California San Francisco, San Francisco, CA; 2) Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA.

The prevalence and morbidity of asthma varies widely among global populations and racial/ethnic groups within the U.S. We previously identified a genome-wide significant admixture mapping peak at 18q21.1, whereby local Native American ancestry was associated with an increased risk of asthma in a meta-analysis of 3,902 Hispanic/Latino individuals. The ancestry association was replicated in a large independent study of 3,774 Latinos; however, the variation behind the ancestry association remains to be identified. Towards this goal, we sequenced a 342 Kb contiguous region across the top of the admixture mapping peak including all coding sequences (including *SMAD2* and *ZBTB7C*) and complete non-coding/intergenic sequences in 1,978 Mexicans and Puerto Ricans with and without asthma from the Genes-environments & Admixture in Latino Americans study (GALA II study). No new individual variant was found to be associated with asthma in either Mexicans or Puerto Ricans adjusting for global and local ancestry, or in a meta-analysis across populations. Collapsing tests showed no significant contribution of coding variation in either *SMAD2* or *ZBTB7C*. However, we identified a significant cumulative contribution of rare, non-coding variants 5' upstream of *SMAD2* in Mexicans using the sequence kernel association test (SKAT test, permutation $p<10^{-4}$) by employing a sliding window approach to grouping variants. The association was specific to individuals of Mexican ethnicity, and was consistent in location to the most significant allelic associations at common variants identified through traditional genome-wide association testing. Using rtPCR in a subset of individuals, we also tested for the presence of individual and cumulative rare variant eQTLs for *SMAD2* and *ZBTB7C*. Overall we identified a significant contribution of rare, non-coding variation to asthma susceptibility that are likely to effect the transcription of *SMAD2*. Furthermore, the association appears to be population-specific, consistent with the hypothesis that admixture mapping can accelerate the search for rare, population-specific variation that contributes to complex disease.

862S

Replication and fine-mapping of trait-stratified genome-wide association study identifies novel genetic associations with cytokine phenotypes in systemic lupus erythematosus. *T.B. Niewold[1], M. Imgruet[1], Y. Ghodke-Puranik[1], J.M. Dorschner[1], J.A. Kelly[2], M. Marion[3], J.M. Guthridge[2], C.D. Langefeld[3], J.B. Harley[4], J.A. James[2], K.L. Sivils[2].* 1) Rheumatology and Immunology, Mayo Clinic, Rochester, MN; 2) Arthritis & Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Department of Biostatistical Sciences, Wake Forest University, Winston-Salem, NC; 4) Cincinnati Children's Hospital Medical Center and Cincinnati VA Medical Center, Cincinnati, OH.

Introduction: Systemic lupus erythematosus (SLE) is a highly heterogeneous disorder, characterized by differences in serum cytokines and clinical manifestations. High serum interferon alpha (IFN-α) is an important heritable phenotype in SLE which is involved in primary disease pathogenesis, and this phenotype accounts for some of the biological heterogeneity between SLE patients. The aim of the study was to replicate and fine-map previously detected genetic associations with serum IFN-α in SLE. Methods: We previously undertook a case-case genome-wide association study of SLE patients stratified by ancestry and extremes of phenotype in serum IFN-α. Single nucleotide polymorphisms (SNPs) in seven loci identified in this screen were selected for follow up in a large independent cohort of more than 1300 SLE patients (672 European-ancestry, 420 African ancestry, and 231 Hispanic/Amerindian ancestry). Each ancestral background was analyzed separately, and a panel of 334 ancestry-informative markers was used to control for ancestry and admixture. Results: SNPs in the *PPM1H* and *EFNA5* loci demonstrated strong association with serum IFN-α in eQTL analyses (p<10-4 for each association) in European ancestry. In African ancestry subjects, SNPs in both *LPAR1* and *EFNA5* were associated with serum IFN-α, and one of the SNPs was common between European- and African- ancestry subjects. In Hispanic/Amerindian ancestry patients, *LRRC20* demonstrated nominal evidence for association with serum IFN-α. Conclusions: This study demonstrates the power of using a serologic subphenotype to elucidate genetic factors involved in complex autoimmune disease. The distinct associations observed in different ancestral backgrounds emphasize the heterogeneity of molecular pathogenesis in SLE, and the need for stratification by subphenotypes in genetic studies. We hypothesize that these genetic variants play a role in disease manifestations and severity in SLE.

Refinement of association signals and residual heritability in host control of HIV viral load. *P.J. McLaren[1,2], J. Fellay[1,2], the International Collaboration for the Genomics of HIV.* 1) School of Life Science, EPFL, Lausanne, Vaud, Switzerland; 2) Swiss Institute of bioinformatics, Lausanne, Vaud, Switzerland.

Background: Genome-wide association studies of HIV outcome consistently identify the MHC region as the major genetic influence on disease progression. Through establishment of the International Collaboration for the Genomics of HIV we sought to bring together all existing GWAS data in HIV patients to maximize power to uncover further association signals.

Methods: Genome-wide SNP data were collected from 25 clinical centers. Plasma viral load measurements obtained during the chronic phase of untreated infection were available for 6,315 individuals of European ancestry. Missing genotypes were imputed using the 1,000 Genomes Project reference. Single marker association testing was performed per study using linear regression and combined across studies by meta-analysis. Classical HLA alleles and amino acid variants were imputed using the SNP2HLA pipeline. Heritability estimates were calculated using GCTA.

Results: Consistent with previous studies, the top association signal was amino acid position 97 in HLA-B (p=4e-143), with independent associations at positions 67 (p=4e-112) and 45 (p=8e-49). Controlling for these positions fully accounted for classical HLA-B allele associations. Residual association at rs9264942, a marker of HLA-C expression level, was retained after controlling for amino acid effects (conditional p=1e-11). Outside of the MHC, a second peak of association in the CCR5 region (top SNP rs4317138 p=8e-19) was observed. Conditioning for the known effects of CCR5Δ32 and CCR2V64I we found evidence for residual association at rs4683217 (p=5e-10) upstream of CCR2, suggesting the presence of additional functional variants in this region. Considering all SNPs and assuming an additive genetic model, we obtained a narrow-sense heritability (h2) estimate of 26% (p<2e-16) for viral load. Removing the HLA and CCR5 regions, we observed a reduced, yet still significant h2 estimate of 16% (p=5e-8).

Conclusions: By combining available GWAS data in HIV infected individuals we refined the known association signals in HLA-B and CCR5. Controlling for these main effects, we uncovered additional, independent associations in known regions. Heritability analysis suggested that variation outside known regions, captured through common SNPs, also contribute to HIV control.

864T

Study of genetic risk factors for susceptibility to leprosy - the chromosomal region 6q25-q27 revisited. *G.B. RAMOS[1], H. SALOMAO[1], A.S. FRANCIO[1], C.C. CARDOSO[4,5], M.O. MORAES[4], A.C. PEREIRA[3], R.I. WERNECK[2], M.T. MIRA[1,2].* 1) School of Medicine, Pontifícia Universidade Católica do Paraná, Curitiba, Paraná, Brazil; 2) Health and Biosciencies School, Pontificia Universidade Católica do Paraná, Curitiba, Paraná, Brazil; 3) Instituto Lauro de Souza Lima, Bauru, São Paulo, Brazil; 4) Laboratório de Hanseníase, Instituto Oswaldo Cruz, FIOCRUZ, Rio de Janeiro, Rio de Janeiro,; 5) Laboratório de Virologia Molecular, Departamento de Genética, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Leprosy, a chronic infectious disease, affects approximately 220,000 new individuals worldwide every year. Genetic studies have identified several genes and genomic regions contributing to the control of host susceptibility to leprosy. In 2004, a study identified variants of genes *PARK2/PACRG* associated with the disease, but the association signal observed does not seem to entirely explain the genetic effect observed for this locus, suggesting the presence of additional candidates genes. Here, we test variants of *SOD2*, located near to *PARK2/PACRG* at the 6q25-q27 region, for association with leprosy in four Brazilian population samples of distinct design and ethnic background. The primary population included 186 volunteers distributed in 71 trios (55 independent) composed by one affected individual and their parents, recruited at the Prata Village, located at the Amazonic state of Pará; the replication study involved three case-control samples from the southern, southeastern and central-western regions of Brazil: Curitiba, Paraná (198 cases and 183 controls); Rio de Janeiro, Rio de Janeiro (507 cases and 236 controls) and Rondonópolis, Mato Grosso (411 cases and 424 controls), respectively. SNP markers covering the entire *SOD2* locus were genotyped by fluorescence-based TaqMan and/or Sequenon technology. Family-based association analysis was performed as implemented in the software FBAT, version 2.0.4. Logistic regression was applied to the case-control samples, as implemented in the software SAS, version 9.1. Family-based analysis revealed borderline evidence of association, after adjusting for age and gender (p_c), between leprosy and alleles of markers rs5746136 (p_c = 0.07; OR = 2.084), rs4880 (p_c = 0.07; OR = 0.256) and rs295340 (p_c = 0.042; OR = 2.637). Findings were similar in the population sample of Curitiba: rs5746136 (p_c = 0.15; OR = 1.394), rs4880 (p_c = 0.03; OR = 0.578) and rs295340 (p_c = 0.04; OR = 1.855). No association was found in the population samples of Rondonópolis and Rio de Janeiro. These preliminary results suggest evidence of association between *SOD2* with leprosy in at least two independent, ethnically distinct Brazilian population samples; further analysis of LD patterns and association using a combined population sample is currently ongoing.

Next-generation sequencing and targeted fine linkage disequilibrium mapping reveal FREM1 mutations associated with HIV acquisition in a sub-Saharan African cohort of female sex workers. *J.F. Tuff[1], D. La[1], N. Klaponski[2], V. Ly[2], A. Yuen[1], B. Liang[2], S. Tyler[2], F.A. Plummer[2,3], M. Luo[1,3].* 1) JC Wilt Infectious Diseases Research Centre, Winnipeg, MB, Canada; 2) National Microbiology Laboratory, Winnipeg, MB, Canada; 3) University of Manitoba, Department of Medical Microbiology, Winnipeg, MB, Canada.

There is considerable heterogeneity in susceptibility to HIV-1 (HIV) infection among individuals. This variability in risk can be attributed to a combination of environmental, viral, and host genetics. A group of women in the Pumwani Sexworker (ML) Cohort, established in Nairobi, Kenya, exhibit a HIV-exposed seronegative (HESN) phenotype, despite repeated exposure through high-risk sex work. We previously described the identification of an intronic single nucleotide polymorphism (SNP) (rs1552896; NM_144966.5:c.1881+58G>C) in FRAS1 related extracellular matrix 1 (*FREM1* [MIM: 608944]) as the highest-ranking correlate of this protective phenotype in a low-resolution genome-wide association study. To further investigate this association, we herein sought to identify *FREM1* mutations in linkage disequilibrium (LD) with rs1552896, followed by fine mapping of polymorphic loci deemed most likely to be functionally causal as determined by SIFT/PolyPhen-2 or ENCODE via RegulomeDB. We conducted pyrosequencing of *FREM1* (n=69) with Roche 454 GS FLX high throughput sequencing technology, and identified 1576 polymorphisms, 966 of which were newly discovered. Four of the 69 polymorphisms showing putative LD with rs1552896 (LOD ≥2) were chosen for fine mapping via PCR and Sanger sequencing: (i) rs2779500 (NM_144966.5:c.1315G>C, NP_659403.4:p.Val-439Leu (n=541)), (ii) rs1353223 (NM_144966.5:c.1495A>G, NP_659403.4:p.Ile499Val (n=633)), (iii) rs10810271 (NM_144966.5:c.1262-1086A>G, (n=347)) and (iv) a novel microsatellite allele (c.1261+1207CCCT[8]TCCT[7]; Mi8*7, (n=1956)) found within a newly characterized complex tandem tetranucleotide repeat (CTTR). Fine mapping confirmed significant LD between rs1552896 and each of rs2779500 (LOD 6.94, D' 0.993, r^2 0.048), rs1353223 (LOD 3.92, D' 1.0, r^2 0.019), rs10810271 (LOD 5.29, D' 1.0, r^2 0.049) and Mi8*7 (LOD 85.37, D' 0.59, r^2 0.348) but only Mi8*7 was shown to associate with HESN ($p=7.50 \times 10^{-3}$, OR=2.17, 95% CI 1.21-3.88). Analysis of samples successfully genotyped at both the rs1552896 and CTTR loci (n=1046) revealed that Mi8*7 is more strongly associated with HESN ($p=7.67 \times 10^{-3}$, OR=2.18, 95% CI 1.21-3.90) than is rs1552896 (p=8.77 x 10-3, OR=2.15, 95% CI 1.20-3.84) suggesting that Mi8*7 is a better marker for HESN in FREM1. We further show that Mi8*7 belongs to a subgroup of *FREM1* CTTR ($(CCCT)_{any}(TCCT)_{7-12}$) that, when homozygous, is also correlated with the HESN phenotype ($p=1.99 \times 10^{-4}$, OR=2.22, 95% CI 1.45-3.40).

The Role of *ALDH7A1* in Body Composition among West Africans. *A.R. Bentley, G.J. Chen, D. Shriner, A.P. Doumatey, A.A. Adebowale, C.N. Rotimi.* Center for Research in Genomics and Global Health, Natl Human Genome Research Institute, Bethesda, MD.

West Africa is experiencing some of the fastest growth in Type 2 Diabetes (T2D) prevalence in the world. It is believed that much of this increase is secondary to ongoing changes in body composition (BC). In this study, we investigated the association of BC indices (BMI, Fat Mass [FM], Fat Free Mass [FFM], and % Fat Mass [PFM]) with a locus (5 q22-q31) previously identified in a T2D linkage analysis in West Africans (WA). Previously we performed fine-mapping of this region using 1405 SNPs genotyped in 931 WA. Seven SNPs were associated with at least one BC index, with the strongest association for rs2306617 (*ALDH7A1*) and BMI (β 1.3, $p=1.0 \times 10^{-6}$). Based on these prior results, we conducted targeted resequencing of *ALDH7A1* in 142 WA (48 obese, T2D; 48 non-obese, T2D; 48 obese, non-T2D). Identified SNPs were genotyped in 1726 WA, and the 37 SNPs that met quality control standards were evaluated in linear regression models. Three variants were associated with the BC indices, with the most striking association for rs3736174 with FFM (β 2.1 kg, $p=9.9 \times 10^{-11}$) and BMI (β 0.9, $p=2.8 \times 10^{-5}$). Other associated variants include rs1138005 with FFM (β -2.2 kg, $p=2.6 \times 10^{-4}$) and rs7447380 with BMI (β 2.7, p=0.001). Of note, these variants have been annotated for promoter and enhancer marks, with rs3736174, in particular, influencing gene expression in cell types of relevance to BC (chondrocytes, adipocytes, and mesenchymal stem cells). The stronger results with FFM, and the previous identification of *ALDH7A1* in a GWAS of osteoporosis, led us to investigate the association of this gene on bone phenotypes. We evaluated phenotype data for Aldh7a1 knock-out mice (Jackson Laboratory, Project NIH-0076). Among the 16 mice on which DEXA scans had been performed, the null genotype was associated with a higher ratio of bone mineral content to lean body mass (p=0.04). The null genotype was not associated with markers of adiposity. The associations of this locus with FFM in WA and bone mineral content in mice suggest that BMI associations with *ALDH7A1* may, in fact, reflect an influence of this locus on body weight through bone mineralization. *ALDH7A1* encodes an aldehyde dehydrogenase, and reactive aldehydes have been shown to affect bone remodeling. Taken together, this work suggests that *ALDH7A1* influences body composition, which may result from perturbations in bone mineralization.

Targeted sequencing of GWAS loci: insight into genetic etiology of cleft lip and palate. *E.J. Leslie[1], M.A. Taub[2], Q. Zhang[3], K. Meltz Steinberg[3], D.C. Koboldt[3], Y. Kousa[4], D.E. Nonsyndromic cleft lip with or without cleft palate (CL/P) is a common birth defect with complex inheritance. Despite substantial progress in identifying risk loci by multiple genome-wide association studies (GWAS), the causal variants at each locus remain unidentified. To this end, we performed the first targeted sequencing of GWAS loci for CL/P. We sequenced thirteen regions from GWAS and candidate gene studies, totaling 6.3Mb, in 1521 Asian and Caucasian trios with CL/P and performed statistical analyses on *de novo* variants (DNVs) and single nucleotide variants (SNVs). We identified 123 novel DNVs, including a missense DNV in the *PAX7* DNA-binding domain disrupting DNA-binding by EMSA. This *PAX7* DNV is only the third CL/P coding DNV ever reported. Multiple DNVs occurred in putative regulatory elements or confirmed craniofacial enhancers. Specifically, one DNV occurred in a human neural crest enhancer downstream of *FGFR2* and two DNVs occurred in another enhancer near *HHAT*. To determine if rare coding SNVs were over-transmitted to affected offspring we performed gene-based burden tests. Although there were no significant results after correcting for multiple testing, there are many compelling SNVs worthy of follow-up in functional studies. For example, we identified four nonsense SNVs in *ARHGAP29*, the gene previously identified as the best CL/P candidate at the 1p22 region. We also used ScanTrio to identify windows containing significant over- or under-transmission of rare SNVs and assessed significance through permutations of transmitted and untransmitted haplotypes. This analysis revealed promising clusters of rare SNVs near GWAS hits on 8q24 and *NOG*. Further, our analysis of common SNVs recapitulated the GWAS results and identified multiple highly associated SNVs in craniofacial regulatory elements on 8q24 and near *NOG* and *NTN1*. While cleft palate has not been reported in *Ntn1*$^{-/-}$ mice, we note that such mice die perinatally from inability to feed, a common issue in mice with a cleft. To support the role of *Nog* and *Ntn1* in CL/P, we analyzed the expression patterns of these signaling molecules. Nog is expressed in oral periderm, a critical cell type for palatal elevation and fusion, while Ntn1 is expressed in palatal mesenchyme, localizing to the basement membrane of the medial edge epithelium and the oral surface of the palatal shelves. In aggregate this targeted sequencing study has identified several regions and variants that may be causal for CL/P.

Integrating functional data to prioritize causal variants in statistical fine-mapping studies. *G. Kichaev[1], WY. Yang[2], S. Lindstrom[3], F. Hormozdiari[2], E. Eskin[1,2,5], AL. Price[3,4], P. Kraft[3,4], B. Pasaniuc[1,5,6].* 1) Bioinformatics Inter-departmental Program, UCLA, Los Angeles, CA., USA; 2) Dept of Computer Science, UCLA, Los Angeles, CA., USA; 3) Program in Genetic Epidemiology and Statistical Genetics, Harvard School of Public Health, Boston MA., USA; 4) Dept of Biostatistics, Harvard School of Public Healthm Boston MA., USA; 5) Dept of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA., USA; 6) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA., USA.

Standard statistical approaches for prioritization of variants for functional testing in fine-mapping studies either use marginal association statistics or estimate posterior probabilities for variants to be causal under simplifying assumptions. Here we present a probabilistic framework that integrates association strength with genomic functional annotation data (e.g. ENCODE) to improve accuracy in selecting plausible causal variants for functional validation. A key feature of our approach is that it empirically estimates the contribution of each functional annotation to the trait of interest while allowing for multiple causal variants at any risk locus. We devise efficient algorithms that estimate the parameters of our model across all risk loci to further increase performance. In fine-mapping simulations based on 1000 Genomes data our approach reduces the average number of SNPs to be tested in functional assays to identify 90% of all causal SNPs from an average of 12.3 variants per locus when ranking by marginal association statistics (or 25.0 when ranking by posterior probabilities under single causal variant assumption [Maller et al 2012]) to 9.7 variants per locus. We validate our findings using data from a large scale meta-analysis of four blood lipids traits [Teslovich et al 2010] and find that the relative probability for causality is increased for variants in exons and transcription start sites and decreased in repressed genomic regions at the risk loci of these traits. Using these highly predictive trait-specific functional annotations, we estimate causality probabilities across all traits and variants, reducing the size of the 90% confidence set from an average of 17.5 to 13.5 variants per locus in this data.

Analysis of genes involved in carnitine metabolism and functions in autistic patients by targeted sequencing. *J. Ge[1], X. Wang[1], H. Cui[1], B. Zhang[1], H. Xu[2], P. Fang[1], A. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Fudan Unviersity, Shanghai, China.

A recent study reported the link between the deficiency of the trimethyllysine hydroxylase epsilon (TMLHE), the first enzyme on the carnitine biosynthesis pathway, and the risk of autism, raising the possibility that carnitine might be important in the autism etiology. The well-established function of carnitine is its role in fatty acid metabolism as a molecule transporting the fatty acids and acetate across the mitochondrial membrane. The carnitine homeostasis in humans is maintained through intake from dietary sources, endogenous synthesis, and reabsorption in the kidney. To understand whether carnitine has influence on the risk of autism, we analyzed the genes functioning in carnitine biosynthesis, carnitine transporters, carnitine-acylcarnitine acyltransferases, carnitine acylcarnitine translocases, as well as several other genes that can influence carnitine metabolism, such as genes that can cause secondary carnitine deficiency. Using the Fluidigm Access Array™ System for high-throughput PCR amplification and Illumina MiSeq next-generation sequencing, we have sequenced the exons of these 23 genes in 384 autistic probands from the Simons Simplex Collection (SSC). Totals of 108 heterozygous and 2 hemizygous protein changing rare mutations were found as follows: ACADL: c.928_9294 times; CPT1C:p.M798V and ALDH9A1: p.A9G 3times; and CPT2:p.T150A, SLC22A5:p.D122Y, ACADM: p.D266G and ACADM: p.D270G 2 times. The two hemizygous mutations are SLC6A14: p.T418S and SLC25A43: p.R323Q. Interestingly, we found that 2 patients carrying 3 heterzygous mutations in different genes, and 18 patients carrying 2 heterzygous mutations. We are now checking the inheritance of these mutations and expanding our study to the full SSC cohort.

870T

Genetic contributions to obesity and metabolic risk in Mexican-American children. *R.J. Mudgway, S.L. Spilman, A.P. Mallya, J.T. McCracken, E.L. Nurmi.* Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA.

Background: Hispanic populations have among the highest rates of obesity compared to other racial/ethnic groups. Genetic moderators of weight and metabolic factors may help explain vulnerability to obesity in these higher risk populations. Previous studies have identified signaling networks involved in obesity risk, including energy balance, monoaminergic, and growth factor systems. We examined common genetic variants in these candidate pathways for association with BMI and metabolic factors in a sample of Mexican-American children. **Methods:** Baseline data from 356 Mexican-American children 6-12 years old from the Los Angeles area were collected from matched overweight and lean groups. Physiological measures were recorded for each subject, including BMI, fat mass, physical measurements, serum chemistry (such as lipid and glucose levels), respiratory function, and resting energy expenditure. Families underwent a month-long nutrition and diet intervention and returned for follow-up measures. Association between metabolic phenotypes and complete common genetic variantion in energy balance candidates (MC4R, NPY), monoamine receptors (ADRA2A, HTR2C, DRD1-5), and brain-derived neurotrophic factor (BDNF). Key variants showing association with obesity risk in prior literature (FTO and PRKAR2B) were also included. **Results:** In agreement with published reports in Caucasians, the minor (C) allele of rs1421085 in FTO, was associated with increased BMI in Mexican-American children (p=0.027) while the minor allele (G) of rs13224682 in PRKAR2B was associated with leanness (p=0.04). We found novel effects at DRD1, where rs4867798 was associated with baseline BMI (p=0.038) and rs5326 with BMI change over 1 month ($p=2.62\times10^{-4}$). In the X-linked HTR2C gene, rs518147 demonstrated a gender specific effect, where the common allele (C) was associated with higher BMI in girls (p=0.003). Additionally, exploratory analyses revealed a potential role for ADRA2A in resting energy expenditure, MC4R in baseline lipid levels, and both FTO and BDNF in lipid and glucose changes over time. **Conclusions:** Common genetic variation in energy balance, monoamine, and growth factor candidate pathways for obesity were nominally associated with weight and metabolic profile in Mexican-American children. These results warrant replication in large, independent samples and could help target for intervention children at risk for obesity and suggest personalized treatment strategies.

871S

The analysis of *MC1R* polymorphisms can be used as a tool to predict complex phenotypes, such as skin and hair color in Brazilian population? *F. Goncalves, C. Fridman.* Legal Medicine, Ethics and Occupational Health, Medical School, University of Sao Paulo, Sao Paulo, Brazil.

Human pigmentation traits, including color variation in skin, eye, and hair, belong to the most visible and differentiating human traits. The genetic basis underlying variation in human pigmentation has been the subject of intensive research by investigators in a variety of life science communities, including forensic purposes, in which the use of these trials can help identifying missing person or guide some police investigations. The two types of melanin synthesized in well defined chemical reactions are the protective dark colored eumelanin and the sulphur containing light red-yellow pheomelanin. Eumelanin together with pheomelanin constitute the two main pigments of the skin and hair. The events leading to the melanogenesis are controlled by different genes, that we can highlight the melanocortin 1 receptor gene (*MC1R*) which encodes a protein in melanocytes responsible for melanin synthesis regulation. Polymorphisms in *MC1R*, which result in a loss of function of the receptor, are associated with increased pheomelanin production, which leads to lighter skin and hair color in European population. The aim of this study was evaluated the association between the polymorphisms in the only one exon of *MC1R* gene and hair and skin color in a sample of 401 individuals of admixed population from Brazil, intending to use the data in forensic genetics casework in several situations. No deviation in Hardy-Weinberg equilibrium was observed for all the polymorphisms analyzed. We found a strong association between the SNP rs885479 (G>A) and yellow skin color (OR:148.14; CI: 6.95-315.2 to polymorphic homozygous genotype and OR: 14.0; IC: 2.68-72.99 to heterozygous genotype). In the analyses of hair color, we found associations between the red hair color and the heterozygous genotype to the SNP rs1805007 (C>T - OR: 73.89; CI: 3.27-166.4) and rs1110400 (T>C OR: 43.18; CI: 1.83-1020.8). Our data corroborate the findings of other studies in homogeneous populations, suggesting that the analysis of *MC1R* polymorphisms can be used as a tool to access some phenotypic traits and use the obtained in attempt to help forensic investigations. We are increasing our sample and additional analyzes are ongoing to confirm these results. These results are part of a major project which the aim is to study the correlation of several pigmentation genes and skin, hair and eye color. Financial Support: FAPESP2012/02043-6, LIM40-HCFMUSP.

872M

Genetic risk variants for body mass index are associated with decreased excessive daytime sleepiness in 9,832 individuals of European ancestry from NHLBI cohorts. *J.M. Lane[1,2,3], R. Saxena[1,2,3], A.C. Bjonnes[1,2,3], B. Cade[3], S. Redline[3], F.A.J.L. Scheer[3], N. Punjab[4], D. Gottlieb[3].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Division of Sleep Medicine, Brigham and Women's Hospital and Harvard Medical School Boston, MA; 4) Division of Pulmonary and Critical Medicine, Johns Hopkins University, Baltimore, MD.

Nearly half of US adults report suffering from excessive daytime sleepiness (EDS) at least a few days a month, leading to cognitive, psychological and metabolic issues, such as obesity. We therefore asked if there is a common genetic basis for both mass index (BMI) and EDS. We evaluated the relationship between EDS and a genetic risk score for BMI comprised of genetic variants identified in genome-wide association studies. We used data from NHLBI cohorts with genotype and phenotype data in subjects of European ancestry (self-report dichotomous trait) (n=11,737). Analysis was adjusted for age, gender, and ancestry principal components. A fixed effects, inverse-variance meta-analysis was performed. Risk scores were calculated using 18 SNPs previously associated with BMI. We find increased odds of EDS in overweight (OR 1.020, p=0.041), obese (OR 1.083, p less than 0.0001), and morbidly obese (OR 1.195, p less than 0.0001) individuals of European ancestry versus normal BMI (N=11,737). We find a significant association between EDS and genetic variants in BDNF and FTO. In total 14/18 SNPs demonstrate decreased risk of EDS with BMI risk alleles, even after adjustment for BMI. A weighted BMI risk score is significantly associated with EDS (OR [95%CI] 0.96 [0.95-0.98], p=1.74E-05) and is independent of BMI (0.96 [0.94-0.97], p=5.62E-07). We also tested for effect modification by the covariates age, gender, and season and the comorbidities sleep apnea and mood disorder. The prevalence of EDS varies significantly by age (p less than 0.001), peaking at 55 years. Age significantly modifies the relationship between EDS and BMI genetic risk score (Pint=0.017). There was no significant interaction with gender, sleep apnea, mood disorder, or season of measurement. Our association results capture an effect on EDS beyond BMI. Paradoxically, BMI raising alleles individually or in aggregate are associated with a decreased odds of EDS, indicating divergent physiological roles for underlying pathways. Mechanistic understanding of BMI risk variants may provide parallel insights into excessive daytime sleepiness.

873T

Promoter Polymorphism and low Serum Levels of Mannose Binding Lectin as risk factor for Rheumatoid Arthritis in Indian population. *A. Sodhi[1], J. Singh[2], S. Singh[2], S. Arora[3], M. Kaur[1].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Department of Molecular Biology and Biochemistry, Guru Nanak Dev University, Amritsar, India; 3) Rheumatology clinic, Amritsar, India.

Mannose Binding Lectin-2 (MBL-2) is a C-type serum lectin synthesized by the liver as an acute phase protein. MBL-2 gene is located on chromosome 10q11.2- q21and various single nucleotide polymorphism (SNPs) in this gene has been reported to be associated with infection as well as autoimmune diseases. Promoterpolymorphism in MBL-2 gene is reported to be associated withaltered serum MBL levels which are associated with increased risk of various disease conditions. Rheumatoid arthritis (RA) is an autoimmune disease characterized by chronic inflammation and destruction of articular cartilage as well as synovial hyperplasia. Prevalence of RA is 0.5% - 1.0% of the global population and is increasing dramatically.The present study aimed to investigate the frequency of the mutations at positions -550 and -221 of promoter region inMBL-2 genealong with serum MBL and hs-CRP serum levels. The study was approved by institutional ethical committee as per declaration of Helsinki and informed consent was obtained from each individual. Blood samples were collected from 202 RA patients and 200 age, gender and ethnicity matched healthy subjects. Information regarding anthropometric variables, Demographic features, disease duration, and disease activity score was also recorded. Single nucleotide polymorphism in the MBL promoter (-550nt, -221nt) were analyzed by Amplification refectory mutation system-PCR (ARMS-PCR). Functional serum MBL-2 and hs-CRP levels were analyzed using commercially available kits. Out of two SNPs studied, significant difference was observed in genotypic as well as allelic frequencies of H/L (-550nt) polymorphism ($p<0.0001$). L allele of -550 is at risk for RA patients (odd ratio: 1.079 CI 95%: 0.021-2.021; $p<0.0001$). Combination of two promoter polymorphism YXLL is risk over YXHH (odd ratio: 12.12 CI95%: 3.71-39.19; $p<0.00001$) and H allele is protective over L allele (Odd ratio: 0.132; CI 95%: 0.04-0.388; $p<0.0002$). Serum MBL-2 levels were found to be significantly ($p<0.001$) lower in RA patients as compare to healthy controls and hs-CRP serum levels were found significantly ($p<0.01$) higher in RA as compared to healthy controls.The present study showed that the polymorphism in the promoter region of the MBL gene may be a genetic marker associated with RA and presence of mutation in the -550 H/L promoter region of the MBL-2 gene correlated to low MBL serum levels.

874S

Carboxypeptidase E and dopamine transporter SNPs are associated with percent weight change in kidney transplant recipients. *A.G. Stanfill[1, 3], A.K. Cashion[2], D.K. Hathaway[3], Y.P. Conley[1].* 1) Health Promotion and Development, University of Pittsburgh, Pittsburgh, PA., USA; 2) National Institute of Nursing Research, National Institutes of Health, Bethesda, MD; 3) University of Tennessee Health Science Center, Memphis, TN.

Variations in dopaminergic pathway genes have recently gained attention for being associated with weight gain and obesity. These genes include the dopamine active transporter gene (SLC6A3 or DAT1), which codes for the transporter responsible for dopamine reuptake from the synapse, and the carboxypeptidase E (CPE) gene, which has been shown to have a regulatory effect on that transporter. While the associations are exciting, there are often logistical difficulties in the longitudinal study of the genetics of weight gain. Kidney transplant recipients make an ideal population for these types of genetic association studies, as approximately 30% of recipients gain a significant amount of weight (>10 kg) in the first year after surgery. Although many clinicians attribute this weight gain to immunosuppressant therapies, this assumption has not been supported in the literature. Furthermore, there is no known relationship between dopamine function and renal disease, although gene expression work in this population has shown a significant relationship between weight gain and dopaminergic pathway genes. The purpose of this study was to test variations in SLC6A3/DAT1 and CPE for associations with weight gain, using kidney transplant recipients as a model population. Blood samples were previously collected from 70 kidney transplant recipients (43% female, 57% African American, aged 50.7 ±13.2 years, baseline weight 181.9 ±39.4 pounds) at the time of surgery. Two SNPs in SLC6A3 (rs6347, rs6350) and three SNPs in CPE (rs1583645, rs1946816, rs34516004) were genotyped using Taqman assays. Associations with percent weight change at 12 months post-transplant were done using dose dependent and risk allele analyses. ANOVA showed a dose dependent effect for rs6347 ($p=0.05$) and rs1946816 ($p=0.019$). Risk allele chi squares showed a statistically significant effect for the A risk allele rs6347 ($p=0.0003$), and for the C risk allele of rs1946816 ($p=0.00004$). The C allele of rs1946816 also showed a negative correlation with weight change ($r=-0.22$, $p=0.05$). Multiple regression modeling supported these associations (rs6347 TT genotype $p=0.053$, rs1946816 CC $p=0.048$). While this was done as a pilot study, these results are promising for repetition with a larger sample size. If confirmed in a larger sample, the results could be translated into potential clinical applications to identify individuals most genetically at risk for weight gain post-transplant.

875M

Candidate gene association study of chronic obstructive pulmonary disease using a targeted high throughput sequencing approach. *J. Klar[1], H. Matsson[2], C. Söderhäll[2], H. Backman[3], A. Lindberg[3], E. Rönmark[3], J. Kere[2], B. Lundbäck[4], N. Dahl[1].* 1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Department of Biosciences and Nutrition and Center for Innovative Medicine (CIMED), Karolinska Institutet, Huddinge, Sweden; 3) The OLIN studies, Sunderby Hospital of Norrbotten, Luleå, Sweden; 4) Krefting Research Centre, Institute of Medicine, University of Gothenburg, Sweden.

Background: Chronic obstructive pulmonary disease (COPD) is a common disease in Sweden, affecting approximately one in six in age over 40 years, with severe impact on health and quality of life. COPD results from environmental factors, especially cigarette smoking, with contributions from yet unknown genetic background factors and by gene-environment interactions. Not all smokers develop COPD suggesting that genetic factors modulate the life-time risk and conversely, non-smokers can be at elevated risk for COPD. The general objective of this project is to get insight into the mechanisms and interactions of specific genes and genetic pathways that contribute to the development of COPD.

Aim: To investigate candidate genes, with emphasis on genes important for lung development and homeostasis, in defined populations of smokers and non-smokers in search for genetic variations associated with development of COPD.

Methods: : We conducted a candidate gene analysis on 200 kb of enriched sequences, including 22 genes implicated in lung development and 71 genes and regions previously associated with COPD. Targeted enrichment (HaloPlex; Agilent) and high throughput sequencing (Illumina) was performed on 96 patients and 96 healthy controls retrieved from the Swedish Obstructive Lung Disease in Norrbotten (OLIN) Studies sample set.

Results: We identified a total of 2,151 SNPs of which 78, distributed in 45 gene regions, have significantly different allele frequencies in COPD cases than controls. All COPD associated SNPs showed a strong effect on the development of COPD, as indicated either by low or high odds ratios (OR). The SNPs are mainly located in genes that cluster in pathways associated with cell proliferation, including genes involved in both development and damage repair of the lung.

Conclusion: Our preliminary results confirm previous findings and, in addition, high effect sizes of SNP variants associated with COPD compared to other studies. The strong effect sizes are possibly attributed to the genetic background of our study populations. The results support the idea that variants in genes for lung development are important determinants of adult lung function that may ultimately contribute to COPD.

876T

SNP variants in MHC are associated with sarcoidosis susceptibility and subgroups - a joint case-control association study in four European populations. *A. Wennerström[1,2,3], E. Lahtela[2], V. Sarcoidosis is a multiorgan inflammatory disorder of unknown aetiology. The most probable pathophysiology of sarcoidosis, the dysregulation of the immune response strongly suggests benefits from a better understanding of the role of the immune mediating genes (e.g. MHC genes) in sarcoidosis susceptibility. We present results from a Finnish case-control discovery sample as well as three independent replication studies from the Swedish, Dutch and Czech populations. We studied four genes in the MHC Class III region (LTA, TNF, AGER, BTNL2) and HLA-DRA in relation to HLA-DRB1 alleles to detect variants predisposing to sarcoidosis and to identify genetic differences between patient subgroups. Patients with sarcoidosis (n=805) were further subdivided based on the disease activity and the presence of Löfgren syndrome. In a meta-analysis, seven SNPs were associated with non-Löfgren sarcoidosis (NL; the strongest association with rs3177928 in HLA-DRA, P=1.79E-07, OR=1.9) and eight with Löfgren syndrome (LS; the strongest association with rs3129843 in BTNL2/HLA-DRA region, P= 3.44E-12, OR=3.4) when compared with healthy controls (n=870). The high LD between SNPs and an HLA-DRB1 challenged the result interpretation. In addition to these SNPs, population-specific associations for sarcoidosis were observed. In conclusion, there is clear evidence that polymorphisms in the BTNL2 and HLA-DRA have a role insarcoidosis susceptibility. Most importantly, our study revealed sarcoidosis-related variants that were shared across ethnicities as well as ethnicity-specific genetic markers. Future functional studies are required to reveal the causal variants of these associations and the immunogenetic basis related to sarcoidosis.

877S

Assessment of *LGALS3* genetic variants rs4644, rs4652, rs2075601 and galectin-3 levels as risk factor in Rheumatoid Arthritis. *T. Kaur[1], M. Kaur[1], S. Singh[2], S. Arora[3], J. Singh[2].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Department of Molecular Biology and Biochemistry, Guru Nanak Dev University, Amritsar; 3) Rheumatology Clinic, Amritsar.

Galectin-3 is a pro-inflammatory molecule family encoded by *LGALS3* gene on 14q21 chromosome. It can act as a key player in various inflammatory diseases by activation of macrophages and neutrophils. Rheumatoid arthritis (RA)is a chronic, inflammatory, autoimmune disease characterized by destruction of peripheral joints leading to deformity and disability. Worldwide, 1% of population issuffering from RA. Elevated levels of galectin-3 have been implicated in serum and synovial fluid of RA patients. A single study involving *LGALS3* genetic variants have indicated its association with RA. The present study has been proposed to evaluate *LGALS3* variants and its protein serum levels in RA in Indian population.The present case-control study included 200 RA patients, diagnosed according to 1987 revised criteria of American college of Rheumatology and acohort of 200 age, genderand ethnicity matched controls.The study was approved by institutional ethical committee in accordance with declaration of Helsinki and written informed consent was obtained from each participant. Genetic typing for rs4644 and rs4652 was done by PCR-RFLP method while for rs2075601 by tetra primer PCR method and by Sanger Sequencing. Serum galectin-3 and serum hs-CRP levels were assessed in both patients and controls using commercial available ELISA kits (Abcam, UK and MyBiosource, USA respectively).Suitable statistical analysis was performed using SPSS version18.0.Significant difference in allelic distribution has been observed in RA patients as compared to controls ($p<0.05$) and there was suggestive evidence of an association in a Co-dominant model (AA vs AC = AC vs CC; OR= 1.37, 95% CI 1.00-1.88, p = 0.048) for rs4644 SNP. For rs4652 SNP, present study found a dominant mode of association with RA (AC/CC vs AA; OR- 3.947, 95% CI 0.86 -19.67, p= 0.047) and AA genotype was found as a risk factor. For rs2075601 SNP, the frequency of TT genotype was found to be prevalent in RA patients (11%) than controls (7%). Different genetic combinations for three SNPs showed that heterozygosity at three loci was risk factor for our RA population.Significantly elevated serum galectin-3 levels and hs-CRP levels have been observed in RA patients than controls ($p<0.001$, $p<0.001$ respectively). In present study, association of *LGALS3* variant and its high protein serum levels with RA suggested the role of galectin-3 as a genetic marker with disease.

878M

Genetic association study between 39 genes and nonsyndromic cleft lip and cleft palate in Brazilian population. *TK. Araujo[1], R. Secolin[1], TM. Félix[2], MIB. Fontes[1,3], IL. Monlleó[4], J. Souza[5], AC. Fett-Conte[6], EM. Ribeiro[7], AC. Xavier[8], A. Rezende[9], M. Simioni[1], VL. Gil-da-Silva-Lopes[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas (UNICAMP), Brazil; 2) Medical Genetics Service, Hospital de Clínicas de Porto Alegre (HCPA), Brazil; 3) Medical Genetics Sector, State University of Alagoas (UNCISAL), Brazil; 4) Clinical Genetics Service, Federal University of Alagoas (UFAL), Brazil; 5) Medical Genetics Sector, Assistance Center for Cleft Lip and Palate (CAIF), Brazil; 6) Molecular Biology Department, Medicine School of Sao José do Rio Preto (FAMERP/FUNFARME), Brazil; 7) Medical Genetics Sector, Hospital Infantil Albert Sabin (HIAS), Brazil; 8) Center for Research and Rehabilitation of Lip and Palate Lesions (CRRLPL), Centrinho Prefeito Luiz Gomes, Brazil; 9) Center of Health Sciences, Department of Clinical and Toxicological Analysis, University Federal of Rio Grande do Norte (UFRN), Brazil.

The objective of this study was to evaluate genetic association of 39 candidate genes and Nonsyndromic cleft lip with cleft palate (NSCLP) in a sample from Brazilian population. It was performed a case-control association study composed of 537 individuals. The case group was compound of 182 cases with NSCLP (99 males and 83 females) enrolled in Brazilian Database on Orofacial Clefts and previously evaluated by clinical geneticist. A control group of healthy individuals with no history of orofacial cleft in three generations was included. Statistical power of the sample was evaluated using Gpower software. Two hundred fifty-three tagging single nucleotide polymorphism (tagSNPs) were genotyped by the OpenArray™TaqMan system (Applied Biosystems). The association analysis was performed by logistic regression using Plink software. A stepwise regression analysis was performed using the R program. The statistical results were corrected for multiple testing using the Bonferroni correction for each polymorphism evaluated. The sample showed 80.11% of statistical power to detect genetic association. Twenty-four SNPs spanning 16 genes were statistically associated with the etiology of NSCLP in the sample. The associated genes were: *TCBE3* rs2235541*T (p=0.032); *MSX1* rs3775261*T (p=0.009); *SPRY1* rs300566*A (p=0.017); *MSX2* rs4868442*T (p=0.020); *PRSS35* rs4706180*C (p=0.032); rs512140*T (p=0.035); *TFAP2A* rs537112*T (p=0.015); rs533558*G (p=0.001), rs303048*T (p=0.006); rs1675414*C (p=0.042); *SHH* rs1233556*T (p=0.047); *VAX1* rs10787760*G (p=0.011); rs7086344*T (p=0.000); rs6585429*T (p=0.013); *TBx10* rs3758938*G (p=0.015); *WNT11* rs7936750*G (p=0.018); *PAX9* rs1955734*T (p=0.001); *BMP4* rs17563*C (p=0.016); *JAG2* rs11621316*G (p=0.003); *KIF7* rs4932238*C (p=0.007); rs4932240*T (p=0.029); *AXIN2* rs11655966*T (p=0.030); *DVL2* rs2074222*G (p=0.002); rs222850*C (p=0.016). The stepwise regression analysis showed that SNPs associated contribute together to 15.5% of the determinants of etiology of NSCLP in this sample. In conclusion, these data suggest that these genes are associated with NSCLP in the Brazilian population. In addition, this is the first study to suggest association between *KIF7* and *TCEB3* genes and etiology of NSCLP. Supported by: FAPESP, CNPq.

879T

Exome sequencing and targeted DNA resequencing reveals association of the MYO5B SNP rs183559995 with risk of Familial Nonsyndromic Cleft Lip and Palate. *S. Beiraghi[1], H.A. Stessman[2], A.K. Mitra[2], R.J. Schaefer[3], W. Wang[3], C.L. Myers[3], B.G. Van Ness[2].* 1) Division of Pediatric Dentistry, University of Minnesota, Minneapolis, MN; 2) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 3) Department of Computer Science and Engineering, University of Minnesota, Minneapolis, MN.

Non-syndromic cleft lip with or without palate (NSCL/P) is one of the most common congenital birth defects with an incidence of 1/500-1/1000. Genetic factors have been shown to play significant role in the development of NSCL/P. Using non-parametric linkage analysis study on a six-generation family (n=27) with probable autosomal dominant, low penetrance inheritance of NSCL/P, we have previously reported that a 5.7-Mb genomic region on 18q21.1 that potentially contains a pathogenic, high-risk variant for NSCL/P. In the current study, we performed exome sequencing on 6 affected individuals, 2 obligate carriers, and 4 unaffected individuals from the NSCL/P family using Illumina HiSeq with TruSeq Exome Enrichment. 100 Western European (CEPH) genomes from the 1000 Genomes Project were utilized as unaffected controls owing to low penetrance for NSCL/P within this family. All sequences were mapped to hg19 human reference genome using Burrows Wheeler Aligner 0.5.9 (BWA) and variants were called using SAMtools and GATK Unified Genotyper for all sites with greater than 8 reads. High quality variants were used as markers in genome wide association analysis linked to the affected phenotype (NSCL/P) using PLINK whole genome association analysis toolset. Four (4) candidate SNPs within the same gene, MYO5B, a myosin family member involved in protein trafficking, as well as additional variants (SNVs and INDELs) were identified that may contribute to NSCL/P disease etiology. Subsequent targeted Sanger re-sequencing in 33 family members demonstrated that the MYO5B intronic SNP rs183559995 (G/A) was significantly associated with the NSCL/P trait (p= 0.001, 95% CI=2.25-185.3, OR=15). Our results indicate that this SNP is a strong candidate gene for familial NSCL/P. Further functional studies will be required to determine its significance with regard to MYO5B structure and function.

880S

Rare Variants Within 7p Region Associated with Carotid Bifurcation Intima-Media Thickness Among Dominican Republic Families. *N.D. Dueker[1], A. Beecham[1], L. Wang[2], S. Blanton[2], C. Dong[3], S. Guo[1], D. Cabral[3], E. Sabala[2,3], T. Rundek[3], R.L. Sacco[2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Neurology, Epidemiology and Public Health, Miller School of Medicine, University of Miami, Miami, FL.

Ischemic stroke (IS) and myocardial infarction (MI) are leading causes of mortality and disability in the US. Though both IS and MI are suggested to be genetically controlled, only a small proportion of the risk for both is explained. One mechanism to identify candidate loci for these vascular disorders is to identify the genetic determinants of subclinical phenotypes, such as carotid intima-media thickness (cIMT). We have previously shown cIMT measures to be heritable and found evidence for linkage and association of common variants on 7p with carotid bifurcation IMT (BIF). Therefore, we sought to further characterize the 7p region and to identify additional candidate variants, hypothesizing that rare variants in this region are associated with BIF. To test this hypothesis, we sequenced the 1 LOD unit down region on 7p in nine extended families from the Dominican Republic with strong evidence for linkage to BIF in this region (family specific LOD score > 0.1). Using this data, we performed the family-based sequence kernel association test (famSKAT) on all genes within the 7p region to identify those associated with BIF. Analyses were restricted to single nucleotide variants (SNVs) with minor allele frequency (MAF) <5%. A total of 70 genes were included in our analyses and one gene, nucleotide-binding oligomerization domain (*NOD1*), met our Bonferroni corrected threshold of p=0.0007 (famSKAT p=0.0003; # SNVs=23). NOD1 is an excellent candidate gene as it is expressed in the brain and the heart, and a previous study found the *NOD1* G796A polymorphism to be significantly more common in stroke patients seropositive for Chlamydia pneumoniae compared to controls seropositive for Chlamydia pneumoniae. In addition to *NOD1*, we also identified 10 moderately-associated genes with p<0.05, including *GHRHR* which encodes the growth hormone releasing hormone receptor, a receptor that when activated, improves injury response after MI (famSKAT p=0.02; # SNVs=24). In exploratory analyses, we restricted our analysis to exonic variants with MAF<5% and found similar results. Taken together, our study provides suggestive evidence for a role of rare variants within our previously identified 7p region in BIF. Sequencing within additional families is currently in progress.

881M

No association of PTPN22 and SUMO4 Polymorphisms with predisposition to type 1diabetes (T1D) in a cohort of south Indian subjects. *B.C. Gorijala[1], U. Ratnamala[2], S.K. Nath[3], U. Radhakrishna[4].* 1) Oncology Department, Krishna Institute of Medical Sciences, Secunderabad, Andhra Pradesh, India; 2) Department of Pharmacology, Creighton University, Omaha, NE, United States; 3) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK, United States,; 4) Beaumont Research Institute, Royal Oak, MI, USA.

Type 1 diabetes, (T1D) (juvenile or insulin-dependent diabetes mellitus) is an autoimmune disease characterized by the lack of insulin due to an autoimmune destruction of pancreatic beta cells. The estimated incidence of T1D varies from 8-17/100,000 in Northern Europe and the U.S. The general incidence of T1D in India is 10.6 cases/year/100,000. The exact etiology and pathogenesis of T1D is still unknown, however genetic factors are believed to be a major component for the development of T1D. Additionally, modifying epigenetic factors such as diet, environmental, infections and lifestyle play an important role in disease expression. To date, several genome-wise association and candidate gene studies have identified more than 25 genetics association with high confidence, including PTPN22, SUMO4, CTLA4 and IL2RA. However no common gene mutations or pathogenic causative genomic variations have been identified. We have recruited 500 sporadic T1D patients, and an equal number of age-matched controls from southern India. We have recently screened PTPN22 and SUMO4 genetic variants in 100 T1D patients and equal controls using a SNP array. Our results did not show any association with PTPN22 (rs2476601, 1858C>T). This SNP was monomorphic (G/G) in both T1D. This is consistent with other Asian populations. The data of SUMO4 variation (rs237025, 163A > G, M55V) which has been shown to be a susceptibility variant for TD1, a higher frequency of combined AG and GG genotypes (64%) in the affecteds than in matched controls (56%). However, the “G” allele frequency between cases and controls are not statistically significant (40% in cases vs. 35% in controls, OR (C.I.) = 1.23 (0.82-1.85), chi2=1.07, p=0.30), mostlikely due to small sample sizes.

882T

Evaluation of Genetic Polymorphism of *MBL2* Gene and Pulmonary Function Test in Chronic Obstructive Pulmonary Disease. *A. Sharma[1], G. Gandhi[1], B. Malhotra[3], J. Singh[2], S. Singh[2], M. Kaur[1].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Department of Molecular Biology and Biochemistry, Guru Nanak Dev University, Amritsar, India; 3) Department of Tuberculosis and Chest Diseases, Govt. Medical College, Amritsar, India.

Chronic Obstructive Pulmonary disease (COPD) is characterized by narrowing of airways due to abnormal inflammatory response to noxious particles leading to progressive reduction in the pulmonary function. Worldwide, COPD is the fourth leading cause of morbidity and mortality. In India, its prevalence is 4.1%. Several molecules of innate and adaptive immune system are implicated in disease etiology and pathogenesis. Mannose-binding lectin (MBL) is a pattern-recognition protein which binds to carbohydrates of infectious agents or cells resulting in activation of complement system and thus causing stimulation of inflammatory reactions. Objectives of the present study were to evaluate *MBL2* gene polymorphisms in COPD patients and its association with pulmonary function test (PFT). The study was approved by Institutional Ethical Committee. After informed consent, blood samples were collected from 80 COPD patients and 72 age, gender and ethnicity matched controls. Genomic DNA was isolated from blood samples using inorganic method. Single nucleotide polymorphisms (SNPs) of codon 54 and 57 of the *MBL2* gene were studied by PCR-RFLP using restriction enzymes BanI and MboII respectively. SNP of 5’UTR region (allele P/Q) was studied by ARMS-PCR. Pulmonary function test was performed using Medicaid system. For the diagnosis and categorization of COPD patients GOLD (2012) guidelines were used. All statistical analyses were performed using SPSS version 16.0. No significant difference was observed in genotypic and allelic distribution of codon 54, 57 and P/Q alleles in comparison with controls. Genetic combination, heterozygosity for codon 54, P/Q and homozygosity for codon 57 (GAAACT), appears to be a risk factor (OR=4.301; CI=1.06- 17.45; p=0.04) for susceptibility to develop COPD with respect to AAAACT. All the pulmonary function test parameters viz. forced vital capacity (FVC), forced expiratory volume in one second (FEV1), FEV1/FVC ratio and peak expiratory flow (PEF) were found to be significantly reduced in patients than controls (p<0.001). On the basis of disease severity, patients were stratified into mild (3.75%), moderate (23.75%), severe (40.00%) and very severe (32.50%) disease stages. Significant association was found with GGAACC for FEV1 (p<0.001) in case of severe COPD patients and GAAACC for FVC (p=0.039) in case of mild COPD patients. The results of the present study showed that *MBL2* polymorphisms may be involved in pathogenesis of COPD.

883S

Age-related hearing impairment associated with GJB2 single mutation IVS1+1G>A in the Yakut population in Eastern Siberia. *N.A. Barashkov[1,2], F.M. Teryutin[1,2], V.G. Pshennikova[1], A.V. Age-Related Hearing Impairment (ARHI) is one of the frequent sensory disorders registered in 50% of individuals over 80 years. ARHI is a multifactorial disorder due to environmental and poor-known genetic components. In this study, we present the data on age-related hearing impairment of 48 heterozygous carriers of mutation IVS1+1G>A (GJB2 gene) and 97 subjects with GJB2 genotype wt/wt in the Republic of Sakha/Yakutia (Eastern Siberia, Russia). This subarctic territory was found as the region with the most extensive accumulation of mutation IVS1+1G>A in the world as a result of founder effect in the unique Yakut population isolate. The GJB2 gene resequencing and detailed audiological analysis in the frequency range 0.25, 0.5, 1.0, 2.0, 4.0, 8.0 kHz were performed in all examined subjects that allowed to investigate genotype-phenotype correlations between the presence of single mutation IVS1+1G>A and hearing of subjects from examined groups. We revealed the linear correlation between increase of average hearing thresholds at speech frequencies (PTA0.5,1.0,2.0,4.0 kHz) and age of individuals with GJB2 genotype IVS1+1G>A/wt (rs=0.499, p=0.006860 for males and rs=0.427, p=0.000277 for females). Moreover, the average hearing thresholds on high frequency (8.0 kHz) in individuals with genotype IVS1+1G>A/wt (both sexes) were significantly worse than in individuals with genotype wt/wt ($p<0.05$). Age of hearing loss manifestation in individuals with genotype IVS1+1G>A/wt was estimated to be ~ 40 years (rs=0.504, p=0.003). These findings demonstrate that the single IVS1+1G>A mutation (GJB2) is associated with age-related hearing impairment (ARHI) of the IVS1+1G>A carriers in the Yakuts.

884M

Enzymatic properties of the catalytic domain of mouse acidic mammalian chitinase expressed in *Escherichia coli*. *A. Kashimura, K. Okawa, M. Kimura, K. Okazaki, M. Sakaguchi, Y. Sugahara, F. Oyama.* Applied Chemistr, Faculty of Engineering, Kogakuin University, Hachioji, tokyo, Japan.

Acidic mammalian chitinase (AMCase) was discovered to perform compensatory role of chitotriosidase and was named for its acidic isoelectric point. Unlike other chitinases, which are inactive at low pH, mouse AMCase has been shown to be most active at pH 2.0 with acidic stability. AMCase has attracted considerable attention due to its increased expression under pathological conditions. Significant increases of AMCase mRNA and protein were detected in an induced asthma mouse model. Polymorphisms and haplotypes of AMCase are associated with bronchial asthma in humans. Furthermore, AMCase expression is increased by antigen-induced mouse models of allergic lung inflammation. Little is known, however, about the pathophysiological functions of AMCase in mice and humans. Mouse AMCase contains an N-terminal catalytic domain and a C-terminal chitin-binding domain (CBD). It has been generally considered that CBD recognizes chitin and catalytic domain degrade it. We expressed the catalytic domain of AMCase in Escherichia coli as a fusion protein. We found that the enzymatic properties of the recombinant catalytic domain against 4-nitrophenyl N,N'-diacetyl-β-D-chitobioside were essentially consistent with those of full-length AMCase as for the pH and temperature optima as well as pH and thermal stabilities. This recombinant catalytic domain can be used to elucidate detailed biological functions of the mouse chitinase.

***Nicastrin* knockdown in keratinocytes induces expression profiles for decreased expression of cell cycle genes and increases gene expression related to type-1 interferon response.** *E.D.O. Roberson[1,2], L. Cao[1].*
1) Dept of Medicine, Washington University, St. Louis, MO; 2) Dept of Genetics, Washington University, St. Louis, MO.

Hidradenitis suppurativa (HS) is chronic, painful and disfiguring skin disease. It is characterized by the development of intensely painful, deep-seated nodules and abscesses in the axillae, inner thighs, and groin. Mild forms are nodular, but more severe disease progresses to interconnected abscesses. Nicastrin (NCSTN) is frequently mutated in familial HS, primarily via frameshifting indels. We sought to recapitulate the likely NCSTN haploinsufficiency state in cell culture models using siRNA knockdowns. We knocked down the gene expression of NCSTN in both human embryonic kidney (HEK293) and human epidermal keratinocyte (HEK001) cell lines to less than 50% of wildtype level. RNA from the resulting cells, along with luciferase siRNA control, was profiled using Illumina HT12v4 microarrays. Genes were considered differentially expressed if the false-discovery rate corrected p-value was less than 0.05 and the absolute fold-change was at least 1.50. HEK293 cells with NCSTN knockdown had 650 genes with significantly increased expression and 872 genes with significantly decreased expression. Among genes with significantly increased expression, there was enrichment for genes related to the p53 signaling pathway and caspase cleavage of cytoskeletal proteins. Among the genes with significantly decreased expression, there was enrichment of genes related to response to interferon-alpha and cholesterol biosynthesis. HEK001 cells with NCSTN knockdown demonstrated 407 genes with significantly increased and 359 genes with significantly decreased expression. Genes with significantly increased expression were enriched for type-1 interferon-mediated signaling and a response to interferon-beta. This was accompanied by an enrichment of genes with interferon regulatory motif (IRF) transcription factor motifs. Genes with significantly decreased expression were enriched for genes involved in the cell cycle, organelle fission, DNA replication and cytokinesis. The transcriptome of HS affected skin is largely unexplored. Using this cell line model, we are able to demonstrate a possible increase in caspase activity (HEK293), increased inflammatory propensity (HEK001), and decreased cell proliferation (HEK001) under NCSTN depletion. NCSTN haploinsufficiency may predispose to loss of hair follicular support cells by increased cell death in response to stress and decreased follicular cell proliferation. This study highlights the need to study affected HS tissue.

Functional study of Peptidylarginine deiminase type 4 as genetic risk factor for RA. *A. Suzuki[1], Y. Kochi[1], F. Shoda[2], K. Fujio[2], E. Kanno[1], H. Matsumura[1], R. Yamada[1,3], K. Yamamoto[1,2].* 1) IMS, RIKEN, Yokohama City, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Center for Genomic Medicine, Kyoto University, Kyoto, Japan.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. Previouly, peptidylariginine deiminase type 4 (PADI4) was identified as a susceptibility gene for RA in a Japanese population by case-control association study (Ref 1). PADI4 is a member of the PADI gene family and converts arginine residue (peptidylarginine) to citrulline residue (peptidylcitrulline). PADI4 is highly expressed in bone marrow, macrophages, neutrophils and monocytes. Peptidylcitrulline is an interesting molecule in RA, because it is an antigen of ACPA and only PADs (translated protein from PADI genes) can provide peptidylcitrullines, via modification of protein substrates. To evaluate the importance of PADI4 gene in the progression of RA, we generated Padi4 -/- DBA1J mice. We used Padi4-/- mice to show that PAD4 is significantly affected to progress of collagen induced arthritis (CIA), well known as an RA model animal. Expression of various inflammatory cytokines and Padi genes in immune cells was detected by real-time TaqMan assay. Cytokine concentrations in sera were measured by enzyme-linked immunosorbent assay. We demonstrated that Padi4 expression was induced by CII immunization. In Padi4-/- mice, inflammatory cytokine levels were significantly decreased compared with those in wild-type mice. Interestingly, Padi2 expression was induced in immune cells of Padi4-/- mice in compensation for the defect in Padi4. 1) Suzuki, A. et al Nat. Genet.34, 395-402 (2003).

Functional characterization of a TERT-CLPTM1L multi-cancer risk locus on chr5p15.33. *L. Amundadottir[1], J. Jia[1], J. Choi[1], I. Collins[1], M. Xu[1], J. Hoskins[1], T. Zhang[1], M. Zhang[1], R. Koster[1], P. PanScan Consortium[2], G. Petersen[3], J. Fang[1], K. Brown[1].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 3) Department of Health Sciences Research, Mayo Clinic, Rochester, MN.

Genome wide association studies (GWAS) have mapped multiple independent cancer risk loci (n=6) to a small region on chr5p15.33 for at least ten distinct cancers, including bladder, breast, glioma, lung, melanoma, non-melanoma skin, ovarian, pancreas, prostate, and testicular germ cell cancer. This region harbors two plausible target genes, *TERT* which encodes the catalytic subunit of telomerase reverse transcriptase which maintains chromosome ends by adding telomeres repeats, and *CLPTM1L* which encodes the cleft lip and palate transmembrane protein 1-like protein which promotes cancer cell growth, protect cells from apoptosis, and can induce abnormal cytokinesis. The most significant pancreatic cancer GWAS SNP on chr5p15.33 was rs401681 (P=3.7×10^{-7}, OR=1.19) located in the 13th intron of the *CLPTM1L* gene. Imputation and fine mapping in pancreatic cancer improved this signal by three orders of magnitude (P=1.4×10^{-10}, OR=1.30) to a set of 7 highly correlated SNPs. Electrophoretic mobility shift assays (EMSA) and Luciferase assays across these SNPs led us to a single SNP that showed allele specific effects in both assays and overlapped with prominent ENCODE marks indicating regulatory potential. Examining this SNP across pancreatic cancer, melanoma, lung cancer and testicular cancer cell lines established a consistent pattern of a specific protein binding and enhanced regulatory activity for the risk allele across 8 cancer cell lines (1-2 per cancer type). Promoter siRNA targeting analysis across the regulatory region harboring the putative functional SNP resulted in a strong inhibition of *TERT* expression (average 60%, range 45-85%) but no effect on *CLPTM1L* expression. Furthermore, allele specific siRNA targeting showed stronger inhibition of *TERT* expression from the risk as compared to the protective allele. Current work focuses on identifying the protein(s) that differentially bind this variant through proteomics, and performing eQTL analysis to correlate genotypes to expression of *TERT* and *CLPTM1L*. Our results indicate that for pancreatic cancer, the multi-cancer risk locus within CLPTM1L (tagged by rs401681) may be explained by a single SNP that confers allele specific enhancer effects and influences *TERT* gene expression. The effects were consistent with elevated levels of the *TERT* expression in carriers of the risk allele. Additionally, our data suggest that this variant may represent a risk-conferring variant at this locus for multiple cancers.

Functional BDNF gene variants increase risk to moderate-severe allergic rhinitis (AR). *AK. Andiappan[1,2], JM. Quek[2], C. Schurmann[5,6], A. Teumer[5], HJ. Westra[7], T. Esko[8], L. Franke[7], JJ. Liu[3], FT. Chew[2], A. Larbi[1], DY. Wang[4], O. Rotzschke[1].* 1) Singapore Immunology Network, Singapore, Singapore; 2) Department of Biological Sciences, NUS; 3) Genome Institute of singapore, Singapore; 4) Department of Otolaryngology, NUS; 5) Institute for Community Medicine, University Medicine Greifswald, Greifswald, Germany; 6) Department of Functional Genomics, Interfaculty Institute for Genetics and Functional Genomics, University Medicine Greifswald, Greifswald, Germany; 7) Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 8) Estonian Genome Center, University of Tartu, Tartu, Estonia.

Background: BDNF is a secretory protein belonging to the neurotrophin family which regulates the inflammatory cascade leading to allergic disease. Increased BDNF levels have been associated to severity of allergic phenotypes such as AR, asthma and eczema. No prior genetic study has investigated the relationship between BDNF polymorphisms and moderate-severe AR susceptibility. Objective: Aim of the study was to assess the association of genetic variants of BNDF with moderate-severe allergic rhinitis, and to determine whether this has in any functional consequences. Methods: TagSNPs spanning the BDNF gene were selected from the human HapMap CHB (Chinese) population. These BDNF tagSNPs were then tested for association with moderate-severe AR in a population of 2216 Shandong Chinese. The association was replicated in another independent Singapore Chinese population of 1239 individuals. The impact of the associated tagSNP on BDNF mRNA expression was determined using data from whole blood eQTLdata. The results were confirmed by using a luciferase reporter assay to evaluate the impact of associated SNP on BDNF expression in vitro. Results: The association analysis revealed that the tagSNP rs10767664 was significantly associated with susceptibility to moderate-severe AR in both the Shandong and Singapore Chinese populations (meta p= 0.000298 and OR= 1.242). The individuals bearing the minor AA genotype of rs10767664, associated with increased risk for moderate-severe AR. The tagSNP rs10767664 was linked to the functional coding variant rs6265. Importantly, the minor alleles of rs10767664 and rs6265 were signifcantly associated with BDNF mRNA expression on whole blood. This correlation was also validated in a large eQTL meta-analysis comprising of 5416 individuals in total. Finally we demonstrated in an in vitro model that the “GG” genotype of the functional rs6265 lead to higher BDNF expression, which could result in a higher risk to the AR phenotype. Conclusion: A common variant of the BDNF gene is associated with increased risk towards moderate-severe AR. The potentially causative "GG" genotype of rs6265 appears to augment expression of BDNF mRNA in whole blood as demonstrated in an in vitro system and thereby lead to disease through activating an inflammatory cascade.

889S

A non-coding variant near *BMP2* associated with sagittal non-syndromic craniosynostosis causes differential GFP expression in zebrafish. *C.M. Justice[1], J. Kim[2], S.D. Kim[2], G. Yagnik[2], B. Carrington[3], R. Sood[3], A.F. Wilson[2], S.A. Boyadjiev[2].* 1) Genometrics Section, Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 2) Section of Genetics, Department of Pediatrics, University of California Davis Medical Center, Sacramento, CA; 3) Zebrafish Core, Translational and Functional Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Craniosynostosis (CS) is a common congenital malformation in which one or more of the cranial sutures of an infant skull fuse prematurely. Approximately 80% of the CS cases are non-syndromic with unknown etiology, and approximately 50% of these involve the sagittal suture. Sagittal non-syndromic craniosynostosis (sNSC) has an estimated prevalence of about 2 per 10,000 live births. Our recent genome-wide association study of sNSC in 130 non-Hispanic White (NHW) trios identified a significant association to rs1884302, which is 346kb 3’ of *BMP2*. We did not identify any coding variant in *BMP2*, suggesting that variants in the region near *BMP2* may harbor regulatory elements responsible for the phenotype. We measured the expression of *BMP2* in primary calvarial osteoblasts derived from patients with sNSC and observed overexpression of *BMP2* in 2 out of 8 sNSC osteoblasts cell lines, as well as heightened BMP2-signaling. A 716bp fragment amplified from a proband encompassing rs1884302 was observed to enhance the promoter activity of *BMP2* in a *Renilla* luciferase assay. In order to determine if variation at this SNP causes functional changes, 716 bp fragments with the risk allele C (MAF=0.34 in NHW) and wild-type T allele at rs1884302 were cloned into a zebrafish enhancer detector (ZED) vector for *Danio rerio* transgenesis. Stable transgenic lines from 2 independent founders for each allele were observed for green fluorescent protein (GFP) expression driven by the cloned fragment. We observed strong expression of GFP in the brain region of the transgenic fish with the C (risk) allele, but not with the T (wild-type) allele of rs1884302. Our *in vitro* results suggest that the C allele at rs1884302 may, in fact, be regulating expression of *BMP2*, while our *in vivo* results indicate that the presence of the C allele at this SNP acts as an enhancer.

Functional Investigation of Celiac Susceptibility Gene LPP in T Cells. *B. Molloy, M. Freeley, E. Quinn, R. McGinn, A. Long, R. McManus.* Department of Clinical Medicine, Institute of Molecular Medicine, St. James's Hospital, Dublin 8, Ireland.

Celiac Disease (CeD) is a common, complex and chronic immune-mediated disease affecting the small intestine. CD4 T cells are known to play an important role in celiac disease etiology as they initiate an immune response to gluten displayed by antigen presenting cells. A large case control study using the Immunochip identified the transcription factor /adhesion protein Lipoma-preferred partner (LPP) as the most significantly associated non-HLA risk locus with an associated p value of 10^-49 (Trynka et al, 2011). LPP has known roles in cancer and smooth muscle migration but little is known if it plays a role in T cells or how it may contribute to celiac disease pathophysiology (Grunewald et al, 2009). mRNA sequence data of CD4 T cells from our lab (data not shown) shows that LPP is expressed at higher levels in celiac samples compared to controls. We aimed to investigate the role of LPP in T cells. In this study we wanted to firstly confirm the expression of LPP in CD4 T cells and examine the effect LPP may have on cell migration through siRNA knockdown. In addition, using qPCR we tested a number of potential LPP targets that demonstrated dysregulation in our sequencing study for differences in expression in the presence or absence of LPP. We confirmed LPP expression in peripheral blood T lymphocytes. T cells knocked down for LPP showed defects in transwell migration in response to chemotactic signals. Furthermore, preliminary data shows that when stimulated with the chemokine CXCL12, knockdown of LPP is associated with alterations in the mRNA levels of the potential LPP interactors or transcriptional targets MMP25, TIMP1 and CXCR4 suggesting a possible mechanism by which LPP contributes to disease pathophysiology. Ongoing investigation including the use of flow cytometry aims to further delineate the role of LPP in T cells.

Why do Genetic "Risk Factors" for Major Diseases not Always Negatively Affect Survival? *S. Ukraintseva[1], K. Arbeev[1], A. Kulminski[1], I. Akushevich[1], D. Wu[1], G. Joshi[2], I. Culminskaya[1], K. Land[1], E. Stallard[1], A. Yashin[1].* 1) Center for Population Health Aging, Duke University, Durham, NC; 2) University at Buffalo, NY.

Common complex diseases, such as cancer, CVD, diabetes and AD, are major contributors to mortality. However, genetic variants that have been associated with increased risks of such diseases are often found in genomes of long-lived people, and do not seem to compromise longevity. Here we discuss several genetic mechanisms that might plausibly explain the seemingly paradoxical situations in which genetic "risk factors" for major diseases may be neutral or even beneficial in relation to survival and longevity of their carriers. Such mechanisms include (but are not limited to): (i) trade-off-like effects of genes on risks of/mortalities from different health disorders; (ii) age-specific influence of genes on vulnerability to diseases and death; (iii) gene-gene interaction (epistasis); (iv) gene-environment interaction. We review current evidence in support of this explanation and conclude that being a genetic risk factor for major disease does not necessarily mean being the risk factor for all-cause mortality. The net effect of a disease risk allele on person's survival may be negative, neutral or positive, depending on a balance of detrimental and beneficial effects of such allele on various health and aging related traits. This balance may change with age, environmental conditions and genetic surrounding. Facilitating research on conditional effects of genes is of critical importance for better understanding the complex relationships between diseases and longevity and for advancing the area of personalized prevention.

Disruption of the CTNND2 gene causes learning problems within the dyslexia spectrum. *A. Lindstrand[1,2,3], W. Hofmeister[1,2], D. Nilsson[1,2,3,4], A. Topa[5], BM. Anderlid[1,2,3], F. Darki[6], H. Matsson[7], I. Tapia Páez[7], T. Klingberg[6], L. Samuelsson[5], V. Wirta[8], F. Vezzi[9], J. Kere[7,10], M. Nordenskjöld[1,2,3], E. Syk Lundberg[1,2,3].* 1) Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Center for Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 4) Science for Life Laboratory, Karolinska Institutet Science Park, Solna, Sweden; 5) Department of Clinical Genetics, Sahlgrenska University Hospital, Gothenburg, Sweden; 6) Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden; 7) Department of Biosciences and Nutrition, and Center for Innovative Medicine, Karolinska Institutet, Huddinge, Sweden; 8) SciLifeLab, School of Biotechnology, KTH Royal Institute of Technology, Stockholm, Sweden; 9) SciLifeLab, Department of Biochemistry and Biophysics, Stockholm University, Stockholm, Sweden; 10) Molecular Neurology Research Program, University of Helsinki, and Folkhälsan Institute of Genetics, Helsinki, Finland.

Cytogenetically visible chromosomal translocations are highly informative as they can pinpoint strong effect genes even in complex genetic disorders. Here we report a mother and daughter with borderline intelligence and learning problems within the dyslexia spectrum and two apparently balanced reciprocal translocations; t(1;8)(p22;q24) and t(5;18)(p15;q11). By low coverage mate-pair whole genome sequencing we were able to pinpoint the genomic breaks to 2 kb intervals. We then located the chromosome 5p breakpoint to intron 9 of *CTNND2* by direct sequencing. An additional case with similar phenotypic presentation and a 163 kb microdeletion exclusively involving *CTNND2* was identified with genome wide array comparative genomic hybridization. This microdeletion at 5p15.2 is also present in mosaic state in the patient's mother, but absent from the healthy siblings. We investigated the effect of *CTNND2* polymorphisms on normal variability and identified a polymorphism (rs2561622) with significant effect on phonological ability and white matter volume in the left frontal lobe, close to cortical regions previously associated with phonological processing. Finally, given the potential role of CTNND2 in neuron motility, we used morpholino knockdown in zebrafish embryos to assess its effects on neuronal migration *in vivo*. Analysis of the zebrafish forebrain revealed a subpopulation of neurons misplaced between the diencephalon and telencephalon. Taken together, our human genetic and *in vivo* data suggest that defective migration of subpopulations of neuronal cells due to haploinsufficiency of CTNND2 contribute to the cognitive dysfunction in our patients.

Genetic and phenotypic correlations between surrogate measures of insulin release obtained from oral glucose tolerance test data. *A.P. Gjesing[1], R. Ribel-Madsen[1], M.N. Harder[1], H. Eiberg[2], N. Grarup[1], C.T. Ekstrøm[3], O. Pedersen[1], T. Hansen[1]*. 1) The Novo Nordisk Foundation Center for Basic Meta, University of Copenhagen, Copenhagen, Denmark; 2) Department of Cellular and Molecular Medicine, Faculty of Health and Medical Sciences, University of Copenhagen; 3) Department of Biostatistics, Faculty of Health and Medical Sciences, University of Copenhagen.

Aim: Decreased beta-cell function is a key player in development of type 2 diabetes. Large hypothesis-free studies aiming to identify new gene variants that explain the heritable component of beta-cell function apply various surrogate measures of insulin release. We examined to which extent common surrogate measures of insulin release have shared genetic causes. Methods: Genetic and phenotypic correlations were calculated in a family-cohort (n=292) in which beta-cell indices were estimated based on fasting and oral glucose-stimulated plasma glucose and serum insulin levels. Furthermore, we genotyped by the Metabochip a large population-based cohort (n=6269) for common genetic variants known to associate with type 2 diabetes, fasting plasma glucose levels or fasting serum insulin levels to examine their association with various indices. Results: The phenotypic and genetic correlations differed noteworthy for the traits compared, emphasizing that the phenotypic correlation is an insufficient measure of the magnitude of shared genetic impact. Also, we found that corrected insulin response, insulinogenic index, and area under the curve for insulin after an oral glucose challenge shared the majority of their genetic background with genetic correlation between 0.81 and 0.99. The BIGTT index for acute insulin release differed genetically from the latter traits with genetic correlations between 0.51 and 0.81 due to less influence by incretin- related genes and more influence by insulin sensitivity-related genes on the BIGTT index. The homeostasis model assessment for beta-cell function was genetically closely related to fasting insulin with a genetic correlation of 0.90. By examining variants known to associate with type 2 diabetes, fasting plasma glucose levels or fasting serum insulin levels in a large population-based study sample, it was evident that traits displaying a high level of genetic correlation tended to share a larger number of associated SNPs. We also identified a few SNPs that associated exclusively with only one of the measures of insulin secretion and the biological effect of these SNPs gave clues to understand how the indexes for insulin secretion could reflect different physiological mechanisms. Conclusion: The level of shared genetic background varies between surrogate measures of insulin release, and this should be considered when designing a genetic association study to best obtain information on different mechanisms of insulin release.

894T

Potential Transcriptional Mediators for Established Type 2 Diabetes Variants in Southwestern American Indians. *R.L. Hanson[1], L.J. Baier[1], S. Kobes[1], R.G. Nelson[1], E.J. Weil[1], A. Nair[1], Y.L. Muller[1], M. Traurig[1], S. Kumar[2], H.H. Göring[2], J. Blangero[2], J.E. Curran[2]*. 1) Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ; 2) Texas Biomedical Research Institute, San Antonio, TX.

A number of single nucleotide polymorphisms (SNPs) reproducibly associated with type 2 diabetes mellitus (T2DM) have been identified, but the molecular mechanisms by which these variants influence susceptibility to T2DM remain largely unknown. We analyzed potential mediation between T2DM variants and gene transcription in peripheral blood. Participants included 1416 American Indians (23% with T2DM), from urban Phoenix, Arizona, in whom transciptomic measurements had been made on the Illumina HumanHT-12 v4 Expression Beadchip. Genotypes were generated for 44 established T2DM-susceptibility SNPs, 42 ancestry informative markers, used to control for admixture, and 42 “random” SNPs, which were used for genomic control. In these samples 7 of the T2DM markers had nominally-significant ($p<0.05$) associations consistent with the established direction, including SNPs in *GCK*, *CDC123*, *GRB14*, *SLC16A11*, *FTO* and 2 SNPs in *KCNQ*1. We analyzed association of these 7 SNPs with all 15,854 unique transcripts that were significantly expressed and that, according to REMOAT, did not contain SNPs. This resulted in 85 transcripts that had suggestive association ($p<0.005$) with at least one of the 7 SNPs, and these were tested for potential mediation of the relationship between the SNP and T2DM using the Sobel test. Nominally significant mediation was identified for 4 transcripts, involving 3 SNPs (in *SLC16A11*, *FTO* and *CDC123*). The strongest results were for the *SLC16A11* SNP rs75493593 and the *RNASEK* transcript, located 33 kb away. This SNP was associated with T2DM (odds ratio=1.36 per copy of the risk allele, $p=0.0017$) and the risk allele was associated with lower expression of *RNASEK* (by 0.17 SD per copy, $p=1.6\times10^{-5}$). Lower expression of *RNASEK* was associated with T2DM (odds ratio=1.22 per SD decrease in expression, $p=0.0062$, controlled for, age, sex, heritage and the SNP). Mediation analysis was consistent with *RNASEK* expression as a partial mediator of the SNP effect ($p=0.012$). Additional potential mediators included rs75493593 and expression of *ADAM15* ($p=0.021$), rs8050136 (*FTO*) and expression of *GTF2H3* ($p=0.041$), and rs10906115 (*CDC123*) and expression of *PRO0641* ($p=0.048$). These analyses identify potential transcriptional mediators of the relationship between T2DM-associated variants and the risk of type 2 diabetes, but the results need to be confirmed in additional populations.

895S

A common Greenlandic TBC1D4 variant confers muscle insulin resistance and type 2 diabetes. *I. Moltke[1,2], N. Grarup[3], M.E. Jørgensen[4], P. Bjerregaard[5], J.T. Treebak[3], M. Fumagalli[6], T.S. Korneliussen[7], M.A. Andersen[3], T.S. Nielsen[3], N.T. Krarup[3], A.P. Gjesing[3], J.R. Zierath[3], A. Linneberg[8], X. Wu[9], G. Sun[9], X. Jin[9], J. Al-Aama[9], J. Wang[9], K. Borch-Johnsen[10], O. Pedersen[3], R. Nielsen[6], A. Albrechtsen[2], T. Hansen[3].* 1) Department of Human Genetics, University of Chicago, Chicago, IL, USA; 2) The Bioinformatics Centre, Department of Biology, University of Copenhagen, Copenhagen, Denmark; 3) The Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 4) Steno Diabetes Center, Gentofte, Denmark; 5) National Institute of Public Health, University of Southern Denmark, Copenhagen, Denmark; 6) Department of Integrative Biology, University of California, Berkeley, CA, USA; 7) Centre for GeoGenetics, Natural History Museum of Denmark, University of Copenhagen, Copenhagen, Denmark; 8) Research Centre for Prevention and Health, Glostrup University Hospital, Glostrup, Denmark; 9) BGI-Shenzhen, Shenzhen, China; 10) Holbæk Hospital, Holbæk, Denmark.

The Greenlandic population is a historically small and isolated founder population, which has experienced a dramatic increase in type 2 diabetes (T2D) prevalence. Motivated by this, we performed genetic association mapping of four T2D-related quantitative traits in up to 2757 Greenlandic individuals without clinically diagnosed T2D. Using a linear mixed model to test for association while controlling for false positives due to admixture and relatedness, we analyzed Illumina MetaboChip data and exome sequencing data. Our analyses led to the discovery of a nonsense variant in the gene *TBC1D4* with an allele frequency of 17% in the Greenlandic population. Under a recessive model, homozygous carriers of this variant have markedly higher levels of plasma glucose (β=3.8 mmol/L, P=2.5×10^{-35}) and serum insulin (β=165 pmol/L, P=1.5×10^{-20}) two hours after an oral glucose load compared to individuals with other genotypes. Furthermore, they have marginally lower plasma glucose (β=-0.18 mmol/L, P=1.1×10^{-6}) and serum insulin (β=-8.3 pmol/L, P=0.0014) at fasting and markedly higher T2D risk (OR 10.3, P=1.6×10^{-24}). Heterozygous carriers of the variant have a significant, but moderate, increase in 2-hour plasma glucose (β=0.43 mmol/L, P=5.3×10^{-5}). These findings were all replicated in up to 1064 individuals from a different Greenlandic cohort. The nonsense variant is located in an exon that is exclusive to a long isoform of TBC1D4, which is mainly expressed in skeletal muscle. Analyses of muscle biopsies showed decreasing mRNA and protein abundance of this isoform with increasing number of copies of the variant. A similar decrease was observed in protein abundance of the glucose transporter GLUT4. Since TBC1D4 is known to be a mediator of insulin-stimulated glucose uptake in cells through regulation of GLUT4 mobilization, these results suggest that the variant, which leads to premature termination of the long TBC1D4 isoform, causes insulin resistance in skeletal muscle and thereby increased risk of developing T2D. The observed effect sizes are several times larger than any previous findings in large-scale genome-wide association studies of these traits and the identified variant accounts for more than 10% of all cases of T2D in Greenland. This finding provides new insights into T2D and constitutes further proof of the value of conducting genetic association studies outside the traditional setting of large homogeneous populations.

The Type 1 Diabetes Susceptibility Gene CLEC16A encodes protein which restrains NK Cells function. *R. Pandey[1], M. Bakay[1], S. Yoeun[1], J. Kushner[2], H. Hakonarson[1].* 1) Centre for Applied Genomics, Children's Hospital Of Philadelphia, Philadelphia, PA; 2) Department of Pediatric Medicine, Endocrine-Metabolism, Texas Children's Hospital, Houstan, TX.

Type 1 Diabetes (T1D) is a multi-factorial childhood disease with a strong genetic component. Several GWAS had showed association of CLEC16A with T1D, which encodes a protein of unknown function. The highest levels of CLEC16A expression were identified in NK cells, which are required for development of T1D. Therefore, defining the role of CLEC16A in NK cells will provide insight into the pathogenesis of T1D. We reported previously that protective alleles of CLEC16A [A/A] are associated with higher levels of mRNA. Thus, we hypothesize that CLEC16A functions in NK cells to restrain secretory functions including cytokine release and cytotoxicity. First we investigated the expression of CLEC16A in human immune cells and non-immune tissues on mRNA level by RT-PCR and on protein level by western blot. To address the role of CLEC16A in NK cells we studied consequences of knockdown in NK cell lines and ex-vivo NK cells and over-expression of this protein in NK cell line. Using a retroviral expression system, we created NK cell lines stably over-expressing the canonical form of CLEC16A with a GFP expression reporter. Expression was validated by Western blot analysis. Cytotoxicity and INF-γ production were decreased in NK cells stably overexpressing CLEC16A. Optimized protocols using CLEC16A siRNA mediated knockdown enabled a 70% reduction in Clec16A protein levels in NK cells and 35% increase in cytotoxicity compared to cells receiving control siRNA. We performed conjugation assay to rule out decreased target cell killing. CLEC16A over-expresing NK cells formed smaller number of conjugates for all time points with no difference in CD107a expression. Subcellular localization studies revealed cytosolic localization. CLEC16A knockdown in mice resulted in increase in NK cell cytotoxicity of the YAC-1 targets in comparison to control. Taken together, our results indicate that CLEC16A serve a role in restraining two major functions of NK cells, cytotoxicity and cytokine release. Studies are in progress to validate the mechanism. Our improved understanding of this novel TD1-linked gene and the protein it codes will likely suggest new therapeutic interventions in T1D.

897T

Understanding genetic interactions underlying type I diabetes based on chromatin interactions and across-pathway interactions. *MK. Sung, H. Bang, WJ. Yang, KS. Lee, KB. Lee, K. Kim, K. Jang, JK. Choi, First and second author have equal contribution.* KAIST, Daejeon, South Korea.

Genome-wide association studies (GWAS) prove the highly polygenic architecture of complex diseases or traits; single-locus-based methods are usually unable to detect all involved loci especially when individual loci exert little effects. Moreover, the majority of associated SNPs reside in non-coding regions, making it difficult to understand their phenotypic contribution. In this work, we studied epistatic interactions associated with seven common disease phenotypes using the data from the Wellcome Trust Case Control Consortium (WTCCC). For a systematic annotation of non-coding SNPs, we employed whole-genome multiple-cell-type enhancer data by Maurano et al. and Andersson et al. Especially, Maurano et al. identified distal enhancer-to-promoter connections using DNase I profiles across 349 diverse cell types and Andersson et al. identified extensive active enhancers and their target promoters by using CAGE data based on FANTOM5 panel of ~ 400 distinct cell types. We performed functional enrichment analysis using affected gene list. Two T1D related pathways are of particular interest because they appeared in numerous epistatic interactions within as well as between pathways, which are NK cell mediated cytotoxicity (FDR 2.2e-03) and antigen processing & presentation pathway (FDR 0). T1D is considered to be primarily a T-cell mediated disease and the strongest genetic association identified so far is that with HLA class II genes, which interact with T cell. However, β-cell destruction is influenced by the crosstalk between immune system such as NK cells, B lymphocytes and APC. In addition, several studies have shown that NK cells are involved both in T1D progression and prevention. We found a number of epistatic pairs with significant interaction effect, which act as bridge to connect two pathways. For example, 28 pairs involve SNP rs115340904 (chr6: 31245821) which are known to be previously linked to T1D (p-value 8.6e-93) and is located in DHS correlated enhancer (in LD with r2 >0.8) with putative promoter regions of MICA, MICB, TNF, NCR3, HLA-B and HLA-C, participating in NK cell function. The paired SNPs of rs115340904 are located around MHC II and III regions (chr6: 31296226 - 32740411). Our results illustrate how extensive non-coding variant annotation based on the chromatin interactions of distal enhancers can be used to dissect complex genetic interactions across multiple pathways in complex diseases.

898S

DIO2 rSNPs, transcriptional factor binding sites and disease. *N. Buroker.* Pediatrics, 356320, University of Washington, 1959 Pacific Ave NE, Seattle, WA.

The TIO2 gene transcribes deiodinase type 2 that converts the thyroid prohormone, thyroxine (T4), to the biologically active triiodothyronine (T3). The thyroid hormone T3 plays an important role in the regulation of energy balance and glucose metabolism. Regulatory SNPs (rSNPs) in the promoter region novel SNP (-2035bp), 5'UTR (rs12885300), intron one (rs225010, 225011 and rs225012), exon two [rs225014 (Thr92Ala)] and 3' UTR (rs6574549 and rs225015) of the DIO2 gene are in linkage disequilibrium. These rSNP alleles alter the DNA landscape for potential transcriptional factors (TFs) to attach resulting in changes in transcription factor binding sites (TFBS). The alleles of each rSNP were found to produce unique TFBS resulting in potential changes in TF DIO2 regulation. These regulatory changes are discussed with respect to disease and sickness.

899M

Harnessing genome engineering to characterize the role of STRs in gene regulation. *D. Zielinski[1], M. Gymrek[1,2], Y. Erlich[1].* 1) Whitehead Institute for Biomedical Research, Cambridge, MA; 2) Harvard-MIT Division of Health Sciences and Technology, MIT, Cambridge, MA.

Most variants associated with complex traits reside in noncoding DNA, suggesting an important role for cis-regulatory elements. Efforts to discover cis eQTLs (expression Quantitative Trait Loci) have mainly focused on the contribution of SNPs to gene expression. However, several candidate gene studies in human and model organisms suggest that Short Tandem Repeat (STR) variations can modulate expression levels and splicing of nearby transcripts. After identifying significant associations between STR variations and expression profiles across hundreds of samples from the 1000 Genomes Project, we are experimentally validating the effects of these candidate STRs on expression levels in human lymphoblastoid cell lines. Specifically, we are using the CRISPR/Cas genome engineering system to generate a distribution of STR alleles and measuring the associated gene expression levels. In addition to validating our in silico findings, this technique will allow us to fine map individual eQTL signals and determine whether the STR is the true causal signal at these candidate loci.

Functional genomics of the costimulatory locus in autoimmune disease. *L. Petukhova[1, 2], T. Yamany[2], L. Bian[2], Z. Dai[2], E.N. Drill[2,5], J.D. Broadbent[4], P.L. Nagy[4], R. Clynes[2,6], A.M. Christiano[2,3].* 1) Department of Epidemiology, Columbia University, New York, NY; 2) Department of Dermatology, Columbia University, New York, NY; 3) Department of Genetics and Development, Columbia University, New York, NY; 4) Department of Pathology and Cell Biology, Columbia University, New York, NY; 5) Department of Biostatistics, Columbia University, New York, NY; 6) Department of Medicine, Columbia University, New York, NY.

The costimulatory locus contains three key immunoregulatory genes (CD28, CTLA4, and ICOS), and was one of the first genomic regions associated with autoimmune disease outside of the HLA locus. GWAS have provided robust agnostic evidence for association of this region with type 1 diabetes, rheumatoid arthritis, celiac disease, Graves disease and alopecia areata (AA). Despite the extensive evidence for conferring risk, the mechanisms by which genetic variants contribute to disease have remained elusive. Furthermore, the efficacy of therapies that target the costimulatory pathway demonstrates that it is a critical axis of autoimmunity for some patients. In order to systematically identify all disease risk variants at this locus, we performed targeted resequencing of the costimulatory locus in 122 AA patients from our GWAS cohort, targeting the entire 297Kb region. This experiment identified 1209 variants that passed rigorous QC filters, which we computationally phased, allowing us to assign alleles to chromosomes. Among the 244 sequenced chromosomes, we identified 88 chromosomes that carried GWAS-identified risk haplotypes. We next identified 208 variants that were significantly enriched on the chromosomes carrying GWAS risk haplotypes ($p<4.1e-5$). Among these enriched SNPs, there is one CTLA4 protein coding variant (rs231775; p. T17A), and eight SNPs annotated with regulatory functions in CD4 cells in public databases. Importantly, we validated regulatory effects by demonstrating that four of these regulatory variants affect the distribution of CTLA4 isoforms in activated human T-cells and show that this shift inhibits T cell cytokine production, and TCR-mediated MAPK activation in CTLA4 deficient Jurkat cells. The identification of risk variants with biological consequences perturbing the costimulatory axis provides a crucial step forward in understanding how this locus contributes to autoimmune disease.

901S

Allele specific chromatin interaction of 9p21 endometriosis risk locus regulates expression of *ANRIL*. *H. Nakaoka, A. Gurumurthy, T. Hayano, K. Hosomichi, I. Inoue.* Division of Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan.

With the advent of genome-wide association studies (GWASs), a large number of SNPs associated with human complex diseases and phenotypes have been discovered. Most of the identified SNPs are located on intron and intergenic regions rather than coding regions, implying that the SNPs are associated with the disease risk through the regulation of expression levels of nearby genes. Although recent studies from ENCODE project demonstrated that a large proportion of the SNPs identified by GWASs were located on open chromatin regions or DNase I hypersensitive sites (DHSs), regulatory mechanisms underlying these genotype-phenotype relationships remain to be completely elucidated. In this study, we explored the regulatory mechanism of a SNP on chromosome 9p21 that was associated with the risk of endometriosis by using functional genomics approaches.

In order to fine-map the 9p21 endometriosis risk locus, we performed a target re-sequencing of 9p21 region for 48 Japanese individuals and constructed a linkage disequilibrium (LD) map of this region. Combined with DNase-seq data from ENCODE project, we identified three candidate SNPs that were in high LD with the GWAS hit SNP and located on DHSs. Since these candidate SNPs were distant from 9p21 genes, we hypothesized that these SNP were on regulatory elements with enhancer activities through long-range chromatin interactions. Therefore, we performed chromatin conformation capture (3C) analysis followed by next generation sequencing. We observed that one of the candidate SNPs showed chromatin interaction with the promoter region of *ANRIL* (or *CDKN2B-AS1*) in an allele specific manner. By using bioinformatics analysis and chromatin immunoprecipitation (ChIP) assay, we found that the SNP disrupted a DNA binding motif of a transcription factor that was involved in Wnt signaling pathway. Finally, we demonstrated that the SNP was a cis-acting expression quantitative trait nucleotide of *ANRIL* by using allele specific expression analysis of RNA-sequencing data for normal endometrial tissues and endometrial carcinoma cell lines. These results may elucidate the regulatory mechanism underlying 9p21 endometriosis risk locus.

902M

A Genomewide Association Study of Alcohol Dependence in the Irish Affected Sib Pair Study of Alcohol Dependence. *B.P. Riley[1, 2, 3, 4], A.E. Adkins[1, 2, 3], L.M. Hack[1, 2, 3], T.B. Bigdeli[1, 2, 3], M.S. Grotewiel[1, 4], A.G. Davies[1, 5], J.C. Bettinger[1,5], C.A. Prescott[6], M. Mamdani[1, 2, 3], V. Williamson[1, 2, 3], D.M. Dick[1, 2, 3, 4, 7], V.I. Vladimirov[1, 2, 3], B.T. Webb[1, 2, 3, 4], K.S. Kendler[1, 2, 3, 4].* 1) VCU Alcohol Research Center, Virginia Commonwealth Univ, Richmond, VA; 2) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth Univ, Richmond, VA; 3) Dept of Psychiatry, Virginia Commonwealth Univ, Richmond, VA; 4) Dept of Human & Molecular Genetics, Virginia Commonwealth Univ, Richmond, VA; 5) Dept of Pharmacology and Toxicology, Virginia Commonwealth Univ, Richmond, VA; 6) Dept of Psychology, University of Southern California, Los Angeles, CA; 7) Dept. of Psychology, Virginia Commonwealth Univ, Richmond, VA.

Background: We report results from a genomewide association study (GWAS) in an ethnically homogeneous Irish sample (N=706 related cases, 1755 population controls) with strong supporting evidence from VCU Alcohol Research Center (VCU ARC) model organism (MO) studies. Methods: GWAS cases from the Irish Affected Sib Pair Study of Alcohol Dependence (IASPSAD) were diagnosed using DSM-IV criteria. Affymetrix V6.0 arrays were genotyped at 3 separate core facilities and BeagleCall was used to call genotypes. IMPUTE2 and the 1000 Genomes reference haplotype panel (March 2012 freeze) were used to impute unmeasured genotypes. After QC filtering, imputation, and post-imputation filtering, 710 AD cases, 1755 controls and 8.2 million SNPs remained. Probabilities were converted to dosages with MACH2. Case/control association analysis was run using MQLS to correct for the non-independence of siblings. A sex weighted prevalence estimate of 8.9% was used for controls. We used a significance threshold of p<3.06E-8 based on the number of independent LD blocks in 1000 genomes data. FDR q-values were calculated with QVALUE in R. Results: SNPs in the COL6A3 gene on chromosome 2 and an intergenic region of chromosome 3 near the ECT2 gene were genomewide significant. SNPs in 8 independent genomic regions had FDR q-values <1% (notably in KLF12, POMT2/TMED8, LOC339975 and RYR3). Knockdown of a COL6A3 ortholog by RNAi in C. elegans leads to significant reductions in the development of acute functional tolerance (AFT). Knockdown of POMT2 by RNAi in D. melanogaster leads to significant reduction in ethanol sensitivity. The C. elegans klf-3 (orthologous to human KLF12) mutant does not develop acute functional tolerance and RNAi knockdown of the D. melanogaster homolog of KLF12, luna, results in enhanced sensitivity to ethanol. Finally, a loss of function allele of unc-68, the C. elegans homolog of RYR3, confers resistance to ethanol. Human replication data support LOC339975, a long non-coding RNA predicted to regulate 12 microRNAs that in turn regulate genes including numerous genes previously implicated in alcohol phenotypes such as SLC6A3, GABRG1, CNR1, ESR1, ACSL4 and multiple alcohol aldehyde dehydrogenase genes. Discussion: Our case-control GWAS detected numerous associated loci supported by functional assays in model organisms or directly linked to implicated genes in humans, a powerful combined approach elucidate genetic risk factors underlying alcohol dependence.

eMERGE Phenome-Wide Association Study (PheWAS) Identifies Clinical Associations and Pleiotropy for Functional Variants. *A. Verma[1], S. Verma[1], S. Pendergrass[1], D. Crawford[2], D. Crosslin[4], H. Kuivaniemi[3], W. Bush[2], Y. Bradford[5], I. Kullo[7], S. Bielinski[7], R. Li[8], J. Denny[5], P. Peissig[6], S. Hebbring[6], E. Pugh[9], M. Andrade[7], M. Ritchie[1], G. Tromp[2].* 1) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA; 2) Case Western University, Cleveland, OH; 3) Geisinger Health System, Danville, PA; 4) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 5) Vanderbilt University, Nashville, TN; 6) Marshfield Clinic, Marshfield, WI; 7) Mayo Clinic, Rochester, MN; 8) National Human Genome Research Institute, Bethesda, MD; 9) John Hopkins University, Baltimore, MD.

We performed a phenome-wide association study (PheWAS) exploring the association between stop-gained genetic variants and a comprehensive group of phenotypes to identify novel associations and potential pleiotropy. Using multiple bioinformatics tools we selected 38 functionally relevant stop-gained/null genetic variants within the genotypic data of 37,972 unrelated patients from seven study sites in the Electronic Medical Records and Genomics (eMERGE) Network. We calculated comprehensive associations between these variants and case-control status for 3,518 ICD-9 diagnosis codes (requiring ≥ 3 visits per individual to identify case status, ≥10 case subjects per ICD-9 code). Associations were adjusted for age, sex, site, platform and the first 3 principal components. A total of 418 associations passed a liberal significance threshold of p< 0.01. The most significant association was between GLG1 rs9445 and "chronic non-alcoholic liver disease" ($p=4.12\times10^{-5}$, $\beta=2.60$). We identified many potentially pleiotropic associations at p< 0.01, 35 out of 38 SNPs demonstrated associations with more than one phenotype, and 17 SNPs were each associated with > 10 different ICD-9 codes. For example, we found associations for IL34 rs4985556 with 25 diagnoses, such as "lupus erythematosus" ($p=5.94\times10^{-3}$, $\beta=0.98$) and for GBE1 rs2229519 with 33 diagnoses, such as "hypertension" ($p=1.2\times10^{-3}$, $\beta=0.067$), "hyperlipidemia" ($p=6.66\times10^{-3}$, $\beta=0.058$), and "ocular hypertension" (2.49×10^{-3}, $\beta=0.21$). We will seek replication of these results. In conclusion, our PheWAS shows stop-gained variants may have important pleiotropic effects, and that PheWAS are a powerful strategy to mine the full potential of the EMR for genome-phenome associations.

904S

Lupus associated coding polymorphism rs1143679 within ITGAM acts in both nucleotide and protein level to develop disease phenotypes. *A.K. Maiti[1], K. Bhattarai[1], P. Motghare[1], X. Kim-Howard[1], J-P. Anaya[2], S.K. Nath[1].* 1) Gen Epidemiology Unit, A & CI, OMRF, Oklahoma City, OK; 2) Universidad del Rosario-Corporación para Investigaciones Biológicas, Bogotá, Colombia.

Integrin alpha M (ITGAM; CD11b) is a component of the macrophage-1 antigen complex, which mediates leukocyte adhesion, migration and phagocytosis as part of the immune system. We previously identified a missense polymorphism, rs1143679 (R77H) at the exon 3, that is strongly associated with systemic lupus erythematosus (SLE). We explored the molecular mechanism by which the rs1143679 risk allele in ITGAM contribute to the development of SLE disease manifestations. We show that rs1143679 carrying DNA sequences act as strong transcriptional enhancer and the risk allele affects the expression of ITGAM gene in vivo. This SNP binds with NFKB1, EBF1 and Ku70/80 protein in vitro and in vivo in the monocytes of SLE patients and healthy individuals but with reduced efficiency in the presence of risk allele. The observed reduced ITGAM expression in risk allele carrying individual's monocytes is attributed to reduced interaction of these proteins with RNA pol II at the ITGAM promoter implicating reduced transcription of this gene resulting in less mRNA and protein production. KU70/80 is a lupus auto-antigen and apart from its DNA repair function, also acts as transcription factor and binds with several enhancer SNPs that are associated with lupus. Using NextGen ChIP-seq, we mapped Ku70/80 binding genomic regions that could indicate lupus associated genomic regions. Our genome-wide analysis reveal that genes that are regulated by Ku70/80 interacts with numerous previously identified lupus associated genes, implicating the disruption of these pathways in presence of Ku70/80 autoantibody could play critical role in SLE pathogenesis. At the protein level, we also show that the mutant ITGAM (CD11b) protein for this SNP inefficiently interacts with one of its ligand protein, vitronectin,that plays critical role in glomerulonephritis. Thus, risk allele carrying sequences affects in both nucleotide and protein levels due to reduced transcription of ITGAM gene resulting in reduced protein production as well as mutant protein production that could explain the strong association of this SNP with lupus.

905M

Host genetic variation and Kaposi's Sarcoma-associated herpesvirus infection. *N. Sallah, C. Franklin, A. Palser, P. Kellam, I. Barroso.* Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

Kaposi's sarcoma-associated herpesvirus (KSHV) is an oncogenic gammaherpesvirus associated with a variety of lymphoproliferative diseases particularly Kaposi's sarcoma (KS), Primary effusion lymphoma (PEL) and Multicentric Castlemans disease (MCD). The virus establishes a lifelong infection with a lytic phase in which active virus replication facilitates spread and pathogenesis; and an immunologically silent latent phase that promotes persistence in B-cells. Despite high seroprevalence, only a small proportion of infected people develop tumours, in addition, striking geographic distribution and familial clustering of disease is suggestive of a possible genetic predisposition to disease. Host and virus genetic variation and their influence on KSHV infection and epidemiology remain largely uncharacterized. Here we establish a pipeline to investigate how the genetics of host-virus interactions influence KSHV pathogenesis. Studies have identified a B-cell transcription factor, X-box binding protein-1 (*XBP-1*) as a key regulator of the lytic switch that links terminal differentiation, B-cell receptor activation and virus production. Thus far, we have identified 40 genetic variants of *XBP-1* in whole genome and exome datasets and are currently using PEL cell lines to investigate the biological effects of polymorphisms found in known functional domains. The pipeline used here from identification and annotation of variants to assaying for phenotypic differences can be employed for other host genes important in viral pathogenesis to elucidate function.

Studying the effects of pubertal timing-associated gene *LIN28B* on early vertebrate development using zebrafish as a model. *J.T. Leinonen[1], Y.C. Chen[2], H. Koivula[2], P. Panula[2], E. Widén[1].* 1) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Finland; 2) Neuroscience Center and Institute of Biomedicine, Anatomy, University of Helsinki, Finland.

Sequence variation near *LIN28B* has repeatedly been associated with pubertal timing in several genome-wide association studies, and animal models suggest that the evolutionarily conserved *LIN28* genes encoding for RNA-binding proteins are crucial regulators of development and growth, expressed already during fetal life. Normal puberty requires appropriate fetal development. The mechanism linking *LIN28B* to puberty is unknown, but we hypothesized it may influence early developmental processes, in particular the formation of the hypothalamic pituitary gonadal -axis. Our specific aim is to elucidate the function of the puberty-associated gene *LIN28B* by assessing 1) its embryonic temporal and spatial expression patterns, 2) the impact of its downregulation and, 3) the impact of its upregulation in developing zebrafish, a model system allowing efficient evaluation of early development and growth. Knockdown- and overexpression-experiments showed that the correct function of *LIN28B* is essential for proper embryonic development. Both *LIN28B* knockdown, as induced by morpholino oligonucleotide injection, and overexpression, induced by mRNA injections, caused a dose-dependent variety of phenotypes, with high doses being lethal and lower doses causing severe to mild malformations. The brain morphology associating with *LIN28B* downregulation was severely compromised. Co-injection of morpholino and mRNA resulted in phenotypic rescue, suggesting that the knockdown phenotypes are specific to *LIN28B* downregulation. The spatiotemporal expression patterns of *LIN28B* in wild-type zebrafish, assessed by RNA in situ hybridization on whole mount embryos and tissue sections, indicated that while the expression is not spatially restricted during the first 24 hours of development, it subsequently appears most prominent in developing organ primordia, including regions in the telencephalon. Interestingly, the timing of the formation and migration of gonadotrophin releasing hormone (GnRH) neurons to the hypothalamus, which is essential for normal sexual development in vertebrates, coincide with *LIN28B* expression. We therefore intend to investigate whether *LIN28B* and *GnRH3*-expression may be co-localized. Taken together, the experiments indicate that changes in *LIN28B* expression have far-reaching consequences for the development of vertebrate body plan, and we further plan to study the impact of *LIN28B* on the development of the GnRH neuronal network.

907S

Microglia deficiency in TREM2 R47H carriers with familial late onset Alzheimer disease. *E. Korvatska[1], S. Jayadev[2], P. McMillan[1,3], J.B. Leverenz[4], G.A. Garden[2], T.D. Bird[2,3,5], W.H. Raskind[1,5,6].* 1) Psychiatry, University of Washington, Seattle, WA; 2) Neurology, University of Washington, Seattle, WA; 3) GRECC, VA Puget Sound Health Care System, Seattle, WA; 4) Pathology Anatomy and Cell Biology7, Thomas Jefferson University, Philadelphia, Pen; 5) Medicine, University of Washington, Seattle, WA; 6) MIRECC, VA Puget Sound Health Care System, Seattle, WA.

A rare missense variant R47H in the TREM2 gene is a recently identified strong risk factor for Alzheimer disease (AD). TREM2 is expressed by microglia and plays a role in immune responses in the CNS. We report a large multigeneration family affected with late-onset AD in which multiple affected members (11/15) carry the variant. Neuropathologic examination of 11 available brains from family members found features typical of AD that included neuritic amyloid plaques and neurofibrillary tangles (Braak stages 5-6) in all affected patients. Vascular pathology features were common in the R47H-positive patients (4/7). Results of ongoing assessments of microglia status in TREM2-R47H carriers will be reported.

Functional study of a novel unexpected interferon-responsive gene, GRAMD1B, identified in Multiplex MS families. *F. Martinelli Boneschi[1], A.M. Osiceanu[1], F. Esposito[1], A. Zauli[1], M. Sorosina[1], B. Bettegazzi[4], D. Cittaro[2], E. Mascia[1], S. Santoro[1], A. Calabria[3], D. Lazarevic[2], D. Zacchetti[4], G. Comi[1], E. Stupka[2].* 1) DEPT NEUROLOGY AND INSPE, SCIENTIFIC INSTITUTE SAN RAFFAELE, MILAN, MI, Italy; 2) CENTER OF TRANSLATIONAL GENOMICS AND BIOINFORMATICS, SCIENTIFIC INSTITUTE SAN RAFFAELE, MILAN, MI, Italy; 3) SAN RAFFAELE TELETHON INSTITUTE FOR GENE THERAPY (HSR-TIGET), SCIENTIFIC INSTITUTE SAN RAFFAELE, MILAN, MI, Italy; 4) CELLULAR NEUROPHYSIOLOGY UNIT, SCIENTIFIC INSTITUTE SAN RAFFAELE, MILAN, MI, Italy.

BACKGROUND: While the role of common genetic variants is clearly established in multiple sclerosis (MS[MIM126200]), the heritability of the disease is still poorly explained, suggesting the existence of rare variants implicated in the susceptibility to the disease. OBJECTIVE: To identify low-frequency and rare genetic variants contributing to MS susceptibility in an Italian multiplex family. DESIGN/METHODS: SNP microarray genotyping and whole-genome sequencing (mean coverage: 20x) in 4 MS patients and 4 unaffected individuals belonging to an Italian multiplex family originating from a first cousin consanguinueous marriage have been performed. The Merlin software was used for the linkage analyses and SNPeff and GATK software were applied to prioritize rare variants. RESULTS: Filtering criteria, including a linkage analysis that identified a unique signal showing a LOD score <2.0 at chr11q23.3, narrowed down the list of variants up to a rare functional variant which determines an amino acid change, S601P, at an unexplored gene, *GRAMD1B*. The mutation is in a context that is highly conserved across species, and it segregates along the family consistent with an autosomal recessive transmission (p=0.02). By performing WG expression, we found that the gene was downregulated in affected relatives (p=0.01) with the exception of the only case who was IFNβ treated. We performed a IFNβ stimulation of PBMCs isolated from 20 healthy controls, showing an increase in *GRAMD1B* expression (p<0.001). We also observed a significantly higher expression of *GRAMD1B* in the brain tissue, and in immune cells, compared to other cells and tissues (p<0.05). Moreover, we observed a significant increase of expression in activated rat microglial cells compared to unstimulated ones (p<0.05), suggesting a putative role of the protein in the modulation of the immune system. Ongoing experiments are aimed to: 1) explore the role of GRAMD1B in the IFNβ pathway; 2) identify the localization of the protein; 3) study the effect of the mutation on the expression, localization and/or function of the GRAMD1B protein in MS etiology. . CONCLUSIONS: The use of next-generation sequencing approach in an Italian MS multiplex family has been successful in identifying a novel rare variant in an unknown gene recently found to be associated with IgE levels. Further investigations are ongoing to explore the role of the variant.

909T

The causal basis of Hirschsprung disease risk: functional consequences of polymorphisms in two *RET* shadow enhancers. *S. Chatterjee, A. Kapoor, A. Chakravarti.* Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

A significant proportion of the genetic risk of Hirschsprung disease (HSCR) in European ancestry subjects arises from two common variants at the gene encoding the receptor tyrosine kinase RET. We have previously shown that the first variant, rs2435357 (risk/non-risk alleles T/C, T control allele frequency 27%, odds ratio ~4), lies within RET intron 1 and disrupts binding of the transcription factor SOx10. We now demonstrate that the second variant, rs2506030 (risk/non-risk alleles G/A, G control allele frequency 40%, odds ratio ~2), maps 125kb upstream of RET and affects the binding of the transcription factor, Retinoic acid receptor beta (RARβ). In mouse Neuro2a cells, siRNA mediated knock down of either transcription factor reduces *Ret* expression, by 8 fold for *Sox10* ($P= 1.8\times10^{-4}$) and 5.5 fold for *Rarβ* ($P=4\times10^{-4}$). Surprisingly, when *Ret* is significantly ($P=1.1\times10^{-4}$) depleted by siRNA, expression of *Sox10* is decreased by 5 fold ($P=2\times10^{-5}$) but *Rarβ* remained unaffected (P=0.66), suggesting that Sox10 and Ret regulate each other. These results are supported by *in vivo* gene expression data in *Ret* homozygous null mice gut at 2 stages in development (E11.5 and E12.5), as compared to wild type mice at the same stages, where early gut neurogenesis occurs: *Sox10* expression is reduced 4 fold (E11.5, $P=1.2\times10^{-7}$) and 8 fold (E12.5, $P=1.2\times10^{-4}$) but *Rarβ* expression is, as expected, unaffected (E11.5, P=0.64; E12.5, P=0.19). In concert, *Gdnf*, the Ret ligand, expression is increased 1.5 fold (E11.5, P=0.03) and 3.4 fold (E12.5, $P=6\times10^{-4}$) as is the expression of the co-receptor *Gfra1* (3.7 fold at E11.5, P=0.02; 3 fold at E12.5, P=0.03). These in vitro and in vivo data show the presence of compensatory mechanisms within the *Ret* gene regulatory network. Specifically, *Ret*, the major gene for HSCR, is a positive regulator of its own transcription through Sox10. These results explain how common polymorphisms can lead to large genetic effects in HSCR since transcription attenuation of *Ret* from enhancer mutations are amplified through its auto-regulation. These results implicate *RET* as a key rate limiting step in early enteric nervous system (ENS) development and explains why >95% of HSCR cases have at least one *RET* loss-of-function allele. As a more general lesson, the phenotypic impact of transcriptional changes by common regulatory variants can only be understood in the context of its gene regulatory network.

910S

Functional regulatory assessment of the *APOL1* kidney disease risk variants. *P. An[1], J. Kopp[2], C.A. Winkler[1].* 1) Basic Research Laboratory, Leidos Biomedical Research, Inc., Frederick National Lab for Cancer Research, Frederick, MD; 2) Kidney Disease Section, National Institute of Diabetes and Digestive and Kidney Disease, Bethesda, MD.

Background: Apolipoprotein L1(encoded by *APOL1*) is a serum apolipoprotein bound to high-density-lipoprotein (HDL) particles. Common trypanolytic *APOL1* coding variants G1 (S342G:I384M) and G2 (2 aa deletion) are associated with markedly increased risk to kidney diseases including focal segmental glomerulosclerosis (FSGS) (OR 2-29) in Africa Americans and explain much of the excess risk for chronic and endstage kidney diseases. However, the functional basis of the APOL1 and the *APOL1* G1/G2 variants in relation with renal risk are largely unknown. We aimed to assess the potential regulatory functions of the *APOL1* kidney disease risk variants. **Methods:** We performed electrophoretic mobility shift assay (EMSA) to assess the binding of *APOL1* G1/G2 with nuclear transcription factors in the HEK 293 cell line, real-time PCR to quantify gene expression in the lymphoblastoid cell lines (LCLs) derived from FSGS patients, and gene reporter assay to test the regulatory potential of the variants. **Results:** We observed that G1 and G2 variants conferred differential transcription factor binding patterns, G2 allele carriers had increased mRNA gene expression, and the 3' terminus appeared to confer regulation activity. Our preliminary experimental data suggest that the *APOL1* G1/G2 variants may influence *APOL1* gene expression via differential transcription factor binding and gene regulation. **Summary:** *APOL1* gene expression may be differentially regulated by G1 and G2 variants; these results warrant further investigation in podocytes and other renal cell types. Four regulatory variants alter protein binding and contribute to transcriptional activity at the *ANGPTL8* HDL-C GWAS locus. *M.E. Cannon, K.L. Mohlke.* Department of Genetics, University of North Carolina-Chapel Hill, Chapel Hill, NC.

Human genome-wide association studies (GWAS) have identified at least 157 loci that are associated with high-density lipoprotein cholesterol (HDL-C) and other blood lipid traits. A recent GWAS identified four DNA variants strongly associated with HDL-C ($r^2>0.8$ with rs737337, $P=4.6\times10^{-17}$) located upstream of the *ANGPTL8* gene, but the molecular mechanism of how the variants alter gene expression is unknown. All four variants are located in candidate regulatory elements (CREs) defined by epigenetic enhancer marks, transcription factor binding, and open chromatin marks that are correlated with *ANGPTL8* expression across tissues. *ANGPTL8* expression is limited to liver and adipose tissue, despite being entirely contained within one intron of ubiquitously expressed *DOCK6*. We evaluated allelic effects on transcriptional activity and protein binding across liver, adipose, embryonic kidney, and pancreatic islet cell lines. The promoter of *ANGPTL8* and the CREs containing the HDL-associated variants were cloned upstream of a luciferase gene in a promoterless or minimal promoter-containing vector and tested for allelic differences in enhancer activity using transcriptional reporter assays. The *ANGPTL8* promoter demonstrated transcriptional activity in the human HepG2 hepatocellular carcinoma cell line but not in human SW872 liposarcoma, mouse MIN6 insulinoma, or human 293T embryonic kidney cells. The CREs containing rs737337 and rs200788077 increased transcriptional activity 20-fold and 10-fold in HepG2, respectively. The remaining two CREs decreased transcriptional activity in HepG2, suggesting they have repressive activity. We also tested the variants for allelic differences in protein binding in vitro using electrophoretic mobility shift assays and observed allele-specific binding for all four variants. The HDL-decreasing allele rs737337-C demonstrated allele-specific protein binding in HepG2, but not in SW872 cells or MIN6 cells, suggesting that a liver-specific protein complex is binding to rs737337-C. Together, these results indicate that the *ANGPTL8* promoter is an important driver of transcriptional activity, which may be assisted by interactions with the variant-containing CREs. These data suggest a unique and complex molecular mechanism involving promoter-enhancer and/or promoter-repressor interactions that alter transcriptional activity at the *ANGPTL8* HDL-C GWAS locus.

The expression of adipokines in the peripheral blood leukocytes of young patients with myocardial infarction. *R. Richterova[1], P. Cibulkova[1], H. Janyskova[1], P. Drahosova[1], J. Vaclavik[3], M. Svestak[2], D. Stejskal[2].* 1) Laboratore AGEL a.s., Novy Jicin, Novy Jicin, Czech Republic; 2) AGEL Research and Training Institute - Prostějov Branch, Central Moravian Hospital Group, Branch - Prostějov Hospital, Department of Laboratory Medicine, Czech Republic; 3) 3Department of Internal Medicine I - Cardiology, University Hospital Olomouc and Palacký University Faculty of Medicine and Dentistry, Olomouc, Czech Republic.

Adipokines are components of adipose tissue, which have important roles in energy homeostasis, sugar and fat metabolism, control of body temperature, reproduction, immunity and also have an effect on cardiovascular system (CS). Based on the effects on the CS they can be divided into cardioprotective adipokines and adipokines with negatively influence on the CS. Nowadays, little is known about the effect of adipokines in the pathogenesis of the acute coronary syndromes (ACS) in young patients. The aims of our study were: to evaluate possibility to detect mRNA expressions of selected adipokines in the peripheral blood leukocytes of young patients with ACS. We want to verify correlation between mRNAs expression and their products in blood and to evaluate these results with clinical status of tested probands. We prospectively examined 67 patients who had an acute myocardial infarction at a young age (men 18-45 years of age and women 18-55 years of age) and control groups of 79 patients with metabolic syndrome and 49 healthy individuals. RNA was isolated from their peripheral blood leukocytes and transcribed into cDNA. We examined expression below adipokines in peripheral blood leukocytes: aFABP4, Adiponectin, Adiponectin receptor 1, Adiponectin receptor 2, ANGPTL-4 Chemerin, FGF-21, GLP-1, Insulin, Insulin receptor, IL-6, Leptin, Leptin Receptor, Lipocalin 4 MCP-1, Omentin-1, Resistin, Retinol Binding Protein 4, Vaspin, Visfatin; as a housekeeping gene was used Beta-2-microglobulin. To confirm that it establishes mRNA from peripheral blood leukocytes was performed the following experiment: for 3 persons we separated liquid portion (plasma) cell fraction, which we have repeatedly purify with PBS. Then we performed expression isolation and quantification of adipokine's mRNA in whole blood, fluid and cellular portion. Adipokine's mRNA was found only in whole blood and cell content. We confirmed that we are really determined adipokines expression in peripheral leukocytes. The expression of adiponectin receptor 2, leptin and aFABP4 was detected in the group of patients after ACS. A correlation could not be found between aFABP4 gene expression and the concentration of its product in the serum of the group with ACS. We have shown that the mRNA expression of selected adipokines can be quantified in the peripheral blood leukocytes. Whether low expressions of protective adipokines contribute to early manifestations of ACS needs to be explored in further studies.

An atopy-associated variant in the 11q13.5 locus regulates promoter activity. *J. Manz[1,2], A. Kretschmer[1,2,3], G. Möller[4], A. Peters[1,2], J. Adamski[4], M. Waldenberger[1,2], E. Reischl[1,2], S. Weidinger[3].* 1) Research Unit of Molecular Epidemiology, Helmholtz Zentrum Muenchen, German Research Center for Environmental Health Neuherberg, Germany; 2) Institute of Epidemiology II, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany; 3) Department of Dermatology, Venereology and Allergy, University Hospital Schleswig-Holstein, Kiel, Germany; 4) Institute of Experimental Genetics, Genome Analysis Center, Helmholtz Zentrum München, Neuherberg, Germany.

Atopic dermatitis (AD) is a common chronic inflammatory skin disorder with a strong genetic component. Genome-wide association studies (GWAS) robustly identified common risk variants at 11q13.5 located in the intergenic region between *leucine rich repeat containing 32* (*LRRC32*) and *chromosome 11 open reading frame 30* (*C11orf30*). The same locus has also been associated with asthma, hayfever and Crohn's disease (CD). One GWA proxy SNP (rs2155219) is associated with the expression of *LRRC32* and *C11orf30*, but the functional relevance of this SNP has not been investigated yet. Therefore, the aim of this study was to characterize the functional impact of rs2155219 on cis-regulatory transcriptional activity and differential transcription factor binding. Reporter vector constructs carrying the major or minor allele of rs2155219, including two additional variants naturally occurring in this sequence (rs34455012indel; rs11236797C>A), were tested for regulating transcription activity in HaCaT (human keratinocyte), A549 (human alveolar basal epithelium), HeLa (human cervical cancer) and Jurkat (human T lymphocyte) cells using luciferase assays. In addition, different variant combinations within this haplotype (differing from the natural occurring allele composition) were investigated. Differential transcription factor binding was analyzed by electrophoretic mobility shift assays (EMSAs). Reporter vector constructs containing rs2155219 together with the naturally occurring variants acted as enhancer on promoters in HaCaT, A549, HeLa and Jurkat cells. The AD- and CD-risk associated T allele of rs2155219 in combination with rs34455012del and rs12236797A showed significantly higher promoter activity compared to the non-risk allele (in concert with rs34455012ins and rs12236797C allele). Analysis of further variant combinations (not naturally occurring) revealed cell-type specificity of single variants: an even stronger enhancer effect was observed dependent on rs34455012 deletion compared to rs34455012 insertion in A549 and HaCaT cells. Differential binding of putative protein complexes at selected variants was identified. Our study adds functional knowledge at the AD associated 11q13.5 locus by demonstrating that the GWA proxy SNP rs2155219 together with rs34455012indel and rs11236797C>A controls regulatory activity and impacts transcription factor binding.

914M

Obesity and metabolic disorders in children as part of the Reward Deficiency Syndrome: association with the SNP TaqIA C32806T of DRD2 gene. *R.M. Pinto[1,2], D.M. Silva[3], T.C Vieira[1,2], F.J. Queiroz[1,2], F.R. Godoy[1,2], I. Lacerda[1,2], L.S. Teodoro[1,2], M.W. Gonçalves[1,2], A.D da Cruz[1,2].* 1) Pontifícia Universidade Católica de Goiás - PUC/Goiás- Brasil; 2) Núcleo de Pesquisas Replicon- PUC Goiás - Brasil; 3) Universidade Federal de Goiás - Brasil.

The Reward Deficiency Syndrome (RDS) is a hypo-dopaminergic state that predisposes to obsessive-compulsive and impulsive behaviors. Obesity is part of RDS since the individual eats compulsively to compensate the defect in dopamine levels. The allele A1 (T) of the polymorphism TaqIA C32806T in the Dopamine D2 receptor gene (DRD2) is associated with reduction up to 40% of DRD2 levels, and is associated with higher BMI in adults. DRD2 are expressed in β cells and modulate insulin secretion. This is a case control study designed to investigate the relation between the SNP TaqIA C32806T of the DRD2 gene and obesity and metabolic alterations in children. We accessed the nutritional state of 105 children (55 obese/50 eutrophic) based on the definition of the World Health Organization (Z score of BMI). Peripheral blood samples were taken to determine the lipid profile, glucose, insulin and for analysis of DRD2 polymorphism through RFLP-PCR. The Homeostatic Model Assessment (HOMA) was calculated. We found A1 and A2 alleles, resulting in A1A1 (12,4%), A1A2 (33,3%) and A2A2 (54,3%) genotypes. The frequency of the A1 allele in obese and controls was 34,5%; and 23% respectively (p=0,05; RR=1,3). This allele was also associated with lower triglycerides (TG) levels and increased parents' BMI. The children were divided into groups according to the reference values of the metabolic variables studied. Significant difference in allelic distribution was observed in children with total cholesterol (TC) <170mg/dl or TC ≥ 170mg/dl. The HOMA β was abnormal in 52,7%of obese and 10% of eutrophic patients. Allele A1 was present in 38,2% of children with altered HOMA β and 24,6 % of children with normal HOMA β (p=0,037; RR=1,5). Up to the present, only 5 studies have studied the allele A1 frequency in obese children, ranging from 17% to 51%. Our results show for the first time that the A1 allele is associated with TC ≥ 170 mg/dl and lower TG levels. Another unpublished result in the literature is the association of A1 allele with HOMA β ≥175, relative risk conferred of 1,5. The A2 allele was associated with the normality of HOMA β in both obese and eutrophic groups, implicating this allele as a protective factor for pancreatic secretion. The recognition of predisposed individuals through determinations of risks polymorphisms can lead to new paths for treatment and prevention of metabolic abnormalities. We believe that in the future children will be treated based on their genomes.

The International Genomics & Translational Research in Transplantation Network (iGeneTrain). *J. van Setten[1], Y.R. Li[2,3], M.V. Holmes[2], S. Bala[4], K. Birdwell[5], P.I.W. de Bakker[1], P. Jacobson[6], K.J. Karczewski[7], D. MacArthur[7], J.H. Moore[8], W. Oetting[6], M. Snyder[9], J.D. Christie[2], G. Lord[10], E. Schadt[11], A.K. Israni[12], A. Shaked[2], F.W. Asselbergs[1], B.J. Keating[2,3] on behalf of the iGeneTrain consortium.* 1) University Medical Center Utrecht, Utrecht, Netherlands; 2) University of Pennsylvania, Philadelphia, USA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, USA; 4) Yale Medical School, New Haven, USA; 5) School of Medicine, Vanderbilt University, Nashville, USA; 6) College of Pharmacy, University of Minnesota, Minneapolis, USA; 7) Harvard Medical School and Broad Institute, Massachusetts General Hospital, Boston, USA; 8) School of Medicine, Dartmouth, Hanover, USA; 9) Stanford Center for Genomics and Personalized Medicine, Stanford University, Stanford, USA; 10) Guy's and St. Thomas' Hospital and King's College London, London, UK; 11) Institute for Genomics and Multiscale Biology, Icahn School of Medicine, Mount Sinai, New York, USA; 12) Hennepin County Medical Center, Minneapolis, USA.

Over the last two decades, over 300,000 solid organ transplantations have been performed in the USA alone. While there has been significant progress with immuno-suppression therapies, the risk of graft organ rejection is still substantial, even when appropriate HLA matching has been performed. Transplant rejections from male-donor to male-recipient and females to females are much lower than male to female. Cross-ethnic rejection rates are also higher, suggesting that additional genetic factors are at play in the rejection process. Possible sources of genetic variation underpinning rejection are homozygous deletion copy number variants (CNVs) spanning whole gene or exon regions and Loss of Function (LoF) variants ablating two copies of a given gene, resulting in incompatibility across the proteomes of donor and recipient. It has been shown through large-scale whole genome sequencing studies that the average human has 20 genes disrupted (i.e. with LoF) in two copies. Here, we present iGeneTrain, a large-scale international consortium, which ultimately aims to translate genetic data into clinical applications such as more optimal genomic compatibility matching of donor-recipient (D/R) pairs and immune suppression therapy dosing. We designed a low-cost genome-wide SNP array specifically tailored for the transplantation community, including exonic and LoF content, pharmacogenomic markers, CNVs, expression QTL markers, and HLA alleles. To date, we have included over 21,000 individuals. We will perform association testing within groups and cross-organ, maximizing statistical power to identify genetic variation associated with vasculopathy, rejection, and death.

916S

Repair activity of primate-specific alternative single-stranded DNA binding protein aRPA may explain brain-region repeat instability in CAG/CTG trinucleotide repeat diseases. *J. Luo[1], A. Mason[2], M.S. Wold[3], Y.H. Wang[4], A. LaSpada[2], C.E. Pearson[1].* 1) The Hospital for Sick Children, Toronto, Ontario, Canada; 2) University of California, San Diego; 3) University of Iowa; 4) University of Virginia.

Expansion of gene-specific trinucleotide repeat sequences, CAG/CTG causes at least 14 neuromuscular and neurodegenerative diseases. Continued somatic CAG expansions can contribute to disease onset and progression, thereby highlighting a need to understand the expansion process or processes that inhibit this. The processing of mutagenic slipped-DNA structures formed within the repeats is thought to play a role in repeat expansion. Replication protein A (RPA) is a single-strand binding protein that is essential in many DNA metabolic processes, including DNA replication, repair, and recombination. We previously revealed higher levels of RPA in the cerebellum compared to the striatum correlated with the lower levels of CAG expansions in the cerebellum versus the larger expansions in the striatum - which is sensitive to degeneration. A related primate-specific protein called alternative RPA (aRPA) has been shown to be expressed in human tissues at a very low levels relative to RPA; however, its function and relationship to RPA is not known. Here we show that aRPA transcript levels are greatly amplified in the brains of Huntington's disease (HD) patients compared to control brains, while expression of RPA is unaltered. We assessed the ability of RPA and aRPA to repair and process mutagenic slipped-DNA structures at the CAG/CTG repeats and found that RPA enhances the correct repair and processing of slipped-DNAs. However, high levels of aRPA (at aRPA:RPA ratio approximating those in HD brains) can inhibit RPA and eliminate repair. These findings suggest that RPA may protect against trinucleotide repeat mutations and aRPA may modulate this, a phenomena that may be particularly exacerbated in Huntintons patient brains. This furthers our understanding of the both disease-causing repeat mutations, the functions of single-strand binding proteins RPA and aRPA, and disease-specific changes.

917M

Novel Indoleamine 2, 3-Dioxygenase (*IDO*) gene mutation in the Pathogenesis of age-related cataract. *P. Gunda[1], M. Mamata[1], R.K.R Kondreddy[2], N. Thurlapati[3], P. Tirunilai[1].* 1) Dept of Genetics, Osmania University, Hyderabad, India; 2) Sarojini Devi Eye Hospital, Mehdipatnam, Hyderabad, India; 3) Department of Zoology, Osmania University, Hyderabad, India.

Purpose: Exposure to UV light is considered as the major risk factor for the development of age-related cataract. UV filters that are produced during tryptophan catabolism maintain the transparency of the lens and also protect retina from photodamage. Indoleamine 2, 3 dioxygenase (IDO) is the first rate limiting enzyme in the tryptophan catabolism which is encoded by *IDO* gene localized on chromosome 8p12-p11 region. Mutations in *IDO* gene can affect synthesis of UV filters qualitatively or quantitatively. Hence the present study was planned to screen for mutations in *IDO* gene and to evaluate their role in the causation of age-related cataract. **Methods:** Genomic DNA from 331 age-related cataract cases [110-Nuclear cataract, 110-Cortical cataract, 111-Posterior Subscapular types and 210 normal controls were PCR amplified for all regions covering the entire coding sequence and splice junctions of *IDO* gene. Amplified PCR products were analyzed using SSCP followed by sequencing of variant samples in both directions with an automated genetic analysis system (3100; ABI). Structure prediction and energetic analysis of wild-type IDO compared with mutants were predicted using various Bioinformatic tools. **Results:** Mutational screening in exon-7 of *IDO* gene showed the presence of a novel variation (c.596_597 delins TT; rs267606590) in heterozygous pattern in 2 (1 NC & 1 CC) of the cases studied and none among controls, leading to substitution of alanine (A) at position 199 by valine (V) in mutants. SIFT and polyphen tools predicted possible damaging effect of mutation on protein. Protein modeling by Triton package indicated wide variation between the wild type and mutant protein structure. Km values of wild type (68.66±0.26 μM) and mutant IDO proteins (74.92±0.40 μM) showed a significant difference indicating reduced affinity between the enzyme and substrate for mutant protein as compared to wild type. **Conclusion:** The novel variation p.A199V in exon 7 of *IDO* gene among patients with NC and CC cataracts resulting in the low affinity between mutant IDO enzyme and substrate tryptophan is likely to reduce the rate of UV filter synthesis in lens. The reduced levels of UV filters may cause exposure of lens to UV light resulting in aggregation of lens proteins and development of cataract.

918T

Genetic Variants Concomitantly Influence Nonalcoholic Fatty Liver Disease and Correlated Metabolic Traits. *M.F. Feitosa[1], A.T. Kraja[1], E.K. Speliotes[2], M.K. Wojczynski[1], N.D. Palmer[3], L.M. Yerges-Armstrong[4], T.B. Harris[5], C.S. Fox[6], I.B. Borecki[1], GOLD Consortium, GLGC Consortium, CHARGE Adiposity Consortium, GIANT Consortium, MAGIC Consortium.* 1) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 2) Department of Internal Medicine, Division of Gastroenterology and Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Forest School of Medicine, Winston-Salem, NC; 4) Department of Medicine, University of Maryland, Baltimore, MD; 5) National Institute on Aging, National Institutes of Health, Bethesda, MD; 6) Framingham Heart Study, National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health, Framingham, MA.

Nonalcoholic fatty liver disease (NAFLD) is associated with metabolic disorders, including overall and central obesity, dyslipidemia (high levels of triglycerides and low levels of high-density lipoprotein cholesterol), and impaired glucose tolerance (high fasting levels of glucose and insulin). Several variants have been discovered by genomewide association (GWA) studies for NAFLD and for these correlated metabolic disorders; however, few efforts have focused on determining whether the discovered genes/loci concomitantly influence these traits. To identify common variants contributing to pleiotropic effects on NAFLD and correlated metabolic traits, we employed a correlated meta-analysis (CMA) assessing the large published GWA meta-analysis Consortium data of CT measured fatty liver (FL, GOLD): with (i) triglycerides and (ii) high density cholesterol (GLGC), (iii) fasting levels of glucose and (iv) insulin (MAGIC), (v) body mass index and (vi) waist circumference (GIANT), and (vii) abdominal adipose tissues (CHARGE). Our methodological approach yielded evidence of genetic variants (e.g., ZNF14-rs12608822, SUGP2-rs3810444, NOTCH4- rs3130320, ATRAID-rs7437, NAT2-rs1495743, SMPD3-rs2863973, and GCKR-rs780093) with pleiotropic effects on CT measured FL and these metabolic traits. In addition, the CMA approach offered the opportunity to discover novel variants (APBA1-rs1330326, TYW3-rs11161851, LOC400940-rs2693827 and HLA-DKA2-rs2858310) that did not reach the GWA significance level in the primary discovery efforts. The associated variants are enriched for regulatory genetic functions, predict signaling pathway networks, and are associated with cell-specific-types and tissues involved in central nervous system, energy balance, glucose homeostasis, lipid metabolism, and fat liver accumulation. Our findings provide insight into the genetic basis of the correlated architecture of NAFLD metabolic pathway.

919S

Epigenetic effects of environmental enrichment and EGCG treatment on a mouse model of Down Syndrome. *C.N. Hor[1,2], S. Jhanwar[1,2], S. Espeso-Gil[1,2], M. Pons-Espinal[1,2], M.M. de Lagran[1,2], M. Friedländer[1,2], M. Dierssen[1,2], X. Estivill[1,2], S. Ossowski[1,2].* 1) Centre for Genomic Regulation, Barcelona, Barcelona, Spain; 2) Universitat Pompeu Fabra (UPF), Barcelona, Spain.

Epigenetic marks, defined as modifications to the DNA molecule and higher order structure not affecting the nucleotide sequence, have been hypothesized to be the long sought after interface between genes and the environment. The epigenetic state of a locus, i.e. the local combination of epigenetic marks, is thought to be determined partly by the DNA sequence and influenced by environmental cues. To directly explore the effects of genotype and environment under controlled conditions, we subjected transgenic Dyrk1A overexpressing mice (a model of Down syndrome) and their wild-type littermates to an enriched environment and/or treatment with the green tea polyphenol epigallocatechin gallate (EGCG, a Dyrk1A kinase inhibitor), both of which were previously shown to improve the cognitive performance of the transgenic mice. We have generated genome-wide profiles of cytosine methylation, a selection of histone marks and open chromatin in the cerebral cortices of these mice, as well as transcriptome and proteome. The epigenomic data are combined by computational analysis to yield a map of chromatin states, which can then be correlated with transcript and protein levels in each genotype and treatment group. Our analysis can (1) guide the discovery of regulatory elements active in the mouse brain, (2) uncover environment-specific signatures in the epigenome when comparing the profiles of different exposures across one genotype, and (3) elucidate the differential response attributable to the transgene by comparing these changes between the two genotypes. Preliminary analyses suggest that DNA methylation patterns remain stable upon treatments, while H3K36me3, a histone modification present along active gene bodies, is differentially detected in a set of genes enriched in annotation terms related to long term potentiation, which is important for memory and learning.

920M

The Molecular Convergence of non-HLA Ankylosing Spondylitis Risk Genes with Autoimmune Diseases. *D. O'Rielly[1], M. Uddin[2], M. Husan[1], D. Codner[1], P. Rahman[1].* 1) Faculty of Medicine, Memorial University, St. John's, Newfoundland, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario.

Genome-wide association studies (GWAS) and subsequent follow-up studies validated a significant number of non-HLA ankylosing spondylitis (AS) risk genes. Although these genes are independently recognized as small contributory risk factors to the pathogenesis of AS, the combined effect is yet to be quantified. In this study, we hypothesize that AS risk genes converge at the molecular level with related autoimmune disease genes. To identify such convergence a systematic approach is required to further investigate and understand AS pathobiology. A protein-protein interaction network-based method was utilized to infer connectivity between AS genes identified in GWAS studies with other autoimmune risk gene sets. We investigate 418 risk genes from ten (10) autoimmune diseases and their complex interactions with AS. The constructed PPI network demonstrated significantly ($p<1.8 \times 10^{-4}$ after 50,000 permutations) dense modular connectivity for AS genes with six other autoimmune disease genes including Crohn's disease (CD), psoriasis (Ps), ulcerative colitis (UC), celiac disease (CeD), multiple sclerosis (MS), and primary biliary cirrhosis (PBC). The most significant connectivity observed (after correcting for gene number) was with CeD and UC, which is consistent with the known pathobiology of AS, where CD and CeD often manifest as comorbid conditions. To better understand the shared pathway and to identify etiological genes, each non-AS risk gene was ranked according to their contributing connectivity to AS associated genes. We have identified STAT3, JAK2, IL12RB2, LSP1, and NFKBIA genes which are highly clustered with AS associated genes. We have developed a systematic approach to infer causal genes that converge at the molecular level to a common pathway involved in disease pathogenesis. The highly connected non-AS genes identified in this study will be prioritized for further investigation to identify their contribution to AS pathogenesis and to better understand the complex relationship of autoimmune diseases.

921T

Characterizing the Nphp10 (Sdccag8Tn(sb-Tyr)2161B.CA1Cove) mouse model. *K. Weihbrecht[1,2], V. Sheffield[1,3], S. Seo[2].* 1) Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA; 2) Dept. of Ophthalmology, Univ. of Iowa, Iowa City, IA; 3) Howard Hughes Medical Institute, Univ. of Iowa, Iowa City, IA.

A subset of nephronophthisis genes show normal localization to the ciliary-centrosomal complex, creating a linked group of disorders described as nephronophthisis-related ciliopathies (NPHP-RC). Aside from early end-stage renal failure and kidney cysts, seen in patients with just NPHP, the two other main phenotypes of NPHP-RCs are retinal and cerebellar degeneration. One such disease with NPHP-RC phenotypes is Bardet-Biedl Syndrome (BBS), with cardinal phenotypes of retinal degeneration, renal abnormalities, obesity, polydactyl, and learning disabilities. One NPHP gene associated with BBS is serologically defined colon cancer antigen 8 (SDCCAG8), later defined as NPHP10. However, the association with this disease was only recently made and little is known about the molecular function and how it leads to the observed phenotypes. BBS patients with NPHP10 mutations exhibit retinal and renal abnormalities, obesity, and learning disabilities. The purpose of this study is to characterize mouse model Sdccag8Tn(sb-Tyr)2161B.CA1COve, generated by a Sleeping Beauty Transposon (SBT) insertion between exons 12 and 13 of Nphp10. The goal in characterizing this mouse model is to determine its efficacy as a BBS or NPHP disease model, as well as to determine its use for functional analysis of NPHP10. NPHP10 has not been shown to interact with known NPHP complexes, nor has it been shown as an interactor with the other current BBS genes. Thus, the pathway through which NPHP10 leads to BBS phenotypes is novel and this mouse can be used to study the severity of typical BBS phenotypes in a BBS gene found in only a small subset of patients. While Jackson Laboratory reports an SBT insertion between exons 12 and 13 of Nphp10, our work has determined that a deletion occurred after the SBT insertion site, resulting in a loss of Nphp10's exons 13-18 as well as exons 2-13 of neighboring gene Akt3. Using these animals, we have also characterized a subset of phenotypes, including fully penetrant hind limb preaxial polydactyl and patterning defects of the secondary palate via Alcian Blue and Alizarin Red staining and developmental defects of the brain and abnormalities of the lung via H&E staining. Polydactyl, patterning defects, and lung abnormalities are consistent with phenotypes seen in other ciliopathy gene deficient mice and are likely due to loss of Nphp10, whereas the developmental defects of the brain are consistent with an Akt3 knockout animal.

922S

Transcriptome analysis of differentially expressed isoforms in hypertrophied cardiomyocytes derived from human iPSCs using RNA-Seq. *W. Li, P. Aggarwal, A. Turner, A. Matter, U. Broeckel.* Pediatrics Genomics, Medical College of Wisconsin, Milwaukee, WI.

Purpose. Left ventricular hypertrophy (LVH) is a potent risk factor for cardiovascular disease. The development of LVH is accompanied by significant changes in gene expression patterns in cardiomyocytes (CMs). However, traditional methods of transcriptome analysis do not analyze the abundance of individual splice forms (SFs), leaving the potential role of differentially expressed isoforms in complex diseases, including LVH, unexplained. Taking advantage of RNA sequencing, we identify a set of genes that are differentially expressed in hypertrophied CMs and explore the contribution of individual splice-forms to the LVH-transcriptome profile. Methods. We developed a model of human CM hypertrophy using induced, pluripotent stem cell derived CMs (iPSC-CMs). Stimulating the iPSC-CMs with isoproterenol induced characteristic changes associated with the development of LVH, evidenced by an increase in cell surface area and two well-established LVH markers, c-fos and BNP. RNA-Seq was performed for three replicates. Transcripts were assembled using TopHat2 and Bowtie2, and analyzed for relative levels of expression using Cufflinks2. Results. Upon hypertrophic induction, 920 genes exhibited significantly differential expression. 433 of these genes have one SF and 487 have two or more (55 genes had ≥ 5 SFs). Of those that are alternatively spliced, 367 (75.4%) showed significant changes at the global level only, 15 (3.1%) at the splice-form level only, and 105 (27.1%) at both. To explore potential functional implications of differentially expressed SFs, we compared the exons that are unique to only some SFs of each gene to those that are common (common exon) to all SFs. On average, unique exons are approximately twice as long as common exons. Further, unique exons contain numerous well-characterized functional domains. Functional characterization of differentially expressed isoforms will likely provide novel insights into the etiology of LVH. Conclusions. Our study demonstrates that differential splice form expression is prevalent during the development of LVH and likely contributes to the physiology of hypertrophied CMs. The same is likely true for many other complex diseases. Reliance on analysis of global expression patterns alone obscures changes associated with individual splice forms, resulting in a substantial loss of information and potential insights into the development and physiology of complex diseases.

923M

Maternal effects influence the heritability of adult obesity traits but not obesogenic growth trajectories in a model system. *C.A. Schmitt[1,2], S. Service[1], R.M. Cantor[3], A.J. Jasinska[1], M.J. Jorgensen[4], J.R. Kaplan[4], N.B. Freimer[1], The International Vervet Research Consortium.* 1) Center for Neurobehavioral Genetics, University of California - Los Angeles, Los Angeles, CA; 2) Human Evolution Research Center, Museum of Vertebrate Zoology, University of California - Berkeley, Berkeley, CA; 3) Department of Human Genetics, University of California - Los Angeles, Los Angeles, CA; 4) Department of Pathology, Section on Comparative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Obesity arises from a complex interaction of genetic predisposition and environment that can accumulate throughout life. Previous work has shown that there are maternal effects on obesity outcomes in humans and nonhuman primates, but few have investigated the impact of maternal effects on obesogenic growth itself throughout the lifespan. This research investigates the impact of maternal effects on the genetic underpinnings of obesogenic growth from birth to adulthood in a genetically well-characterized model system under a controlled diet and environment: the African green monkey (*Chlorocebus aethiops sabaeus*) in the Vervet Research Colony at Wake Forest School of Medicine. We used growth curve analysis on measures taken thrice yearly on body size and composition - such as body weight (BW) and BMI - in a population of 641 monkeys measured from 2000 through 2013. Of these, 33 individuals, 6 males and 27 females, presented with signs of chronic abdominal obesity - defined as having an adult waist circumference above 40.5 cm for at least three successive measurements. Individuals measured < 6 times were excluded from analysis (max measures = 30, mean = 12.6 ± 6.12). Growth was modeled using three-parameter logistic growth curves in nonlinear mixed models, with parameters modeled as fixed effects and subject and sex/obesity status modeled as random effects. We assessed heritability of individual growth parameters using maximum likelihood variance components analysis in SOLAR, with the variance attributed to maternal ID (c^2) partitioned from environmental variance to determine maternal effects. We found significant heritability and maternal effects on all static measures of adult body condition (e.g., BW, $h^2 = 0.86$, $p = 6.52\times10^{-10}$ and $c^2 = 0.11$, $p = 0.04$; BMI, $h^2 = 0.77$, $p = 1.39\times10^{-09}$ and $c^2 = 0.12$, $p = 0.05$), and high heritability but no evidence for significant maternal effects on parameters of growth (e.g., BW: θ_1, asymptote of growth, $h^2 = 0.77$, $p = 4.93\times10^{-21}$ and $c^2 = 0.05$, $p = 0.11$). This study suggests that although adult obesity is a developmental process driven in part by heritable obesogenic trajectories resulting in faster and longer growth to larger adult size, those trajectories do not appear to be influenced by maternal effects. A better understanding of how growth can be decoupled from maternal effects on adult obesity outcomes will be necessary to assess early obesity risks and inform potential biomedical interventions.

The Genetic Landscape of Hematopoietic Stem Cells. *H. Allayee[1], A.L. Crow[1], J. Hartiala[1], T.J. Spindler[2], A. Ghazalpour[3], L.W. Barsky[2], B.J. Bennett[4], B.W. Parks[3], E. Eskin[3], R. Jain[5], J.A. Epstein[5], A.J. Lusis[3], G.B. Adams[3].* 1) Department of Preventive Medicine, University of Southern California, Los Angeles, CA 90033; 2) Broad Center for Regenerative Medicine and Stem Cell Research at USC, University of Southern California, Los Angeles, CA 90033; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA 90095; 4) Department of Genetics and Nutrition Research Institute, University of North Carolina, Chapel Hill, Kannapolis, NC 28081; 5) Department of Cell and Developmental Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104.

The ability to carry out association studies on a genome-wide basis has revolutionized the field of human genetics. Such GWAS have identified hundreds of novel genes for atherosclerosis, diabetes, cancer, and related quantitative phenotypes. However, human GWAS can be limited since other biomedically relevant phenotypes, such as hematopoietic stem cell (HSC) number/function, are logistically difficult to obtain in large numbers of subjects. To overcome these limitations, we used a GWAS approach with a recently developed panel of inbred and recombinant mouse strains, termed the Hybrid Mouse Diversity Panel (HMDP), to characterize the genetic landscape of HSCs. We used flow cytometry to quantitate the frequency of long-term (LT) and short-term (ST) HSCs, as well as hematopoietic progenitor cells (HPCs), in bone marrow (BM) from 111 HMDP strains. These cell populations varied 25 to 80-fold, thus providing strong evidence for a genetic basis to HSC variation. Consistent with this notion, a GWAS analysis identified 8 loci significantly associated with HSCs (p=6.9E-6 - 7.0E-14), including a locus for ST-HSCs on chromosome 5 (p=6.2E-7). Of the genes in this region, highly significant cis eQTLs was identified for homeodomain only protein (Hopx) in liver (p=3.4E-18) and heart (p= 6.2E-19), suggesting that genetic variation at this locus is functional with respect to Hopx expression. Hopx expression in BM from 25 HMDP strains was significantly positively correlated (r=0.44; p<0.05) with ST-HSCs. To functionally validate Hopx, we characterized BM from Hopx knockout (Hopx -/-) mice by flow cytometry and observed a significant 4-fold reduction in ST-HSC frequency compared to wildtype littermates (p<0.01). Additional analyses revealed that Hopx-/- mice had significantly reduced numbers of quiescent ST-HSCs (60% vs 85%; p<0.05) and increased numbers of cells in the G1 phase (35% vs 10%; p<0.05). Hopx deficiency specifically affected ST-HSCs since there were no differences in the frequency or cell cycle status of HPCs or LT-HSCs. These findings are entirely consistent with Hopx mRNA levels being positively correlated with ST-HSCs and the Hopx locus only being associated with this HSC subset in the GWAS. Taken together, these results provide compelling evidence that Hopx is a novel positive regulator of HSC physiology in mice and demonstrate the power of the HMDP for elucidating the genetic architecture of complex traits that would otherwise not be feasible in humans.

Genotyping-by-sequencing in outbred CFW mice yields a powerful approach for genome-wide mapping of complex trait loci. *P. Carbonetto[1], S. Gopalakrishnan[1], C.C. Parker[2], N.M. Gonzales[1], A. Lionikas[3], C.L. Ackert-Bicknell[4], E.H. Leung[1], E. Aryee[1], J. Park[1], J. Davis[5], A.A. Palmer[1].* 1) Dept. of Human Genetics, University of Chicago, Chicago, IL; 2) Dept. of Psychology and Program in Neuroscience, Middlebury College, Middlebury, VT; 3) School of Medical Sciences, College of Life Sciences and Medicine, University of Aberdeen, Foresterhill, Aberdeen, UK; 4) The Jackson Laboratory, Bar Harbor, Maine; 5) Dept. of Genetics, Stanford School of Medicine, Stanford, CA.

Despite the successes of genome-wide association studies for augmenting our understanding of many common human diseases and disease-related traits, mice still remain an important complementary resource for studying genetics of complex disease. Advantages include being able to control the environment, and measure gene expression in tissues that are ordinarily inaccessible in humans. (We present gene expression from multiple brain regions in a separate poster.) One important disadvantage of working with traditional mouse lab strains compared to humans is that the mice exhibit long-range correlations on their chromosomes, due to a lack of accumulated recombination, often making it very difficult to assign any functional interpretation to a complex trait locus. We describe our efforts to develop a new resource for mapping complex trait loci from CFW mice, a commercial stock of outbred mice, that permits better resolution to map complex traits. We show that CFW mice have desirable properties for QTL mapping, including rapid decay of linkage disequilibrium and a high proportion of common alleles. To ascertain whole-genome variation at low cost, we adapt "genotyping-by-sequencing" (GBS) protocols originally developed for plants, and contribute additional technical improvements to this protocol for outbred mice. To address the problem of false positives caused by "cryptic" or "hidden" relatedness, we test for association using the linear mixed model approach, implemented in the software GEMMA. In a cohort of ~1000 CFW mice, we obtain strong support for genetic associations in a variety of complex traits, including bone-mineral density, testes weight, musculoskeletal traits, prepulse inhibition and methamphetamine sensitivity. In some QTL regions, the association signal isolates only a few genes. We also identify loci that overlap with established complex trait genes, such as testes weight gene Inhba and osteoporosis gene Col1a1. Many of these associations have been replicated in an independent panel of CFW mice developed by our collaborators at University of Oxford. Our findings show that the CFW mouse stock is a practical and powerful resource for identifying loci underlying a variety of complex traits.

An APP, BACE expressing C. elegans model of Alzheimer's disease. *K.N. Ly[1], S.J. Redi[1], K. Henty[1], W.N. Grant[2], R.G. Russell[1].* 1) School of Biolocial Sciences, The University of Auckland, Auckland, New Zealand; 2) Department of Genetics, La Trobe University, Melbourne, Victoria, Australia.

Alzheimer's disease (AD) is a progressive neurodegenerative disorder and is the most common form of dementia, affecting over 44 million people worldwide. Pathologically, AD is characterized by two important hallmarks: extracellular amyloid plaques and intracellular neurofibrillary tangles, made up predominantly by proteins known as β-amyloid (Aβ) and hyperphosphorylated Tau, respectively. Mutations in the Aβ precursor protein (APP) and two proteins involved in Aβ production (presenilin 1 and 2; components of the gamma secretase complex) cause heritable early onset AD, typically prior to 65 years old. However, the majority of AD cases occur in people over the age of 65 with unknown mutations. Despite over two decades of intensive research, the physiological roles and mechanistic contribution of APP and Aβ to late onset AD still remain elusive. *Caenorhabditis elegans* is emerging as a powerful tool in the research of neurodegenerative disorders, complementing the traditional mammalian systems with ease of genetics, simplicity of their neuronal network, and short generation time. Previous studies have shown that transgenic *C. elegans* over-expressing human Aβ in muscle cells develop intracellular Aβ aggregation and a progressive paralysis, while those expressing Aβ in neurons reveal behavioral deficits and rapid paralysis. To further understand Aβ and the processing of its precursor APP, transgenic *C. elegans* strains which express full-length human APP and human β-secretase (an enzyme responsible for the first step of Aβ production) under three promoters: neuronal specific (*snb-1*), *apl-1* (*C. elegans* APP homologue), *sel-1* (*C. elegans* presenilin homologue) have been developed. The approach taken has been to integrate single copies of the human genes using the MOSSCI technique, with and without fluorescent tags, in order to achieve stable expression levels. Promoter appropriate expression has been observed and results from developmental and behavioral studies will be presented.

Characterization of neuronal development in autism using induced pluripotent stem cells reveals disease-specific changes in neurite outgrowth and expression of synaptic function genes. *B.A. DeRosa[1,2], K.C. Belle[1,2], J.M. Lee[1], M.L. Cuccaro[1,2], J.M. Vance[1,2], M.A. Pericak-Vance[1,2], D.M. Dykxhoorn[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. MacDonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Autism spectrum disorders (ASD) comprise a genetically and phenotypically heterogeneous group of neurodevelopmental conditions that are characterized by manifestations of several broadly defined phenotypes, including impairments in communication, social interaction, and behavior. The rapid expansion in the number of newly identified ASD risk loci, coupled to the absence of therapeutics and pharmacological treatments, has shed light on the need for a better understanding of the mechanisms by which specific genetic variants lead to pathophysiological changes associated with the disease. Until recently, functional studies of idiopathic autism were hindered by the lack of genetically-relevant human disease models. With the advent of human induced pluripotent stem cell (iPSC) technology, and recent advancements in neural differentiation methods, it is now possible to functionally analyze specific populations of developing neurons derived from ASD-affected individuals. Since in vitro neuronal differentiation mimics in vivo neurogenesis and neuronal maturation, it is possible to analyze ASD-specific phenotypes throughout neuronal development. In order to characterize the impact of non-syndromic forms of ASD on neurodevelopmental processes, including neurite outgrowth dynamics and network formation, we generated a panel of patient-specific iPSC lines from peripheral blood mononuclear cells attained from clinically and genetically well characterized ASD patients. Neurite outgrowth dynamics and ASD-risk gene expression were analyzed in iPS-derived ASD and control forebrain neurons over a broad time course spanning in vitro neuronal differentiation and maturation. Our results show ASD-associated changes in gene expression profiles and patterns of neurite outgrowth. These analyses provide a solid framework for understanding the molecular and cellular mechanisms that underlie ASD pathophysiology.

Association of Age-related Macular Degeneration (AMD) Susceptible Genes with Second Eye Involvement of AMD. *M. Miyake[1,2], K. Yamashiro[1], K. Kumagai[1], M. Saito[3], M. Kuroda-Sugahara[1], M. Yoshikawa[1], H. Tamura[1], Y. Akagi-Kurashige[1,2], M. Oishi[1], I. Nakata[1,2], H. Nakanishi[1,2], A. Oishi[1], N. Gotoh[1,2], A. Tsujikawa[4], T. Sekiryu[3], Y. Kurimoto[5], C.C. Khor[6], C.Y. Cheng[7], T.Y. Wong[7], R. Yamada[2], F. Matsuda[2], N. Yoshimura[1].* 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Center for Genomic Medicine/Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan; 3) Fukushima Medical School. Fukushima, Japan; 4) Kagawa University, Kagawa, Japan; 5) Kobe City General Hospital, Kobe, Japan; 6) Genome Institute of Singapore, Singapore, Singapore; 7) Singapore Eye Research Institute, Singapore.

BACKGROUND: Age-related macular degeneration (AMD) is a major cause of progressive, irreversible visual impairment among elderly population in developed countries. Especially, bilateral involvement of AMD severely impairs quality of life, so that predicting fellow-eye-involvement of AMD in unilateral cases is of great importance in clinical setting. In 2013, the largest genome-wide association study on age-related macular degeneration (AMD) identified 19 AMD susceptible loci, including 7 novel loci (The AMD Gene Consortium, Nature Genetics). Of these, ARMS2 was reported to be associated with the second eye involvement of AMD, while others have not been evaluated. In this study, we investigated whether these loci were also associated with second eye involvement using Japanese AMD cohorts recruited from 3 institutes. **METHODS:** A total of 1,576 AMD cases were genotyped using illumina OmniExpress, HumanOmni2.5-8, and/or HumanExome, which was imputed to 1,000 genomes cosmopolitan data after a standard quality control. We retrospectively reviewed medical records of 500 unilateral AMD patients from Kyoto University Hospital, 264 patients from Fukushima Medical University, and 130 patients from Kobe City General Hospital. Written informed consent for genetic research had been obtained from all patients. Cox proportional hazard regression analysis was used to examine the association between the genotypes of AMD susceptible single nucleotide polymorphisms (SNPs) and the duration until the development of AMD in the second eye. **RESULTS:** ARMS2 rs10490924 recessive model (Hazard Ratio [HR]$_{meta}$ = 2.04; $P_{meta} = 3.4 \times 10^{-3}$) and CFH rs800292 additive model (HR_{meta} = 1.77; P_{meta} = 0.013) revealed significant association with second eye involvement. Dominant model of TNFRSF10A rs13278062, VEGFA rs943080, and CFI rs4698775 showed consistent effect across 3 datasets (I^2 = 0%; HR_{meta} = 1.46, 1.30, 1.51, respectively). Next, we calculated genetic risk score (GRS) using these 5 SNPs. After 10 years from the first visit, the patients with top-10-percentile of GRS showed 51% of hazard rate, in contrast to 2.3% among patients with lower-10-percentile of GRS. **CONCLUSIONS:** GRS using ARMS2, CFH, TNFRSF10A, VEGFA, and CFI is a good predictor of second eye involvement, which is especially of great importance in the clinical setting.

929M

Nasopharyngeal microbiome composition is associated with lung function in adult Hutterites. *C. Igartua[1], E.R. Davenport[1], J.B. Becker[2], S.R White[2], Y. Gilad[1], C. Ober[1], J.M. Pinto[3].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Section of Pulmonary and Critical Care Medicine, Department of Medicine, University of Chicago, Chicago, IL; 3) Section of Otolaryngology-Head and Neck Surgery, Department of Surgery, University of Chicago, Chicago, IL.

The human microbiome contains trillions of microbes and has been associated with disorders of the airway, such as sinusitis and asthma. We predict that host immunity is related to the composition of bacteria in the airways and that ecologic characteristics of these bacterial communities may be predictive of respiratory disease state. We explore this possibility by considering the relationship between the nasopharyngeal microbiome (an accessible, representative measure of airway bacteria) in 142 adult Hutterites, including 24 asthmatics, and FEV_1/FVC ratio as a measure of lung obstruction, which is significantly associated with asthma in this population. The Hutterites are a founder population of European decent who live communally, thereby ensuring that environmental exposures are relatively similar among individuals. We sequenced the V4 region of the 16S rRNA gene from bacterial cells collected from the nasopharynx and calculated the relative abundance of each bacterium after bioinformatic classification of QC filtered reads using Mothur. After subsampling a maximum of 550,000 reads from each individual (range 273,064-550,000; median 550,000), standardized bacterial reads present in at least 75% of individuals were fit to a standard normal distribution. At the taxonomic level of order, after regressing out age, sex and date of collection, the first principle component, which accounted for 44.4% of the variance between individuals, was associated with the FEV_1/FVC ratio ($p=0.008$). After removing correlated bacteria (Spearman correlation >0.8), we performed association tests for the relative abundance of the 60 bacteria in the taxonomic level of order using a linear mixed model as implemented in GEMMA, which incorporates information on relatedness into the model. Sex, age, and date of collection were included as covariates. The abundance of Enterobacteriales bacteria (gram-negative facultative anaerobes in the class Gammaproteobacteria of the phylum Proteobacteria) was positively correlated with FEV_1/FVC ratio after Bonferroni correction for 60 tests (uncorrected $p=5.3\times10^{-4}$). Our study demonstrates that the nasopharynx is an accessible airway site in which to study microbiome-lung disease associations and suggests that microbes in this anatomic location may reflect environmental exposures and/or host mucosal immunity status related to important disease-associated phenotypes.

930T

Hematopoeitic stem cells target neovascular tissue in a novel preclinical model of proliferative diabetic retinopathy. *K. Wert[1], V. Mahajan[2,3], Y. Yan[4], Y. Li[5,6], J. Tosi[5,6], T. Nagasaki[6], M. Grant[7], S. Tsang[5,6,8].* 1) Jaenisch Laboratory, Whitehead Institute for Biomedical Research, Boston, MA; 2) Department of Ophthalmology & Visual Sciences, University of Iowa, Iowa City, IA; 3) Omics Laboratory, University of Iowa, Iowa City, IA; 4) Department of Pharmacology and Therapeutics, University of Florida, Gainesville, FL; 5) Bernard & Shirlee Brown Glaucoma Laboratory, Columbia University, New York, NY; 6) Edward S. Harkness Eye Institute, Columbia University, New York, NY; 7) Eugene and Marilyn Glick Eye Institute, Department of Ophthalmology, Indiana University School of Medicine, Indianapolis, IN; 8) Department of Pathology & Cellular Biology, Columbia University, New York, NY.

Currently, more than 382 million people have been diagnosed with diabetes, and this number is expected to rise to 592 million people by 2035. Approximately one third of patients diagnosed with diabetes display signs of diabetic retinopathy (DR). Approximately 60% of non-proliferative DR patients progress to the neovascular stage, proliferative DR (PDR). PDR patients will develop vitreous hemorrhage, tractional retinal detachment, neovascular glaucoma and blindness. Most currently available mouse retinopathy models are inadequate for the study of PDR. They only display mild, non-proliferative disease within the lifespan of the animals. An animal model for PDR is critical to study signaling pathways involved in this disease stage. In this study, we examined protein levels from vitreous samples of human patients with PDR. We discovered an increase of hypoxia inducible factor 1 alpha (HIF1a) protein in untreated human PDR patients compared to control groups. During hypoxic conditions, von Hippel Lindau tumor suppressor protein (VHL) releases its normal degradative action on HIF1a. We tested whether the human PDR condition could be modeled by using a knockout of VHL, which would constitutively activate HIF1a and release its inhibition of HIF1a transcriptional activity. Therefore, we created a novel, tissue-specific preclinical model in which *Vhl* was knocked out within the neural retina using a *Ch×10 cre* promoter. This promoter allowed for a complete embryonic retinal loss of *Vhl* gene expression. We found that the mice developed severe proliferative retinopathy that correlated with human PDR. Since hematopoietic stem cells (HSCs) are found to localize to sites of angiogenesis, we hypothesized that HSCs delivered into the intravitreal space of the eye might localize to the sites of neovascularization, where angiogenesis is occurring and abnormal and leaking blood vessels are formed. So, the PDR mouse model was treated using transplantation of HSCs into the intravitreal space of the eye. We found that HSCs localized to the sites of damaged retinal vasculature after intravitreal injection into our novel preclinical PDR model. In summary, we developed a new mouse model for the study of human PDR and other ischemic retinal diseases by constitutive down regulation of HIF1 regulator, VHL. Rapid progression of retinopathy in these mutants will expedite the evaluation of therapeutic agents for this group of blinding disorders, including treatment using HSCs.

The Role of Copy Number Variants in Latino Children with Asthma. *M.L. Spear[1, 2, 3], M. Pino-Yanes[2], C.R. Gignoux[3], C. Eng[2], B.P. Coe[4], C.D. Campbell[4], E.E. Eichler[4, 5], D.G. Torgerson[2], E.G. Burchard[2, 3] on behalf of the GALA I Investigators.* 1) Biomedical Sciences Graduate Program, University of California, San Francisco, San Francisco, CA; 2) Department of Medicine, University of California, San Francisco, San Francisco, CA; 3) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 4) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA; 5) Howard Hughes Medical Institute.

Asthma is a complex respiratory disease influenced by social, environmental, and genetic factors. Twin studies have found the heritability to be between 75% and 92%, suggesting an important genetic contribution to asthma susceptibility. Although variation in over 150 genes has been associated with asthma, they only explain a small fraction of the disease heritability. Copy number variants (CNVs) are an important source of variation in the human genome due to their large size. CNVs have been previously associated with immune-related diseases, however knowledge of their role in asthma is limited. In this study we performed a genome-wide assessment of common CNVs in Latino children from the Genetics of Asthma in Latino Americans (GALA I) study, to identify novel CNVs associated with asthma. CNVs were called from genome-wide SNP genotypes obtained from the Affymetrix 6.0 GeneChip Array (Affymetrix, Santa Clara, Calif) using the Affymetrix Genotyping Console 4.1 software. A total of 733 Puerto Ricans and Mexicans, including 445 cases and 288 controls were included in the study. We limited our analysis to common CNVs present in more than 5% of our case/control population, and greater than 30 kb in length. We performed logistic regression adjusting by genetic ancestry and self-reported ethnicity, to test for an association between asthma and copy number of common CNVs. We identified a significant association between asthma and CNVs on chromosome 3q22.1 (OR = 0.85 [0.79-0.91]; p-value = 4.36×10^{-6}) following multiple testing correction by performing 10^6 permutations. The association was still significant after adjusting by genetic ancestry and ethnicity (OR = 0.85 [0.79-0.92]; p-value = 1.84×10^{-5}). The associated CNV is located within a genomic region previously associated with atopic dermatitis through linkage analysis, and is 300 kb upstream of *COL6A5*. Overall, our findings suggest an important role of a common CNV at 3q22.1 in asthma susceptibility in Latino children.

932M

Family-based Associations and Parent of Origin analyses reveal novel associations with inflammatory bowel disease (IBD). *X. YAN[1], M. DUBINSKY[2], T. HARITUNIANS[1], J. ROTTER[3], K. TAYLOR[3], S. RICH[4], S. Onengut-Gumuscu[4], W. CHEN[4], X. GUO[3], S. TARGEN[1], D. LI[1], D. MCGOVERN[1].* 1) F. Widjaja Foundation Inflammatory Bowel & Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Pediatric IBD Center, Gastroenterology, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center; 4) Center for Public Health Genomics, Dept Public Health Sciences, University of Virginia School of Medicine, Charlottesville, VA.

Background: Only a minority of the heritability for IBD has been explained despite the identification of >160 susceptibility loci. We aimed to identify additional IBD associations by Transmission Disequilibrium Test (TDT) and to assess for any Parent-of-Origin effect to explain, in part, the missing heritability. **Methods:** 965 IBD trios with an affected offspring and both parents genotyped by ImmunoChip were included. We tested for association using TDT and Parent- of-Origin test (PLINK). Novel signals were confirmed by checking for LD and conditional analyses on the known 193 IBD-associated SNPs. An independent confirmation cohort of 2904 cases and 4791 controls was used to validate the TDT associations. 10e4~10e6 permutation and meta-analysis were performed.

Results: SNPs with **TDT** association after conditioning on known IBD SNPs (p<0.01 for SNPs within known region or p<0.0001 for SNPs outside known region, and p<5.0e-4 for conditional analyses) and confirmed in the case/control replication cohort are listed as below: *IL1RL1*(SNP=rs1420101, p_discovery=7.7e-3,p_confirmation=4.5e-5,p_meta=1.92e-5); *SLC2A13/LRRK2*(SNP=rs76904798,p_discovery=1.0e-3,p_confirmation=2.5e-7,p_meta=1.21e-7); *SBNO2*(SNP=rs8099951,p_discovery=6.4e-3,p_confirmation=3.4e-4,p_meta=1.4e-4); *LOC441108*(SNP=rs2158101,p_discovery=4.3e-4,p_confirmation=4.8e-5,p_meta=1.2e-5). **Parent-of-Origin** analyses identified differential transmission at the following genes, which mapped outside known IBD loci: *CTSH*(rs78764205,ptu=134.5:80.5,p_pat=2.3e-4,mtu=110.5:131.5,p_mat=0.18)(known MS, T1D locus); *MYCN*(rs4669018, ptu=151:202,p_pat=6.6e-3,mtu=208:178,p_mat=0.13); *TMEM16C*(rs1353142,ptu=80:113,p_pat=0.02,mtu=107:73,p_mat=0.01); *DLG2* (rs11233971, ptu=13:33,p_pat=0.003, mtu=45:25, p_mat=0.02); *TRPS1*(rs2293888,ptu=136:176,p_pat=0.02,mtu=186:143,p_mat=0.02); *RFX3/GLIS3*(rs13286706, ptu=179:137,p_pat=0.02,mtu=161:197,p_mat=0.06)(known T1D locus); *SAMD3/TMEM200A*(rs9492584, ptu=115.5:139.5,p_pat=0.13,mtu=167.5:119.5,p_mat=0.005); *NID2/PTGDR*(rs802971,ptu=145:103,p_pat=0.008, mtu=98:128,p_mat=0.05 (all p<1.0e-4, p/mtu - paternal/maternal transmitted : untransmitted counts, p_p/mat - paternal/maternal transmission p-value). **Discussion:** TDT analyses have identified additional IBD associations. The Parent-of-Origin analyses identified new IBD signals and if validated may explain some of the missing heritability in IBD.

933T

Parent-of-origin effects of the *APOB* gene on adiposity in young adults. *H. Hochner[1], C. Allard[2], E. Granot-Hershkovitz[1], J. Chen[3], C.M. Sitlani[4,5], S. Sazdovska[1], T. Lumley[6], B. Background: Genome-wide association studies (GWAS) of unrelated individuals have identified multiple loci associated with cardiometabolic phenotypes. However, the magnitude of these associations is small to moderate and the loci account for only a small proportion of the traits' heritability. To date, most association studies have not considered parent-of-origin effects (POEs). **Objectives:** We sought POEs on adiposity and glycemic traits in young adults. **Methods:** The Jerusalem Perinatal Study (JPS) sample comprises 1250 young adults (mean age 32) born in Jerusalem, and their mothers, with recently-collected DNA samples and cardiometabolic measurements. We focused on a set of 18 genes (182 tag SNPs) identified by previous GWAS as associated with selected cardiometabolic traits. Using linear regression, we examined the associations of maternally- and paternally-derived offspring minor alleles with body mass index (BMI), waist circumference (WC), fasting glucose and insulin. To replicate and meta-analyze findings, we performed similar analyses in individuals of European ancestry aged≤50 belonging to extended pedigrees from three additional studies: Framingham Heart Study, Family Heart Study and Erasmus Rucphen Family study (Total maximum N=4800). We considered $p<2.7\times10^{-4}$ statistically significant to account for multiple testing. Replicated findings were followed-up by also assessing POEs on lipids and blood pressure (BP). **Results:** A common coding variant in *APOB* (rs1367117) demonstrated a significant maternally-derived effect on BMI (β=0.8; 95%CI:0.4,1.1; $p=3.1\times10^{-5}$) and WC (β=2.7; 95%CI:1.7,3.7; $p=2.1\times10^{-7}$). The corresponding paternally-derived effects were non-significant (p>0.6). Suggestive maternally-derived associations of this *APOB* SNP were observed with fasting glucose (β=0.9; 95%CI:0.3,1.5; $p=4.0\times10^{-3}$) and insulin (ln-transformed, β=0.06; 95%CI:0.03,0.1; $p=7.4\times10^{-4}$). There was little evidence to suggest POE on lipids, yet maternal POE was observed for systolic BP (β=1.6; 95%CI:0.8,2.5; $p=1.6\times10^{-4}$). Maternal-specific associations with glucose, insulin and systolic BP were attenuated after further adjustment for BMI. **Conclusions:** Our findings demonstrate that a common genetic variation in *APOB* is associated with adiposity through maternal POE, an association that was not previously detected in GWAS of adiposity. These results provide support for a role of POEs in adiposity and related cardiometabolic traits, and motivate further research in this area.

934S

Heritability explained by common SNPs for dietary intake: genome-wide analysis in three US cohorts. *Q. Qi[1], A. Chu[2], J. Huang[3], J. Kang[2], G. Curhan[2,3], L. Pasquale[2], I. De Vivo[2,3], A. Chan[2,3], H. Choi[2,4], R. Tamimi[2,3], P. Ridker[2], D. Hunter[2,3], W. Willett[2,3], E. Rimm[2,3], D. Chaseman[2], F. Hu[2,3], L. Qi[2,3].* 1) Albert Einstein College of Medicine, Bronx, NY; 2) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Harvard School of Public Health, Boston, MA; 4) Boston University School of Medicine, Boston, MA.

Habitual dietary intake is a complex behavior that has been suggested to have a genetic component, with estimated heritability ranging from 8% to 70% in family and twin studies. However, genetic determinants of dietary intake are poorly understood and it is unknown how much heritability for dietary intake can be captured by common SNPs in genome. Using a linear mixed model to fit all SNPs simultaneously by GCTA software, we estimated narrow sense heritability for dietary intake explained by common SNPs (~300,000 to 700,000 SNPs in the genome) among 37,421 unrelated individuals of European ancestry from three US cohorts: the Nurses' Health Study, the Health Professionals Follow-up Study, and the Women's Genome Health Study. Dietary intakes of total energy, macronutrients (percentage of energy intake), and individual foods and beverages were assessed by almost identical validated semiquantitative food frequency questionnaires across three studies, and two major dietary patterns (prudent pattern and Western pattern) were derived using factor analysis. In the combined results from three studies by meta-analysis, small but significant proportions of variance for intakes of total energy (5.8 [95% CI 2.9, 8.7]%; P=0.0001), fat (5.9 [3.0, 8.8]%; P=0.0001), protein (4.8 [1.9, 7.7]%; P=0.001), and carbohydrate (3.4 [0.5, 6.3]%; P=0.02) were explained by all common SNPs. We also found that a number of food and beverage groups (egg, butter, margarine, dairy products, vegetables, whole grains, refined grains, condiments, coffee, alcohol, fruit juice, sugar-sweetened beverages, diet beverages, and water) had genetic influences, with significant heritability estimates ranging from 3.1 [0.2, 6.0] to 9.3 [6.4, 12.2]% (P=0.04 to 5.3×10-10). In addition, a Western dietary pattern (characterized by higher intakes of red and processed meats, sweets, desserts, French fries, and refined grains) showed the highest heritability estimate (10.3 [7.2, 13.4]%; P =4.4×10-10) among dietary intake variables. Our data provide evidence for moderate genetic influence on dietary intake. Genome-wide association studies are warranted to identify genetic variants associated with dietary intake.

935M

The role of STRs in shaping complex traits. *T. Willems[1,2], A. Gordon[1], M. Gymrek[1], Y. Erlich[1].* 1) The Whitehead Institute, Cambridge, MA; 2) Computational and Systems Biology, MIT, Cambridge, MA.

Despite the advent of whole-genome sequencing data and increasingly large sample sizes, genome-wide association studies have failed to fully uncover the genetic basis for the heritability of most complex traits. While various studies have proposed that this "missing heritability" may stem from rare SNPs or epistatic interactions, other variant classes may also be responsible. Recently, a handful of single-gene and genome-wide studies have identified short tandem repeats (STRs), sequences of DNA consisting of repeating patterns of 2-5 base pairs, as modulators of gene expression. To assess whether this class of variant may also influence complex traits, we genotyped ~700K STRs in over 1500 individuals using data from the UK10K project. In conjunction with a wide range of phenotypes, these genotypes were utilized to perform a genome-wide STR GWAS. The resulting analysis identified a handful of STRs strongly associated with a variety of phenotypes, even after controlling for tagging SNPs. In addition, we utilized linear mixed models to jointly assess the phenotypic variance explained by SNPs and STRs. In aggregate, our results shed new light on the issue of "missing heritability" and suggest that STR variations substantially contribute to complex traits.

936T

Regulatory variants explain much more heritability than coding variants across 11 common diseases. *A. Gusev[1], S.H. Lee[2], B.M. Neale[3,4], G. Trynka[5,6,7,8], B.J. Vilhjalmsson[1], H. Common variants implicated by genome-wide association studies (GWAS) of complex diseases are known to be enriched for coding and regulatory variants. We applied methods to partition the heritability explained by genotyped SNPs (h^2_g) across functional categories (while accounting for shared variance due to linkage disequilibrium) to imputed genotype data for 11 common diseases in >60,000 samples. DNaseI Hypersensitivity Sites (DHS), identified in 218 cell-types, spanned 16% of the genome and explained an average of 79% of h^2_g (5.1× enrichment; $P<10^{-20}$); further significant enrichment was observed at enhancer DHS elements ($P=5\times10^{-4}$) and cell-type specific DHS regions with relevance to phenotype. The enrichments were larger and more statistically significant than in analyses that did not use imputed genotypes or were restricted to GWAS-associated loci. In contrast, coding variants, which span 1% of the genome, explained only 8% of h^2_g (13.8× enrichment; $P=5\times10^{-4}$). We showed by extensive simulations that these estimates are robust to diverse genetic architectures, and substantially more accurate than estimates from GWAS that do not account for correlation between SNPs and functional classes. To investigate the potential role of rare coding variation, we extended these analyses to an independent set of 2,500 schizophrenia cases and 3,900 controls genotyped on both GWAS and exome chips, replicating the DHS enrichment but observing no significant contribution from rare coding SNPs. Using our estimates of functional heritability to inform fine-mapping analysis substantially reduced the number of SNPs needed for follow-up. Overall, our results robustly quantify the contribution of functional features to common diseases, and highlight the value of analyzing components of heritability to unravel the functional architecture of common disease.

Haplotypes explain additional heritability of complex traits. *G. Bhatia[1,2], A. Gusev[1,2], S.H. Lee[3,4], S. Ripke[5,6], E.A. Stahl[7], B.M. Neale[5,8], M.J. Daly[5,8], S.M. Purcell[6,7,9,10], N.R. Wray[3], N.A. Zaitlen[11], B. Pasaniuc[12], A.L. Price[1,2], Schizophrenia Working Group of the Psychiatric Genomics Consortium.* 1) Epidemiology, Harvard School of Public Health, Boston, MA; 2) Biostatistics, Harvard School of Public Health, Boston, MA; 3) Queensland Brain Institute, University of Queensland, Brisbane, Queensland, Australia; 4) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 6) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard University, Cambridge, Massachusetts, USA; 7) Division of Psychiatric Genomics, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; 8) Broad Institute of Harvard and MIT, Cambridge, MA 02142;; 9) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 10) Medical and Population Genetics Program, Broad Institute of MIT and Harvard, Cambridge, Massachusetts 02142, USA; 11) Department of Medicine, Lung Biology Center, University of California, San Francisco, San Francisco, California, USA; 12) Department of Pathology and Laboratory Medicine, Geffen School of Medicine at UCLA, Los Angeles, California, USA.

While genome-wide significant associations generally explain only a small proportion of the narrow-sense heritability of complex traits (h^2), recent work has shown that the heritability explained by all genotyped SNPs (h^2_g) explains more of h^2 (Yang et al. 2010). However, much of the heritability is still missing ($h^2_g < h^2$). For example, for schizophrenia, h^2 is estimated at 0.7-0.8 but h^2_g is estimated at 0.2-0.3 (Lee et al. 2012; all values on liability scale). Efforts at increasing coverage through imputation have yielded only small increases in the heritability explained, possibly due to the relatively poor imputation of low-frequency causal variants. We propose to estimate the heritability explained by a set of haplotypes constructed directly from the study sample (h^2_{haplo}). Our method constructs a set of haplotypes by extending shared segments subject to a 4-gamete test using data phased with the HAPI-UR software package (Williams et al. 2012). The haplotype values (0, 1 or 2 copies per individual) are then used to estimate genetic relationships between individuals. These relationships are used as the covariance structure in a linear mixed model, which is used to estimate the heritability explained by this set of haplotypes. Our simulations show that this approach can yield substantial gains in heritability explained relative to genotyped SNPs, and produces robust estimates. We applied our method to WTCCC2 data consisting of 9K multiple sclerosis cases and 5K controls, genotyped at 452K SNPs. We built 37M haploSNPs with MAF > 1%. The heritability explained by this set of haploSNPs was $h^2_{haplo} = 0.39$ (s.e. 0.02), substantially larger than $h^2_g = 0.26$ in the same data. We also applied our method to PGC2 data consisting of 10K schizophrenia cases and 10K controls of European ancestry, all of which were genotyped at the same set of 348K SNPs. We built 28M haploSNPs with MAF > 1%. The heritability explained by this set of haploSNPs was $h^2_{haplo} = 0.38$ (s.e. 0.02), significantly larger than $h^2_g = 0.33$ in the same data. Overall, our results suggest that haplotypes can explain substantially more heritability than genotyped or imputed SNPs. Additionally, haplotype based approaches can shed light on the genetic architecture of complex traits and informing strategies for disease mapping.

938M

Heritability Estimates and Genetic Association for 60+ Complex Traits in a Young Healthy Sibling Cohort. *Q. Ma[1], A.B. Ozel[1], D. Siemieniak[2], K.C. Desch[3], D. Ginsburg[1,2,3,4], J.Z. Li[1].* 1) Departments of Human Genetics, University of Michigan, Ann Arbor, MI 48109; 2) Howard Hughes Medical Institute, Ann Arbor, MI 48109; 3) Pediatrics and Communicable Disease, University of Michigan, Ann Arbor, MI 48109; 4) Internal Medicine, University of Michigan, Ann Arbor, MI 48109.

As genotyping becomes more efficient, sample recruitment and phenotyping remain a major limiting factor. In a GWAS of bleeding and blood clotting traits we sought to increase the utility of the cohort by collecting > 60 self-reported complex traits through web-based questionnaires. The cohort of 1,191 healthy young subjects consists of 509 sibships, 80% Europeans, and age of 14-35 yrs. The traits include 16 quantitative traits (e.g., weight, height, age of menarche, hematological measures RBC, HCT, MCV, MCH, MCHC, RDW, WBC, HGB, PLT, MPV), 21 ordinal traits (e.g., Smoking, BleedingTendency, SkinTags, Acne, TanningTendency, SkinColor, Freckles, DentalCaries, VisionCorrection, EatingSweets, EatingSaltyfood, Athleticability, Aphthousulcers), and 27 nominal traits (e.g., Immunization, ToothExtraction, EyeColor, HairColor, Hairline, EarLobeCreased, EarLobeAttachment, Dimples, Dyslexia, Migraines, Stuttering, Allergies, Flatfeet, Handedness, PhoticSneeze, BrainFreeze, InterlockingFingers, etc.). We used the known relatedness to estimate heritability using Merlin-regress and found that >1/2 of the traits have heritability > 40%. Since the samples have been genotyped over ~800K SNPs in the original GWAS we used SNP data to calculate the actual genetic relatedness, and estimated the variance explained by all the genotyped SNPs using GCTA. With all subjects, pedigree-based estimates were similar to SNP-based estimates; but the latter were often reduced when we select one subject from each sibship to analyze the unrelated subsets. For many traits we identified common variants of significant association. This study demonstrates the feasibility of simultaneous analysis of dozens of traits via web-based profiling.

939T

Additive and epistatic effects of enhancer variants at GWAS risk loci. *O. Corradin[1], P.C. Scacheri[1,2].* 1) Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH; 2) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH.

SNPs associated with common disease through Genome Wide Association Studies (GWAS) often lie in gene enhancer elements located distal to protein-coding genes. The enhancer-SNPs likely confer disease risk by impacting gene expression, but quantifying their effects on target gene expression has proven challenging. Here, through integrative analyses of haplotype block maps, epigenomic landscapes, and GWAS data from six different autoimmune disorders, we show that 94% of instances in which a GWAS SNP lies in an enhancer predicted to regulate a given gene, there is at least one additional SNP that lies in a different enhancer predicted to target the same gene and is located distal to the LD block from which the GWAS-association arose. Using RNA-seq data matched with genotype data from 400 individuals, we show that the distal enhancer variants act additively and epistatically with enhancer-SNPs within the GWAS-associated LD block to affect expression of the target gene. Thus for these loci, the transcriptional effect is dictated by SNPs located within and outside of the GWAS-association signal. Additionally, many of the outside variants disrupt transcription factor binding sites and affect chromatin accessibility. These results have important implications for GWAS and eQTL studies as we demonstrate that for some loci, the transcriptional effect is only apparent when the additive and epistatic effects of enhancer variants are considered. Given that outside variants can boost the transcriptional effect but are often not considered, we propose that the effects of GWAS SNPs are often underestimated, which could explain some of the missing heritability for these disorders. We propose utilizing the chromatin structure to identify epistatic interactions between GWAS SNPs, to interpret the effect of common disease alleles on gene expression, and to help refine the relative risk of enhancer variants on disease susceptibility.

940S

The genetics of exceptional human longevity: new clues from big data on disease. *K. Fortney[1], P. Sebastiani[2], T.T. Perls[3], S.K. Kim[1].* 1) Developmental Biology, Stanford University, Stanford, CA; 2) Biostatistics, Boston University School of Public Health, Boston, MA; 3) Medicine, Boston University School of Medicine, Boston, MA.

In order to begin to decipher the genetic basis of human longevity, we are taking a big data approach to scour large genome-wide association (GWA) datasets on age-related disease to narrow the search for new SNPs associated with longevity. Rather than search for longevity loci directly in centenarian GWAS, we can leverage data from many age-related disease GWAS (often with > 10,000 cases each) by assuming that individuals with extreme longevity are likely to be depleted of polymorphisms associated with disease, such as Alzheimer disease, type 2 diabetes or cardiovascular disease.

So far, we have acquired data from eight large disease GWAS meta-analyses: Cardiovascular disease, diabetes, late-onset Alzheimer disease, age-related macular degeneration, chronic kidney disease, lung cancer, pancreatic cancer, and rheumatoid arthritis. In total, this preliminary dataset contains > 250,000 SNPs for > 150,000 cases of 8 diseases. We combined these data with the results of a GWAS on exceptional longevity that included 801 subjects enrolled in the New England Centenarian Study (Sebastiani et al. 2012). We applied a new statistical method to identify variants that are enriched in people with disease but depleted in centenarians. In this approach, a strong association signal in disease can boost a weak association for longevity to statistical significance. Our approach is potentially a powerful new method to identify longevity loci. We will validate all the candidate SNPs that we identify in independent cohorts of centenarians, to test whether they are robustly associated with human longevity.

941M

A meta-analysis of genome-wide association scans for nevus count reveals PPARGC1B as affecting both moliness and melanoma risk. *N.G. Martin[1], D.L. Duffy[1], G. Zhu[1], G.W. Montgomery[1], N.K. Hayward[1], M. Falchi[2], P. Hysi[2], V. Bataille[2], T.D. Spector[2], G.C. Smith[3], D.M. Evans[3], H. Nan[4], J. Han[4], S. Chanock[4], D. Hunter[4], L. Jacobs[5], T.E. Nijsten[5], F. Liu[5], M.H. Kayser[5].* 1) Gen Epidemiology, Queensland Inst Med Res, Brisbane, QLD, Queensland, Australia; 2) Dept of Twin Research & Genetic Epidemiology, St Thomas Hospital Campus, Kings College, London, SE1 7EH, UK; 3) Department of Social Medicine, University of Bristol, Bristol BS82PS, UK; 4) Channing Laboratory, Harvard Medical School, Boston, MA 02115, USA; 5) Erasmus MC, University Medical Centre, Rotterdam, The Netherlands.

The main clinical interest in total number of acquired melanocytic nevus on the skin is its strong correlation with melanoma risk. We have previously described genome-wide association scans (GWAS) in Australian and British samples that identified loci influencing both nevus count and melanoma. Here we report a meta-analysis of five nevus GWAS from Australia, the Netherlands, United Kingdom (two studies), and the United States, comprising a total of 23,371 phenotyped individuals. We confirm known loci including MTAP, PLA2G6, IRF4 and ASIP and refine the location of the causal variants. Several new regions exhibit suggestive evidence ($P \sim 10^{-6}$-10^{-7}). One notable SNP, rs251464, is in the PPARGC1B gene, previously shown to modify tanning ability via a regulatory effect on MITF, the master melanocyte regulatory gene [Shoag et al Mol Cell. 2013, 49:145-57]. Combining the results for this SNP ($P=8\times10^{-6}$) with results from a melanoma case-control analysis ($P=4.6\times10^{-4}$) reaches a genome-wide significant level and direction of effect was consistent in both phenotypes, with the C allele decreasing both melanoma risk and mole count. Another SNP in PPARGC1B, rs32579, previously flagged as affecting tanning, was shown to not affect nevus count (P=0.19). We now plan to meta-analyse these results with those from a parallel GWAS meta-analysis of melanoma to achieve even greater resolving power for variants influencing early stage oncogenesis.

942T

Identification of 4 novel susceptibility *loci* for intracranial aneurysms in Portuguese using a pooling-based GWAS. *P.CS. Abrantes[1, 2], M.M. Santos[3], J.M. Xavier[1, 2], I. Sousa[1, 2], V. Francisco[1, 2], T. Krug[1, 2], J. Sobral[1, 2], M. Matos[1, 2], A. Jacinto[1, 2, 4], D. Coiteiro[3], S.A. Oliveira[1, 2].* 1) Instituto Medicina Molecular, Faculdade de Medicina, Universidade de Lisboa, 1649-028 Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, 2780-156 Oeiras, Portugal; 3) Department of Neurosurgery, Hospital de Santa Maria, Lisboa, Portugal; 4) Centro de Estudos de Doenças Crónicas (CEDOC), Faculdade de Ciências Médicas, Universidade Nova de Lisboa, 1169-056 Lisboa, Portugal.

Subarachnoid hemorrhage is a life-threatening event that most frequently leads to severe disability and death. Its most frequent cause is the rupture of an intracranial aneurysm (IA). Several studies have consistently demonstrated a genetic component to the risk for IA but until now, its exact etiology remains uncertain.

To identify new susceptibility *loci* for IA, we performed a genome-wide association study (GWAS) using DNA pooling approach on a Portuguese dataset. Pools of 100 IA cases and 92 age- and gender-matched controls were allelotyped in triplicate using the Affymetrix Human SNP Array 6.0. Top SNPs with |RAS diff| ≥13.0% were selected for individual genotyping in the same GWAS dataset. Ninety nine of the 101 SNPs successfully genotyped were technically validated (P<0.05). Replication of validated SNPs was conducted in an independent Portuguese dataset of 100 IA cases and 407 controls.

We identified 4 variants (rs4667622, rs6599001, rs3932338 and rs10943471) associated with IA in both the discovery and replication datasets (individually and in combination). SNPs rs4667622 (*P*combined=4.00E-05, OR_G[95% CI]=1.75[1.33-2.33]) and rs6599001 (*P*combined=2.20E-04, OR_C[95% CI]=2.00[1.39-2.88]) were the most significant. rs4667622 is located on chromosome 2q31.1 within the regulatory region of the myosin IIIB gene (*MYO3B*) and rs6599001 maps to chromosome 3p22.2 upstream of the WD repeat domain 48 gene (*WDR48*). The third most significant genetic association was found with rs10943471 (*P*combined=3.20E-04, OR_G[95% CI]=1.81[1.31-2.51]) which is located on chromosome 6q14.1 in an intergenic region upstream of *HTR1B* (5-hydroxytryptamine (serotonin) receptor 1B). The rs3932338 SNP (*P*combined=1.29E-03, OR_A[95% CI]= 1.59[1.19-2.08]) is located on chromosome 5p14.2 in a gene desert. Additionally, we replicated the previously described association with IA of rs1333040 at the 9p21.3 genomic region (*P*combined=1.93E-02, OR_T[95% CI]=1.41[1.05-1.89]), thus validating our dataset.

Our novel findings in the Portuguese population must be replicated in further datasets to establish their pathogenic role in IA formation.

943S

A GWAS of Risk Genes for Birth of a Child With Down Syndrome. *E. Feingold[1], Z. Zeng[1], E.G. Allen[2], D. Ramachandran[2], M.E. Zwick[2], S.L. Sherman[2].* 1) Dept Human Gen, Univ Pittsburgh, Pittsburgh, PA; 2) Dept Human Gen, Emory University, Atlanta, GA.

We have conducted the first GWAS for risk of having a child with Down syndrome (DS) in approximately 700 mothers of children with maternally-derived free trisomy 21. Mothers, fathers, and children were genotyped at the Center for Inherited Disease Research (CIDR) on the Illumina OmniExpress. Genotypes for chromosome 21 in children were called using methods we previously developed. Genotypes for parents and child were then used to establish parent of origin, stage (meiosis I or meiosis II) and meiotic recombination patterns for each child. We used two different designs for the GWAS. The first uses the fathers as controls. In the second, we take advantage of the fact that the etiologies of meiosis I trisomy 21 and meiosis II trisomy 21 appear to be quite different, and perform a GWAS of mothers of meiosis I cases vs. mothers of meiosis II cases. This approach cannot find variants that are common risk factors for both meiosis I and meiosis II errors, but is a well-controlled design for finding variants that are unique to one or the other. Results include genes that are known to affect meiotic recombination, which is not unexpected since the link between altered recombination and nondisjunction is well established both in humans and experimental organisms.

944M

Genome-wide Association Study, Meta-Analysis and Linkage Study of Gamma-Prime Fibrinogen Plasma Levels in a Healthy Young Cohort. *A. Ozel[1], K. Desch[2], D. Siemieniak[3], D. Ginsburg[1,3], J.Z. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) HHMI, University of Michigan, Ann Arbor, MI.

Gamma-prime fibrinogen (GPF) is one of the isoforms of fibrinogen and a component of the blood-clotting complex, making up ~10% of the total fibrinogen levels in blood. Its role in cardiovascular risk prediction has been recently proposed. Plasma levels of fibrinogen are highly variable among healthy people, with ~50% of their variance attributable to inherited factors. We performed genome-wide association studies in a healthy sibling cohort of 1,152 subjects, focusing on the European subset (n = 940), and a second healthy cohort of 2,304 individuals (Desch et al., 2012). Plasma GPF levels were determined using a monoclonal antibody specific to this isoform of fibrinogen. Heritability (h^2) was estimated as 61.6% (using *Merlin-Regress*) and was consistent with results from *GCTA* (63.3%) and intra-class correlation (65.8%). Common variants at or near the fibrinogen gene cluster on chromosome 4 showed significant association with GPF plasma levels (P < 5.0E-8), explaining 22.6% of GPF variance. The top SNP was rs7654093(T) (MAF = 0.23, P = 4.9E-72) at ~19 kb upstream of the *FGG* (Fibrinogen Gamma Chain). Suggestive evidence of association was found at 8p23.2 (lead SNP: rs70051128(T) with P = 7.9E-7 near the *MCPH1* gene). Meta-analysis of the two cohorts confirmed the signals on chromosome 4, with best p-value of 4.9E-199 and the direction of the effects of the top SNPs were in strong agreement. Linkage analysis using the sibling subset of the two cohorts identified significant signals at a ~40 cM interval on 4q28.3-q34.2 (LOD=5.25, permutation P < 0.05) including the fibrinogen gene cluster, and on a novel locus: a ~37 cM interval on 8p23.3-p12 (LOD=2.00, permutation P = 0.03). The top peak in the linkage analysis explained 33.9% of the variation in the GPF levels. To our knowledge, this is the first genome-wide study investigating gamma prime fibrinogen level variation in a healthy population. These results provide new insight into the regulation of hemostasis, may identify novel genetic modifiers of bleeding and thrombosis risk, and suggest that linkage analysis of blood clotting traits may reveal novel loci supported by association studies.

945T

SORBS1 gene, a new candidate for diabetic kidney disease: results from a multi-stage genome wide association study. *M. Germain[1,2,3], M. Pelozzeli[4], N. Sandholm[5,6,7], AJ. MacKnight[8], K. In order to identify novel susceptibility genes for diabetic nephropathy (DN), we performed a genome-wide association study using 1,000 Genomes-based imputation in individuals with type 1 diabetes. The discovery cohort comprised 683 proteinuric patients with or without renal failure (cases) and 779 patients with diabetes for more than 15 years duration and no evidence of renal disease (controls). None of the single nucleotide polymorphisms (SNPs) tested reached genome-wide statistical significance. The top forty-six SNPs with p-value < 10^{-5} were brought for initial replication in 820 cases and 885 controls part of the US GokinD study. Two SNPs in strong linkage disequilibrium with each other, located in the SORBS1 gene, were consistently and significantly associated with DN ($p = 7.87\ 10^{-6}$ in the discovery, $p = 1.32\ 10^{-4}$ in the initial replication). In the combined samples, the minor allele of the candidate SNP was less frequent in cases than in controls (37% vs 45%) and associated with a decreased risk for DN of OR = 0.74 [0.67 - 0.82]. However, this association was not observed in a second stage DN cohorts (FINNDIANE and UK-ROI) composed of 2,142 cases and 2,494 controls (p = 0.295). We ultimately interrogated transcriptomic analysis of human kidney tissue from type 2 diabetes kidney disease patients and non-diabetic controls. In micro-dissected glomerular (n=17) and tubule (n= 39) samples, SORBS1 showed significant over-expression in tubule samples in diabetic kidney disease versus non-diabetic controls. In addition, SORBS1 expression was significantly and inversely correlated with estimated glomerular filtration rate (eGFR) reflecting kidney function. Altogether, these data suggest that SORBS1 might be a new gene involved in DN.

946S

Polymorphism upstream of cryopyrin gene (*NLRP3*) is associated with severe retinopathy in type 1 diabetes. *S. Hosseini[1], K. Howard[2], L. Sun[3], A.P. Boright[4], D.A. Tregouet[5], N. Sandholm[6], K. Hietala[6], I. Toppila[6], M.S. Lajer[7], M. Marre[8], P. Rossing[7], P.H. Groop[6], A.J. Canty[9], S. Hadjadj[10], B.E. Klein[2], S.B. Bull[3,11], R. Klein[2], A.D. Paterson[1,3], the DCCT/EDIC Research Group.* 1) Genetics & Genomic Biology Program, Hospital for Sick Children Research Institute, Toronto, ON, Canada; 2) Dept of Ophthalmology & Visual Sciences, Univ Wisconsin, Madison, WI, USA; 3) Dalla Lana School of Public Health, Univ Toronto, Toronto, Canada; 4) Dept of Medicine, Univ Toronto and LMC Diabetes & Endocrinology, Toronto, Canada; 5) Sorbonne Universités, UPMC Univ Paris 06, UMR_S 1166 and INSERM, UMR_S 1166 and ICAN Institute for Cardiometabolism and Nutrition, F-75013, Paris, France; 6) Folkhälsan Inst of Genetics, Univ of Helsinki, Helsinki, Finland; 7) Steno Diabetes Center, Gentofte, Denmark; 8) INSERM U695 & Dept of Endocrinology, Bichat-Claude Bernard Univ Hosp, Paris, France; 9) Dept of Mathematics & Statistics, McMaster Univ, Hamilton, Canada; 10) Dept of Endocrinology & Diabetology, Univ of Poitiers, Poitiers, France; 11) Lunenfeld-Tanenbaum Research Institute of Mount Sinai Hospital, Toronto, Canada.

Background: Diabetic retinopathy (DR) is a leading cause of blindness worldwide. Despite strong effects of diabetes duration and glycemic control, several lines of evidence suggest a genetic contribution to the risk, especially for severe DR (SDR defined as severe non-proliferative DR or worse). However, no genetic variant has shown convincing association with DR in genome-wide association studies (GWAS). **Purpose:** To identify common polymorphisms associated with SDR **Methods:** White subjects with type 1 diabetes participating in the Epidemiology of Diabetes Interventions and Complications (EDIC, n=1304) and Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR, n=603) were genotyped by Illumina BeadChip assays. Genotypes of ~2.5M autosomal SNPs from phase 2 and 3 of HapMap were imputed in both studies. SDR status was defined based on fundus photographs at the most recent follow-up visit [level 53/<53 or worse on ETDRS scale or panretinal laser photocoagulation treatment]. Multivariable association analysis of SDR with additive genotype by logistic regression accounted for covariates, including glycemia (measured by A1C) and diabetes duration. GWAS were first performed separately in EDIC divided into 3 subgroups (primary cohort, secondary cohort by treatment group - conventional or intensive) and WESDR; results were combined in a fixed effects meta-analysis. Top association signals (39 loci) were evaluated for replication in three independent white T1D cohorts: Genesis-GeneDiab (n=502), Steno (n=936), FinnDiane (n=2194). **Results:** Among the top hits short of genome-wide significance, an intergenic SNP 27 kb upstream of NLRP3 associated with SDR (P=8E-6) was replicated (P<0.001 accounting for multiple testing). The index SNP at this locus showed similar direction of effect in all the examined populations. In the combined meta-analysis of the discovery and replication studies, each copy of the risk allele increased the odds of SDR by 25% (OR=1.26, 95%CI: 1.15-1.38, P=6E-7). NLRP3 is a member of the inflammasome complex which serves as a platform for the activation of caspase-1 in immune response. SNPs within NLRP3 (not in strong LD with our index) have been associated with Crohn's disease in candidate gene association studies and with C-reactive protein and fibrinogen, two inflammatory markers, in GWAS. **Conclusion:** NLRP3 is the first replicated locus with consistently strong evidence for association with SDR in a meta-GWAS.

947M

Genome-wide meta-analysis identifies novel variants associated with fasting plasma glucose in East Asians. *J. Hwang[1], Y. Cho[2], B. Han[1], B. Kim[1].* 1) KNIH, Osong, South Korea; 2) Department of Biomedical Science, Hallym University, Chuncheon, Korea.

Fasting plasma glucose (FPG) has been recognized as an important indicator for the overall glycemic state preceding the onset of metabolic diseases. Most genome-wide association loci for FPG so far been identified were derived from populations with European ancestry with a few exceptions. To extend a thorough catalog for FPG loci, we conducted meta-analyses of 13 genome-wide association studies in up to 24,740 non-diabetic subjects with East Asian ancestry. Follow-up replication analyses in up to additional 21,345 participants identified three new FPG loci reaching genome-wide significance in or near PDK1-RAPGEF4, KANK1 and IGF1R. Our results could provide additional insight into the genetic variation implicated in fasting glucose regulation.

948T

A Genome-wide Association Study of Apnea-Hypopnea Index in Children with Obstructive Breathing. *r. pellegrino[1,2], e. byrne[1], l. brooks[3], a. pack[2], h. hakonarson[1].* 1) Genetics, CHOP, Philadelphia, PA; 2) Center for Sleep and Circadian Neurobiology, Upenn, Philadelphia, PA; 3) Pulmonary, CHOP, Philadelphia, PA.

Obstructive sleep apnea syndrome (OSAS) is a complex sleep disorder that imposes a large burden on our society in terms of morbidity, quality of life, and healthcare costs. Childhood OSAS is characterized by habitual snoring, disturbed sleep and problems with daytime neurobehavioral functioning. OSAS appears to result from diverse gene-gene interactions and association with environment changes. There have been no published GWAS in children for OSAS. The identification of genetic variants associated with increased risk for OSAS could potentially translate into earlier recognition and treatment with reduced morbidity, and may also serve to identify potential targets for novel therapies. Here, we present a genome-wide association study of the Apnea-Hypopnea Index measured in a cohort of children referred to the sleep clinic at the Children's Hospital of Philadelphia for suspected obstructive breathing. Our aim was to identify common genetic variants that increase OSAS severity in children with sleep difficulties. A total of 2,473 children participated in the sleep study. The primary reason for referral was for suspected OSA and they had a Polysomnography (PSG) exam performed. 1,782 children in the sample were given a potential diagnosis of OSA prior to the sleep study. Also, a total of 1201 children were listed as having at least one mental disorder. All participants were genotyped using either the Illumina HumanHap550 or 610 Quad arrays. The association between the natural log of the Apnea-Hypopnea Index (AHI) and SNP was assessed using a linear model in PLINK. Principal components for each individual were calculated using GCTA, and the first 5 PCs were fitted as covariates in the analysis along with age, gender, BMI and total sleep recording time. No SNPs in the study passed the threshold for genome-wide significance ($p < 5 \times 10\text{-}8$), either within the ethnic groups separately, or in the meta-analysis of both groups. However, many of the marginally significant SNPs are located in or near genes that have shown evidence of association with related traits such as waist circumference and C-reactive protein, suggesting they may become useful biomarkers as we grow our sample size.

949S

The Association between Genetic Markers for Type 2 Diabetes and Carnitines: A Replication of Adult Findings in a Neonatal Population. *CJ. Smith[1], SL. Berberich[2], JC. Murray[3], KK. Ryckman[1].* 1) Department of Epidemiology, University of Iowa, Iowa City, IA; 2) State Hygienic Laboratory, University of Iowa, Iowa City, IA; 3) Department of Pediatrics, University of Iowa, Iowa City, IA.

Background: Utilizing metabolomic technologies, such as tandem mass spectrometry, is of growing interest for understanding the etiology of complex diseases, such as Type 2 Diabetes. Recent genome-wide association studies (GWAS) of the adult human metabolome have identified genetic variants associated with biomarkers that are important in Type 2 Diabetes (T2DM) etiology; however, no studies to our knowledge have examined the relationship between these disease-associated genetic markers at birth and the implications these associations would have for earlier disease prediction. Objective: We examined single nucleotide polymorphisms (SNPs) identified by GWAS to be associated with Type 2 Diabetes, in addition to genes associated with fatty acid metabolism, and their associations with neonatal metabolite levels. **Methods:** Our analysis included genetic data and analyte measurements for 832 singleton Iowa neonates. We examined analytes measured by tandem mass spectrometry as part of routine newborn screening. Sixty-eight SNPs in forty-six genes were genotyped using the Fluidigm® SNP Genotyping platform. We analyzed each SNP-analyte level for association using Kruskal-Wallis tests. **Results:** Seven SNP-analyte associations were significant by Bonferroni correction (P value <6.5×10-5). The CC genotype of rs2014355 in ACADS was significantly associated with higher levels of C4, C4/C2, and C4/C3, with p-values of 4.63E-34, 2.99E-34, and 7.96E-30, respectively. The CC genotype of rs211718 in ACADM was significantly associated with higher levels of C6, C8 and C10 and lower levels of C5DC/C8, with p-values of 2.26E-19, 8.38E-14, 2.42E-08, and 2.86E-15, respectively. **Conclusions:** The C allele of rs2014355 has previously been shown to be associated with decreased insulin sensitivity, and higher C4 levels have been observed in individuals with T2DM compared to those without the disease. The C allele of rs211718 has previously been shown to be associated with increased C10 in adults, and C6 and C8 have been found to be significantly elevated in subjects with T2DM. We have replicated adult SNP-analyte associations in a neonatal population. Capitalizing on the potential of neonatal genetic and metabolic profiles to predict risk for later life chronic conditions will be of paramount importance for personalized medicine, and may provide insight into the pathogenesis of complex metabolic disorders.

950M

A genome-wide association analysis of scarring trachoma in rural Gambia. *C.S. Franklin[1], C.h Roberts[2], S.E. Burr[3], F. Payne[1], W. Bottomley[1], S. Molina-Gonzalez[2], A. Natividad[2], H. Joof[3], P. Makalo[3], N. Faal[3], I. Sarr[3], M.J. Burton[2], T. Clark[2], K. Rockett[4], D. Kwiatkowski[1], A. Sillah[5], R.L. Bailey[2], D.C.W. Mabey[2], I. Barroso[1], M.J. Holland[2].* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) London School of Hygiene and Tropical Medicine, Keppel Street, Bloomsbury, London, United Kingdom; 3) Medical Research Council Unit, Atlantic Blvd, Serrekunda, Gambia; 4) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, United Kingdom; 5) NEHP, Ministry of Health, The Gambia.

Trachoma is the most common infectious cause of blindness worldwide and is a neglected tropical disease that is endemic across much of sub-Saharan Africa. The active form of disease is a severe conjunctivitis that is caused by infection with Chlamydia trachomatis (Ct). The host response to repeated cycles of infection can lead to the formation of trachomatous scarring (TS) on the upper tarsal surface of the eyelid, causing it to deform. This can progress to trachomatous trichiasis (TT), where the eyelashes turn inwards, scratch the cornea resulting in opacity, visual impairment and blindness. Within endemic populations a variable fraction of persons develop TS or TT. Pathology in trachoma appears to be largely due to the host immune response, which suggests an important role for host diversity. Heritability of the immune response to Ct infection has been estimated at 0.39 through twin studies. Environmental risk factors for (TS) are significant and well characterized but the familial clustering of disease also suggests that there is a significant genetic component. We have conducted the first genome-wide association study of TS, based on a Gambian sample of 1090 TS cases and 1531 controls. Genotyping was performed using the Illumina 2.5M chip with subsequent imputation against the 1000 genomes global reference panel. Mixed model association was performed using EMMAX and GEMMA to account for population stratification and relatedness of samples. Although none of the variants reached the genome-wide significance threshold of $p<2.5\times10\text{-}8$, we found several suggestive association signals located in interesting candidate genes, which mapped to pathways involved in the cell cycle, microtubule organisation, cell-cell interactions and the immune response. Our strongest individual association is located within the PREX2 gene, which may have a role in mediating chlamydial cell entry to the host cell. Replication of these putative signals will be attempted in an on-going collection of 2,000 cases and 2,000 matched controls from a Trachoma endemic region in Tanzania.

951T

Genetic variation predicts serum lycopene concentrations in multi-ethnic population of postmenopausal women. *N. Zubair[1], U. Peters[1], C. Kooperberg[1], D. Chongzhi[1], L. Jingmin[1], C. Hutter[2], M. Neuhouser[1], Women's Health Initiative (WHI).* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Background: While the human function of lycopene remains undetermined, this nutrient has been both positively and inversely associated with the risk of several chronic diseases. The inconsistencies in lycopene-disease association studies may stem from a lack of knowledge about the genetic variation in the synthesis, metabolism, and deposition of transport and binding proteins, which potentially influence serum lycopene concentrations. Objective: Here we examined the association between variation across the genome and serum concentrations of lycopene in a multi-ethnic population. Design: Participants included African (n= 914), Hispanic (n= 464), and European American (n=1,203) postmenopausal women from the Women's Health Initiative (WHI). We analyzed ~7 million single nucleotide polymorphisms (SNPs). Linear regression models were used to assess associations between each SNP and serum concentrations (log-transformed, continuous) of lycopene; we adjusted for age, BMI, and population substructure. Models were run separately by ethnicity and then combined in a trans-ethnic fixed effects meta-analysis. Results: In the meta-analysis, the SCARB1 gene, which encodes for a plasma membrane receptor for high-density lipoprotein cholesterol, significantly associated with lycopene concentrations ($rs1672879$, P-meta $< 2.68 \times 10\text{-}9$). Here each additional G allele resulted in a 12% decrease in lycopene levels for African Americans, 20% decrease for Hispanic Americans, and a 9% decrease for European Americans. In addition, two regions significantly associated with serum lycopene levels in African Americans: the SLIT3 gene, which serves as a molecular guidance cue in cellular migration, and the DHRS2 gene, which codes for an oxidoreductase that mitigates the breakdown of steroids. Conclusions: We found three novel loci associated with serum lycopene concentrations, two of which were specific to African Americans. Future functional studies looking at these specific genes may help provide insight into the metabolism and underlying function of lycopene in humans, which may help further elucidate lycopene's influence on disease risk and health.

952S

Systematic genome-wide microbiome association analysis in the Northern-German population identifies genetic variation that impacts microbial diversity in the gut. *A. Franke[1], J. Skiecieviciene[1], J. Wang[2], P. Rausch[2], U. Noethlings[3], W. Lieb[4], T.H. Karlsen[5], J. Baines[2], The PopGen Microbiome Study Group.* 1) Inst Clinical Molec Biol, University of Kiel, Kiel, Germany; 2) Max-Planck Institute of Evolutionary Biology, Ploen, Germany; 3) Institut für Ernährungs- und Lebensmittelwissenschaften (IEL), Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany; 4) Institute of Epidemiology, The PopGen Biobank, University of Kiel, Kiel, Germany; 5) NoPSC Study Group, Rikshospitalet, University of Oslo, Oslo, Norway.

The bacteria of the gut are a community that has co-evolved with the host and confers beneficial effects on human physiology and nutrition, and is crucial for human health. Increasing evidence suggests that the host's genetic variation might influence bacterial composition in addition to other direct (secretions of bile and defensins, control of gut motility etc.) or indirect (food and lifestyle) factors. An effect of host genotype on bacterial composition has been demonstrated by our group and others for single genes (MYD88, NOD2, TLRs, immunoglobin A (IgA)), and the human leukocyte antigen (HLA) region. In order to systematically evaluate the relationship between variation in the human genome to variation in the human microbiome, large-scale GWmAS (genome-wide microbial association studies) studies of population-representative cohorts are needed. Here, we performed a GWmAS of a cross-sectional, population-representative study cohort of Northern Germany (n=757). Ultra-dense SNP genotype information, available from different genotyping platforms, detailed phenotypic and dietary data, 16S rDNA microbiome data (V1-V2 region, 454 Roche platform) were generated for this Northern German cohort. Systematic association studies were performed for alpha diversity, beta diversity and core measurable microbiome measures. Likely due to the lack of statistical power and high inter-individual variability in the microbiome composition none of the detected associations bypassed traditional genome-wide significance (P-value smaller than 5×10E-8). In order to validated the best findings of the screening study, an independent study cohort was recruited from the same geographic region within Northern Germany (n=866). Again, dense SNP genotype data, phenotypic, dietary, and 16S rDNA microbiome data (again V1-V2 region, MiSeq platform; different DNA extraction method), analogous to the discovery cohort, were collected for the replication cohort. Our benchmarking study revealed that only around 6% variability was introduced by the sequencing method. We detected that genetic variation of the host contributes more than 4% to the bacterial community structure. Moreover, we managed to replicate several genetic loci that are implicated in determining microbial diversity.

953M

Identification of Susceptibility Loci for Crohn's Disease in Koreans through Immunochip. *M. Hong[1], H. Choi[1], W.J. Yun[1], J. Baek[1], T. Haritunians[2], S.H. Park[3], B.D. Ye[3], J. Liu[4], D.P.B. McGovern[2], S. Yang[3], K. Song[1].* 1) Dept. Biochemistry and Molecular Biology, Ulsan university College of Medicine, Seoul, Seoul, South Korea; 2) The F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute; Cedars-Sinai Medical Center, Los Angeles, USA; 3) Dept Internal Medicine, Univ Ulsan Colleage of Medicine, Seoul, Korea; 4) Genome Institute of Singapore, Singapore.

We have performed an immunochip study in 1,670 Korean patients with Crohn's disease and 1,438 controls. We confirmed six previously reported loci in Caucasians: GPR35 at 2q37(rs3749172; P = 5.30 x 10-11, OR = 1.45), ZNF365 at 10q21(rs224143; P = 2.20 x 10-9, OR = 1.38), ZMIZ1 at 10q22 (rs1250569; P = 3.05 x 10-7, OR = 1.30), NKX2-3 at 10q24 (rs4409764; P = 7.93 x 10-8, OR = 1.32), PTPN2 at 18p11(rs514000; P = 9.00 x 10-8, OR = 1.33), and USP25 at 21q11(rs2823256; P = 2.49 x 10-7, OR = 1.35), bringing the number of known CD loci (including HLA) in Koreans to 15. The additional six loci increased the total genetic variance for CD risk from 5.31% to 7.27 % in Koreans. Our study provides new biological insight to CD and supports the complementary value of genetic studies in different populations.

954T

Pathway Based Genome-Wide Association Studies Reveal the Association between Growth Factor Activity and Inflammatory Bowel Disease. *C. Kim, J. Li, Z. Wei, C. Cardinale, R. Baldassano, H. Hakonarson, International IBD Genetics Consortium (IIBDGC).* Children's Hospital of Philadelphia The Center for Applied Genomics 3615 Civic Center Blvd Abramson Research Center 1215A Philadelphia PA 19104.

The inflammatory bowel diseases (IBD) known as Crohn's disease (CD) and ulcerative colitis (UC) are related autoimmune conditions with a complex etiology comprised of genetic and environmental factors. Genetic studies have revealed 163 susceptibility genes for IBD, but still do not fully account for the genetic heritability of the disease. We exploited the largest CD data set (20,000 cases + 28,000 controls) and UC data set (17,000 cases + 33,500 controls) to date. We employed pathway-based approaches to identify genes that cooperatively make contributions to the genetic etiology of CD in a meta-analysis of 5 CD cohorts of European ancestry. In addition to the multiple immune-related pathways that have been implicated in the genetic etiology of IBD before, we found significant associations involving genes in growth factor signaling for CD. This result was replicated in an independent cohort genotyped on the ImmunoChip and in another pediatric cohort of European ancestry. This association with growth factor activity is not unique to CD. We found a similar significant association with UC in a meta-analysis of different cohorts. Our findings suggest that genes involved in growth factor signaling pathways may make joint contributions to the etiology of CD and UC, providing novel insight into the genetic mechanisms of these diseases.

955S

Whole-genome imputation identified 3 suggestive loci for inflammatory bowel disease in a Japanese population. *K. Yamazaki[1], Y. Fuyuno[1,2], A. Takahashi[3], T. Kawaguchi[4], M. Takazoe[4], M. Esaki[2], S. Nakamura[2], T. Matsui[5], T. Tanaka[6], M. Motoya[6], Y. Suzuki[7], Y. Kiyohara[8], T. Kitazono[2], Y. Nakamura[9], M. Kubo[1].* 1) Laboratory for Genotyping Development, Center for Integrative Medical Science, RIKEN, Yokohama, Japan; 2) Department of Medicine and Clinical Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 3) Laboratory for Statistical Analysis, Center for Integrative Medical Science, RIKEN, Yokohama, Japan; 4) Department of Medicine, Division of Gastroenterology, Social Insurance Chuo General Hospital, Tokyo, Japan; 5) Department of Gastroenterology, Fukuoka University Chikushi Hospital, Fukuoka, Japan; 6) Department of Gastroenterology, Sapporo Kosei Hospital, Sapporo, Japan; 7) Department of Internal Medicine, Faculty of Medicine, Toho University, Chiba, Japan; 8) Department of Environmental Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 9) Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Crohn's disease (CD) and ulcerative colitis (UC) are the two major forms of inflammatory bowel disease (IBD), induced by multiple factors. Meta-analysis of genome-wide association studies (GWAS) identified 163 susceptibility loci for IBD from European descents. However, there was fewer reports of IBD GWAS from other ethnic groups. Recently, the human genetic resource has been growing over and it can make to impute missing genotypes. Therefore, we performed three GWAS (CD, UC and IBD) using imputation in Japanese population. We imputed genotypes of GWAS subjects which was a total of 376 CD cases, 376 UC cases and 3397 controls as previously reported. After applying stringent quality control for samples and SNPs, we performed the association analyses of 4,062,308 SNPs in CD GWAS, 4,059,167 SNPs in UC GWAS and 4,077,852 SNPs in IBD GWAS with accuracy (Rsq) > 0.9 and MAF > 0.05 of both cases and controls. However, we could not find significant association in each GWAS except for 2 reported loci (*TNFSF15* and MHC region). To identify new susceptibility loci, we performed the replication studies with independent cases and controls. We selected 1,605 SNPs (596 CD specific, 606 UC specific and 403 IBD shared) with P values < 5×10^{-5} after excluding SNPs located in previously reported loci. Among them, we picked up 137 tagging SNPs (53 SNPs as CD specific, 47 SNPs as UC specific and 37 SNPs as IBD shared) and genotyped using 948 CD patients, 361 UC patients and 4,161 controls. By combined analysis, we identified 3 suggestive loci with P value less than 1×10^{-6}. The two candidate loci as CD specific were in *RUNX3* on chromosome 1p36 (rs876109; $P = 4.01 \times 10\text{-}7$, odds ratio (OR) = 0.81) and on chromosome 11q21 (rs4435033; $P = 4.55 \times 10^{-7}$, OR = 1.37). The third locus was in *PARD6G* on 18q23 (rs4798947; $P = 5.39 \times 10^{-7}$, OR = 1.51) as UC specific. Though there was no suggestive locus shared IBD, the strongest association was shown in *TINK* on chromosome 3q26.2 (rs952209; $P = 7.29 \times 10^{-6}$, OR = 1.18). We suggested 2 candidate loci for CD and 1 candidate locus for UC in Japanese population. Further studies will be required what these loci play role in the pathogenesis of IBD.

Genome-wide and exome chip study of subcutaneous and visceral adipose tissue reveals novel gender-specific adiposity loci in Hispanic Americans: The Insulin Resistance Atherosclerosis Family Study (IRASFS). *C. Gao[1,2,3], J. Ziegler[3,4], K.D. Taylor[5], J.M. Norris[6], Y.D.I. Chen[5], J.I. Rotter[5], L.E. Wagenknecht[7], C.D. Langefeld[3,4], N.D. Palmer[2,3,8,9].* 1) Program of Molecular Genetics and Genomics; Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research; Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Public Health Genomics; Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biostatistical Sciences; Wake Forest School of Medicine, Winston-Salem, NC; 5) Institute for Translational Genomics and Population Sciences and Department of Pediatrics; Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 6) Department of Epidemiology, Colorado School of Public Health; University of Colorado, Aurora, CO; 7) Division of Public Health Sciences; Wake Forest School of Medicine, Winston-Salem, NC; 8) Center for Diabetes Research; Wake Forest School of Medicine, Winston-Salem, NC; 9) Department of Biochemistry; Wake Forest School of Medicine, Winston-Salem, NC.

Obesity is a major public health concern with strong correlations to numerous metabolic diseases. Moreover, regional fat deposition has been shown to increase disease risk above and beyond total adiposity. Here we report a genome-wide association study (GWAS) in 994 Hispanic Americans (N_{male}= 408, N_{female}=586) from IRASFS for ~8 million SNPs (genotyped and imputed). In addition, evaluation of low-frequency/rare variants was facilitated using the exome chip (81,560 variants). Association analyses were performed using computed tomography (CT) measures: subcutaneous adipose tissue (SAT), visceral adipose tissue (VAT), VAT adjusted by Body Mass Index (VAT_BMI), and visceral-subcutaneous adipose tissue ratio (VSR). As fat deposition appears to be gender specific, gender-stratified analyses were performed. Our results identified a total of 12 SNPs from five loci reaching genome-wide significance ($P<5.0\times10^{-8}$). SNP rs12657394 (MAF=19%), an intronic variant of *SRFBP1* on chromosome 5, showed strong association with VAT_BMI in males ($P_{male}=3.32\times10^{-8}$; P_{female}= 0.0025). *SRFBP1*, also named as *p49/STRAP*, encodes a Serum Response Factor Binding Protein. It has been shown to be involved in biosynthesis and/or processing of *GLUT4* (Glucose Transporter Type 4) in adipocytes, suggesting a role in regulating glucose homeostasis. SNP rs13247968 (MAF=42%), downstream of *SNX13* (Sorting Nexin 13), was also associated in males with VAT_BMI ($P_{male}=2.30\times10^{-9}$; $P_{female}=0.28$); rs117206355 (MAF=1%), located intergenically on 19p13.13, was strongly associated with VAT_BMI in females ($P_{male}=1.34\times10^{-4}$; $P_{female}=1.86\times10^{-9}$). In addition, two highly correlated intronic SNPs (rs2142795 and rs2425494; MAF=9%) in *PTPRT* showed strong association with VSR in males ($P_{male}=2.30\times10^{-9}$; P_{female}=0.30). rs12123452 (MAF=6%), downstream of *RIMS3*, showed a strong signal for VAT in males ($P_{male}=4.35\times10^{-8}$; $P_{female}=0.12$). To evaluate gender heterogeneity in fat deposition, interaction analyses were performed and significant gene-gender interactions were detected for all five significant loci with the most significant interaction at rs117206355 ($P=8.20\times10^{-5}$). These results revealed five novel adiposity loci displaying strong gender specificity. These observations provide genetic evidence for a differential mechanistic basis of fat deposition between genders and warrant further replication in larger cohorts.

957T

Meta-analysis of macronutrient intake in over 64,000 individuals using 1000 Genomes imputed genotypes confirms the association of *FGF21* with composition of dietary intake and suggests potential tissue-specific effects in liver and skeletal muscle. *A.Y. While dietary proportions of macronutrients, namely carbohydrate, protein, and fat, are relatively constant across populations, inter-individual variation of these quantities has been associated with chronic conditions such as obesity and diabetes. Prior genome-wide investigations based on common HapMap2 imputed genotypes from the CHARGE Nutrition Working Group and DietGen Consortium identified associations at the *FGF21* and *FTO* loci with macronutrient intake, estimated from food frequency questionnaires as the proportion of caloric intake from carbohydrate, protein, or fat. To further investigate the genetics of dietary intake, including associations from regions of low imputation quality in HapMap2 and lower frequency variants (MAF<5%), we performed a combined genome-wide inverse-variance weighted meta-analysis including >64K participants from 18 cohorts of European ancestry (ARIC, CHS, EPIC-Norfolk, FamHS, Fenland, FINRISK, FHS, GOYA MALE, H2000, HealthABC, InCHIANTI, Rotterdam Study I,II & III, WGHS, and YFS) using genotypes imputed to the 1000 Genomes phase 1 release 3 reference panel (March 2012). A total of 11.2 million variants remained after filtering on imputation quality (<0.4) and MAF (<0.01%), of which 43% had MAF<5%. In combined analysis, we confirmed the association of the minor allele for synonymous variant rs838133 (MAF=42%) at the *FGF21* locus with higher carbohydrate (β=0.3%) and lower fat (β=-0.2%) intake at genome-wide significance (p<5e-8) and at suggestive significance with lower protein intake (β=-0.1%, p=1.2e-6). We identified two missense SNPs in *FGF21* (MAF=36%) and *RASIP1* (MAF=49%) in moderate LD (r^2>0.6) with rs838133; only the *RASIP1* SNP is predicted to be damaging based on 3 of 4 protein prediction algorithms. Conditional analyses of rs831833 attenuated associations for both SNPs (p>0.05). No other variants attained genome-wide significance. However, among variants associated with intake of at least one macronutrient (p<1e-5) we found a greater proportion than expected that overlap with chromatin signatures for active gene regulation (H3K4me3) in liver, skeletal muscle and immune cells (p<0.05). An ongoing effort to include 6 additional cohorts (~46K participants) will increase the sample size to >100K making it the largest genome-wide investigation of dietary intake. The larger sample has potential to identify novel loci and therefore pathways for dietary habits and diet-disease relationships.

Genome-Wide Association Study Identifies Novel Genetic Determinants of Emphysema Distribution Patterns. *A. El Boueiz[1,2,3], S.M. Lutz[4], R.P. Bowler[5], M.H. Cho[1,2,3], M.L. McDonald[1,3], N.M. Laird[6], T.H. Beaty[7], J.D. Crapo[5], E.K. Silverman[1,2,3], P.J. Castaldi[1,3], D.L. DeMeo[1,2,3].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 3) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) Department of Biostatistics, Colorado School of Public Health, University of Colorado, Aurora, CO, USA; 5) Division of Pulmonary Medicine, Department of Medicine, National Jewish Health, Denver, CO, USA; 6) Harvard School of Public Health, Boston, MA, USA; 7) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA.

Background: Emphysema is a chronic obstructive lung disease (COPD) with an irreversible destruction of lung parenchyma. The distribution of this destruction throughout the lung varies considerably. Upper lobe emphysema has emerged as an important predictor of response to lung volume reduction surgery. Yet, the determinants of apical versus basal emphysema distributions remain largely enigmatic. Alpha 1-antitrypsin deficiency is often associated with basilar emphysema whereas polymorphisms in xenobiotic enzymes (*GSTP1* and *EPHX1*) in non-alpha 1-antitrypsin deficient smokers have been related to apical predominance. These findings suggest the presence of genetic influences on emphysema distribution patterns. To investigate this hypothesis and identify additional genetic markers of emphysema distributional phenotypes, we performed a GWAS in the COPDGene study. Methods: From the full cohort of smokers in COPDGene, 6,094 non-Hispanic white (NHW) and 2,989 African American (AA) subjects with complete genotype and CT densitometry data were included in this analysis. Genotyping was performed on the Illumina Omni Express platform with additional markers imputed using 1,000 Genomes reference data. Standard subject and genotype level quality filters were applied. Under an additive genetic model adjusting for age, gender, pack-years of smoking, and genetic ancestry, each of the four CT scan emphysema distribution phenotypes (apical percent emphysema, basal percent emphysema, difference, and Log ratio between the two) was tested for genetic associations. Separate analyses in NHW and AA subjects were followed by a meta-analysis. Results: In the meta-analysis, markers from 7 distinct loci were associated with one or more of the emphysema distribution phenotypes at genome-wide significance. 3 loci (4q31 near *HHIP*; 15q25 near *CHRNA3/CHRNA5*; 1q41 near *TGFB2*) have been previously associated with COPD susceptibility, and 4 loci are newly identified (*TLE1*; *RANBP17*; *TOR1*; *NR2F1-AS1*). Of these 7 loci, 4 were nominally significant in both NHW and AA subjects (*CHRNA3/CHRNA5*; *RANBP17*; *TOR1B*; *NR2F1-AS1*) and 3 in NHW subjects only (*HHIP*; *TGFB2*; *TLE1*). Conclusion: This GWAS in NHW and AA individuals identified new loci that may represent risk loci for upper lobe predominant versus diffuse emphysema. Our results support the notion that genetic factors may impact emphysematous destruction. Grant support: The COPDGene study is supported by NIH R01 HL089897 and R01 HL089856.

Heritability and locus susceptibility in age-related macular degeneration varies by clinical phenotypes. *L. Shen[1], T. Hoffmann[2,3], R. Melles[4], L. Sakoda[1], M. Kvale[2], Y. Banda[2], N. Risch[2], C. Schaefer[1], E. Jorgenson[1].* 1) Division of Research, Kaiser Permanente Northern California, Oakland, CA 94612; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA 94143; 3) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA 94143; 4) Department of Ophthalmology, Redwood City Medical Center, Kaiser Permanente Northern California, CA.

Age related macular degeneration (AMD) is a complex, late onset vision disorder that progresses in stages. Majority prior studies focused on advanced AMD, and the most recent genome-wide association study (GWAS) meta-analysis identified 19 independent loci. Other AMD related clinical phenotypes have been less extensively examined. Here, we conducted a GWAS of overall and subgroups of AMD based on imputation to the 1000 Genomes Project reference panel. The analysis included a total of 5,762 overall AMD cases (2,504 with advanced AMD) and 45,929 controls of non-Hispanic white ancestry from the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort as part of Kaiser Permanente Research Program on Genes, Environment and Health. We observed large differences in genetic susceptibility across AMD stages and subtypes. The estimated variance explained by all autosomal SNPs was lower for overall AMD (32%) than advanced AMD (40%), lower for geographic atrophy (GA) (36%) than choroidal neovascularization (NV) (47%), and highest for cases with both NV and GA (52%). For the 19 previously reported risk loci, the proportion of variance explained, area under the ROC curve, and odds ratios also vary by AMD phenotypes. GWAS of the five AMD categories identified a novel association near CSN1S1 with the GA subtype ($p=3.02\times10\text{-}8$). After conditioning on the top SNPs at each risk locus, we identified a non-synonymous SNP in HLA-DBQ1 to be associated with the risk of overall AMD ($p=1.64\times10\text{-}12$). These findings suggest that shared genetic factors underlie the risk of AMD of all stages and forms. The strength of the effects vary by disease severity and subtype.

960T

Genome-Wide Association Study of Serum Sodium Concentration in Han Chinese Population residing in Taiwan. *I. Song[1], J. Yang[1], C. Chen[1], C. Sung[2], S. Lin[2], Y. Chen[1], J. Wu[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, Taiwan; 2) Division of Nephrology, Department of Medicine, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan.

Water is the most important human body component that counts for 60-70% of body weight. Water homeostasis is the essential vital balance which maintains human survival. Serum sodium concentration is the index reflecting the systemic water balancing condition. The normal serum sodium concentration is between 135 to 145 mM. Hypernatremia (>145 mM) was reported to associate with increase motility and hyponatremia (<135 mM) was suggested to be a risk factor for osteoporosis, myocardial infarction, and attention deficits. Recently, high heritability of serum sodium concentration was demonstrated in non-Hispanic Caucasian, African American, and American Indian populations. However, the genetic influences on serum sodium concentration in Han Chinese Taiwan have not yet been studied. Therefore, in current study, we aimed to identify the loci affecting serum sodium concentration. We performed GWAS on 375 individuals with relative high sodium concentration (138-153 mM) and 394 individuals with relative low sodium concentration (85-133 mM). All subjects carry no severe medical illness. We found that chromosomes 14q31.1 ($P<10\text{-}7$) and 17p13.3 ($P<10\text{-}6$) showed strong association. The replication with another independent cohort is in processed. We hope the findings from this study can help in early identifying subject that predisposing to spontaneous or iatrogenic hyper/hyponatremia.

961S

Y Chromosome degradation and male longevity in the Long Life Family Study. *M. Bailey[1], W. Daw[1], J. Lee[2], J. Zmuda[3], B. Thyagarajan[4], P. Sebastiani[5], R. Lin[1], T. Perls[6], K. Christensen[7], M. Province[1].* 1) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO; 2) College of Physicians and Surgeons, Columbia University, New York, NY; 3) Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 5) Department of Biostatistics, Boston University / Boston Medical Center, Boston, MA; 6) Geriatrics, Boston University / Boston Medical Center, Boston, MA; 7) Danish Aging Research Center, University of Southern Denmark, Odense, DENMARK.

Y chromosomal degradation and loss is a known phenomenon in male aging and has been the focus of recent studies. We explored the hypothesis that Y chromosome variants contribute to Y chromosome stability and also to successful aging in the Long Life Family Study (LLFS). We used data on 2182 men, of whom 2135 have 450 Y chromosome genetic markers and intensity data from the Illlumina HumanOmni2.5 GWA chip. LLFS was designed to examine the genetics of healthy aging and families were recruited consisting of siblings who showed exceptional longevity, their children, and spouses where available. The mean age of male subjects on first examination, when DNA was collected, was 71. The mean age of men with Y chr intensity < 0.9 (indicating substantial Y chromosome degradation/loss) was 91, consistent with prior studies. Using a minor allele persistence algorithm, we have identified several SNPs with significant differences in age-specific allele frequencies, possibly associated with Y chromosome loss (p-values < 1.1×10-4, significant for 450 Y chromosome SNPs—Bonferroni alpha correction). Of these, rs17316547 is a variant within a predicted snRNA and is within 30kb of PRKY. Additionally, of the 231 individuals who carry this allele in our data, the youngest recorded death was 83 years old. The PRKY gene is similar to the protein kinase, X-linked gene in the pseudoautosomal region of the X chromosome. The gene is classified as a transcribed pseudogene because it has lost a coding exon that results in all transcripts being candidates for nonsense-mediated decay (NMD) and unlikely to express a protein. Abnormal recombination between this gene and a related gene on chromosome X is a frequent cause of XX males and XY females, making it a plausible biomarker for genomic instability in age related diseases.

962M

Genetic admixture and proliferative diabetic retinopathy in Latinos. *X. Gao[1], W.J. Gauderman[2], P. Marjoram[2], M. Torres[3], Y.I. Chen[4], K.D. Taylor[4], J.I. Rotter[4], R. Varma[3].* 1) Dept Ophthalmology & Visual Sci, Univ Illinois, Chicago, Chicago, IL; 2) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) USC Eye Institute, Department of Ophthalmology, University of Southern California, Los Angeles, CA; 4) 3Institue for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute at Harbor-UCLA, Torrance, CA.

Diabetic retinopathy is a leading cause of blindness in working age adults, and proliferative diabetic retinopathy (PDR) is the most advanced stage of the disease. Epidemiology studies have observed that Latinos have a higher prevalence of severe diabetic retinopathy than whites. The purpose of this study is to test the association between genetic admixture and PDR in Latinos with type 2 diabetes mellitus (T2DM). We conducted a case-control study using 647 T2DM subjects (552 controls and 95 PDR cases) selected from the tails of the diabetic retinopathy distribution from the Los Angeles Latino Eye Study. Genotyping was performed on the Illumina OmniExpress BeadChip (730,525 markers). We estimated genetic ancestry in Latinos using STRUCTURE with the HapMap reference panels. Univariate and multivariate logistic regression analyses were used to test the relationship between the proportions of genetic ancestry in Latinos and PDR. Native American ancestry in Latino T2DM subjects is significantly associated with PDR (P = 0.004) in our univariate analysis. The association remained significant after adjusting for age, sex, hemoglobin A1c, body mass index, systolic blood pressure, education and income. Risk factors for PDR in Latinos in our multivariate analysis include duration of diabetes (P < 0.0001), hemoglobin A1c (P = 0.0003), systolic blood pressure (P = 0.0004), and Native American ancestry (NAA, P = 0.006). The empirical p-value for NAA from permutation tests was 0.005. We also validated the NAA estimates in Latinos using ADMIXTURE with the 1000 Genomes Project reference panels and obtained consistent results. Our results demonstrate for the first time that NAA is a significant risk factor for PDR in Latinos. We are further performing local ancestry analysis, which may identify specific genomic regions associated with PDR in Latinos.

963T

GWAS of 89,283 individuals identifies genetic variants associated with being a morning person. *Y. Hu[1], A. Shmygelska[1], D. Tran[1,2], N. Eriksson[1], J. Tung[1], D. Hinds[1].* 1) 23andMe, Inc, Mountain View, CA, 94043; 2) Department of Biological Sciences, San Jose State University, San Jose, CA, 95112.

Circadian rhythms are a nearly universal feature of living organisms and affect almost every biological process. Our innate preference for mornings or evenings is determined by the phase of a circadian rhythm. We conducted a genome-wide association analysis of self-reported morningness, followed by analyses of biological pathways and its relationship to other phenotypes. We identified a total of 15 loci that were genome-wide-significant. Of those, seven were close to known circadian genes (RSG16, VIP, PER2, HCRTR2, RASD1, PER3 and FBXL3), four were near genes that could plausibly play a role in circadian rhythms (PLCL1, APH1A, FBXL13 and NOL4) and another four were near genes not previously associated with circadian rhythms (TOX3, AK4, DLX5 and ALG10B). We identified circadian and phototransduction related pathways enriched in our results and found morningness associated with many sleep phenotypes such as insomnia and sleep duration. Morningness is also associated with BMI and depression but in a Mendelian randomization analysis we did not find statistical evidence for a causal relationship. Our findings reinforce currently known circadian genes and will guide future studies of circadian rhythm, sleep and related disorders.

964S

Genome-wide Copy Number Scan Identifies Involvement of IRF6 in an Indian Family with Van der Woude Syndrome. *D.S. Manjegowda[1], M. Prasad[2], A.M. Veerappa[3], N.B. Ramachandra[3].* 1) Department of Biomedical Sciences, K. S Hegde Medical Academy, Nitte University, Deralakatte, Mangalore-575018, Karnataka, India; 2) Centre for Cleft Services, St. Joseph Hospital, DCKH-Cleft Centre, Mysore-570015. Karnataka, India; 3) Genomics Laboratory, Department of Studies in Zoology, University of Mysore, Manasagangotri, Mysore-570006, Karnataka, India.

Van der Woude syndrome (VWS) is an autosomal dominant developmental malformation presenting with bilateral lower lip pits related to cleft lip, cleft palate, and other malformations. We performed a whole genome copy number variations (CNV) scan in the members of a VWS family in India using 2.6 million combined SNP and CNV markers. We found CNVs affecting IRF6, a known candidate gene for VWS in all the three cases, while none of the non-VWS member showed any CNVs in the IRF6 region. The duplications and deletions of the chromosomal critical region in 1q32-q41, confirms the involvement of CNVs in IRF6 in south Indian VWS patients. Molecular network analysis of these and other Cleft lip/palate related module genes suggests them to be associated with cytokine-mediated signaling pathway, response to interferon-gamma mediated signaling pathway. This is a maiden study indicating the involvement of CNVs in IRF6 in causing VWS in the Indian population.

965M

Genetic determinants of healthspan - analysis of Wellderly dataset. *W. Sikora-Wohlfeld[1], M. Sirota[1], E. Scott[2], A. Torkamani[2], E. Topol[2], A.J. Butte[1].* 1) Department of Pediatrics, Stanford University, Stanford, CA; 2) Scripps Translational Science Institute, La Jolla, CA.

Understanding the mechanisms of aging would potentially enable detecting and preventing debilitating diseases and expanding the life expectancy. Numerous research efforts have focused on searching for 'longevity genes'. Development of genotyping and genome sequencing techniques enabled direct investigation of the genetic background of longevity. In recent years a number of studies have been conducted, where the genomes of people who have lived to a very advanced age in good health, were analyzed to search for variants for longevity. However, the mechanisms governing long healthspan remain to be explained.

In this study we have analyzed genome sequences of 534 participants of the Wellderly project, who have lived to 80 years or beyond. We compared this cohort to a control group, derived from the 1000 Genomes Project, assuming that the 1000 Genomes participants represent a sample from an ordinary population with average life expectancy. Using principal component analysis to estimate genetic ancestry, we identified a group of 416 Wellderly individuals who matched 174 individuals from CEU and GBR populations in the 1000 Genomes Project.

We performed an association test for a selected set of SNPs known to be associated with common human diseases. We derived this list of SNPs from VARIMED, a database of human disease-SNP associations. At the time of this work, VARIMED contained 466,890 unique SNPs associated with 6,691 disease and related phenotypes, manually curated from 17,088 publications.

Among the top variants differentiating the Wellderly and 1000 Genomes cohorts, we identified four markers in the T cell receptor alpha constant gene (*TRAC*). In addition, we found a marker in the immunoglobulin heavy locus gene (*IGH*). A link between aging and immunity has been established before and the performance of the immune system has been suggested to affect healthspan. While still preliminary, our findings suggest an association between immune pathway genetics and longevity, as well as enabling the exploration of other longevity-related markers.

966T

Adjusting for heritable covariates can bias effect estimates in genome-wide association studies. *H. Aschard, B. Vilhjálmsson, A. Joshi, A. Price, P. Kraft.* Department of Epidemiology, Harvard School of Public Health, Boston, MA.

Adjustment for covariates in genome-wide association studies (GWAS) has a dual purpose: (a) to account for potential confounding factors that can bias SNP effect estimates, and (b) to improve statistical power by reducing residual variance. Recently, researchers have conducted GWAS of human traits and diseases while adjusting for other heritable covariates with another motivation: identifying genetic variants associated only with the primary outcome. We show that this objective is fulfilled when the tested variants have no effect on the covariate or when the correlation between the covariate and the outcome is fully explained by a direct effect of the covariate on the outcome (i.e. mediation). For all other scenarios, an unintended bias is introduced with respect to the primary outcome as a result of the adjustment, and this bias may lead to false positives. We illustrate this point by providing examples from published genome-wide association studies, including a large meta-analysis of waist-to-hip ratio (WHR) adjusted for body mass (BMI) index from the GIANT consortium, where genetic effects may be biased as a result of adjustment for BMI.

We first show that the expected bias of the effect estimate in the covariate adjusted analysis is proportional to the correlation between the covariate and the outcome, and the association between the covariate and the genetic variant tested. We then derive a statistical test to evaluate the presence of such bias using GWAS summary information and the correlation between the covariate and the phenotype. When applied to the GIANT summary statistics, we observed that half of the reported associations with WHR adjusted for BMI are likely influenced by a genetic association with BMI. Finally, we show that heritability estimation of covariate adjusted traits is also subject to the same bias. In particular, we demonstrate that the heritability of an outcome adjusted for a heritable covariate may not necessarily represent the genetic component of the outcome, but rather a heterogeneous mixture of outcome-specific, covariate-specific and shared genetic components.

In summary we highlight that adjusting for heritable human traits such as BMI to remove mediated genetic effect through these variables, as commonly done in many genetic studies, should be done with care as it can induce false signal.

967S

Meta-analysis of genome-wide association studies in alopecia areata reveals new susceptibility loci and resolves HLA associations. *R. Betz[1], L. Petukhova[2,3], S. Ripke[6,7], H. Huang[6,7], S. Alopecia areata (AA) is one of the most prevalent autoimmune diseases, with ten known susceptibility loci so far. Here, we performed a meta-analysis in AA, combining data from two GWAS, and including replication data from Immunochip supplemented with Sequenom genotyping, for a total of 2,807 cases and 6,975 controls. The strongest region of association was the MHC, where we fine-mapped 4 independent effects, all implicating HLA-DR as a key etiologic driver, three of which alter protein sequence in the binding cleft of HLA-DRβ1. Outside the MHC, we identified two novel loci that exceed statistical significance, containing ACOXL/BCL2L11(BIM) (2q13; rs3789129, p=1.51×10-8, ORA=1.3); LRRC32(GARP) (11q13.5; rs2155219, p=1.25×10-8, ORT=1.2). A third region achieved nominal significance: SH2B3(LNK)/ATXN2 (12q24.12; p=1.3×10-7), which has been observed in other autoimmune diseases. Expression analysis of genes in these three regions provide biologic plausibility to these findings and further support the causal role of aberrant immune processes in AA, with contributions from both immune cells as well as the end organ (hair follicle). Finally, we performed a cross phenotype meta-analysis integrating our data with data from seven other autoimmune diseases, providing insight into the molecular taxonomy of autoimmune diseases and the alignment of AA within this class of disorders. Importantly, as GWAS help to resolve disease mechanisms and identify pathogenic pathways perturbed in AA and autoimmunity in general, these approaches advance the field towards precision medicine in autoimmunity.

968M

Examining the genetic basis of variation in sitting height ratio (SHR) using population cohorts. *Y. Chan[1,2,3], E.T. Lim[2,3,4], D. Strachan[5], G. McMahon[6], G. Davey-Smith[6], R.M. Salem[1,2], J.N. Hirschhorn[1,2,3].* 1) Endocrinology, Boston Children's Hospital, Boston, MA; 2) Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Genetics Dept, Harvard Medical School, Boston, MA; 4) Genetics and Genomics, Boston Children's Hospital, Boston, MA; 5) Population Health Research Institute St George's, University of London, London, UK; 6) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK.

Sitting height ratio (SHR) is the ratio of sitting height to total height and is a measure of body proportion. Studying SHR is important because it can be a more sensitive phenotype to detect mild growth disorders than height. While sitting height is heritable, with approximately 70% of variation within a population attributable to genetic factors, the heritability of SHR has not been well-studied. Nonetheless, there can be large differences in the average SHR between populations; for example, the average SHR of European-ancestry individuals is about 1 standard deviation greater than the average SHR of African-ancestry individuals. This difference is one of the largest reported for anthropometric traits. Here, we report the results from the first genome-wide genetic studies of SHR in large population cohorts of different ancestries. Using data from dbGAP, we first examined the association of SHR with European ancestry in 3,069 African-Americans. We observed a highly significant association ($P<5\times10^{-16}$); as expected from the average differences between populations, European ancestry is associated with increased SHR. We next performed genome-wide association studies of SHR on 11,943 European-Americans and 3,069 African-Americans. We discovered three novel loci significantly associated ($P<5\times10^{-8}$) with SHR, near *ANO10*, *PTPRM*, and *ITM2A*. Interestingly, *ITM2A* is on the X-chromosome and is associated with SHR only in women. This locus was recently reported to also be associated with height and is known to escape X-inactivation. However, these three loci do not account for differences in SHR between individuals of European and African ancestries, and there were no significant peaks from admixture mapping, suggesting that the genetic basis for the difference in SHR between populations is largely polygenic. Finally, we tested 421 independent SNPs known to be associated with height and observed that more of these SNPs are nominally associated ($P<0.05$) with SHR than expected by chance ($N=49$, $P=21\times10^{-8}$). Of the 49 height-decreasing alleles, 31 are associated with increased SHR and 18 are associated with decreased SHR, suggesting that different height loci have specific effects on skeletal growth of the spine or long bones. Using our results, we are able to dissect the role of previously reported loci associated with height, as well as new loci associated with SHR, which can potentially aid in therapeutic target discovery for skeletal disorders.

969T

Six novel loci associated with VEGF circulating levels identified by a meta-analysis of genome-wide association studies. *S. Choi[1,2,3], D. Ruggiero[4], R. Sorice[4], T. Nutile[4], C. Song[5,9], N. Vascular Endothelial Growth Factor (VEGF) is the most important pro-angiogenic factor, implicated in both physiological and pathological angiogenesis. A previously published GWAS had identified four loci independently associated with VEGF levels, two on chromosome 6, one on chromosome 9 and one on chromosome 8 (Debette and Visvikis-Siest et al, 2011). We sought to identify additional loci associated with circulating VEGF levels measured on ~13.000 individuals from 6 cohorts using genome wide association data imputed to the 1000genomes v3 panel. A GWAS of VEGF levels was performed in each cohort and the results were meta-analyzed. Five chromosomal regions (5q14.3, 6p21.1, 8q23.1, 9p24.2, 10q21.3) containing SNPs associated with VEGF levels at genome-wide significance ($p<5\times10^{-8}$) were found. To identify independently associated variants within the genome-wide significant genomic regions, conditional analyses were carried out. These analyses revealed 10 independent signals (1 on 5q14.3, 4 on 6p12.1, 1 on 8q23.1, 3 on 9p24.2 and 1 on 10q21.3). Further, 13 loci contained variants suggestively associated at $5\times10^{-8}\leq$p-value$<1\times10^{-5}$. The lead variant for each of the 10 independent signals and the 13 suggestive loci was carried forward to in silico and de novo replication in ~2800 individuals from 4 additional independent cohorts. Ten signals, 8 out of the top 10 independent variants and 2 out of the 13 suggestive signals in the discovery sample, were successfully replicated ($p<5\times10^{-8}$) in the meta-analysis of the combined discovery and replication samples. Overall, we confirmed the association of 4 already known loci and found 6 new signals, 4 located in novel chromosomal regions (5q14.3, 10q21.3, 16q24.2, and 18q22.3) and 2 in previously identified chromosomal regions (6p21.1 and 9p24.2). These 10 variants explain about 51% of the variability of the circulating levels of VEGF. The Ingenuity Pathway Analysis software (IPA) was used to explore the relationships between all genes associated with circulating VEGF levels. Twenty-four genes located in the regions identified by the 10 replicated variants were selected as focus genes. Out of them, 17 genes were connected within a unique network of 70 molecules. The analysis revealed strong functional relations of the gene network with embryonic and organism development, and cardiovascular system development and function. Further analyses will be necessary to identify the functional variants in the identified loci.

Genome-Wide Association Study in Different Stages of Clinical Progression of Alzheimer Disease. *J. Chung[1], L. Farrer[1,2,3,4,5], G. Jun[1,2,3].* 1) Biomedical Genetics, Boston University Medical Campus, Boston, MA; 2) Biostatistics, Boston University, Boston, MA; 3) Ophthalmology, Boston University, Boston, MA; 4) Epidemiology, Boston University, Boston, MA; 5) Neurology, Boston University, Boston, MA.

Background: Amyloid-beta 42 (Aβ42) and phosphorylated tau (p-tau) levels in cerebrospinal fluid (CSF) are key biomarkers for Alzheimer disease (AD) and known to become abnormal before the onset of clinically diagnosed AD. However, the discovery of new genetic risk factors in AD using CSF biomarkers as surrogate measures of disease is challenging in sample comprising a mixture of subjects with AD and mild cognitive impairment (MCI), as well as clinically normal (CN) subjects. Considering different distribution of biomarker levels among these subgroups, we conducted genome-wide association (GWA) analyses separately in these subgroups and in the total sample. Methods: A total of 783 subjects comprising with 112 AD, 483 MCI, and 188 CN participants with GWA data were available from two sets of the Alzheimer's Disease Neuroimaging Initiative (ADNI) Study. The residuals of a quantitative trait of Aβ42/p-tau ratio after adjusting for age and sex were normalized by rank transformation. GWA markers using the normalized trait in each set were analyzed in a linear regression model after accounting for population substructure. The results across sets were combined using meta-analysis. Results: We observed genome-wide significant (GWS, $p<5\times10^{-8}$) association with SNPs in the APOE region and three novel loci including MAST4 (rs80222306, minor allele frequency [MAF]= 14%, meta-analysis p [meta-p]=2.9×10^{-8}), and FBXO16 (rs10112794, MAF= 4%, meta-p=1.1×10^{-8}) in CN subjects, and CCDC3/OPTN (rs12356199, MAF=5%, meta-p=3.4×10^{-8}) in MCI subjects. Associations with several SNPs in CADM1 approached the GWS threshold (rs10891864, MAF=39%, meta-p=5.9×10^{-8}) in AD cases. Rs80222306 was also strongly associated in separate analyses of CSF Aβ42 (meta-p=8.1×10^{-6}) and p-tau (meta-p= 6.0×10^{-5}) levels in CN subjects. None of these genome-wide or near genome-wide significant SNPs outside the APOE region were even nominally significant in other subgroups (meta-p>0.05) and less significant in the total sample (meta-p>4.7×10^{-6}). Conclusion: Our results suggest that markers of AD pathogenesis are influenced by multiple loci which exert their effects at different stages of clinical progression toward AD. Further studies in large independent datasets are warranted to identify the functional variants and understand the mechanisms underlying the stage-specific genetic associations with CSF biomarkers of AD.

971M

Genome-wide association studies for dental caries in African American and Latino populations: Novel genes, heterogeneity, and replication. *J. Colavincenzo[1], J.R. Shaffer[2], E. Feingold[1,2], C. Sanchez[3], T. McHenry[3], F.W.B. Deleyiannis[4], D.W. McNeil[5], R. Crout[6], R.J. Weyant[7], M.L. Marazita[2,3,8].* 1) Department of Biostatistics, Graduate School of Publich Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Department of Surgery, Plastic and Reconstructive Surgery, School of Medicine, University of Colorado, Aurora, CO; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV; 6) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 7) Department of Dental Public Health and Information Management, University of Pittsburgh, Pittsburgh, PA; 8) Clinical and Translational Sciences Institute, and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA.

Motivation: Dental caries is the most common chronic disease worldwide, affecting a majority of children and adults. Disease burden and related comorbidities (pain, tooth loss, missed work/school, difficulty eating, hearing, and sleeping, and emergency room visits) are concentrated in vulnerable populations, including minority groups and those living in poverty or rural areas. Though dental caries experience is highly heritable, few specific risk loci have been identified and rigorously validated. To date, multiple genome-wide association studies (GWAS) in whites have nominated plausible caries risk genes, however, no GWAS in other races or ethnic groups have been performed. Methods: We performed four GWAS scans for dental caries in child and adult African American and Guatemalan cohorts. Results: Several novel caries genes were nominated, including *IGF-1* (insulin-like growth factor 1; p-value 2.7E-8), which is thought to be important for tooth development and saliva production. Additionally, loci previously implicated in GWAS of whites showed evidence of replication, including *LPO* (lactoperoxidase), an oral bactericidal enzyme. Conclusions: This study provides further support for the role of previously nominated genes, and suggests that studying cohorts with different ancestry and environment may help discover a wider range of caries genes. Grants: R01-DE014899, U01-DE018903, R01-DE016148.

972T

Genetic determinants of normal human facial variation. *J.B. Cole[1], M. Manyama[2], J. Larson[2], D.K. Liberton[2], T.M. Ferrara[1], S.L. Riccardi[1], M. Li[3], W. Mio[3], S.A. Santorico[1], B. Hallgrimsson[2], R.A. Spritz[1].* 1) Human Medical Genetics and Genomics Program, University of Colorado Denver, Anschutz Medical Campus, Aurora, CO; 2) Department of Cell Biology & Anatomy, University of Calgary, Calgary, AB; 3) Department of Mathematics, Florida State University, Tallahassee, FL.

Facial shape exhibits perhaps the greatest range of variation of any normal human trait, yet at the same time represents the most recognizable human characteristic. Facial shape comprises a multiplicity of complex multifactorial traits with clear genetic components. Nevertheless, little is known about normal human facial development. To identify genetic determinants of normal human facial shape variation, we carried out a large genome-wide association study (GWAS), replication study, and meta-analysis in 6300 normal African Bantu children from Tanzania. We used advanced 3D imaging technology, a revolutionary automated landmarking method, and geometric morphometrics to capture and analyze quantitative facial shape phenotypes, followed by genome-wide analysis of over 2.5 million SNPs. Our GWAS identified a number of loci with association surpassing criterion for genome-wide significance in an African population (P<2.5E-08). These include a gene desert at chr11q23.1 associated with nasal ala length, *AKAP13* associated with philtrum width, *DRAM2* associated with upper facial height, *PTCH1* associated with allometry, *DHX34* associated with upper facial depth, *SCHIP1* associated with centroid size, and *SRC* associated with nasal width. *AKAP13* encodes an A-kinase anchor protein. *DRAM2* encodes an inducer of autophagy. *PTCH1* encodes a receptor for sonic hedgehog, and *PTCH1* mutations result in holoprosencephaly. *DHX34* encodes a regulator of nonsense-mediated RNA decay that is essential for embryonic head development in zebrafish. *SCHIP1* encodes a schwannomin interacting protein with limited functional information. *SRC* has an essential role in bone remodeling, and *Src*-knockout mice have broad, abnormal facies. Our GWAS of normal facial shape in an African population did not confirm previously-reported association of mid-nasal shape with *PAX3* in European-derived whites, did not identify loci that have been associated with non-syndromic cleft lip/palate, and largely did not identify loci that are associated with single-gene disorders of facial morphogenesis. Most of the loci that were associated with facial shape in our GWAS encode proteins that either participate in basic cellular processes or for which functions remain largely unknown. Our results thus provide both novel candidate genes and novel insights into early development of the human face.

973S

Contribution of common polygenic variation captured by the Immunochip to celiac disease heritability in an independent Irish population. *C. Coleman[1], EM. Quinn[1], AW. Ryan[1], RJL. Anney[2], V. Trimble[1], DW. Morris[2], G. Donohoe[2], J. Conroy[3], G. Trynka[4], C. Wijmenga[5], S. Ennis[3], R. McManus[1].* 1) 1Department of Medicine, Institute of Molecular Medicine, Trinity College Dublin, St. James's Hospital, Dublin 8, Ireland; 2) Department of Psychiatry, Trinity College Dublin, Dublin, Ireland; 3) Conway Institute, University College Dublin, Ireland; 4) Genetics Department, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 5) Genetics Department, University Medical Center and University of Groningen, The Netherlands.

Celiac disease (CD) is a chronic immune-mediated disease with a prevalence of ~1% in European populations. Following the large Immunochip study of Trynka et al (2011) the HLA and 39 other CD susceptiblity loci are known. In an independent Irish CD case-control study we examined whether reported risk alleles were similar in direction of effect and whether a weighted burden of risk alleles (or polygenic risk score) could be used to distinguish case status. The polygenic risk score (Purcell et al 2009) has been used to examine the influence of risk alleles en masse to disease susceptibility in several complex disorders. Following stringent quality control we analyzed 143,074 markers genotyped on Immunochip in 425 cases and 453 controls. To examine concordance in the observed direction of effect in our sample, we performed a binomial sign-test for LD independent markers identified as genome-wide significant by Trynka et al. Secondly, for LD independent markers we calculated the polygenic risk score for each individual in our study. Regression was performed for disease status adjusting for marker-count-per-score (missingness), gender and population covariates. Binomial sign test indicated there was significant concordance in direction of effect between studies. 83% (122/147) of genome-wide significant SNPs show effect in the same direction (Pr (K>=122)=7.9×10 -17). When restricted to non-HLA markers 10/11 (91%) show effect in the same direction (Pr (K>= 10)=0.0059). The polygene analysis showed that polygenic risk scores were significantly associated with coeliac case-control status across a range of p threshold values. Including the HLA markers up to 36% of the variance was explained by the polygenic score (SNPs P< 0.0001; P=7.86×10 -67). 12% of the variance could be explained by the non-HLA SNPs alone (SNPs P< 0.001; P=9.56×10 -22). We have replicated the findings of a large CD association study in an independent Irish population. Use of the polygene risk analysis allows for highly significant findings even in a reduced sample size. Polygenic scores explained a significant proportion of the variance in coeliac disease confirming the contribution of common SNPs to CD susceptibility.

974M

Genetic insights into primary biliary cirrhosis - an international collaborative meta-analysis and replication study. *H.J. Cordell[1], Y. Han[2], Y. Li[2], G.F. Mells[3], G.M. Hirschfield[4], G. Xie[5], B. Juran[6], M.E. Gerschwin[7], P. Invernizzi[8], K. Lazaridis[6], C.A. Anderson[9], M.F. Seldin[7], C. Amos[2], R.N. Sandford[3], K. Siminovitch[5], Canadian-US, Italian and UK-PBC Consortia.* 1) Newcastle University, UK; 2) Dartmouth College, USA; 3) University of Cambridge, UK; 4) University of Birmingham, UK; 5) Mount Sinai Hospital, Toronto, Canada; 6) Mayo Clinic, USA; 7) UC Davis, USA; 8) Humanitas, Italy; 9) Wellcome Trust Sanger Institute, UK.

Primary biliary cirrhosis (PBC) results from an interaction of genetic and environmental factors. To date, four genome-wide association studies (GWAS) and two Illumina Immunoarray studies of PBC have helped delineate the genetic architecture of this disease. These studies have confirmed associations at the human leukocyte antigen (HLA)-region and identified 27 non-HLA susceptibility loci. Candidate genes are notably involved in the IL-12 signalling cascade. To identify additional risk loci for PBC, we have undertaken genome-wide meta-analysis (GWMA) of discovery datasets from the North American, the Italian and the UK GWAS of PBC, with a combined, post-QC sample size of 2745 cases and 9802 controls. Genome-wide imputation of each discovery dataset was undertaken in MACH using HapMap3 as reference panel; GWMA was undertaken using ProbABEL and META. Following meta-analysis, the index single nucleotide polymorphisms (SNPs) at selected loci with P_GWMA<2×10-5 were genotyped in a validation cohort consisting of 3716 cases and 4261 controls. To prioritise candidate variants and genes at confirmed risk loci, we used the ENCODE and the 1000Genomes datasets to identify SNPs within regulatory elements and non-synonymous (ns) SNPs in strong linkage disequilibrium (LD) with the index variant (r2>0.8). We identified seven previously unknown risk loci for PBC. Functional annotation of these loci revealed SNPs within regulatory elements that are predicted to affect expression of DGKQ (4p16), PAM (5q14) and IL21R (16p12), that are strongly-correlated to the index variant. Other candidate genes include IL12B (5q31), which forms part of the IL-12 signalling cascade, and CCL20 (2q36), which is involved in chemo-attraction of lymphocytes and dendritic cells towards epithelia and is expressed by TH17 cells originating from Foxp3+ T cells. Pathway analysis identified several highly plausible gene sets associated with PBC, including the IL-12 and JAK-STAT signalling pathways, and implicated several other immune processes in the pathogenesis of PBC, including innate immune processes (e.g. IFN-α,β signaling). Conclusion: This uniquely powered international collaborative GWMA and replication study confirms additional immunologically relevant loci that are associated with the risk of developing PBC.

975T

A Genome Wide Association Study of peanut sensitisation in the Manchester Asthma and Allergy Study. *J.A. Curtin[1], A. Custovic[1], A. Simpson[1], E.N.C. Mills[2].* 1) Centre for Respiratory Medicine and Allergy,Institute of Inflammation and Repair, University of Manchester, Manchester, Manchester, United Kingdom; 2) Institute of Inflammation and Repair, Manchester Academic Health Sciences Centre, Manchester Institute of Biotechnology, University of Manchester, United Kingdom.

Background: Very little is known about the molecular mechanisms underlying food allergy, including the model food allergen peanut. Twin studies indicate a significant genetic influence on peanut allergy, with one study estimated the heritability of peanut allergy at 81. 6%. Within the setting of a prospective birth cohort study, the Manchester Asthma and Allergy Study (MAAS), we investigated if a Genome-wide association study (GWAS) could help explain some of the heritability of peanut sensitisation. **Methods:** DNA was genotyped using Illumina 610 quad chips. Following standard QC we imputed additional genotypes (IMPUTE version 2.2.2) with the "1000 Genomes Phase I integrated variant set" reference genotypes; we excluded SNPs with INFO <0.4 and MAF <0.01. Genome-wide association study (GWAS) was performed for children that were skin prick positive to peanut at either at age 8 or 11 (46 cases, 554 controls). **Results:** We identified 66 regions that were associated with peanut sensitisation at genome-wide significance (p<5×10-8). Some of the most significantly association regions included the *CLDN14* (p=4×10-22), *DACH1* (p=7×10-23) and *CBFA2T2* (p= 8×10-23) genes. CLDN14 is part of the claudin family which is an important component of tight junctions. DACH1 is a chromatin-associated protein that helps regulate gene expression during development. *CBFA2T2* forms part of a fused gene that can be important in myeloid leukemia. *CBFA2T2* is a parologue of *DEAF1* which is reported to control the expression of genes encoding peripheral tissue antigens in type 1 diabetes. In drosophilia DEAF1 is reported to be a regulator of the innate immune response. Interestingly *CCL5* ($p=2\times10^{-8}$) was also associated with peanut sensitisation. CCL5 is a chemokine that is involved in immunoregulatory and inflammatory processes. **Conclusion:** This is the first GWAS of peanut sensitisation in children and we provide additional evidence that peanut sensitisation is heritable. We have identified several loci associated with peanut allergy that contain plausible candidate genes. Replication of these results will provide further evidence of these associations. Further studies will also be required using cohorts of individuals with either challenge-confirmed food allergy or a clear history of severe reactions linked to peanut consumption.

976S

A genome-wide association study identifies a LEPR gene as a novel predisposing factor for childhood FPG. *M. GO, J. HWNAG, L. Heo, T. Park, B. Kim.* KNIH, Osong, South Korea.

To date, genome-wide population-based association studies have been predominantly conducted on genetic predispositions in adult individuals. In uncovering childhood FPG susceptibility, a combined meta-analysis identified a novel LEPR locus (rs17407594) reaching genome-wide significance (n = 1,260, Padd = 4.98 ' 10-8). We also observed an association with T2D risk in the AGEN consortium (n = 18,817, Padd = 2.06 ' 10-2). In conclusion, our findings might expand understanding of genetic architecture contributing to glucose regulation and T2D risk.

977M

Comprehensive curation and visualization of ethnicity information from published genome-wide association studies (GWAS): an improved GWAS Catalog. *L.A. Hindorff[1], J.A.L. MacArthur[2], J. Morales[2], E.H. Bowler[2], P. Hall[1], K. Klemm[3], H. Junkins[1], T. Burdett[2], D. Welter[2], T. Manolio[1], H. Parkinson[2].* 1) Division of Genomic Medicine, NHGRI, NIH, Bethesda, MD; 2) European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 3) Division of Policy, Communication and Education, NHGRI, NIH, Bethesda, MD.

Genome-wide association studies (GWAS) have been prolific, with over 1,900 publications identifying 13,400 genetic variants associated with a broad range of human diseases and traits. The GWAS Catalog, available at http://www.genome.gov/gwastudies and http://www.ebi.ac.uk/fgpt/gwas/ , has served as a repository and visual summary of published GWAS findings since 2008. For each published GWAS study the Catalog includes publication, trait and SNP-trait association information, including SNP identifier, gene and risk allele, P-value, and a brief cohort description. To date the majority of GWAS studies have primarily been carried out in populations of European ancestry. This raises the question of how generalizable these trait-associations are across diverse populations. GWAS in diverse populations are now becoming more common, raising the importance of systematically curating detailed ancestry information to allow this question to be answered. Efforts to curate in greater detail the race/ancestry information from Catalog papers and to integrate this expanded information into a user-friendly interface will be described. Building upon an existing framework that relies largely on author-reported descriptors of ethnicity and ancestry, the more detailed ancestry data are based on systematic criteria and extracted as semi-structured fields. Information is curated at various levels of granularity - broad ancestral categories (e.g. “European”, “Hispanic/Latin American”), specific countries of origin and recruitment, and finer geographic descriptors where available (e.g. city and state). The public availability of these data will coincide with the release of an improved web interface that will enable visualization and searchability of ancestry data. A preview of the curation criteria and visualization of the ancestry data, with opportunity for detailed comment, will be presented and available at http://www.ebi.ac.uk/fgpt/gwas/ . The incorporation of detailed ancestry information, with associated search and visualization features, will enable users to investigate the generalizability of trait-associations across diverse populations and identify those limited to specific ancestries.

978T

Variants within ADAMTS9-AS2 influence fingerprint patterns. *Y.YW. Ho[1, 2], D.M. Evans[3, 4, 5], G.W. Montgomery[1], A.K. Henders[1], J.P. Kemp[3, 4, 5], N.J. Timpson[4, 5], B. St Pourcain[4, 5], D.Z. Loesch[6], G.D. Smith[4, 5], N.G. Martin[1], S.E. Medland[1].* 1) QIMR Berghofer, Herston, QLD, Australia; 2) School of Psychology, The University of Queensland, St. Lucia, QLD, Australia; 3) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK; 4) School of Social & Community Medicine, University of Bristol, Oakfield House, Oakfield Grove, Bristol, UK; 5) University of Queensland Diamantina Institute, Translational Research Institute, Brisbane, Australia; 6) Department of Psychology, La Trobe University, Melbourne, Australia.

Dermatoglyphics (the scientific study of dermal ridges on the distal phalanges, palms, and soles of primates) is a complex quantitative trait, which provides a model for genetic investigation. The current study sought to identify the genetic influences on fingerprint patterns across all 10 fingers, utilizing genome-wide association and meta-analysis. Data were collected from three samples, consisting of 2296 participants from the QIMR Brisbane Adolescent Twin Study, 1859 from the QIMR health and lifestyle study, and 5339 from the Avon Longitudinal Study of Parents and Children (ALSPAC). Results of meta-analyses across samples identified an effect for *rs1523452*, within *ADAMTS9-AS2* for whorls on the little fingers (left, p = 3.43×10-27, r = .124; right, p = 6.25×10-15, r = .089) and ring fingers (left, p = 7.18×10-13, r = .083; right, p = 3.87 x 10-11, r = .076) of both hands. Post-hoc TATES multivariate analyses were also conducted on the QIMR and ALSPAC samples, which showed strong association at this locus (p = 2.51 ×10-08, p = 7.42 ×10-19 respectively). As genetic variants within *ADAMTS9* have previously been associated with type 2 diabetes and waist-hip ratio, these results suggest variants influencing prenatal growth, evidenced by their effect on formation of ridge patterns, have ongoing effects on later development.

979S

Genome-wide association and local ancestry analyses of high-altitude adaptations in Tibetans. *C. Jeong[1], B. Basnyat[2], G. Childs[3], S. Craig[4], D. Witonsky[1], C. Beall[5], A. Di Rienzo[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Oxford University Clinical Research Unit, Patan Hospital, Kathmandu, Nepal; 3) Department of Anthropology, Washington University in St. Louis, St. Louis, MO, USA; 4) Department of Anthropology, Dartmouth College, Hanover, NH, USA; 5) Department of Anthropology, Case Western Reserve University, Cleveland, OH, USA.

Indigenous human populations in the Tibetan plateau show a set of physiological traits distinct from those of acclimatized lowlanders, e.g. unelevated hemoglobin concentration (Hb) up to 4,000 m altitude and extremely low arterial blood oxygen saturation level (SaO_2). Several population genomic studies of Tibetans independently identified two candidate genes, *EGLN1* (egl nine homolog 1) and *EPAS1* (endothelial PAS-domain containing protein 1), which harbor extreme allele frequency divergence and signatures of positive selection. However, the genetic basis of the distinctive Tibetan high-altitude physiology remains poorly understood. We performed a genome-wide association study of two key physiological traits, Hb and SaO_2, in a group of 880 ethnic Tibetan women born and raised at altitudes ranging from 2,982 m to 4,052 m in Nepal. Both phenotypes were controlled for known covariates. No genome-wide significant association was found applying the Bonferroni correction for the 363,954 SNPs tested. However, SNPs around *EPAS1* gene are associated with Hb (linear mixed model (LMM) $p \geq 2.27\times10^{-5}$) and those around *HIF1A* are associated with SaO_2 (LMM $p \geq 2.72\times10^{-4}$), thus confirming a role for oxygen homeostasis systems in Tibetan adaptations. Next, we conducted a local ancestry analysis across 337 unrelated Tibetans, to find out loci with excess high-altitude ancestry represented by the Sherpa in this study. Both *EPAS1* and *EGLN1* show marked enrichment in high-altitude ancestry: 73.1% (+6.1 standard deviation; SD; the top signal) for *EPAS1* and 60.1% (+3.3 SD; top 0.2%) for *EGLN1*. The genome-wide mean high-altitude ancestry is 45.1% with SD = 4.6%. Last, we explored if SNPs with excess high-altitude ancestry were preferentially associated with high-altitude phenotypes. High-altitude ancestry proportion shows a marginally negative correlation with Hb association p-value (Spearman’s rank correlation p = 0.054). However, without *EPAS1* SNPs, this correlation becomes weaker (p = 0.100). Our study presents the first genome-wide association study for two physiological traits in Tibetans and our local ancestry analysis raises the possibility that phenotypes other than hemoglobin level and oxygen saturation are important in Tibetan physiology.

980M

GWAS meta-analysis of primary sclerosing cholangitis identifies new disease loci and further clarifies the genetic relationship with inflammatory bowel disease. *S. Ji[1], B.D. Juran[2], E. Melum[3], S. Mucha[4], J.Z. Liu[1], A. Franke[4], T.H. Karlsen[3], K.N. Lazaridis[2], C.A. Anderson[1] on behalf of the International Primary Sclerosing Cholangitis Study Group (IPSCSG).* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 2) Center for Basic Research in Digestive Diseases, Division of Gastroenterology and Hepatology, Mayo Clinic, College of Medicine, Rochester, Minnesota, USA; 3) 3.Norwegian PSC Research Center, Department of Transplantation Medicine, Division of Cancer Medicine, Surgery and Transplantation, Oslo University Hospital, Rikshospitalet, Oslo, Norway; 4) Institute of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Germany.

Primary sclerosing cholangitis (PSC) is a chronic biliary disease, with a 9-39 fold sibling relative risk and marked comorbidity with inflammatory bowel disease (IBD). Previous PSC genome-wide association studies (GWASs) have identified six non-HLA risk loci. Recently, the IPSCSG performed an Immunochip-based genetic association study across 3,789 PSC cases and 25,079 controls from North America and Europe that identified nine new non-HLA risk loci. Here, we report the most highly powered genome-wide study of PSC to date, combining GWAS data from 2,871 PSC cases and 12,019 controls from Europe and North America. Following quality control and genotype imputation, over 7 million SNPs genome-wide were tested for association to PSC. We found genome-wide significant evidence of association ($p<5\times10^{-8}$) for nine novel loci, as well as at previously identified PSC risk loci including the HLA. Newly associated loci include those previously reported to be associated with other autoimmune disorders and genes with known immune-related function such as FUT2, MANBA, and UBASH3A. Analyses comparing our data to those from the largest GWAS of IBD showed high genetic correlation (0.4-0.5, estimated from genome-wide SNPs) between PSC and ulcerative colitis (UC), whereas Crohn's disease (CD) had near zero correlation with PSC patients without IBD. Furthermore, we observed an increase in the genetic correlation between PSC and UC after removing SNPs within the HLA region, suggesting that the HLA contribution to risk differs between the two diseases. We next tested for allele frequency differences between our PSC-only cases and those with comorbid UC, identifying 3 loci of suggestive significance ($p=5\times10^{-6\sim-8}$). These, and 70 loci from our standard case-control analysis are currently being tested for association in an independent replication panel of around 2,000 cases and 4,000 controls, and the results will be presented. In summary, we have identified nine novel PSC risk loci and more are anticipated post-replication. As expected, five of the new risk loci have been previously associated with other immune-mediated diseases. We show that PSC is genetically distinct to IBD, but is genetically correlated with UC (but not CD). In addition, we suggest that the HLA may play the major role in determining the presence or absence of UC in individuals who have an increased risk of PSC.

981T

Integrated analysis of known height association signals with novel signals from an East Asian GWAS decodes the genetic architecture of height through *in silico* functional candidate prioritization and gene network analysis. *T.A. Johnson[1], K.A. Boroevich[1], T. Tanaka[2], L. Qi[3], M. He[4], M. Xu[5], T. Wu[4], M. Kubo[6], T. Tsunoda[1], Asian Genetic Epidemiology Network (AGEN) Consortium.* 1) Lab for Medical Science Mathematics, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 2) Lab for Cardiovascular Diseases, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 3) Dept of Nutrition, Harvard School of Public Health, Boston, MA, USA; 4) MOE Key Lab of Environment and Health, School of Public Health, Tongji Medical College, Huazhong University of Science & Technology, Wuhan, Hubei, China; 5) Key Lab for Endocrine and Metabolic Diseases of Ministry of Health, Shanghai Clinical Center for Endocrine and Metabolic Diseases, Shanghai Institute of Endocrine and Metabolic Diseases, Dept of Endocrinology and Metabolism, Ruijin Hospital Affiliated to; 6) Lab for Genotyping Development, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan.

Genome-wide association studies of human height have identified over 200 loci to-date, but the vast majority were found using samples of European ancestry. To expand our understanding of how height associated variants, genes, and networks are shared between ethnicities or restricted to particular ethnic groups, we analyzed 43,418 BioBank Japan (BBJ) samples and 7.8 million variants imputed using 1000 Genomes Project (1000G) reference haplotypes. We found 65 association signals with $P\leq5\times10^{-8}$, including 23 previously unreported loci, and replicated 14 of those signals using Asian Genetic Epidemiology Network (AGEN) samples (n=36,225). To further explore inter- and intra-ethnic group associated signals, we identified 251 known loci from 484 previously reported SNPs combined with 64,515 1000G variants that were in linkage disequilibrium (LD; $r^2>0.2$); 131 of those signals had evidence for association in the BBJ dataset. We extrapolated *P*-values for 1000G SNPs based on r^2 with Genetic Investigation of ANthropometric Traits (GIANT) consortium data, and found that ten of the BBJ replicated and three non-replicated loci showed evidence of association in the European ancestry data. LD cluster analysis and stepwise model selection for the 145 BBJ associated loci found evidence for secondary signals in 31 loci. To identify candidate causal SNPs and underlying genes, we intersected the variants from 265 known or novel loci with genomic annotations and classified them based on the level of evidence for protein-coding changes (PolyPhen2) or regulatory function (transcription factor binding/motifs, DNase hypersensitivity, promoter/3'-UTR/5'-UTR, micro-RNA target sites). Using association strength and functional class, we extracted 1,333 candidate causal SNPs and 470 genes; only 2.5% of candidate SNPs impacted coding sequence. To identify a smaller set of candidate causal genes, we used STRING-DB 9.1 data to perform a gene network randomization analysis and step-wise gene prioritization. The final gene network highlights an interconnectedness between a number of pathways related to growth and development including Estradiol synthesis and estrogen receptor signaling, Insulin-like growth factor/Growth hormone axis, and Indian Hedgehog signaling. These findings significantly add to our current understanding of genes and pathways that impact variation in human height, and likely represent variants that are important for other common human diseases and phenotypic variation.

982S

Genome-wide association study of comorbidity of alcohol and nicotine dependences. *J. Jung, H. Zhang, B. Grant.* Laboratory of epidemiology and biometry, National Institute on Alcohol Abuse and Alcoholism/National Institutes of Health, Bethesda, MD.

Alcohol and nicotine dependences are common psychiatric disorders that are often developed together. Both disorders are genetically influenced with heritability of 55% and 60% respectively, and co-occurrence of both lifetime dependences is influenced by a substantial genetic correlation between both disorders. We analyzed Study of Addiction: Genetics and Environment (SAGE) to perform a genome-wide association study of a comorbidity of both alcohol dependence (AD) and nicotine dependence (ND), which were diagnosed by the Diagnostic and Statistical Manual of Mental Disorders-IV. Samples in SAGE were genotyped by illumine Human 1M BeadChip Array. European American (EA) samples of 1180 cases and 1378 controls of AD and 1163 cases and 1392 controls of ND were analyzed. Correlated binary model with bivariate odd ratio were utilized to test association of co-occurrence with SNPs after controlling for age, sex and two population stratification scores. We found that rs12439549 in Gamma-aminobutyric acid (GABA) A receptor, gamma 3 (GABRG3) is associated with co-occurrence of both disorders (p-value =1.56e-05). We replicate the results by African American (AA) samples with 709 cases and 516 controls of AD and 659 cases and 692 controls of ND (p-value =9.5e-04). The gene GABRG3 is known to be linked with alcohol dependence. In addition we found that in both EA and AA groups the additional common 109 genes are associated with the comorbidity by a threshold of 10e-02. This finding is very significant to understand the etiology of the co-occurrence of both disorders.

983M

Mapping variation in response to vitamin D in the immune system. *S.N. Kariuki, C. Jeong, J. Maranville, S. Baxter, D. Witonsky, A. Di Rienzo.* Department of Human Genetics, University of Chicago, Chicago, IL, USA.

The active hormonal form of vitamin D, 1,25-dihydroxyvitamin D ($1,25(OH)_2D_3$) is a potent modulator of immune response. Inhibition of lymphocyte proliferation is one of the effects of $1,25(OH)_2D_3$ on the immune system and it varies across individuals. Our objective was to understand the genetic basis for variation in this cellular phenotype, which we refer to as Iv. We conducted a genome-wide association study (GWAS) of Iv in peripheral blood mononuclear cells (PBMCs) from 88 healthy African American individuals. They were genotyped at 511,618 single nucleotide polymorphisms (SNPs) using Illumina arrays, and additional genotypes were imputed using Impute2, resulting in a total of 3,952,978 SNP genotype data available for these individuals. The PBMCs were treated with $1,25(OH)_2D_3$ for 48 hours, and Iv was determined by subtracting proliferation in vehicle-treated cells from proliferation in $1,25(OH)_2D_3$-treated cells. Associations between SNPs and Iv were tested using a likelihood-ratio test. We also measured transcriptome-wide gene expression in PBMCs from the same individuals treated with $1,25(OH)_2D_3$ for 6 hours. *cis*-eQTL mapping was performed using the Bayesian Regression for Identifying Gene-Environment interactions (BRIdGE) program. We found strong signals of association between intergenic SNPs in chromosomes 5 (rs7724571, p=3.57×10-8) and chromosome 18 (rs7228926, p=4.97×10-8) with Iv. The top SNPs in chromosome 5 are near the chemokine (C-C motif) ligand 28 (*CCL28*) gene, which encodes a cytokine that plays an important role in the chemotactic activity of $CD4^+$ and $CD8^+$ T cells. We also found 17 SNPs which are significantly associated with expression of genes in response to $1,25(OH)_2D_3$ treatment. These genes include two pore segment channel 2 (*TPCN2*), which is expressed in multiple cell types and has been implicated in blonde versus brown hair pigmentation, and interleukin 4 receptor (*IL4R*), which is expressed in immune cells and bronchial epithelial cells, and has been implicated in asthma risk. In summary, we found that SNPs in chromosomes 5 and 18 are associated with inter-individual variation in the Iv phenotype, accounting for ~46% of this variation. We also found 17 *cis*-eQTLs associated with differential expression of genes in response to vitamin D treatment. Further functional studies of the top GWAS SNPs and the *cis*-eQTLS will enable us to elucidate how these genetic variants influence the action of $1,25(OH)_2D_3$ in the immune system.

984T

Comparing of GWAS data for the personality in four Korean cohort. *B. Kim[1], H. Kim[1], H. Cho[1], S. Roh[1], M. Lee[2], S. Yang[2], N.H. Cho[3], C. Shin[4], J. Sung[2], H. Kim[1].* 1) Department of Biochemistry, School of medicine, Ewha Womans University, Seoul, Korea; 2) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health, Seoul National University, Seoul, Korea; 3) Department of Preventive Medicine, Ajou University School, Suwon, Korea; 4) Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Korea University Hospital, Ansan, Korea.

Personality is a determinant of behavior and lifestyle associated with health and human diseases. Despite high heritability ranging from 33 to 60%, the understanding of the genetic origins of personality trait variation is extremely limited. To identify genetic variants associated with each of the five dimensions of personality, we performed a genome wide association (GWA) meta-analysis of four cohort, which are the rural Ansung (1,126 adults) and urban Ansan cohort (1,683 adults), healthy Twin Study (979 adults) and young women cohort (1,089 adults) in Korea. Personality traits were measured with the Revised NEO Personality Inventory for the five-factor model of personality, using the Korean short version of the original NEO-PI-R, a 90-item measure of the five factors of personality. Genomic DNA was extracted from whole-blood samples using a commercial isolation Kit according to the manufacturer's protocols. We used PLINK for the quality control procedure and PLINK, BEAGLE, SHAPEIT, and IMPUTE2 for SNP imputation, due to different chip platform. After imputation, we used PLINK and GenABEL for association analysis and METAL software for meta-analysis of Ansung and Ansan cohort (1,387,466 SNPs), young women cohort (1,581,609 SNPs), and healthy Twin Study (1,387,466 SNPs). There are no SNPs reached genome-wide thresholds of 5×10E-08 for statistical significance. In the result of this study, however, we found the association between Neuroticism and DRD1 (p= 1×10E-05), Extraversion and CDKAL1 (p=2×10E-06), Openness to experience and ERBB4 (p=4×10E-06), Agreeableness and FAM110B (p=1×10E-05), and Conscientiousness and IGF2BP3 (p=4×10E-07). Among five-factor personality, we speculated that Neuroticism could associate with D1 subtype of the dopamine receptor. It will explain the relationship of personality and some behavioral responses. In addition, Openness to experience could associate with cancer and Conscientiousness could associate with insulin-like growth factor II and RNA synthesis or metabolism. But these suggestions should be replicated and confirmed by further studies. [This research was supported by a grant of Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number : HI14C0072)].

985S

Genome-wide association study (GWAS) of atopic dermatitis in Korean children. *K.W. Kim[1,2], R.A. Myers[1], J.H. Lee[3], EJ. Kim[4], D. Yoon[4], JS. Lee[4], KE. Kim[2], D.L. Nicolae[1], C. Ober[1], M.H. Sohn[2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pediatrics, Yonsei University College of Medicine, Seoul, Korea; 3) Department of Oral Biology, Yonsei University College of Dentistry, Seoul, Korea; 4) Research Center for Standardization of Allergic Disease, Allergy TF, Department of Immunology and Pathology, Korea National Institute of Health, Osong, Korea.

Atopic dermatitis (AD) is a heritable chronic inflammatory skin disease, which commonly presents during childhood when it is strongly associated with allergic sensitization. Previous GWAS of AD have not included Korean populations. Here, we conducted the first GWAS of moderate to severe AD in Korean children. Our study included 246 children with both AD and allergic sensitization (specific IgE to ≥1 food or airborne allergen) and 551 adult controls with a negative history of both AD and allergic sensitization (negative skin prick tests to common allergens). DNA from these individuals was genotyped using the Affymetrix Axiom or 5.0 chip; a set of common SNPs were imputed using minimac and the 1000 Genome Asian reference panel. 2.7 million SNPs remained after quality control (QC) checks, which included allele frequency comparisons between controls genotyped on different chips and inclusion of only high imputation accuracy (r^2>0.9) SNPs, in addition to standard QC criteria. Associations with SNPs at a locus on 13q21.31 were associated with AD at genome-wide levels of significance ($p<1.8\times10^{-8}$). This locus is in a gene desert and >1Mb from the closest genes, *PCDH9* and *PCDH20*. SNPs at four additional loci had p-values $<1\times10^{-6}$, including SNPs at 15q24.3 that are eQTLs for *PSTPIP1* in monocytes after treatment LPS (Fairfax BP et al. Science2014;343:1246949) and at 6q22.33 in the *THEMIS* gene. *PSTPIP1* is involved in aberrant inflammation in the skin, a primary feature of AD, and *THEMIS* modulates regulatory T cell function, a key cell type in inflammatory responses. We also identified SNPs at 2p24.3 in the *NBAS* gene and at 10p14, and replicated previous AD associations with SNPs in *KIF3A* (chr5q31.1, p=0.002), *RAD50* (5q31.1, p=0.03) and *ZNF365* (10q21.2, p=0.03). In summary, our study of Korean children identified new susceptibility loci for AD that are related to the potential dysregulation of immune cells in this disease, and extends our understanding of the pathophysiology of AD.

986M

The genetic landscape of pediatric autoimmune diseases. *Y.R. Li[1,2], J. Li[1], J.A. Ellis[3], S. Kugathasan[4], M.L. Becker[5], A. Latiano[28], E. Perez[7], R.K. Russell[8], D.C. Wilson[9], M.S. Autoimmune diseases affect seven to ten percent of individuals living in the Western Hemisphere, and represent a significant cause of chronic morbidity and disability. High rates of comorbidity and familial clustering suggest that strong genetic predisposition underlies autoimmune disease susceptibility, and genome wide association studies (GWAS) have identified hundreds of susceptibility genes associated with autoimmune diseases with some shared across clinically-distinct disease groups. To investigate the genetic architecture of pediatric autoimmune diseases (pAIDs), we performed a heterogeneity-sensitive GWAS (hsGWAS) across 10 pAIDs in a nested case-control study including over 5,200 cases and 11,000 controls. We identified 86 independent pAID association loci reaching GWS ($P < 5 \times 10\text{-}8$), including lead SNPs mapping to candidate genes with established immunoregulatory functions (e.g., CD40LG; $P < 3.08 \times 10\text{-}11$ and NFATC3; $P < 1.18 \times 10\text{-}8$). Of the 147 lead GWS (86) and marginally significant (61) loci, 97% were supported by functional (n=30), regulatory (n=55), conservational (n=30) or literature-reported (n=40) data, which is enriched as compared to that observed at random across the genome ($p<0.021$), particularly for DNAse hypersensitivity sites ($p < 0.01$) as well as for genetic association annotations, eQTLs, and coding variants ($p<0.001$). In addition, we extensively characterized the expression profiles of the candidate genes mapped by the lead loci in human tissues and murine immune-specific cell typing, providing evidence to support a disease-specific gene expression signature across subsets of immune cell lineages. Integration of multiple in silico analytical approaches identified highly shared autoimmune signals (e.g., IL2-IL21 $P < 6.24 \times 10\text{-}12$) and converging roles for JAK-STAT, innate, and TH1-TH2/TH17 mediated T-cell signaling across pAIDs and as molecular pathways representing attractive pharmacological targets for pAIDs.

Genomewide associaiton study identifies six novel loci associated with plasma carnitine levels. *H. Li, Y. Hu, R. Zeng, X. Lin.* Chinese Academy of Sciences, Shanghai Institutes for Biological Sciences, Shanghai, China.

Carnitine, a nutrient that plays important role in energy and fatty acid metabolism, has recently been showed to have protective effect on type 2 diabetes, obesity and cardiovascular diseases in both animal studies and clinical trials. Carnitine is mainly synthesized by the liver and the kidneys from the essential amino acids lysine and methionine. To identify genetic variants that affect circulating levels of various types of carnitines, a genomewide association study was performed in population of Chinese Hans with 2228 individuals from the Nutrition and Health of Aging Population in China (NHAPC) cohort. Association analyses were performed in Beijing and Shanghai subpopulations separately and summary statistics were calculated using inverse variance weighted fixed effect meta-analyses. We identified five novel loci at MCCC1, CPS1, FADS1-FADS2, DLG4 and LRP8-CPT2 that were associated with carnitines at genomewide significance. Of which, common variants in MCCC1, CPS1, FADS1-FADS2 and DLG4 were significantly associated with plamsa levels of C5OH ($P=1.47\times10\text{-}13$), C6DC ($P=3.78\times10\text{-}10$) and C20:4(n-6) ($P=6.80\times10\text{-}18$), and C12/C10 ratio ($P=7.96\times10\text{-}11$), respectively, while genetic variants in LRP8-CPT2 were significnatly associated with both lower C6DC ($P=7.22\times10\text{-}10$) and higher C16 ($P=1.06\times10\text{-}12$) levels. We observed an independent locus (rs7516477) at ACADM that showed associations with C8 ($P=6.51\times10\text{-}14$) level and C12/C10 ratio ($P=6.92\times10\text{-}21$), and is not in linkage disequilibrium (LD) ($r2\leq0.018$).with the previously reported genetic variants (rs11163924 and rs211718) in ACADM in populations of European origin. We also confirmed the previously reported associations between ACADS-rs2066938 and C4 level ($P=8.97\times10\text{-}20$) and between ACADS-rs2014355 and C3/C4 ratio ($P=9.20\times10\text{-}89$) in our study. In conclusion, we have identified six novel loci that were associated with various types of carnitines at genomewide significance in this study of Chinese Hans, and also confirmed the previously reported ACADS locus for C4-carnitine. Our findings provide novel insight into the genetic basis of carnitine biosynthesis.

With a prevalence of 1:25,000 common variable immunodeficiency disorder (CVID) is a clinically important form of primary immune deficiency, where inadequate quantity and quality of immunoglobulins results in susceptibility to bacterial infections. CVID is a heterogeneous disorder with variable comorbidities and the underlying genetic mechanisms are poorly understood. A previous genome-wide association study reported association between human leukocyte antigen (*HLA*) complex and CVID. To explore whether further common genetic variants outside the *HLA* complex contribute to CVID susceptibility, we conducted an association analysis of 123,127 common single nucleotide polymorphisms (SNPs) in a cohort of 778 cases and 10,999 healthy controls of European ancestry through dense genotyping of immune-related loci on the immunochip (iCHIP). In this largest CVID genetic study performed to date, we replicated the *HLA* association and further identified the first non-HLA CVID risk locus at *CLEC16A* (rs17806056, P = 2.0×10-9). Although the function of *CLEC16A* is largely unknown, it encodes a C-type lectin-like domain protein that is expressed in B-cells, dendritic cells and natural killer cells. Because of the critical role of B-cell function in CVID development, we further examined the B cell phenotype in Clec16a knock down (KD) mice. We found Clec16a KD mice manifested a reduced percentage of B-cells and increased IgM secretion. Taken together, our results suggest *CLEC16A* affects B-cell survival and function. The reported association of *CLEC16A* with multiple autoimmune disorders presents a compelling link between these disorders and autoimmunity commonly seen in CVID .

989M

Common variants near ABCA1, AFAP1 and GMDS confer risk of primary open-angle glaucoma. *S. Macgregor[1], P. Gharahkhani[1], R. Fogarty[2], S. Sharma[2], A.W. Hewitt[4], S. Martin[2], MH. Law[1], K. Primary open-angle glaucoma (POAG) is a major cause of irreversible blindness worldwide. We performed a genome-wide association study in an Australian discovery cohort comprising 1,155 advanced POAG cases and 1,992 controls. Association of the top SNPs from the discovery stage was investigated in two Australian replication cohorts (total 932 cases, 6862 controls) and two US replication cohorts (total 2616 cases, 2634 controls).

Meta-analysis of all cohorts revealed three novel (genome-wide significant) loci associated with development of POAG. These loci are located upstream of *ABCA1* (rs2472493 [G] OR=1.31, P= 2.1×10^{-19}), within *AFAP1* (rs4619890 [G] OR=1.20, P= 7.0×10^{-10}) and within *GMDS* (rs11969985 [G] OR=1.31, and P= 7.7×10^{-10}). Additionally there was strong evidence for association at SNP rs2276035 within the gene *ARHGEF12* in some samples, although heterogeneity of effect in other samples meant this result did not reach genome-wide significance overall. Using RT-PCR, we showed that all three genomewide significant genes are expressed within both human retina and other ocular tissues. For *ABCA1* and *AFAP1*, using immunolabelling we demonstrated protein distribution in the eye consistent with the expression findings.

ABCA1 is a membrane-bound receptor involved in phospholipid and cholesterol efflux from cells. ABCA1 has been reported to regulate neuroinflammation and neurodegeneration through co-ordinated activity in various cell types in mouse brain and it may be involved in glaucoma through a similar function in the retina. *AFAP1* encodes a protein that binds to actin filaments and allows their crosslinking. Actin cytoskeleton-modulating signals have been shown to be involved in the regulation of aqueous outflow and intraocular pressure, which are important parts of glaucoma pathogenesis.

These new loci, in addition to the previously identified risk loci, will help improve risk profiling for glaucoma with better opportunities for management of high-risk individuals.

CTNNA3 and SEMA3D: Promising loci for asthma exacerbation identified through multiple cohorts. *M. McGeachie[1], A.C. Wu[1], S.M. Tse[1], G.L. Clemmer[1], J. Sordillo[1], P. Weeke[2], C. Shaffer[2], J. Denny[2], D.M. Roden[2], B.A. Raby[1], S.T. Weiss[1], K.G. Tantisira[1].* 1) Channing Div Network Med, Dept of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Office of Personalized Medicine, Vanderbilt University School of Medicine, Nashville TN.

INTRODUCTION Asthma affects 300 million people worldwide and asthma exacerbations are a major cause of morbidity and medical cost. The objective of this study was to identify genomic predictors of exacerbations in subjects with asthma. METHODS In the Childhood Asthma Management Program (CAMP) and Childhood Asthma Research and Education (CARE) trials, acute asthma exacerbation was defined by treatment with a five-day prednisone course. We first performed a GWAS in CAMP, and to verify that the top hits from the GWAS were not artifacts of a non-normally distributed phenotype, we further performed permutation testing on the top 50 GWAS SNPs. We combined p-values from the CAMP permutation tests with the GWAS results from 205 participants of CARE. From BioVU, the DNA biobank for Vanderbilt University Medical Center, we identified a cohort of 786 subjects who had asthma, with 191 experiencing an asthma-related exacerbation, defined as a hospitalization or emergency department visit. We used CD4+ lymphocyte genome-wide mRNA expression profiling from the ABRIDGE project to identify associations of top SNPs with mRNA abundance of nearby genes. RESULTS In CAMP and CARE we identified a locus in CTNNA3 reaching genome-wide significance (rs7895190, p = 4.44E-09); we also prioritized other top hits for replication (rs746578 in TTN, p = 2.15E-06; rs993312 in SEMA3D, p = 7.63E-04). In replication in BioVU, rs993312 was significantly associated with exacerbations (p = 0.008). Rs746578 was in strong LD with a variant, rs10997296, identified as an eQTL for CTNNA3 in CD4+ cells from the ABRIDGE cohort (p = 0.00079). DISCUSSION The CTNNA3 SNP, rs7915690, is intronic. It is in strong LD (r2 = 0.97) with a predicted regulatory variant, rs10997296, that is a strong enhancer in human mammary epithelial cells (ENCODE); and in a DNAse I hypersensitivity site in small airway epithelial cells (ENCODE). This variant was identified as an eQTL for CTNNA3. The SEMA3D SNP, rs993312, is intronic and in strong LD (r2 = 0.99) with a regulatory SNP, rs55834466. The ENCODE project identifies rs55834466 as a strong enhancer in epidermal keratinocytes and human mammary epithelial cells, in addition SEMA3D is relatively overexpressed in the lung (Illumina Human BodyMap). CONCLUSIONS We identified two exacerbation-associated regulatory SNPs from GWAS of asthma clinical trials. One met genome-wide significance thresholds while the other replicated in a clinical Biobank database.

991S

Genome-wide association study of exfoliation syndrome/exfoliation glaucoma in a Japanese population. *M. Nakano[1], Y. Ikeda[2], Y. Tokuda[1], H. Adachi[1], M. Ueno[2], K. Imai[2], R. Sato[1], N. Omi[1], K. Mori[2], S. Kinoshita[2], K. Tashiro[1].* 1) Dept Genomic Med Sci, Kyoto Prefectural Univ Med, Kyoto, Japan; 2) Dept Ophthal, Kyoto Prefectural Univ Med, Kyoto, Japan.

Purpose: The common variants in lysyl oxidase-like 1 gene (*LOXL1*) at chromosome 15q24.1 are well known to be associated with exfoliation glaucoma (XFG) patients developed through exfoliation syndrome (XFS[MIM 177650]). However, LOXL1 by itself seemed to be insufficient for explaining the molecular mechanism of XFG pathogenesis. Moreover, the risk allele of a variant (rs1048661) in exon 1 of *LOXL1* has found to be inverted between Asian and Caucasian populations, suggesting that the variants in other genes should also be contributing to the genetic heritability of XFS/XFG. Therefore, we newly conducted a genome-wide association study (GWAS) using a Japanese population in an attempt to discover genetic markers for XFS/XFG. **Methods:** We first conducted a GWAS using the Japanese subjects and analyzed 652,792 autosomal common single-nucleotide polymorphisms (SNPs) in 201 XFS/XFG patients and 697 controls. We then replicated the results of GWAS using an independent population consisted of 121 XFS/XFG patients and 263 controls. We also performed a conditional analysis to analyze the combinational effect of the variants identified from the different genes. We finally confirmed the expression of the identified genes in human ocular tissues. **Results:** As a result of GWAS, 34 genome-wide significant SNPs ($P = 5.56 \times 10^{-8}$ - 3.46×10^{-54}) were indeed identified as a cluster only from chromosome 15q24.1. However, the significant SNPs were distributed in not only *LOXL1* but also two other adjacent genes in the locus. The significance of these SNPs was confirmed by the replication analysis. We also identified a suggestive association between the variants of one of the two genes and *LOXL1* by the conditional analysis. Both two genes were expressed in the ocular tissues. **Conclusions:** We have successfully identified some novel variants associated with XFS/XFG. The results suggested that the combination of newly discovered variants in these genes would be useful for precise XFG risk assessment especially in Asian population, as well as for elucidating the molecular mechanism of XFG pathogenesis through XFS.

992M

Genome-wide association study identifies two distinct risk haplotypes at LBX1, and links ITPR1 and SOX5 to adolescent idiopathic scoliosis. *L. Nelson[1], R. Chettier[2], J.W. Ogilvie[2], H.M. Albertsen[2], K. Ward[2].* 1) Affiliated Genetics, Salt Lake City, UT; 2) Juneau Biosciences, Salt Lake City, UT.

Background: Adolescent idiopathic scoliosis (AIS) is a common pediatric disorder that affects 2-4% of children. Genetic factors have been suspected for decades and recent studies have identified possible proteins involved in the condition. In spite of studies showing high heritability in AIS, the genetic risk factors for susceptibility to AIS across different ethnic groups remain largely unknown. A few AIS related genome-wide association study studies (GWAS) in Asian populations have revealed promising candidates. In particular, a recent genome-wide association study conducted in a Japanese population has identified LBX1 as a strong susceptibility locus for AIS. In this study we explore genetic association to AIS in subjects of European descent. **Methods:**A GWAS comparing 853 female Caucasian patients with adolescent idiopathic scoliosis with 1,368 ethnically matched unaffected females from the general population. **Results:** Using stringent quality filters we replicated the LBX1 association and identified two novel loci, ITPR1 and SOX5, associated with AIS at a genome-wide significance level below 5×10^{-8}. Our strongest association was found on LBX1 locus [rs11190878 (OR= 0.59,p=2.23×10^{-14}) and rs7893223 (OR=0.63,p=1.01×10^{-10})]. Using imputation, the previously reported marker rs11190870, also showed association (OR=0.65, p=3.64×10^{-11}) with AIS in this study. In haplotype analysis, the LBX1 haplotype ATT comprising the risk alleles for rs11190878, rs11190870 and rs7893223 showed the strongest association to AIS (OR=1.62, p= 9.48×10^{-15}) as a recessive model. The GCC haplotype was a protective haplotype for the same markers (OR=0.5, p=2.03×10^{-11}). These results suggest that the mutations on LBX1 loci are quite old and LBX1 gene is a potential susceptibility loci for AIS across many populations. We also identified ITPR1 and SOX5 as novel candidates for AIS. Together, LBX1, ITPR1 and SOX5 explain 4.2% of the phenotypic variance. **Conclusion:** This is the first large GWAS study of European descent in AIS to show a significant effect of a risk haplotype that spans the LBX1 locus and extends into the LBX1 antisense RNA1 locus. In addition, we report ITPR1 and SOX5 as new candidate risk loci for AIS patients of European descent. These markers identified will help in elucidating the pathogenesis of AIS.

993T

Genome-wide association of 44,714 subjects of African ancestry imputed to the 1000 Genomes reference panel identified two novel loci influencing body mass index. *M.C.Y. Ng[1], M. Graff[2], A. North[2], African Ancestry Anthropometry Genetic Consortium.* 1) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 2) Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) The Genetics of Obesity and Related Metabolic Traits Program, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 4) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 5) Departments of Genetics, Biostatistics, Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 6) Division of Sleep Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 7) Cardiovascular Health Research Unit, University of Washington, Seattle, WA, USA; 8) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO, USA; 9) The GeneSTAR Research Program, Department of Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD, USA; 10) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI, USA; 11) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA; 12) Divisions of Endocrinology and Genetics and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Boston, MA, USA; 13) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, USA; 14) Department of Epidemiology and Prevention, Division of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 15) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS, USA; 16) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Obesity is a major public health problem with disproportionally high prevalence in African Americans. Our previous genome-wide association (GWA) meta-analysis in individuals of African ancestry, imputed to the HapMap 2 reference panel, confirmed 5 loci previously established in European ancestry populations and identified 2 novel loci for association with body mass index (BMI). As individuals of African ancestry display greater genetic variation than European or Asian ancestry populations, we hypothesized that a GWA study imputed to the 1000 Genomes reference panel might prove particularly useful for identifying additional variants associated with BMI in African ancestry individuals. As such, The African Ancestry Anthropometry Genetic Consortium (AAAGC) imputed data to the 1000 Genomes Phase 1 cosmopolitan reference panel in 44,714 individuals of African ancestry from 19 GWA studies. Following single variant association for BMI in individual studies under an additive model, meta-analyses were performed for 22 million variants using the fixed-effects inverse variance method. Analyses were performed in all individuals combined as well as stratified by sex. We observed genome-wide significant (*P*<5E-8) associations at 7 established BMI loci (near *SEC16B*, *TMEM18*, *GNPDA2*, *GALNT10*, *KLHL32*, *FTO* and *MC4R*) and 2 novel loci (near *PFKP* and *SYCP2L*) in the overall sample, as well as 2 novel loci in sex-stratified analyses (near *INTS10* in men, near *LRFN5* in women). Among the established loci, the index SNPs in this study were in strong linkage disequilibrium (LD), measured in r^2, with the index SNPs in both African and European ancestry studies imputed to the HapMap reference panel, enable fine mapping of associated signals shared between the two populations. Among the novel loci except for *LRFN5*, all index SNPs are of low-frequency (minor allele frequency 1% - 6%), were not present in the HapMap reference panel, and have even lower frequencies (0% - 0.6%) in other non-African ancestry populations. *PFKP* encodes the platelet isoform of phosphofructokinase that is a key regulator in glycolysis. Follow-up analyses to fine-map loci and identify causal genes and variants are ongoing. Our results suggest that a high-density reference panel including low-frequency variants improves the coverage of the genome and unmasks novel loci that may be missed due to lower LD in African ancestry populations. Further replication studies are required to confirm our novel findings.

994S

The Genetics of Erectile Dysfunction Risk in Men with Type 1 Diabetes. *M.R. Palmer[1], J.M. Hotaling[2], A.D. Paterson[3], H. Wessells[1].* 1) Urology, University of Washington, Seattle, WA; 2) Urology, University of Utah, Seattle, WA; 3) Genetics & Genome Blology, University of Toronto, Toronto, Canada.

Erectile dysfunction (ED) affects greater than 40% of men over 40 years old. Major risk factors include age, hypertension, and heart disease. However, there is also a genetic component to ED risk. A twin study showed that ED has 30% heritability. In addition, several small genome-wide association studies have linked genetic variants to increased risk of ED in men with diabetes, as well as in patients who have undergone radiation therapy for prostate cancer. We have ED phenotype data for men from a cohort of men with type 1 diabetes. Longitudinal data includes a yearly single-item survey question over 20 years, and a more detailed follow up study at year 17. A pilot GWAS in this population at year 10 showed association of ED with two SNVs near ALCAM (activated leukocyte cell adhesion molecule). Over the 20 years, 445 individuals had at least one report of ED, and 290 had none. In this population, ED is significantly associated with age, BMI, and HBA1C (all $p < 0.01$, t-test). We plan to use genetic data and new phenotype information from these men to replicate the association of variants that have previously been found to be significant or sub-significant. We will perform a cross-sectional case-control analysis, as well as a time-to-event analysis using a Cox proportional hazards model. The models will stratify for BMI, age, HBA1C, and other factors that associate with ED status, and use PCA to correct for ancestry. Identification of variants associated with ED risk will be useful for prediction and early treatment in diabetic men.

995M

Common genetic variation explains a substantial fraction of nicotine and cotinine glucuronidation in multiple populatons. *Y.M. Patel[1], D.O. Stram[1], L. Le Marchand[3], S.S. Hecht[2], C.A. Haiman[1], S.E. Murphy[2].* 1) Department of Preventive Medicine and Norris Comprehensive Cancer Center Keck School of Medicine University of Southern California Los Angeles, CA 90032; 2) University of Minnesota VFW Cancer Research Center 406 Harvard Street SE Minneapolis, MN 55455; 3) University of Hawaii Cancer Center 701 Ilalo St #600, Honolulu, HI 96813.

Evaluating the role of genetics in the metabolism of nicotine may be important in understanding racial/ethnic differences in lung cancer risk among smokers. Noted racial disparities in risk may be related to differences in internal carcinogen dose resulting from faster metabolism including the glucuronidation of nicotine and cotinine. We conducted a genome-wide association study (GWAS) in search of common genetic variants that may be predictive of nicotine and cotinine glucuronidation in a multiethnic sample of 2,239 current smokers representing 5 ethnic populations. The phenotypes analyzed were cotinine and nicotine glucuronidation. Cotinine glucuronidation is a ratio derived from the difference of total and free cotinine, divided by total cotinine. Nicotine glucuronidation is similarly created. In an analysis of 11,892,802 genotyped and imputed variants appearing in the thousand genomes project, 1,241 were found to be strongly associated with cotinine glucuronidation at $p<5\times10\text{-}8$. The vast majority were within the region *4q13*, near the previously reported gene *UGT2B10*. Fifteen different SNPs in 9 different regions were globally significant and contributed independent information genome-wide ($p<1\times10\text{-}3$ in stepwise regression). Together, these 15 SNPs explain 33.2% of variation observed in cotinine glucuronidation which ranged from 55% for African Americans to 19% among Japanese Americans. The strongest single SNP association was rs115765562 ($p= 1.60\times10\text{-}155$), near *UGT2B10*, which is highly correlated with a known splice site variant, rs116294140, in *UGT2B10*. This splice variant in combination with an Arg67Try nonsynonymous SNP rs61750900 explain 24.3% of variation in cotinine glucuronidation, indicating effects seen through putative functional missense and splice site variants might be the underlying explanation for the associations. Our analysis has determined that a high fraction of individual variation of cotinine glucuronidation is explained by genetic differences. We also noted that in our data African Americans and Japanese Americans have the lowest cotinine glucuronidation levels and they also tend to smoke fewer cigarettes per day and have lower nicotine equivalents than do Europeans. However, their lung cancer risks (higher in African Americans and lower in Japanese Americans) are quite different. This observation therefore does not strongly support an important role of glucuronidation in determining the factors underling these risk differences.

996T

Search for new risk gene for Stevens-Johnson Syndrome independent of *HLA* risk allele. *H. Sawai[1], M. Ueta[2, 3], Y. Hitomi[1], C. Sotozono[2], S. Kinoshita[2], K. Tokunaga[1]*. 1) Department of Human Genetics, The University of Tokyo, Tokyo, Japan; 2) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 3) Research Center for Inflammation and Regenerative Medicine, Faculty of Life and Medical Sciences, Doshisha University, Kyoto, Japan.

Stevens-Johnson syndrome (SJS) and its severe form, toxic epidermal necrolysis (TEN), are acute inflammatory vesiculobullous reactions of the skin and mucous membranes including the ocular surface, oral cavity, and genitals. These reactions are very rare but are often associated with inciting drugs and infectious agents. We previously revealed the association between a specific *HLA-A* allele (*HLA-A*02:06*) and SJS/TEN with severe ocular surface complications (SOC) in Japanese population. We also performed genome-wide association study (GWAS) using Japanese SJS/TEN with SOC cases and healthy controls, and found that the *HLA-A* region showed the strongest association with susceptibility to SJS/TEN with SOC (odds ratio [OR] = 4.40, $p = 3.5 \times 10^{-14}$). To identify host genetic factor(s) contributing independently of *HLA-A*02:06* to SJS/TEN with SOC, we conducted a GWAS with *HLA-A*02:06* negative individuals.

We genotyped a total of 820 samples including 118 Japanese SJS/TEN patients and 702 Japanese healthy controls using the Affymetrix AXIOM Genome-Wide ASI 1 Array. We excluded one case sample with an overall call rate less than 97%, and recalled the remaining 819 samples by using Genotype Console v4.1.4 software. All samples used for GWAS passed a heterozygosity check, and five related samples identified by descendent testing were excluded. A principal component analysis found six outliers to be excluded by the Smirnov-Grubbs test, and we showed that all 117 cases and 691 controls formed a single cluster with the HapMap JPT samples but not with CHB samples. We further excluded samples with *HLA-A*02:06* and finally used 59 cases and 597 controls for the GWAS. The chi-square test was applied to an allele frequency model.

Four loci showed genome-wide marginal associations with SJS/TEN (OR = 5.75, $p = 1.19 \times 10^{-7}$ for *IKZF1*; OR = 2.80, $p = 2.95 \times 10^{-7}$ for Gene A; OR = 2.71, $p = 2.07 \times 10^{-7}$ for Gene B; OR = 5.34, $p = 2.50 \times 10^{-7}$ for Gene C). One of four loci (*IKZF1*) showed a significant association with SJS/TEN with SOC in the previous GWAS using all the patients and controls followed by a replication study using Korean samples (Ueta *et al.*).

997S

Investigation of genetic variation underlying central obesity among Indian Asians. *W.R. Scott[1,5], W. Zhang[1], M. Loh[1], S-T. Tan[4,5], B. Lehne[1], U. Afzal[1], P. Elliott[1,3], J. Scott[2,5], J. Chambers[1,2,4], J. Kooner[2,4,5]*. 1) Epidemiology and Biostatistics, Imperial College London, Norfolk Place, London, UK; 2) Imperial College Healthcare NHS Trust, DuCane Road, London, UK; 3) MRC-PHE Centre for Environment and Health, Imperial College London, Norfolk Place, London, UK; 4) Ealing Hospital NHS Trust, Southall, Middlesex, UK; 5) National Heart and Lung Institute, Imperial College London, Hammersmith Hospital, Ducane Road, London, UK.

Indian Asians are 1/4 of the world's population and have increased susceptibility to central obesity and related metabolic disturbances. Previous studies investigating the genetic basis of central obesity have been carried out in predominantly European populations. Few studies have investigated the contribution of genetic variation to increased susceptibility to central obesity in Indian Asians.

We studied Indian Asian and European men and women, aged 35-75 years, participating in the London Life Sciences Prospective Population (LOLIPOP) study. Waist hip ratio (WHR) was higher in Indian Asians compared to Europeans (0.94 [95% C.I. 0.86-1.02] v. 0.91 [95% C.I. 0.83-0.99] $P<0.0001$). To investigate genetic variation underlying central obesity among Indian Asians we examined: i) known genetic variants, comprising the 46 SNPs associated with body mass index and WHR in European genome-wide association studies (n=10,318); ii) common genetic variants through genome-wide association (n=10,318); iii) exonic variants through Illumina HumanExome array (n=2,637). Our sample size provides 80% power to detect SNPs explaining >0.3% of trait variance at $P<5\times10\text{-}8$.

We observed no systematic differences in risk allele frequencies or effect sizes of the 46 known adiposity SNPs in Indian Asians compared to Europeans (Sign test P=0.185; P=0.145 respectively). Combined these variants explained <1% of population variation in WHR among Indian Asians. Next we carried out a genome-wide association study of WHR in Indian Asians. Variants from 1000 Genomes haplotypes were imputed into available genome-wide SNP data. >6M SNPs (MAF >5%) passed quality control. No new variants were associated with WHR at $P<5\times10\text{-}8$. We then evaluated exonic variants (247,870 SNPs; 97.4% call rate) for association with WHR in Indian Asians. Again we found no novel associations with WHR ($P<2\times10\text{-}7$; Bonferroni corrected for the number of independent tests). These findings argue against a role for cosmopolitan variants underlying central obesity in Indian Asians. Future efforts aimed at identifying the genetic basis of central obesity in Indian Asians should be focused on other mechanisms, including population-specific variants and transgenerational epigenetic modifications.

998M

Common variants at c11orf30 and CAPN14 are associated with eosinophilic esophagitis. *P.M.A. Sleiman[1,2], M-L. Wang[2,3], A. Cianferoni[2,4], S. Aceves[5], N. Gonsalves[6], K. Nadeau[7], G.T. Furuta[8], J. Spergel[2,4], H. Hakonarson[1,2]*. 1) The Center for Applied Genomics, The Children's Hospital of Philadelphia, PA, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania Philadelphia, PA, USA; 3) Division of GI, Hepatology, and Nutrition, The Children's Hospital of Philadelphia, PA, USA; 4) Division of Allergy and Immunology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 5) Division of Allergy, Immunology, 9500 Gilman Drive MC-0760, Department of Pediatrics and Medicine, University of California, San Diego and Rady Children's Hospital, San Diego, CA, USA; 6) Division of Gastroenterology & Hepatology, Northwestern University - The Feinberg School of Medicine, Chicago, IL, USA; 7) Stanford University School of Medicine, Lucile Packard Children's Hospital, Stanford Hospital and Clinics, Division of Allergy, Immunology, and Rheumatology, CA, USA; 8) Digestive Health Institute, Section of Pediatric Gastroenterology, Hepatology and Nutrition, Children's Hospital Colorado, Gastrointestinal Eosinophilic Diseases Program, Department of Pediatrics, Mucosal Inflammation Program, University of Colorado.

Eosinophilic esophagitis (EoE) is an inflammatory disorder of the esophagus histologically characterized by accumulation of eosinophils in the esophageal epithelium. Clinical symptoms of EoE include dysphagia, failure to thrive, vomiting and epigastric or chest pain. A diagnosis of EoE is made following endoscopy and biopsy upon finding isolated eosinophils in the esophagus having ruled out gastroesophageal reflux. The stringent diagnostic criteria for EoE, that include biopsy proven eosinophilic infiltration of the esophagus, result in a phenotypically homogenous case series that is well powered for GWAS and a potentially powerful model to study the genetics of food allergy and atopy in general. We had previously reported association of the TSLP/WDR36 locus with EoE, here, we report the results of an expanded GWAS totaling 934 cases and 6512 controls in an imputed dataset that included ~2.3M variants. The dataset was split into discovery and replication sets based on the Illumina arrays on which the samples were genotyped (HH550/HH610 or OmniExpress). Following GWAS of the discovery cohort (n= 601 cases and 5837 controls) by logistic regression of the binary EoE phenotype adjusting for sex and the first 10 eigenvectors of the principal component analysis, three loci remained genome wide significant (cutoff $P \leq 5\times10\text{-}8$) following multiple testing correction. The previously reported TSLP/WDR36 locus and two novel loci, c11orf30, which has been previously associated with both atopic and autoimmune disease, and CAPN14, that encodes a calpain whose expression is highly enriched in the esophagus. The same variants at all three loci were also associated with EoE in the replication cohort (n= 333 cases 675 controls). RNAseq of primary epithelial cells derived from esophageal biopsy of 9 EoE patients and 3 controls confirmed expression of TSLP, c11orf30 and CAPN14 in esophageal epithelial cells. Analysis of differential expression between cases and controls showed CAPN14 expression was almost 4 fold increased in EoE cases. c11orf30 and TSLP showed subtle, albeit not statistically significant expression level changes. TSLP and c11orf30 variants have now been associated with a number of atopic conditions and asthma. CAPN14 may be specific to EoE explaining the tissue specificity, it appears to be expressed exclusively in the esophagus and our results also indicate CAPN14 is overexpressed in EoE esophageal epithelial cells compared with controls.

999T

Genome-wide association study imputed to 1000 genomes identifies novel loci associated with lung function. *M. Soler Artigas[1,2], L.V. Wain[1,2], N. Shrine[1,2], J. Huffman[3], I. Sayers[4], D. Strachan[5], I.P. Hall[4], M.D. Tobin[1,2], UK BiLEVE consortium, SpiroMeta consortium.* 1) Departments of Health Sciences and Genetics, Adrian Building, University of Leicester, Leicester, UK; 2) National Institute for Health Research (NIHR) Leicester Respiratory Biomedical Research Unit, Glenfield Hospital, Leicester; 3) MRC Human Genetics, MRC IGMM, University of Edinburgh, Edinburgh, Scotland, UK; 4) Division of Respiratory Medicine, University Hospital of Nottingham, Nottingham, UK; 5) Division of Population Health Sciences and Education, St George's, University of London, London, UK.

Lung function measures predict morbidity and mortality, and are used in the diagnosis of chronic obstructive pulmonary disease (COPD), which affected 64 million people worldwide in 2004. Currently genome-wide association studies have identified 26 loci associated with lung function, however they explain only a small proportion of the variance of the lung function measures. In order to identify new loci associated with lung function, in the SpiroMeta consortium we have undertaken the largest meta-analysis of 1000 genomes imputed GWAS of lung function measures to date, analysing around 24 million variants in 38,194 individuals of European ancestry. We studied three quantitative lung function measures: forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC) and the ratio of FEV_1 to forced vital capacity (FEV_1/FVC). These were adjusted for age, sex, height and ancestry principal components, and stratified by ever smoking status. Genomic control was applied at study level and after meta-analysing the results across studies. After undertaking quality control checks on the top signals, we selected 56 independent loci with P-value<5×10^{-6} for any of the three traits for follow-up; 53 of which were novel and 3 within known regions but still significant when conditioning on the previously discovered sentinel SNPs. The follow-up stage is being undertaken in ~55,000 individuals, including the UK BiLEVE consortium which has genotyped a subset of individuals from UK Biobank. Pending additional follow-up data, our interim findings show that 16 loci meet the genome-wide significance threshold when meta-analysing the discovery and the follow-up stages, and 13 also replicate independently if using a Bonferroni corrected threshold for 56 tests. Currently, the strongest signals are two new signals within known loci for FEV_1/FVC: an intergenic SNP ($P<10^{-25}$) between *GPR126* and *LOC153910* which is in strong LD with a non-synonymous variant and an intronic SNP in *NPNT* ($P<10^{-22}$); as well as a new locus for FVC, an intergenic insertion ($P<10^{-17}$) upstream *PTHLH* and *CCDC91*. This research has been conducted using the UK Biobank Resource.

The spirometric measurement of pulmonary function forced expiratory volume in one second (FEV1) is a heritable trait that reflects physiological condition of the lung and airway. We conducted a family-based association test with 706 GENDISCAN study participants from 72 Mongolian families to find candidate genetic determinants of pulmonary function. We identified 7 SNPs at 5 different loci showing significant association with FEV1. We chose nine candidate genes from the 5 loci, and tested 381 SNPs on or near the candidate genes for association with FEV1 in 2,729 subjects of Korea Healthy Twin study. Finally, we could identify TMEM132C as a potential candidate gene at 12q24.3, a previously reported locus of asthma and spirometric indices. We also showed significant association with the FEV1 phenotype and two adjacent candidate genes (UNC93A and TTLL2) in the 6q27 region which has been previously identified as a pulmonary function locus in the Framingham cohort study. Our findings suggest novel candidate genes of pulmonary function in North-east Asians.

Genome-wide association study implicates *LEKR1* at 3q25.31 and an intergenic region at 8q24.21 in Primary Spontaneous Pneumothorax risk. *I. Sousa[1,2], P. Abrantes[1,2], V. Francisco[1,2], G. Teixeira[3], M. Monteiro[4], J. Neves[4], A. Norte[5], C. Robalo Cordeiro[5], J. Moura e Sá[6], P. Santos[1,2], M. Oliveira[7], S. Sousa[8], M. Fradinho[9], F. Malheiro[10], E. Reis[4], L. Negrão[11], S. Feijó[12], S.A. Oliveira[1,2].* 1) Soliveira lab - Genomics of Complex Diseases, Instituto de Medicina Molecular, Faculdade de Medicina da Univ de Lisboa, Lisboa, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Hospital Infante D. Pedro, Aveiro, Portugal; 4) Hospital de Santo António (Centro Hospitalar do Porto), Porto, Portugal; 5) Centro de Pneumologia, Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal; 6) Centro Hospitalar de Vila Nova de Gaia, Vila Nova de Gaia, Portugal; 7) Universidade de Évora, Évora, Portugal; 8) Hospital de S. Bernardo (Centro Hospitalar de Setúbal, E.P.E.), Setúbal, Portugal; 9) Hospital Egas Moniz (Centro Hospitalar de Lisboa Ocidental), Lisboa, Portugal; 10) Hospital da Luz, Lisboa, Portugal; 11) Instituto Português do Sangue e da Transplantação, Centro Regional de Sangue de Lisboa, Lisboa, Portugal; 12) Hospital de Santa Maria, Lisboa, Portugal.

Primary spontaneous pneumothorax (PSP) is characterised by the presence of air in the pleural cavity that occurs without preceding trauma or known cause in individuals with no lung disease. Despite elevated incidence and recurrence rates, little is known about its aetiology. So far, the genetics of PSP remains largely unresolved and virtually no research has been dedicated to the identification of genetic factors for risk or recurrence of sporadic PSP.

To identify genetic variants contributing to sporadic PSP risk, we conducted the first PSP genome-wide association study (GWAS). Two replicate pools of 92 Portuguese PSP cases and of 129 age- and sex-matched controls were allelotyped in triplicate on the Affymetrix Human SNP Array 6.0 arrays. Tested markers were ranked by relative allele score difference between cases and controls ($|RAS_{diff}|$), through a novel cluster method and a combined Z-test. 101 out of the 108 most significant SNPs were technically validated by individual genotyping ($P < 5.00 \times10^{-2}$). Replication of validated SNPs was carried out in an independent Portuguese dataset of 100 cases and 425 controls.

Two single nucleotide polymorphisms (SNPs), rs2101167 in *LEKR1* (leucine, glutamate and lysine rich 1) at 3q25.31 and the intergenic variant rs4733649 at 8q24.21 were strongly associated ($P < 5.00 \times10^{-4}$) with sporadic PSP in the combined datasets. The study reported herein provides for the first time genetic clues for sporadic PSP risk, but future studies are warranted to uncover the function of these polymorphisms.

1002T

Genomewide association for rotator cuff disease identifies two significant SNPs. *C.C. Teerlink[1], J.M. Farnham[1], L.A. Cannon-Albright[1,2,3], R.Z. Tashjian[4].* 1) Dept Internal Medicine, Univ Utah Sch Med, Salt Lake City, UT; 2) George E. Wahlen Dept of Veterans Affairs Medical Center, Salt Lake City, UT; 3) Huntsman Cancer Institute, Salt Lake City, UT; 4) Dept of Orthopaedics, University of Utah School of Medicine, Salt Lake City, UT.

Previous evidence suggests a familial predisposition for the development of rotator cuff tearing. There is limited data identifying specific genes associated with rotator cuff tearing. We collected 238 blood samples for DNA extraction from patients with MRI-confirmed full-thickness rotator cuff tears for the purpose of conducting a genome-wide association analysis. Samples were genotyped on the illumina Omni5.0 SNP platform. We used 2756 genetically matched Caucasian controls from the illumina icontrols database genotyped on the illumina 550K platform. The intersection of the two platforms contains 272,704 markers across the genome that passed typical quality control metrics. We used GEMMA software to conduct tests of association at each marker. GEMMA software empirically estimates a kinship covariance matrix for all pairs of individuals, which is used in the analysis to mitigate potential effects of population stratification and cryptic relatedness. Our analysis identified two SNPs that exceeded the threshold for significance ($p < 1.8\text{-}7$) after adjusting for multiple testing. One SNP (rs11939479; p = 6.9-10; OR = 2.8) resides on 4q32.3 in the SPOCK3 gene. SPOCK3 codes for a proteoglycan which are typically expressed in connective tissue. The other significant SNP (rs7897503; p =1.2-7; OR = 2.0) resides on 10q21.1, approximately 200 Kb downstream of PCHD15, which is a member of the cadherin family of genes that are generally involved in cell-cell adhesion. To our knowledge, these findings represent the first attempt to identify genetic factors influencing rotator cuff disease via a genome-wide association. Identification of potential genes or genetic variants associated with rotator cuff tearing may help in identifying individuals at-risk for the development of rotator cuff tearing as well as identifying possible genetic targets to for biologic augments to improve rotator cuff repair healing.

1003S

A genome-wide meta-analysis of hyper- and hypothyroidism and thyroid function. *A. Teumer[1], M. Medici[2], H. Völzke[1], R. Peeters[2], the CHARGE thyroid function working group.* 1) Institute for Community Medicine, University Medicine Greifswald, Greifswald, Germany; 2) Department of Internal Medicine, Erasmus Medical Center Rotterdam, Rotterdam, The Netherlands.

Thyroid hormones play a key role in cellular growth, development and metabolism. Overt thyroid dysfunction leads to common endocrine disorders affecting approximately 10% of individuals over their life span. Milder changes in thyroid function are associated with weight changes, coronary heart disease, atrial fibrillation, osteoporosis, psychiatric disorders, and mortality. Circulating concentrations of thyroid hormones have a strong heritable component. Using genome-wide association studies (GWAS) in predominantly population-based cohorts, we and others have identified 26 genetic loci associated with serum TSH and free T4 levels. However, the variance explained by these loci is still low, i.e. 5.64% and 2.30% for TSH and free T4, respectively. To find novel loci associated with thyroid function, we have increased our sample size substantially to conduct a new GWAS in more than 33,000 individuals. In contrast to former studies, these analyses will be performed by imputing against a recent 1000 genomes panel, which gives us the opportunity to fine-map known loci and reveal additional loci due to better imputation and tagging of causal SNPs. Sex-stratified analyses of TSH and free T4 will be performed in individuals with TSH values within the reference range, allowing the analysis of interactions by sex. Additionally, we are performing a GWAS for hypo- and hyperthyroidism which will address genetic influences for more overt forms of thyroid disorders. Preliminary results in up to 1800 cases showed that 11 of the 26 SNPs known to be associated with serum TSH and free T4 in euthyroid subjects, including PDE8B and PDE10A, are also associated with hypothyroidism ($p < 4E-4$) or hyperthyroidism ($p < 4E-5$). In this 1000 genomes based GWAS, we expect to reveal additional loci influencing thyroid function as well as hypo- and hyperthyroidism.

1004M

Genome-wide Mega-Analysis on Myopia and Refractive Error in CREAM and 23andMe. *V.J.M. Verhoeven[1,2,3,4], R. Wojciechowski[5,6], P.G. Hysi[7], Q. Fan[8], A.K. Kiefer[9], N. Eriksson[9], C.J. Hammond[7], N.A. Furlotte[9], C.C.W. Klaver[1,2], Consortium for Refractive Error and Myopia (CREAM).* 1) Deparment of Ophthalmology, Erasmus Medical Center, Rotterdam, the Netherlands; 2) Deparment of Epidemiology, Erasmus Medical Center, Rotterdam, the Netherlands; 3) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore, Singapore; 4) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 5) 5.Department of Twin Research and Genetic Epidemiology, King's College London School of Medicine, London, United Kingdom; 6) 6.Inherited Disease Research Branch, National Human Genome Research Institute, US National Institutes of Health, Baltimore, Maryland, United States; 7) 7.Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, United States; 8) 8.Saw Swee Hock School of Public Health, National University Health Systems, National University of Singapore, Singapore, Singapore; 9) 23andMe, Mountain View, California, United States of America.

Purpose: Myopia is widely recognized as a multifactorial, complex genetic disorder. Recently, multiple loci for refractive phenotypes were identified separately by the Consortium for Refractive Error and Myopia (CREAM) and investigators from 23andMe, Inc. We aimed to identify additional genetic loci that explain the genetic architecture of refractive error using higher power and denser imputation by meta-analyzing data from CREAM and 23andMe. Methods: We conducted a genome-wide association study (GWAS) meta-analysis of refractive error including 63,697 individuals (49,808 Caucasians; 13,899 Asians) from the CREAM consortium using a linear regression model. Age-at-onset of myopia for 104,294 individuals from the 23andMe dataset was analyzed using survival analysis (Cox proportional hazards model). GWAS regression results from both studies were meta-analyzed by z-scores using a fixed effects model. We performed pathway analyses using Ingenuity IPA and public databases. Results: Over 100 regions across the genome reached genome-wide significance at P-value $< 5.0\times10^{-8}$. The most significant P-value was 2.74×10^{-54} for rs670352 near the known refractive error gene *GJD2*. We confirmed association with all but 2 from 36 previously reported CREAM and 23andMe genes. We identified 71 new genome-wide significant associations with refractive error and myopia. These SNPs explain ~12% of the variance of all common SNPs for SE. The results confirm over-representation of known pathways, such as extracellular matrix, ion channel activity, and glutamate signaling but also suggested potentially new mechanisms, including signaling of calcium, VEGF and TGF-β, mitochondrial function, and apoptosis. Conclusions: This study is the largest meta-analysis on refractive error known to date. This large catalogue of genetic variants opens up new insights in myopigenesis.

1005T

Genetic discovery in the 23andMe participant cohort. *D.A. Hinds, C.A.M. Northover, M.H. McIntyre, C. Wilson, K.E. Huber, A. Kleinman, F. Sathirapongsasuti, R.K. Bell, E. Pierson, K. Bryc, A.S. Shmygelska, N.A. Furlotte, Y. Hu, C. Tian, E.Y. Durand, C.Y. McLean, B. Naughton, J.L. Mountain, N. Eriksson, J.Y. Tung.* 23andMe, Inc., Mountain View, CA.

The 23andMe cohort now includes more than 550,000 genotyped subjects who have consented to participate in research, including more than 100,000 individuals with substantial non-European ancestry. Most participants provide phenotypic information through web based surveys covering a wide range of topics. The scale of this cohort has required us to develop specialized solutions for many tasks where conventional approaches have inconvenient scaling properties. These include methods for ancestry inference and detection of identity by descent; phasing and imputation; and genome-wide association testing. While most of our data is collected on the "sample of convenience" of 23andMe customers, we have recruited cohorts in several disease areas, including Parkinson's disease, myeloproliferative neoplasms, and inflammatory bowel disease. Over the next year, we expect to take advantage of much deeper imputation panels to extend the range of allele frequencies we can effectively interrogate.

Our status as a commercial company poses challenges with respect to our participation in the scientific community and our responsibilities to protect the privacy of our customers, many of whom did not join 23andMe with the intent to participate in research. We have tried to balance these demands through publication of GWAS findings and participation in collaborations to enable discoveries using the data our customers have shared, while controlling access to potentially identifiable aggregated data, and in rare cases, only providing access to individual-level data with explicit customer consent. We have over 25 active academic collaborations in atopic disease, infectious disease, autoimmune disease, fertility, migraine, Parkinson's disease, and morphological phenotypes, among others.

Cohort growth has expanded the range of phenotypes for which we are able to make discoveries, to where we can now make meaningful scientific contributions even for phenotypes that have been intensively investigated by large consortia. The dataset is now also sufficiently large to identify robust associations with categories of phenotypes that have until now been essentially intractable to genetic analysis, including cognition and behavior. The data provide unique insights into the genetic architecture of human phenotypic variation.

1006S

A genome-wide regulatory haplotype analysis of asthma. *D.C. Croteau-Chonka[1], W. Qiu[1], S.T. Weiss[1,2], B.A. Raby[1,3], EVE Consortium.* 1) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Partners Center for Personalized Medicine, Partners Health Care, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Genome-wide association studies (GWAS), including two large meta-analyses of >35,000 individuals (the GABRIEL and EVE asthma consortia), have identified more than ten highly-reproducible asthma susceptibility loci. We can now start to look beyond single-marker main effects on asthma to epistasis and the role of functional regulatory haplotypes, namely the joint effect of pairs of regulatory and deleterious coding single nucleotide polymorphisms (SNPs) on disease susceptibility. Such associations may give further insight into potential underlying mechanisms at asthma GWAS loci.

We have performed a pilot genome-wide haplotype association analysis of asthma susceptibility in 359 cases from the Childhood Asthma Management Program (CAMP) along with 846 healthy Illumina iControlDB controls. We constrained our analyses to a set of 526 genes with significant evidence within 50 kb windows of expression quantitative trait loci (eQTL) (false discovery rate (FDR) < 5%) in disease-relevant CD4+ T-lymphocytes (Murphy *et al.* (2010), *Hum Mol Genet.*). The dataset thus consisted of 1,609 eQTL SNPs matched with 831 coding SNPs in their respective target genes. We performed an H - 1 degrees-of-freedom case-control omnibus haplotype test of each of the SNP pairs (where $H = 3$ or 4 observed haplotypes).

Among 2,538 omnibus tests, we identified 149 associations significant at nominal $P < 0.05$, but no associations significant at FDR < 5%. A visual inspection of the distribution of omnibus associations suggested a moderate departure from the expected distribution, though there was no substantial evidence of inflation ($\lambda_{GC} = 1.05$). One of the most significant omnibus tests ($P = 0.0087$) included a quinone oxidoreductase gene called *CRYZ*, which is near a GWAS SNP associated with circulating levels of resistin. A pro-inflammatory hormone, resistin is thought to be a potential biomarker for asthma.

The next stage of the analysis will be to include all 4,903 cases, 3,371 controls, and 1,677 pseudo-controls among 12 cohorts from the entire EVE Consortium. We will use meta-analysis to integrate all of the individual cohort haplotype results together using Stouffer's method, setting the cohort weights to be their effective sample sizes. The marked increase in sample size will substantially improve our ability to detect regulatory haplotypes of asthma.

1007M

Genetic analysis of central serous chorioretinopathy and polypoidal choroidal vasculopathy. *J. Ahn[1,2], N.K. Ryoo[1,3], S.J. Woo[1,3], H.S. Cheong[4], K.H. Park[1,3].* 1) Department of Ophthalmology, Seoul National University, College of Medicine, Seoul, Korea; 2) Department of Ophthalmology, Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, Korea; 3) Department of Ophthalmology, Seoul National University Bundang Hospital, Seongnam, Korea; 4) Department of Genetic Epidemiology, SNP Genetics Incorporation, Seoul, Korea.

Central serous chorioretinopathy (CSC) and polypoidal choroidal vasculopathy (PCV) are both common retinal disorders affecting the macula. Although PCV is often considered a subtype of exudative age-related macular degeneration (AMD), CSC and PCV share many clinical characteristics such as choroidal vascular hyperpermeability, choroidal thickening demonstrated on enhanced-depth imaging optical coherence tomography and inner choroidal vasculature abnormalities seen on indocyanine angiography. In this study, we performed genetic analysis of CSC and PCV using genome-wide association study (GWAS) and exome chip data to compare the genetic makeup of the two disease entities. This was a case-control analysis consisting of 168 PCV, 167 CSC patients and 543 control subjects. A subgroup analysis of 50 CSC patients diagnosed as the "chronic" phenotype, with persistent or progressive visual symptoms for more than 6 months, was performed additionally. PCV and control subjects were genotyped using Illumina OmniExpress and CSC patients were genotyped with the HumanExome beadchips. Integrated analysis of GWAS and exome array data was done and a total of 12,777 SNPs were included. The well-known ARMS2 rs10490924 SNP showed significant association with PCV compared to the control (P=1.78E-13). A novel SNP rs2455512 was found to be associated with all and chronic CSC patients compared to the control group (P=2.13E-11 and 6.92E-11, respectively). There were 3 SNPs (rs8098316, rs1363098, rs1214752) that showed borderline significant association with all CSC patients compared to control (P=1.85E-05, 4.90E-05, and 8.74E-05, respectively). In the analysis of chronic CSC versus the control group, 4 SNPs (rs12843815, rs6843141, rs11158685, rs4800452) reached borderline significance (P=1.46E-05. 7.18E-05. 7.19E-05, and 8.89E-05). This is the first study to perform comparative genetic analysis of CSC and PCV and we found differences in the significant SNPs for each disease entity compared to the control group. The novel SNPs that were found to be associated with CSC require further replication studies.

1008T

Known Age-Related Macular Degeneration Risk Variants Are Not Associated with Rapid Disease Progression or Good Treatment Response. *M.D. Courtenay[1], W. Cade[1], G. Wang[1], S.G. Schwartz[2], J.L. Kovach[2], A. Agarwal[3], M.A. Brantley[3], W.K. Scott[1], J.L. Haines[4], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 3) Ophthalmology and Visual Sciences, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Age-related macular degeneration (AMD) is the leading cause of irreversible vision loss among older adults in developed countries. Genome-wide association meta-analysis has implicated common variations in 19 genes as AMD risk factors. Given the strong genetic influence on the risk of developing AMD, and the substantial variation in progression to advanced AMD and in treatment response, we investigated whether these clinical endpoints are also influenced by the known genetic variation. In an existing dataset, 16 of the 19 GWAS loci were used to calculate a genetic risk score (summed number of risk alleles weighted by effect sizes) for each individual as outlined in Fritsche et al., 2013. To maximize our power for discovery, we created two "clinically extreme" case/control datasets with the following characteristics: 1) Rapid clinical progression of 36 individuals with early AMD or geographic atrophy to neovascular AMD within one year vs. 31 early AMD patients who did not progress over five or more years, and 2) 20 patients with bilateral neovascular AMD who were treated with intravitreal injections of anti-angiogenic agents for one year and demonstrated bilateral good treatment response (three lines of vision gain on the Snellen vision chart, prolonged or persistent (at least 6 months) absence of subretinal fluid (SRF) and absence of intraretinal fluid (IRF) on OCT, presence of unchanged small intraretinal cysts with no recurrence of SRF) vs. 22 neovascular AMD patients who demonstrated a poor response in one or both eyes (three lines of vision loss, persistent SRF and IRF, formation of disciform scar). The genetic risk score was tested for association with rapid AMD progression or good treatment response with logistic regression adjusting for age and sex. Risk score was not associated in either dataset in our study (progression P=0.43 and treatment P=0.63). Therefore, the genetic effects of the 19 known AMD risk loci are not associated with rapid progression or good treatment response in this small dataset, but perhaps a larger sample size would have sufficient power to demonstrate an effect. Nevertheless, unknown genetic factors may still be regulating variability in progression and treatment response. Whole exome sequencing is currently underway in this dataset to test if novel rare or common variants are associated with these clinical endpoints.

1009S

Large association study of exonic variants in idiopathic achalasia. *J. Becker[1,2], T. Schwämmle[1,2], M.M. Wouters[3], S. Niebisch[4], E. Mangold[1], H.G. Schulz[5], G.E. Boeckxstaens[3], M.M. Nöthen[1,2], I. Gockel[4], M. Knapp[6], J. Schumacher[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany; 3) Translational Research Center for Gastrointestinal Disorders, Catholic University of Leuven, Leuven, Belgium; 4) Department of General, Visceral and Transplant Surgery, University Medical Center, University of Mainz, Mainz, Germany; 5) Department of General and Abdominal Surgery, Protestant Hospital Castrop-Rauxel, Castrop-Rauxel, Germany; 6) Institute for Medical Biometry, Informatics, and Epidemiology, University of Bonn, Bonn, Germany.

Idiopathic achalasia is a severe disorder of the lower esophageal sphincter (LES) with a lifetime prevalence of 1:10,000. The disease is characterized by the degeneration of neurons in the myenteric plexus leading to the development of a megaesophagus with irreversible loss of LES function. On the etiological level, achalasia is a multifactorial disorder with environmental and genetic factors being risk-associated. By testing markers in immune-relevant loci using the Illumina's Immunochip and subsequent HLA imputation, we already identified strong association signals reaching genome-wide significance within the HLA-DQ complex indicating that autoimmune processes contribute to the pathophysiology of achalasia. The aim of the present study was to determine the role of exonic variants in the development of achalasia. We therefore performed an association study using Illumina's Exomechips which have been developed based on the data of 12,000 exomes. The chip contains more than 240,000 - mainly functional-relevant - markers. We genotyped 677 patients with idiopathic achalasia and 2,316 population-based controls from Central Europe and after quality control (QC) steps 106,417 markers remained for association testing. The analysis yielded a strong association signal within the HLA region ($P<5\times10^{-08}$). We carried out a conditional analysis adjusting for the variants within the HLA-DQ complex identified before. The analysis revealed that the HLA signal on the Exomechip is not independent of the already known achalasia risk variants within this region. Next, we focused on variants outside the HLA region and chose 57 markers ($P<10^{-03}$) for a successive replication step in 383 patients and 1,017 population-based controls of Central European descent. Of 51 variants surpassing QC steps, 5 markers reached a *P*-value below 0.1 in the replication step with the same allelic direction as seen in the initial Exomechip study. These 5 markers are either low-frequent (N=4, $MAF_{Controls}<5\%$) or common (N=1) variants and are located within the genes *CRISP3*, *HBS1L*, *IGSF22*, *KRTAP12-1* and *LMOD3*. Our study provides evidence that low-frequent and common exonic variants play a role in the pathophysiology of achalasia. Currently, we test the 5 associated markers of the replication step in a third cohort of achalasia patients and controls in order to confirm the contribution of these variants to the development of achalasia.

Identification of novel and rare coding variants associated with free fatty acids and serum fatty acid profile. *X. Sim[1], R.P. Welch[1], A.U. Jackson[1], H.M. Stringham[1], T.M. Teslovich[1], P.S. Chines[2], N. Narisu[2], C. Fuchsberger[1,3], J.R. Huyghe[1], A.E. Locke[1], M. Cannon[4], M. Ala-Korpela[5], M. Boehnke[1], K.L. Mohlke[4], M. Laakso[6].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 2) Genome Technology Branch, National Human Genome Research Institute, Bethesda, Maryland, USA; 3) Center for Biomedicine, European Academy of Bozen/Bolzano (EURAC), Bolzano, Italy; 4) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 5) Computational Medicine Research Group, Institute of Health Sciences, University of Oulu, Finland; 6) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Fatty acid (FA) levels play a critical role in insulin sensitivity, and are often elevated in obese or individuals with type 2 diabetes. Previous GWAS studies have implicated common genetic variants with FAs, however, genetic contributions at coding and low frequency variants remain largely unknown. We assayed exomic variation in 6,373 non-diabetic Finnish males from population-based METSIM study with Illumina HumanExome array (N=~242,000) and Illumina OmniExpress genotypes imputed to GoT2D reference panel (N=~19.3M). Free FA (FFA) was measured on enzymatic colorimetric method while FA profile (including n-3, n-6, n-7, n-9, mono/poly-unsaturated, phosphatidylcholines, and sphingomyelins) were measured using proton nuclear magnetic resonance spectroscopy. Inverse normalised residuals were generated after adjusting for age, BMI, and smoking as a primary model. We identified genome-wide associations at 19 unique loci with multiple FAs. An intergenic variant (MAF=17%, $P=2\times10^{-9}$) was associated with FFA, near *PPP1R3B*, a glycogen-targeting regulatory subunit regulating liver glycogen metabolism. The remaining 18 loci included previously identified FA (e.g. *FADS1-2-3*, *CPT1A*), lipids and glycemic loci. As FAs are correlated with lipids and glycemic traits, we repeated association analyses on an adjusted model, conditioning these traits from FA levels. We identified 2 additional loci with the adjusted model only: (i) common intronic variant rs4985154 at *PDXDC1* associated with polyunsaturated FAs other than linoleic acid [MAF=34.4%, $P=5\times10^{-8}$], and (ii) rare missense variant rs199717050 at *LCAT* associated with both phosphatidylcholine and other cholines (PC) and total phosphoglycerides (TotPG) [MAF=.46%, $P_{PC}=7\times10^{-10}$, $P_{ToTPG}=3\times10^{-8}$]. We also note that associations at 9 loci were substantially diminished after conditioning on lipids and glycemic traits, suggesting that they were mediated by the major classes of liproproteins and insulin measures. Finally, we aggregated rare (<1%) protein-altering variants and carried out gene-level association analysis using SKAT-O. We identified gene-level associations at *LIPG* with PC [$P=2\times10^{-7}$] and TotPG [$P=5\times10^{-8}$], combining evidence across 3 missense variants and a splice acceptor on the primary model. We demonstrate that rare coding genetic variants influence FAs, and could be informative about biological pathways in lipid metabolism and insulin sensitivity.

1011T

Replication of the association signals of thyrotoxic periodic paralysis (TPP) at chromosome 17q24.3. *P. Chen[1,2,3,4,5], T. Chang[2,6].* 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 5) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan; 6) Department of Internal Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan.

Thyrotoxic periodic paralysis (TPP) is a characteristic disease featured by episodic attacks of hypokalemia and muscle weakness in certain thyrotoxic individuals. Epidemiology data of TPP show male predominance and huge inter-population prevalence difference. Up to 10% of thyrotoxic Asian males develop TPP, while only less than 0.1% thyrotoxic Caucasian males do. In 2010, Ryan et al. (Cell 140(1): 88-98) found that *KCNJ18* mutations could be found in 33% of their patients but not in controls; those mutations were mainly found in patients of European descent. In 2012, Cheung et al. (Nat Genet 44(9): 1026-1029) published a GWAS (genome-wide association study) in ethnic southern Chinese and reported a single susceptibility locus at chromosome 17q24.3 near *KCNJ2*; the odds ratio was estimated to be ~3.3. It is not clear whether these two loci are genuine risk loci for TPP. Furthermore, if these two loci do confer susceptibility, it is not clear about the real causative genes and the risk alleles. To address these issues, we conducted a GWAS with 41 TPP patients as cases and 725 thyrotoxic, non-TPP individuals as the control individuals. All of the participants are of ethnic Chinese Han population background in Taiwan. We used Axiom Genome-Wide CHB Array Plate from Affymetrix as the genotyping platform, which contains 642,832 common SNPs (MAF>5%) in the Chinese Han genome. Our results showed several SNPs with p values smaller than 5×10^{-7} (trend test and/or allelic test) at chromosome 17q24.3. Association signals at 2q31.2, 2q36.3, 9q22.1 and 18q21 were also identified. We further perform Sanger sequencing of the coding regions of the *KCNJ2* gene; however, no disease causing variants could be found. On the other hand, our GWAS did not show association signals at or near *KCNJ18*. Sanger sequencing of the coding regions of the *KCNJ18* also showed negative results. Our results demonstrate that 17q24.3 is the true TPP susceptibility locus in ethnic Chinese Han individuals. However, the genuine causative variants are still unidentified yet.

The PhenX Toolkit: A Genomic Resource for Standard Measures of Phenotypes and Exposures. *W. Huggins[1], H. Pan[1], D.S. Nettles[1], E.B. Bullard[1], T. Hendershot[1], J.G. Pratt[1], D.R. Maiese[1], D.C. Brown[1], M. Phillips[1], T.H. Brandon[2], S.T. Tiffany[3], G.K. Brown[4], P.H. Byers[5], M.L. Marazita[6], C.A. McCarty[7], K.P. Conway[8], G.K. Farber[9], K.L. Wanke[10], E.M. Ramos[11], C.M. Hamilton[1].* 1) RTI International, Research Triangle Park, NC; 2) Moffitt Cancer Center, Tampa, FL; 3) University at Buffalo, State University of New York, Buffalo, NY; 4) University of Pennsylvania, Philadelphia, PA; 5) University of Washington School of Medicine, Seattle WA; 6) University of Pittsburgh, Pittsburgh, PA; 7) Essentia Institute of Rural Health, Duluth, MN; 8) National Institute on Drug Abuse, Bethesda, MD; 9) National Institute of Mental Health, Bethesda, MD; 10) Office of Disease Prevention, National Institutes of Health, Bethesda, MD; 11) National Human Genome Research Institute, Bethesda, MD.

The PhenX (consensus measures for **Phen**otypes and e**X**posures) Toolkit (https://www.phenxtoolkit.org/) is a well-established, Web-based catalog of measures for collaborative biomedical research. PhenX Working Groups (WGs) consider measures that are suitable for a variety of study designs, including longitudinal and clinical studies as well as genomic studies. Expert Review Panels are being convened to ensure that the current Toolkit measures are responsive to the evolving needs of the biomedical community. PhenX phase 1 focused on measures of phenotypes and exposures relevant to genomic studies of common complex diseases and released measures for 21 research domains (including Demographics, Nutrition, Diabetes, and Environmental Exposures) in the PhenX Toolkit. PhenX phase 1 also added depth to the Toolkit in the area of Substance Abuse and Addiction by adding one Core collection and six Specialty collections. PhenX phase 2 expands the scope of the Toolkit to address four new domains and also adds depth in the areas of Mental Health Research and Tobacco Regulatory Research. The first new domain to be addressed is Rare Conditions; preliminary measures and Toolkit annotations will be presented. “PhenX Measures for Mental Health Research,” funded by the National Institute of Mental Health, aims to add several Specialty collections (Suicide, PTSD, and Eating Disorders) and one Core collection to the Toolkit. “PhenX Measures for Tobacco Regulatory Research,” funded by the Tobacco Regulatory Science Program, aims to add several Specialty collections (Social/Cognitive, Bio-behavioral, Agent, Vector, and Environment) and one Core collection to the Toolkit. Preliminary measures for the Suicide and Social/Cognitive WGs will be presented. To support investigators who want to collect data via the Web, Web-based versions of PhenX protocols will be made available as Research Electronic Data Capture (REDCap) modules. Study variables in the database of Genotypes and Phenotypes (dbGaP) are being classified as identical, comparable, or related to PhenX variables. The dbGaP advanced search tool uses these mappings to help investigators discover variables and studies that are suitable for cross-study analysis. The PhenX Toolkit provides the biomedical research community with easy access to recommended, low-burden measures that have the potential to increase the overall impact of individual studies. *Funding provided by U01 HG004597, 3U01 HG004597-02S1, and U41 HG007050.*.

Analysis of Interleukin 10 haplotypes with soluble IL-10 levels and autoantibody production in Mexican patients with primary Sjögren’s syndrome. *M. Vázquez-Villamar[1], CA. Palafox-Sánchez[1,2], JF. Muñoz-Valle[1], Y. Valle[1], D. Salazar-Camarena[1], BA. Treviño-Talavera[1], G. Orozco-Barocio[2], E. Oregon-Romero[1].* 1) Instituto de Investigación en Ciencias Biomédicas (IICB), Universidad de Guadalajara, Guadalajara, México; 2) Servicio de Reumatología, Hospital General de Occidente, Zapopan, México.

Background: Primary Sjögren's syndrome (pSS) is a systemic autoimmune disease characterized by lymphocytic infiltration of salivary and lachrymal glands, leading to xerostomia (dry mouth) and xeroftalmia (eye dryness). Infiltrating monocytes produce interleukin 10 (IL-10) that is capable of promoting the activation and differentiation of B cell as well as autoantibodies production, such as anti-Ro and anti-La which have an important role in the pathogenesis of pSS. Three polymorphic sites in positions -1082(A/G), -819(C/T), and -592(C/A) in the IL10 promoter can form haplotypes that may influence the IL-10 production. Objective: To determine the frequency of IL10 haplotypes and serum levels of IL-10 (sIL10), anti-Ro, and anti-La antibodies in patients with SSp. Methods: The study included 111 patients with pSS, from the Department of Rheumatology (HGO, SSJ, Zapopan, Jalisco, Mexico). As a control group, 260 subjects were included. IL10 polymorphisms were genotyped by PCR/RFLP technique. The haplotype frequencies were inferred by EmapFre software. Levels of sIL-10, anti-Ro, and anti-La autoantibodies were performed by ELISA. Rheumatoid factor (RF) levels were determined by nephelometry. Statistical analysis was performed with Stata 9.0 and GraphPad Prims 6 software. Results: The polymorphisms were in Hardy-Weinberg equilibrium and showed a high linkage disequilibrium (100%, pc=3673^{-18}). The most frequent haplotypes were: ACC (44%), ATA (23%) and GTA (16%). The ATC haplotype was associated with increased risk for pSS (OR 3.42, CI:1.06-11.04, p=0.0395). Higher sIL10 levels were observed in patients with pSS than in the control group (3.0 vs 2.4 pg/mL, p<0.0001). sIL-10 correlated with anti-Ro(r=0.3615, p= 0.0053) and anti-La(r=0.2, p=0.0401) autoantibodies. Patients positive to anti-Ro showed higher levels of sIL-10 than negative patients (3.2 vs 2.9 pg/mL, p=0.0243). Similar results were found to pSS positive to anti-La antibodies (3.4 vs 2.9 pg/mL, p=0.0027). Conclusions: Our results suggest that carriers of the haplotype ATC have 3.42-folds more likely to develop SSp, however, due to their low frequency in our population lacks clinical utility. Serum IL-10 levels are increased in pSS patients and are positively correlated with autoantibodies which suggest its role as a pathogenic cytokine in pSS. However, the low associations of IL-10 with the clinical parameters suggest that it should not be considered as a biomarker of the disease.

1014T

Large scale meta-analysis of 1000G imputed genotypes in 95,061 subjects reveals 7 novel loci for loss of kidney function. *M. Gorski[1,2], the CKDGen Consortium.* 1) Department of Genetic Epidemiology, University of Regensburg, Regensburg, Bayern, Germany; 2) Department of Nephrology, University Hospital Regensburg, Regensburg, Germany.

Meta-analyses of genome-wide association studies (GWAS) using Hapmap imputed genotypes have successfully revealed several susceptibility loci for estimated glomerular filtration rate (eGFR). 1000G imputed genotypes promise to reveal novel loci and to give additional insights into the genetic architecture of kidney function measured by eGFR. A large scale meta-analysis of 1000G imputed genotypes has not yet been performed. The objective was to answer if a meta-analysis of 1000G imputed GWAS can identify loci for the quantitative measure eGFR, and to evaluate how potentially new loci compare to previous meta-analysis based on Hapmap imputed genotypes. GFR was estimated by the four-variable MDRD Study Equation. GWAS were performed on genotype dosages, imputed with reference panels of up to 30 million variants in 32 studies including 95,061 subjects. We identified 7 new susceptibility loci for reduced eGFR (p values range from 2.89E-08 to 6.21E-11). The loci were in or near the genes LPHN2, ACVR2A, KIAA1715, ARL15, SLC17A1, ASTN2 and SLC7A6. The lead variants of the novel loci were either new in the 1000G reference panel or were previously included in Hapmap panels but did not show genome wide significance. One of the loci, SLC7A6, was suggested in previous work based on pathway derived candidates. We also replicated 31 of 53 lead SNPs in known loci with genome wide significance (p-values < 5E-8). Our large-scale meta-analysis of 1000G imputed genotypes in 95,061 subjects identified novel susceptibility loci for the kidney function measure eGFR, mostly due to the higher coverage of variants in the latest reference panels. Lead SNPs in 2 of the novel loci (SLC17A1 and KIAA1715) are non-common (minor allele frequency 2.8% and 3.6%).

1015S

Association analysis of *PPARG* (p.Pro12Ala) polymorphism with type 2 diabetic retinopathy in patients from north India. *N. Kaur, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: To determine whether p.Pro12Ala polymorphism in *PPARG* is associated with type 2 diabetic retinopathy in patients from north India. **Material & Methods:** Present case-control association study included total 1613 individuals, of which 717 were diagnosed as diabetic retinopathy (DR) patients due to presence of neovascularisation, microaneurysms and hemorrhage in their retina. 608 T2DM patients without any sign of retinopathy (CDR) and 288 healthy controls (NDC) without diabetes and any sign of retinopathy, were also collected and analyzed. The mean duration of diabetes in DR and CDR group was 12.440±6.356 and 8.050±5.772, respectively. The genotyping for p.Pro12Ala polymorphism of *PPARG* in these total 1613 cases and controls was performed by Taqman Drug Metabolism Genotyping Assays using Real time PCR. Further, few genotypes were confirmed by direct DNA sequence analysis of the amplified products. Statistical analysis was performed using SPSS for windows version 16 (SPSS Inc). Binary logistic regression analyses were used to determine odds ratio (OR). Hardy-Weinberg equilibrium was tested using Cochran-Armitage trend test (2 x 3 contingency table) based on linear regression model. **Results:** The genotype distribution and allele frequency of p.Pro12Ala (*PPARG*) polymorphism did not differ significantly (p>0.05) between DR and CDR. However, statistically significant differences in genotype (p=0.002) and allele distribution (p= 0.0326) were observed on comparing DR with NDC group. A significantly higher frequency of heterozygous CG genotype was observed in DR group as compared to NDC group (19.66% vs 10.76%). On comparison of CDR and NDC groups statistically significant differences in the genotype distribution were observed (p=0.0005) whereas distribution of allele frequency did not differ significantly (p=0.091) among these two groups. The homozygosity of dominant allele CC was found to be more common in NDCs as compared to CDRs (86.11% vs 78.94%) which suggested the evidence of the association of this genotype in dominant mode of inheritance (OR; 1.65, 95% CI: 1.72-2.43, p=0.009). **Conclusion:** These findings suggest a statistically significant association of *PPARG* (p.Pro12Ala) polymorphism with T2DM when compared with healthy controls. However, no significant association has been observed on comparing DR cases with T2DM patients in tested north Indian patients.

1016M

To study the association of -106 C/T polymorphism in the aldose reductse (*AKR1B1*) gene with diabetic retinopathy. *Vanita. Kumar, N. Kaur.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Purpose: Present study aimed to assess the association of -106C/T polymorphism of the aldose reductase gene (*AKR1B1*) with retinopathy in type 2 diabetic cases from North India. **Material and Methods:** The present study included 213 patients diagnosed with diabetic retinopathy and 233 type 2 diabetes mellitus (T2DM) cases without any sign of retinopathy, taken as controls. All the cases and controls were recruited from Dr. Daljit Singh Eye Hospital, Amritsar. All the participating individuals underwent complete ophthalmologic examination that included visual acuity testing, Humphrey's perimetry, optical coherence tomography (OCT) and fundus examination after pupil dilation. The genotyping was performed by direct DNA sequence analysis of the amplified products. Statistical analysis was performed using SPSS for windows (Version. 16.0). Genotype distributions and allele frequencies were evaluated using statistical calculator (StatPac V. 3. 0). MedCalc (V 9. 3. 9. 0) was used to determine the odds ratios (OR) and 95% confidence intervals (CI). **Results:** The alleles (p=0.8842) and genotypes frequencies (p=0.6304) showed no statistical differences when DR cases were compared with controls (T2DM). OR analysis also revealed no significant co-relation of -106 C/T polymorphism with DR. **Conclusions:** Present findings suggest lack of association of -106 C/T polymorphism in *AKR1B1* with diabetic retinopathy in tested patients from north India.

Menopausal age shares a common genetic background with diabetes and lipid traits: a study on 13.484 Finns. *A. Joensuu[1, 2], J. Kettunen[3, 2], S. Ripatti[1, 2, 4], J. Sinisalo[5], M.S. Nieminen[5], M-L. Lokki[6], A. Jula[7], J.G. Eriksson[8], V. Salomaa[2], M. Perola[2, 1, 9], K. Auro[2, 1].* 1) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) National Institute for Health and Welfare (THL), Helsinki, Finland; 3) University of Oulu, Finland; 4) Hjelt Institute, University of Helsinki, Finland; 5) Heart and Lung Center HUCH, Helsinki University Central Hospital, Finland; 6) Haartman Institute, University of Helsinki, Finland; 7) National Institute for Health and Welfare (THL), Turku, Finland; 8) Department of General Practice and Primary Health Care, University of Helsinki, Finland; 9) University of Tartu, Estonia.

Background: The average age for menopause in western countries is 51 years, but individual variation is high with natural menopause occurring between 40-60 years of age. Later age at menopause has been associated with decreased risk of cardiovascular diseases and osteoporosis as well as increased life expectancy. However, associations between menopausal age and diabetes are controversial and no genetic links have been reported. Smoking has been shown to have a lowering effect on menopausal age whereas obesity raises the age at natural menopause, possibly due to the secretion of hormones from adipose tissue. These and other confounding environmental effects might disturb some of the reported associations between menopausal age and diseases. Methods: Stolk et al. performed a large meta-analysis of genome-wide association studies reporting 17 genetic variants which associate with age at natural menopause (Nat.Genet. 2012). We constructed a genetic score of menopausal age by summing the reported effect sizes (years/allele) of these polymorphisms in five Finnish cohorts (FINRISK1997, PredictCVD, Health2000, Corogene and HBCS) and studied its associations to prevalent and incident diabetes. Logistic and survival analysis corrected by age and geographical variables were performed in individual cohorts and combined in meta-analysis.

Results: One-year increase in the genetic score (range -2.30 - 3.13 years) associated significantly with future diabetes in women (N=2831, hazard ratio=1.46, P=0.0083) but not in men (P=0.3). Interestingly, the genetic score associated nominally with prevalent diabetes in men (N=6249, odds ratio=0.86, P=0.016) but no association was seen in women (P=0.7). In women nominal association of higher menopausal age score was seen also in linear analysis with higher triglyceride levels (P=0.021) and lower HDL cholesterol (P=0.025), but no associations were detected in men. Conclusions: The timing of menopause may share a common genetic background with metabolic endpoints. Our results suggest that genetic variants previously associated with menopausal age have a gender-specific impact on future risk of diabetes: in women these genetic variants increased the risk of future diabetes 1.5-fold, whereas in men the effect was slightly protective on prevalent diabetes. These results may provide valuable insights on biomolecular mechanisms underlying metabolic traits.

1018S

eSNP regulators of genes underlying Mendelian diseases are enriched among T2D-associated variants. *J. Torres, K. Shah, N. Cox.* Medicne/Genetic Medicine, The University of Chicago, Chicago, IL, IL.

Thousands of associations between Mendelian and complex diseases have been recently detected through extensive data mining of medical records from more than 110 million patients and constitute a "non-degenerate Mendelian code" (Blair et al., Cell 2013). Given that common variants within Mendelian disease (MD) genes implicated by this code were found to be significantly associated with common diseases (Blair et al. 2013), we hypothesized that regulators of MD gene expression would be overrepresented among top signals from GWAS on T2D. We evaluated single nucleotide polymorphisms associated with gene expression (eSNPs) mapped in human adipose, skeletal muscle, lymphoblastoid cell lines (LCLs) and nine additional tissues mapped by the GTEX Consortium for enrichment among T2D-associated variants in the Wellcome Trust Case Control Consortium T2D GWAS dataset. We excluded eSNPs for genes underlying monogenic forms of diabetes to ensure that any observed enrichment would not be attributable to effects from established diabetes genes. The proportion of eSNPs for MD genes with false discovery rate (FDR) q-values $\leq 5\%$ is 2×10^{-4} whereas the proportion for all GWAS-interrogated SNPs is 3×10^{-5}. The MD eSNPs most associated with T2D correspond with myeloid differentiation primary response gene (*MyD88*). MyD88 deficiency caused by loss of function mutations has been observed in patients with increased susceptibility to pyogenic bacterial infections. Moreover, the L265P mutation is common in patients diagnosed with Waldenstrom macroglobulinemia. Interestingly, we did not observe an enrichment of eSNPs for MD genes previously associated with T2D. The narrow-sense heritability explained by eSNPs of MD genes is disproportionate relative to the proportion of all SNPs in this set by a factor of 2.18. Taken together, these results support an important yet complex role for genetic regulators of MD genes in T2D susceptibility.

1019M

Association analysis of a *SLC16A11* variant with type 2 diabetes in 12,811 American Indians and evidence for its association with *RNASEK* expression. *M. Traurig[1], A. Marinelarena[1], S. Kobes[1], S. Cole[2], R.L. Hanson[1], W.C. Knowler[1], C. Bogardus[1], L.J. Baier[1].* 1) NIH, Phoenix, AZ; 2) Texas Biomedical Research Institute, San Antonio, TX.

A recent GWAS in Mexican and Latin American populations identified 5 highly concordant exonic SNPs, rs75493593, rs75418188, rs13342232, rs13342692, and rs117767867, in the *SLC16A11* gene that were associated with type 2 diabetes. In the present study, we examined whether these SNPs are also associated with type 2 diabetes in American Indians. Whole genome sequencing data for 234 Pima Indians showed that all 5 of the SNPs were in near complete concordance (r^2=0.99), therefore, rs75493593 was selected as the representative SNP for genotyping in 7,710 American Indians (3,625 were full-heritage Pima Indians and the remaining 4,085 were on average 1/2 Pima and 3/4 American Indian). No association with diabetes was observed (*P*=0.38, OR=1.04 [0.95-1.14] adjusted for age, sex, heritage, and family relationship). To gain more power, rs75493593 was genotyped in two additional samples of American Indians consisting of various tribes who were participants of the Family Investigation of Nephropathy and Diabetes study (*n*=3,095) and Strong Heart Study (*n*=2,421). Analysis of all American Indian samples combined (*n*=12,811) showed a nominal association between rs75493593 and type 2 diabetes (*P*=0.001, OR=1.11 [1.04-1.19] adjusted for age, sex, and study center). To determine a possible mechanism for the association with diabetes, genotypic data for rs75493593 was merged with genome-wide adipose tissue and skeletal muscle gene expression data obtained in a prior study in Pima Indians using the Affymetrix Human Exon 1.0 ST Array. The top genome-wide expression quantitative trait loci (eQTL) for both adipose tissue and skeletal muscle was *RNASEK* located 33 kb upstream of *SLC16A11* (adipose, *n*=187, *P*=0.0004; skeletal muscle, *n*=196, *P*=0.001). The association between rs75493593 and *RNASEK* expression levels in adipose tissue was validated by qRT-PCR in a subset of the microarray subjects (*n*=159, *P*=0.01). These results suggest that rs75493593 or a highly concordant variant may affect *RNASEK* transcription. In conclusion, our study shows that either *SLC16A11* or *RNASEK* could potentially play a minor role in type 2 diabetes for some American Indian populations.

1020T

Asthma susceptibility genetic variants are more strongly associated with phenotypically similar subgroups of patients. *E. Lavoie-Charland[1], J.-C. Bérubé[1], L.-P. Boulet[1], Y. Bossé[1,2].* 1) IUCPQ, Québec, Canada; 2) Department of Molecular Medicine, Laval University, Québec, Canada.

Large scale genome-wide association studies (GWAS) identified polymorphisms reproducibly associated with asthma. Most GWAS were performed with a broadly defined asthma phenotype, leaving the role of susceptibility variants/genes largely undefined. We recently identified four homogeneous subgroups of asthma patients defined by factor and cluster analysis: 1) older patients with low atopy and low lung functions (n=104), 2) patients with high atopy (n=138), 3) young non-smoking women with low blood cell count (n=175), and 4) patients with smoking history (n=105). The goal of this study is to evaluate if GWAS-nominated variants are more strongly associated with asthma patients sharing the same clinical characteristics, which may help reveal the role of recently identified genes. Genotyping of GWAS-nominated variants were performed in the Quebec City Case-Control Asthma Cohort (QCCCAC). The QCCCAC consists of 982 unrelated French Canadian subjects (566 cases and 416 controls) with data collected on lung functions, blood cell counts, atopy, disease history and medication. Genetic association analyses were performed to compare allele frequencies of GWAS-nominated variants between cases and controls. SNPs in or near genes *GSDML, IL13, IL18R1, IL33, LRRC32, RAD50, RORA* and *ZNFN1A3* demonstrated some evidence of replication (p-value < 0.05) for association with asthma. Allele frequencies were then compared between subgroups of phenotypically similar asthma patients and controls. Thirty SNPs were more strongly associated with a subgroup than with asthma in general. Rs10197862, an intronic variant in *IL1RL1/IL18R1*, was the most strongly associated SNP with the high atopy subgroup (p = 0.0009). SNPs located in regions encoding interleukins (*IL1RL1/IL18R1, IL13, IL33*) were associated with the high atopy subgroup or with the young non-smoking women with low blood cell count subgroup. Two SNPs were more strongly associated with the smoking history subgroup than with asthma or any other subgroups: rs1544791 (*PDE4D*) and rs3806932 (*TSLP*). Compared to previous GWAS, sixteen SNPs were only replicated in subgroups, while two were only replicated in the whole cohort. This study shows that a large part of GWAS-nominated SNPs are more strongly associated with more homogeneous subgroups of asthma than broadly defined asthma.

1021S

Pooled targeted resequencing to identify genomic variants associated with crohn's disease in Korea. *C. PARK[1,2], S. HONG[3], S. LEE[1,2,4], J. CHAE[1,2], J. KIM[1,2,4], Y. KIM[4].* 1) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul, South Korea; 2) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea; 3) Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 4) Medical Research Center, Genomic Medicine Institute (GMI), Seoul National University, Seoul, Korea.

Background/Aim: Crohn's disease (CD) is an inflammatory bowel disease. The cause is unknown but recent genome-wide association studies have identified over 100 CD susceptibility loci in Caucasian populations. However, genetic susceptibility loci for CD differ between Asian and Western populations. To identify the genetic susceptibility loci for CD, Next generation sequencing of a pooled DNA samples (pooled sequencing) was performed. **Method:** We performed the pooled sequencing for exons and UTRs of 135 genes associated with CD in 500 CD patients and 1000 controls (pooled 50 DNA samples at equal concentration into 30 pools). We performed sequencing with the Illumina HiSeq 2000. To call variants from the sequencing data, reads were aligned to the human reference genome (HG19) using the Bowtie 2 alignment program, and the variants were called using CRISP with the default parameters. Allele frequency differences between case and control groups were calculated using a chi-squared test or a fisher exact test. For the replication study, 500 CD patients and 1000 controls (no pooled sequencing samples) were genotyped by TaqMan SNP genotyping assay. SNPs with deviation from Hardy-Weinberg equilibrium (p<0.001) were excluded. Association analysis was performed using PLINK. **Results:** In pooled sequencing result, we identified a total of 5,854 variants. Significant difference in allele frequencies between cases and controls were observed for 33 common variants in 12 genes (quality score>15000, p<0.01) and 4 rare exonic variants in 4 genes (quality score>300, p<0.02). For the replication study, 11 common and 4 rare variants were selected. In replication study, we confirmed two previously reported SNPs associated CD in Korean: rs3810936 in *TNFSF15* (OR=1.89, p=1.11×10-15) and rs76418789 in *IL23R* (OR=0.517, p=6.75×10-6). We identified one SNP rs2241880 in *ATG16L1* (OR=1.37, p= 0.00015) that failed to be replicated previously in Asian population. We also found five novel CD susceptibility loci: rs3181374 in *TNFSF8* (OR=1.639, p=2.39×10-10), rs28362680 in *BTNL2* (OR=1.452, p=6.76×10-06), rs3208181 in *HLA-DQA2* (OR=1.38, p=0.0009), rs1053004 in *STAT3* (OR=1.29, p=0.002) and rs2273650 in *NFKBIA* (OR=0.81, p= 0.0192), and one rare CD susceptibility locus: rs200735402 in *CARD9* (OR=0.07, p= 0.0002). **Conclusion:** Using pooled sequencing, we identified new susceptibility variants for CD as well as confirmed previously reported loci in GWAS.

1022M

Association of HLA-DPB1 alleles with CHB infection and HBV related HCC in Asia. *N. Nishida[1,2], H. Sawai[2], K. Kashiwase[3], M. Sugiyama[1], Y. Mawatari[1], K. Tokunaga[2], M. Mizokami[1].* 1) Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Chiba, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Bunkyo-ku, Tokyo, Japan; 3) HLA Laboratory, Japanese Red Cross kanto-Koshinetsu Block Blood Center, Koutou-ku, Tokyo, Japan.

In the previous report, HLA-DPA1*01:03-DPB1*04:02 and HLA-DPA1*02:02-DPB1*05:01 showed significant associations with chronic hepatitis B (CHB) infection in Japanese as a protective and a risk haplotype, respectively (Kamatani et al., 2009). However, there have been no reports of HLA-DP genes to be associated with disease progression from CHB to liver cirrhosis (LC) or hepatocellular carcinoma (HCC). We conducted HLA-DP genotyping using a total of 3,167 samples (including Japanese, Korean, Hong Kong and Thai) for HBV patients (including CHB, LC and HCC), healthy controls and resolved individuals (HBsAg-negative and anti-HBc-positive), based on PCR-SSO system according to manufacturer's protocol. The Fisher's exact test in a two-by-two cross table was applied to acquire exact P values. For a meta-analysis in four populations, we used the DerSimonian-Laird method, which assumes a random-effects model to calculate the pooled effect estimate. A total of 2,895 samples were successfully genotyped. There were a total of 272 dropped samples in HLA-DP genotyping, a large part of which were belonging to Korean HBV patients and Hong Kong resolved individuals, presumably due to low concentration or low quality of DNA samples. Consequently, we identified one high-risk haplotype (HLA-DPA1*02:01-DPB1*09:01) and one protective haplotype (HLA-DPA1*01:03-DPB1*04:01) to be associated with CHB infection over the previously reported HLA-DP haplotypes in Asian populations. Moreover, a significant association of DPB1*02:01 was identified to be protective not only against HBV infection, but against disease progression from CHB to HCC. Trans-ethnic association study of HLA-DP in Asian populations revealed that specific HLA-DPB1 alleles (i.e. DPB1*02:01, *04:01, and *04:02) worked to be protective against HBV infection, and different alleles (i.e. DPB1*05:01, *09:01) worked to be susceptible to HBV infection. To determine all the associated DPB1 alleles for HBV infection would enable HBV infected individuals to divide into two groups who need treatment or not.

New mutations in the *MYOC* gene in patients with juvenile open-angle glaucoma. *J.P.C. Vasconcellos[1], P.V. Svidnicki[2], C.A. Braghini[2], M.B. Melo[2].* 1) Dept Ophthalmology, Univ Campinas - UNICAMP, Campinas SP, Brazil; 2) CBMEG, Univ Campinas - UNICAMP, Campinas SP, Brazil.

Glaucoma is the leading cause of irreversible blindness and is characterized by progressive optic disc cupping with corresponding visual field loss. Both intraocular pressure (IOP) and positive family history are risk factors for the development of the disease. Juvenile open angle glaucoma (JOAG) is a more severe form of open angle glaucoma characterized by an early onset (10 to 35 years of age). Mutations in the myocilin gene (*MYOC*) account for most cases of JOAG. This study was approved by the Ethics Committee of the University of Campinas. DNA samples from 98 unrelated Brazilian patients with JOAG and 92 normal individuals were screened for mutations in the three exons and intron/exon junctions of the *MYOC* gene through direct sequencing. In order to evaluate clinical aspects, ophthalmologic examination included evaluation of the visual field and optic disc, intraocular pressure measurement, and gonioscopy. Mutation screening revealed two new glaucoma causing mutations: the frame-shift mutation 1356delT and X505W. Besides, the previously described glaucoma-causing mutations: C433R (27 patients), Q368X (2 patients), P370L (1 patient) and K423E (1 patient) were also identified. Among neutral variants, we observed the previously reported G122G (1 patient), R76K (14 patients), P13P (1 patient), 730+35g>a (53 patients) and the unreported variants *15 t>a (2 patients), *54g>t (1 patient) and *393 c>g (1 patient). This study provides an overview of *MYOC* mutation spectra and frequencies in JOAG Brazilian patients. These findings may be important for the increase of *MYOC* mutations panel and their effects on phenotype. Financial Support: Fapesp 02/11575-0.

1024S

Association of ADIPOQ rs266729, rs17300539, rs2241766 and rs17846866 with Type 2 Diabetes and Diabetic Retinopathy in North-West Indian population. *A. BHANWER, R. SIKKA, K. MATHAROO.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

ADIPOQ is an adipokine gene present on chromosome#3 (3q27.3) and is known to be associated with Type 2 diabetes (T2D) and metabolic syndromes. It is specifically and abundantly expressed in the adipose tissue and sensitizes the body to insulin. Adiponectin act as an anti-inflammatory adipokine with anti-diabetic properties. However, the role of ADIPOQ polymorphism has not been clarified but it seems to play a role in vascular damage by interfering with anti-inflammatory and anti-diabetic effects of adiponectin, which may contribute to worsening or acceleration of microvascular complications. Polymorphisms in ADIPOQ gene influences the protein function leading to acceleration of microvascular complications through vascular damage. Therefore, in the present study, we aimed to explore the role of ADIPOQ rs266729, rs17300539, rs2241766 and rs17846866 with the aetiology of T2D and diabetic retinopathy (DR). A total of 454 individuals (207 DR and 247 T2D) and 241 gender matched above 50 years of age healthy controls were included from the region of Amritsar. Genotyping was done by using PCR-RFLP for rs266729, rs17300539, rs2241766 and PCR-ARMS for rs17846866. rs266729 CG+GG and GG genotypes tend to give 1.8 and 1.9 fold risk, respectively towards DR when compared with T2D cases and 1.7-1.9 fold risk towards DR when compared to healthy control. For rs17300539, AA genotype tends to give 4 fold risk towards DR when compared with T2D cases however; AA+GA and GA genotypes tend to give 2-4 fold risk towards DR when compared with healthy controls. In rs2241766, wild genotype TT gives 2 and 2.5 fold risk towards DR when compared with T2D and controls, respectively. However, TG genotype tends to give protection towards DR when compared with T2D [OR=0.39 (0.21-0.73)] and healthy controls [OR=0.35 (1.9-0.65)]. In case of rs17846866, GG+TG and GG genotypes tend to give 2 fold risk towards DR when compared with T2D and healthy controls. However, no association was observed for rs266729, rs2241766 and rs17846866 with T2D. In conclusion, rs266729, rs17300539, rs2241766 and rs17846866 seem to be associated with risk of DR when compared with T2D cases as well as with healthy controls in the population of Punjab.

1025M

More evidence for association of a rare TREM2 variant (R47H) with Alzheimer's disease risk. *S.L. Rosenthal[1], M.N. Bamne[1], X. Wang[1], S. Berman[2], B.E. Snitz[2], W.E. Klunk[3], R.A. Sweet[3], F.Y. Demirci[1], O.L. Lopez[2], M.I. Kamboh[1].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Neurology, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 3) Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

Over twenty risk loci have been identified for late-onset Alzheimer's disease (LOAD). Among them, only one, *APOE*, produces a strong effect size for this neurodegenerative disease. Individuals homozygous for the *APOE*4* allele have a 60% increased lifetime risk of developing LOAD. Recent sequencing efforts have detected a rare variant in *TREM2*, R47H, that has an effect size similar to that of *APOE*. In our study, we genotyped this variant in a case-control population of Caucasian descent derived from two study cohorts: 1283 cases (mean age-at-onset, AAO=73.26 $\pm$ 6.76) and 996 controls (mean age= 75.67 $\pm$ 6.37) from the University of Pittsburgh Alzheimer's Disease Research Center, and 338 cases (mean AAO=84 $\pm$ 3.98) and 1950 controls (mean age=83.15 $\pm$ 9.93) from the Gingko Evaluation of Memory study. In the total sample, carriers of the R47H variant had a significantly increased risk of having LOAD (OR=7.40, p=3.66E-06). We also examined the effect of this variant on psychosis in LOAD and Aβ deposition (as measured by Pittsburgh compound B uptake) and found no significant association between this variant and either phenotype. We have successfully replicated the association of the *TREM2* R47H variant with LOAD risk in Caucasians. Combined with other studies, our results provide further evidence for the involvement of *TREM2*, specifically the R47H variant, in modulating LOAD risk.

1026T

The *IL10* ACA haplotype is associated with rheumatoid arthritis in patients from Western Mexico. *J. Hernandez-Bello[1], M. Vazquez-Villamar[1], E. Oregon-Romero[1], Y. Valle[1], J.R. Padilla-Gutierrez[1], G. Martinez-Bonilla[2], J.F. Muñoz-Valle[1].* 1) Instituto de Investigación en Ciencias Biomedicas, CUCS, Universidad de Guadalajara. Guadalajara, Jalisco, Mexico; 2) Servicio de Reumatologia, Hospital Civil de Guadalajara, Fray Antonio Alcalde. Guadalajara, Jalisco Mexico.

Background: Rheumatoid arthritis (RA [MIM 180300]) is a chronic autoimmune disease of unknown etiology affecting approximately 1% of the population worldwide. RA is characterized by a cartilage and bone erosion resulting from chronic synovial inflammation. Interleukin 10 (IL-10) is an immunomodulatory cytokine involved in the regulation of synovitis, the B cells activation and in a subsequent production of autoantibodies such as anti-cyclic citrullinated peptide (anti-CCP) and rheumatoid factor (RF). Three polymorphisms of *IL10* gene at -1082 A>G (rs1800896), -819 C>T (rs3021097) and -592 C>A (rs1800872) form three major haplotypes (GCC, ACC, and ATA). These haplotypes have been associated with high, medium, and low IL-10 production and have been reported as a risk factor for autoimmune diseases. However, their distribution and association with RA in population from Western Mexico is unknown. **Aim:** Evaluate the association of *IL10* haplotypes with susceptibility to RA in patients from Western Mexico. **Materials and methods:** We studied 260 RA patients classified according to ACR/EULAR 2010 criteria and 260 control subjects (CS), both study groups from Western Mexico. The -1082 A>G, -819 C>T and -592 C>A polymorphisms of the *IL10* gene were genotyped by using PCR-RFLP. The haplotype frequencies were inferred using the HEMHAPFRE software and the statistical analysis was performed using Stata software, release 9.0. **Results:** In RA and CS eight haplotypes were constructed after performing haplotypic analysis by using maximum likelihood method and their frequencies were: ACC (44.25% vs 46.53%), ATA (25.4% vs 23.18%), GCC (12.64% vs 14.23%), GTA (13.42% vs 14.13%), ATC (1.9% vs 1.05 %), ACA (1.53% vs. 0.19%), GTC (0.44% vs. 0.69%) and GCA (0.43% vs 0%). We observed significant difference in the distribution of genotypic frequencies between both study groups ($p = 0.04$), with an OR 8.7 (95 % CI 1.04-67.83) for the ACA haplotype, which indicates an association of the ACA haplotype with an increased risk of RA. Moreover, no significant difference was observed between the distribution of the three polymorphisms in RA and controls. **Conclusions:** The ACA haplotype of the *IL10* gene may be a marker for the susceptibility to RA in populations from Western Mexico.

Serum Uric Acid Levels Are Associated with Polymorphism in the SLC2A9, SF1 and GCKR Genes in Chinese Subjects. *C. Hu, X. Sun, R. Zhang, W. Jia.* Shanghai Diabetes Inst, Shanghai, Shanghai, China.

Recent reports on genome2wide association studies focusing on serum uric acid concentrations identified several novel associated loci in European descent samples. In the current study, we aimed to evaluate the association between these loci and concentrations of serum uric acid in the Chinese. We genotyped fourteen single nucleotide polymorphisms (SNPs) from eleven loci mapped in or near PDZK1, GCKR, LRP2, SLC2A9, ABCG2, LRRC16A, SLC17A1,SLC17A3, SLC22A11, SLC22A12 and SF1 in the Shanghai Chinese, including 2329 participants from a community based study. As uric acid metabolism differs between genders, all of the variants were analyzed for gender differences. SNPs including rs780094 in GCKR, rs11722228 in SLC2A9 and rs606458 in SF1 showed association to serum uric acid levels in males after adjustment for age and BMI as confounders (p= 0.016, 0.0011 and 0.030, respectively); SLC2A9 rs3775948 demonstrated a trend towards association to uric acid (p=0.071). In females, only rs506338 in SLC22A12 was detected to potentially associate with uric acid (p=0.0569). After combined analysis between males and females, we only detected that SLC2A9 rs3775948 and SF1 rs606458 were related to uric acid(p=0.036 and 0.043, respectively). The interaction between rs11722228 in SLC2A9 and gender on serum uric acid levels existed in our samples. In conclusions: We showed that GCKR,SLC2A9 and SF1 variants modulated uric acid levels in the Shanghai Chinese. Moreover, gender difference between GCKR and SLC2A9 polymorphisms and uric acid levels was also found in our study. The findings provide a perspective that genetic variation is one of the key influences upon regulation of serum uric acid levels in humans.

1028M

Transferrin receptor and hereditary hemochromatosis gene variants interact to modify childhood leukemia risk. *A.E. Kennedy[1], E. DeRycke[1], G.Y. Lai[1], K.Y. Kamdar[2], P.J. Lupo[2], M.F. Okcu[2], M.E. Scheurer[2], M.K. Baum[3], D. Seminara[1], M.T. Dorak[4].* 1) Epidemiology and Genomics Research Program, Division of Cancer Control and Population Sciences, National Cancer Institute, NIH, Rockville, MD; 2) Section of Hematology-Oncology, Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Department of Dietetics and Nutrition, Robert Stempel College of Public Health & Social Work, Florida International University, Miami, FL; 4) School of Health Sciences, Liverpool Hope University, Liverpool, United Kingdom.

An interaction between the transferrin receptor (*TFRC*) rs3817672 (S142G) and hereditary hemochromatosis gene (*HFE*) rs1800672 (C282Y) is associated with increased risk for multiple myeloma, breast, colorectal and hepatocellular cancers as well as childhood acute lymphoblastic leukemia (ALL) risk in European studies. *HFE* C282Y and H63D correlate with body iron levels. Since HFE and TFRC proteins biologically interact in iron transfer across membranes, the observed statistical interaction suggests that the involvement of *HFE* variants in cancer risk modification is mediated via their synergistic effect on body iron levels. We sought to replicate the *HFE*x*TFRC* interaction in childhood ALL in a US-based study, and used bioinformatic tools to assess the contribution of *TFRC* S142G to this association. Genotyping was conducted in a multi-ethnic sample from Houston, TX (161 incident cases with childhood ALL and 231 controls, all <18 yr). Being positive for either *HFE* variant yielded an elevated odds ratio for childhood ALL risk in males (1.4, 95% CI=0.8 to 2.4), which increased to 3.0 (95% CI=1.3 to 6.8) in the presence of the S142G allele A homozygosity ($P_{interaction}$=0.04). A comprehensive screening of empirical and bioinformatic data showed that allele A shows allele-specific expression, the non-conservative amino acid substitution is within the helix portion of the protein and predicted to alter the secondary structure (but not in the transferrin or HFE binding sites), and the SNP alters a splicing site. S142G itself is not associated with any disease individually, except that it is in linkage disequilibrium ($r^2 > 0.8$) with rs9859260, which correlates with a red cell index. None of the other 21 variants in LD with S142G has a higher functionality score or a trait association. One plausible mechanism may be that S142G generates a splice variant that interacts with HFE differently. Thus, it appears that S142G is the causal SNP interacting with HFE in cancer risk associations. The interaction of *HFE* with *TFRC* in modification of risk for cancers has now been replicated in several studies and in multiple cancers. Although *HFE* and *TFRC* variants do not show individual associations with cancer risk in GWAS, their interaction should be explored in existing GWAS data in cancer to ultimately establish it as a possible risk factor. The biological basis of this association has implications on public health and policy on unregulated use of iron supplements.

Introduction: Systemic lupus erythematosus (SLE) is a heterogeneous disease involving several immune cell types and pro-inflammatory signals.- Peroxisome proliferator-activated receptor (PPAR) polymorphisms have been associated with a variety of metabolic and kidney disorders. The Pro12Ala polymorphism (rs1801282) in PPARG gene, a Pro-to-Ala exchange that results in the substitution of proline with alanine at codon 12, was previously associated with diabetic nephropaty; we therefore hypothesized that Pro12Ala PPARG polymorphism might be involved in the pathophysiology of lupus nephropaty in Mexican patients with SLE. Aim. To analyze the allelic and genotype frequencies of Pro12Ala polymorphism in the PPARG gene in general population and patients with systemic lupus erythematosus (SLE) with or without lupus nephritis (LN) from Western Mexico. Material. Cross-sectional study. Fifty mestizo Mexican individuals from general population from Norwestern México, 17 patients from the nephrology clinic with a diagnosis of SLE and LN and 20 patients with SLE without evidence of LN (according the American College of Rheumatology (ACR), and the International Society of Nephrology and Renal Pathology Society (ISN / RPS) criteries) were included. Methods: Genomic DNA was extracted from a blood sample using a conventional method. A PCR-RFLPs protocol was used to amplify a fragment of 306 base pairs (bp) of PPARG gene, and then digested with the Hga I restriction enzyme. The digestion products were identified by gel electrophoresis on 10% polyacrylamide (29:1) stained with silver nitrate. Results: The general population is in Hardy Weinberg Equilibrium. We found only one individual in the group of patients without the variant submitted NL homozygous genotype (Ala12Ala). The genotype and allele frequencies in the three groups are shown in Table 1. Statistical analysis was performed using the Finetti diagram and only statistically significant differences were found when comparing the alleles in SLE patients with or without NL, where the risk allele is 12Ala. (OR = 9.6, C.I. 2.115-43.583 p=0.00197). (*) Conclusions: This is the first report of an association analysis of PPARG Pro12Ala gene polymorphism with SLE in Mexican population and the results suggest that the presence of the variant allele (Ala) confers risk for LN; however it is necessary to increase the sample size to confirm this assertion.

1030S

Quantification of Hirschsprung disease susceptibility from common polymorphisms in relation to gender, segment length of aganglionosis and familiality. *A. Kapoor[1], Q. Jiang[1, 2], C. Berrios[1], A. Chakravarti[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA; 2) Department of Medical Genetics, Capital Institute of Pediatrics, Beijing, China.

Hirschsprung disease (HSCR), a congenital developmental defect of the enteric nervous system, is a multifactorial disorder in which common, low penetrance, noncoding variants at *RET*, *NRG1* and *SEMA3* underlie disease risk, primarily in male, short segment simplex (~70%) cases. Rare, high penetrance, coding variants in at least a dozen genes collectively underlie disease risk in <25%, enriched for female, long segment multiplex cases. We have used the largest collection of HSCR cases and relatives of European ancestry ascertained in the USA (~1100 individuals: 365 probands, 40 affected relatives and 710 unaffected relatives) to directly assess the joint contribution of *RET* (rs2435357, rs2506030), *NRG1* (rs7835688, rs16879552) and *SEMA3* (rs1583147, rs12707682, rs11766001) common variants and risk covariates to HSCR susceptibility. Case-control analysis in 342 cases and 379 controls, showed significant associations at *RET* at rs2435357 (odds ratio (OR) = 3.7 and $P=1.2\times10^{-31}$) and at rs2506030 (OR= 1.9 and $P=3.5\times10^{-9}$), and at *SEMA3* rs11766001 (OR=1.5 and P=0.002). These results were corroborated by transmission disequilibrium tests in 243 trios demonstrating that these associations were not due to cryptic population structure (OR=4.7, $P=5.1\times10^{-25}$; OR=1.9, $P=3.6\times10^{-6}$; OR=1.7, P=0.002 for rs2435357, rs2506030 and rs11766001, respectively). We failed to find any evidence of a reported *NRG1* effect, indicating that this association is likely restricted to Asians where it was first reported. HSCR disease risk was directly related to and highly significant by dosage of 3+ risk alleles at rs2435357, rs2506030 and rs11766001 (OR=1.85, P=0.001; OR=3.29, $P=5.95\times10^{-7}$; OR=10.35, $P=6.56\times10^{-5}$ for 3, 4 and 5+ alleles, respectively); fewer alleles were protective. These risks translated into a significantly higher incidence (penetrance) by allelic dosage: 24.6, 42.2 and 141.3 cases per 100,000 live-births as compared to the population average of 15/100,000. Common allele dosage-based disease risk was significantly higher in males (P=0.005), and higher but not significant in short segment and simplex cases. Finally, despite our over-ascertainment of familial cases, sibling recurrence risk is 29% in sibships of probands with <3 risk alleles as compared to 19% when probands had ≥3 risk alleles. Consequently, these common polymorphisms delineate a class of frequent HSCR cases that have lower recurrence rates within sibships, a feature that should inform genetic counseling.

1031M

Association between common variant near *CAV1* and *CAV2* genes and phenotypic features of primary open-angle glaucoma. *F. Mabuchi[1], Y. Sakurada[1], S. Yoneyama[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: It was reported that common variants near caveolin 1 (*CAV1*) and caveolin 2 (*CAV2*) genes were associated with primary open-angle glaucoma (POAG). This study was performed to assess the association between the common variant near these genes and the phenotypic features in patients with POAG, including normal tension glaucoma (NTG) and high tension glaucoma (HTG). Methods: Four hundred and one Japanese patients with POAG, including 176 patients with NTG and 225 patients with HTG, and 191 control subjects without glaucoma were analyzed for the common variant (rs1052990) near *CAV1* and *CAV2* genes. The genotype and allele frequencies were compared between the patients with NTG or HTG and the control subjects. Demographic and clinical features, including age at diagnosis of glaucoma, gender, family history of glaucoma, refractive error, maximum intraocular pressure (IOP), vertical cup-to-disc ratio, and history of glaucoma surgery, were compared between the genotypes in patients with POAG. A multiple linear regression analysis was carried out with the maximum IOP as a dependent variable and age, gender, and the common variant as independent variables. Results: There was a significant difference (P = 0.024, analysis of variance) of the maximum IOP among GG (21.8 ± 4.6mmHg, mean ± standard deviation), GT (22.7 ± 6.6mmHg), and TT (24.9 ± 9.2mmHg) genotypes in patients with POAG, although no significant differences of the genotype and allele frequencies could be found between the patients with NTG (GG: 4.0%, GT: 36.4%, TT: 59.6%, P = 0.90; G allele: 22.2%, T allele: 77.8%, P = 0.99) or HTG (GG: 4.9%, GT: 31.1%, TT: 64.0%, P = 0.76; G allele: 20.4%, T allele: 79.6%, P = 0.61) and the control subjects (GG: 4.7%, GT: 34.6%, TT: 60.7%, G allele: 22.0%, T allele: 78.0%). Based on multiple linear regression analysis, a significant relationship was confirmed between the common variant and the maximum IOP ($\beta = 0.12$, standard error = 0.70, P = 0.017). Conclusion: The association of the common variant near *CAV1* and *CAV2* genes with a maximum IOP in patients with POAG suggests that this locus may contribute to the pathogenesis of POAG as a genetic risk factor associated with IOP elevation.

1032T

GSTT1 and GSTM1 gene frequency in Punjabi population exposed to pesticides. *M. Ahluwalia, A. Kaur.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

The glutathione-S-transferase (GST) enzyme system play an important role in defence mechanism against environmental chemicals and endogenous substances. Many of these enzymes show variability among individuals due to their polymorphic character and thus show difference in predisposition to various diseases such as cancers, neurological disorders, endocrine system disruption, and etc. The aim of the study was to determine GSTT1 and GSTM1 gene deletions in 69 individuals from different regions of Punjab involved in agricultural activities such as preparation, loading, spraying and storage of pesticides, harvesting of crops etc. Genotyping was done by Multiplex Polymerase chain reaction approach. The deleted GSTT1 and GSTM1 genes show frequency of 14.5% and 50.7% respectively. The results suggest an increased tendency of exposure related diseases due to complete gene deletion of either of the two genes. However, 5.7% population has shown deletion of both the genes and are expected to have significantly reduced detoxification tendency and thus an increased risk to diseases caused by exposure to environmental carcinogens. The study thus provides the basis for gene-environment association studies to be carried out. The detection of oxidative stress in serum by biochemical methods is in progress.

Relationships between genetic ancestries and nicotine and tobacco carcinogen metabolisms in the Multiethnic Cohort. *H. Wang[1], S. Park[2], C. Haiman[2], S. Murphy[3], S. Hecht[3], B. Henderson[2], L. Kolonel[1], D. Stram[2], L. Le Marchand[1].* 1) UH Cancer Center, Honolulu, HI; 2) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Masonic Cancer Center, University of Minnesota, Minneapolis, MN.

It has been reported in the Multiethnic Cohort (MEC) study that major (2-to-5-fold) differences exist among US racial/ethnic minorities in the risk of lung cancer associated with cigarette smoking, even after taking into account self-reported dose and duration. Native Hawaiians and African Americans have a higher risk for lung cancer than European Americans, who in turn have a higher risk than Japanese Americans and Latinos. Here we tested the hypothesis that genetic ancestries are related to nicotine metabolism (up to 80% through C-oxidation by CYP2A6) and internal dose of tobacco smoke carcinogens, thus contributing to the observed differences in lung cancer risk across populations. Genetic ancestries were estimated using STRUCTURE based on 121 ancestral informative markers for 2,170 MEC African Americans, European Americans, Japanese Americans, Latinos, and Native Hawaiians, along with 5 HapMap reference populations, namely, ASW, CEU, YRI, JPT and MEX. Percent ancestries, i.e. African, American Indian, Native Hawaiian and East Asian ancestries were obtained and categorized according to deciles. Nicotine metabolism (total trans-3'-hydroxycotinine: free cotinine) and exposure to and detoxification of nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), a major tobacco-specific lung carcinogen, were regressed on percent ancestries in a linear regression model, adjusting for age, sex, assay batch, creatinine and internal dose of nicotine. African ancestry was related to a lower level of CYP2A6 activity (P = 0.12) and a higher level of exposure to (P = 0.03) and non-significant lower level of detoxification of (P = 0.93) NNK. East Asian and Native Hawaiian ancestries were related to lower levels of CYP2A6 activity (P's ≤ 0.002), lower levels of exposure to (P's ≤ 0.04) and of detoxification of (P's <0.0001) NNK. American Indian ancestry (in Latinos) was related to a higher level of CYP2A6 activity (P < 0.0001), a non-significant lower level of exposure to (P = 0.81) and significant lower level of detoxification of (P = 0.002) NNK. These results are consistent with and could partly explain the observed differences in lung cancer risk due to smoking in African Americans, East Asians, Latinos, compared to European Americans, but could not explain the high disease risk of Native Hawaiians, suggesting more factors contribute to risk in this recently admixed population.

1034M

Haplotype association and synergistic effect of Renin-angiotensin aldosterone system gene polymorphisms causing susceptibility to essential hypertension in Indian patients. *C. Bhupatiraju[1], MV. Uppuluri[1], P. Gunda[1], D. Pandharpurkar[2], P. Tirunilai[1]*. 1) Dept of Genetics, Osmania University, Hyderabad, India; 2) Gandhi Medical College and Hospital, Hyderabad, India.

The present study investigates association of essential hypertension (EHT) with candidate gene polymorphisms involved in vasoconstriction (*REN, AGT, ACE, AGTR1* and α_{2B}*-ADR*) and vasodilation (*BDKRB2*); haplotype association and epistatic interactions between them. Evaluation of 316 hypertensives and 293 controls for various epidemiological parameters confirmed the association of gender, obesity, family history and non-vegetarian diet with EHT. Study of candidate gene polymorphisms suggests significant association of -g.5434C>T and g.18-83G>A of *REN*; g.-217G>A of *AGT*; ±9bp of *BDKRB2* and I/D of α_{2B}*-ADR* with EHT. The study suggests high risk for developing EHT for a) CT genotypes and allele C carriers of g.-5434C>T, which was high in females b) females with II genotype of α_{2B}*-ADR* I/D and in those consuming non-veg and males with ID genotype and alcoholics c) males with g.-217A variant of *AGT* and d) +9bp allele carriers of *BDKRB2* ±9bp especially in males. The positive association of g.-217A variant and +9bp variant with EHT may be correlated with varied transcriptional activities of the respective genes resulting in vasoconstriction. Analysis for epistatic interactions suggest a high risk for individuals with i) g.-5434CC and g.18-83GA, ii) g.-5434TT and g.18-83GA and iii) g.-5434TT and g.18-83GG genotypic combinations of *REN* gene causing susceptibility to EHT. High risk with respect to epidemiological factors was observed for females with positive family history of EHT. The gene-environmental interaction analysis suggests strong synergisism between α_{2B}*-ADR* I/D polymorphism and gender. Estimates of the degree of linkage disequilibrium (LD) revealed a complete linkage disequilibrium between g.-152G>A and p.M235T and between p.T174M and g.-5312C>T polymorphisms in both hypertensives and controls. Among hypertensives complete LD was observed between g.-152G>A and g.-58C>T, g.-20C>A and g.1166A>C, p.T174M and g.1166A>C and g.-5434C>T and g.18-83G>A polymorphisms, while LD between these polymorphisms was absent or weaker among the controls. In general the study suggest the need for evaluation of life style habits like smoking, alcohol and diet at an early age and monitoring the BMI levels regularly. The genes showing polymorphisms with significant risk of developing EHT may provide clues for designing drugs whose mode of action would be genotype based. Any such effort to ameliorate the suffering due to the disease improves the quality of life of affected.

1035T

Genetic variation and Insulin Resistance in middle age Chinese men. *r. villegas[1], r. Delahanty[1], s. Williams[2], r. o'bryan[1], y. Gao[3], q. cai[1], H. li[3], y.x. Xiang[3], w. zheng[1], xo. Shu[1]*. 1) Vanderbilt University Medical Center, 2525 , Nashville TN, 37203-1738 USA; 2) 2Geisel School of Medicine, Dartmouth College, USA; 3) Department of Epidemiology, Shanghai Cancer Institute, 2200/25# Xie Tu Road, Shanghai 200032, P.R. China.

Introduction: Insulin resistance is a necessary condition for T2D to develop and results from an interaction between genetic and environmental factors. Understanding factors associated with insulin resistance and its genetic controls is of particular importance for the prevention of T2D, because insulin resistance is reversible. In this project we evaluated the association of genetic polymorphisms in the first three genes in the insulin signaling pathway (the insulin receptor, INSR, and insulin receptor substrates 1 and 2, IRS1 and IRS2), glucose transporter 4 (GLUT4), and genes identified from GWAS of T2D quantitative traits with insulin resistance. We also evaluated gene environment interactions and insulin resistance. Methods: We investigated the independent and combined effect of variants in the study genes with exercise participation, waist to hip ratio (WHR) and body mass index (BMI) with both fasting insulin and the homeostasis model assessment of insulin resistance (HOMA-IR) as outcomes. We used data from 1952 non diabetic male participants of an ongoing, population-based prospective study conducted in Shanghai, China. Assessment of physical activity was obtained by using a validated physical activity questionnaire and total METs (metabolic equivalent task (MET)-hr/day) was calculated. Anthropometric variables were measured by trained interviewers. The association between single nucleotide polymorphisms (SNPs) and insulin and HOMA-IR was assessed by linear regression analyses. Results: A total of 87 SNPs were included in the analysis. We found one candidate gene, IGF1, had evidence for association with both insulin and HOMA-IR. We observed interactions with BMI and fasting insulin in 2 SNPs from INSR and 2 SNPs in the GLUT4 genes. Only one SNP, rs10417205 had an interaction factor with a P value <0.05 with HOMA-IR. A total of 4 SNPs in the INSR gene, 1 SNP in the INSR2 gene and 2 SNPs in the GLUT4 gene showed interactions with WHR. We also found that 4 SNPs in INSR had a P value for interaction less than 0.05 with total METs of physical activity with HOMA-IR, while we only observed 2 interactions with a P<0.05 with fasting insulin. Conclusion: Our data support the hypothesis that the IGF1 gene variation is associated with insulin resistance among middle age Chinese men. We also found interactions between some of the study genes with physical activity, BMI and WHR with insulin resistance.

1036S

EWAS to GxE: A robust strategy for detecting gene-environment interaction models for age-related cataract. *M.A. Hall[1], J.R. Wallace[1], S.A. Pendergrass[1], R. Berg[2], T. Kitchner[2], P. Peissig[2], M. Brilliant[2], C.A. McCarty[3], M.D. Ritchie[1]*. 1) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Marshfield Clinic, Marshfield WI; 3) Essentia Rural Health, Duluth, MN.

Gene-environment interactions (GxE) are essential to elucidating the underlying nature of complex traits. Despite the importance of GxE, extensive computational demands and adjusting for multiple tests make uncovering these interactions a challenge when explored with an exhaustive combinatorial search. We address this using an environment wide association study (EWAS) to identify predictive environmental factors, followed by a test for interaction with genome-wide SNPs for association with cataract. EWAS tests a diverse set of environmental variables in a high-throughput manner for trait association. Subsequently, putative predictors identified by EWAS can be tested for GxE to further explain the trait. Using PLATO software, we performed a dietary EWAS by evaluating 57 dietary exposures from the National Cancer Institute developed Dietary History Questionnaire using logistic regression, adjusting for age, gender, and type 2 diabetes (T2D) status in 2,629 samples (932 controls, 348 males (M); 1,697 cataract cases, 711 M) of European descent from the Marshfield Clinic Personalized Medicine Research Project, part of the Electronic Medical Records & Genomics (eMERGE) Network. Seven dietary measures were predictive of cataract ($p < 0.05$). A monounsaturated omega-9 fatty acid known as erucic acid (FA22:1) ($p=5.5\times10^{-4}$) met a Bonferroni corrected p-value threshold ($\alpha=0.05$). We then tested FA 22:1 for GxE using 498,829 SNPs in a subset of samples for whom genetic data was available (831 controls, 314 M; 1,511 cases, 633 M) using logistic regression adjusted for age, gender, and T2D status. Twenty SNP-FA22:1 models were statistically significant ($p<1.0\times10^{-4}$). The most significant GxE model was between FA22:1 and rs726712, an intronic SNP in *LPP* ($p=2.9\times10^{-5}$). The erucic acid-cataract association is novel; although significantly depleted levels of two polyunsaturated fatty acids have been found in cataractous human lenses when compared to mature typical lenses. *LPP* encodes a protein involved in cell-cell adhesion. A variety of studies have previously demonstrated the importance of cell-cell adhesion in cataract development, yet this is the first example of association with this specific factor. These findings indicate the role of GxE in susceptibility to cataract and demonstrate the utility of EWAS as a data-driven filtering method for investigating the genetic and environmental interplay of common, complex diseases.

1037M

Polygenic and Localized Genotype by Diabetes Duration Interaction Effects on Gene Expression. *J.W. Kent[1], J.M Proffitt[1], E.I. Drigalenko[1], H.H.H. Goring[1], J. Charlesworth[2], F. Thameem[3], J.E. Curran[1], M.P. Johnson[1], T.D. Dyer[1], S.A. Cole[1], M.C. Mahaney[1], L. Almasy[1], E.K. Moses[4], R. Duggirala[1], H.E. Abboud[3], J. Blangero[1], S. Williams-Blangero[1]*. 1) Dept Genetics, Tx Biomed Res Inst, San Antonio, TX; 2) Menzies Res Inst Tasmania, Hobart, TAS, Australia; 3) Univ of Tx Health Sci Center San Antonio, Div Nephrology, San Antonio, TX; 4) Centre for Genetic Origins of Health & Disease, Univ Western Australia, Perth, WA, Australia.

While prolonged hyperglycemia can lead to nephropathy, not all individuals with diabetes progress to kidney damage at the same rate. The causes of this differential risk are largely unknown. We used genome-wide RNA expression profiles of peripheral blood mononuclear cells (PBMCs) collected at initial recruitment from 1240 Mexican American participants in the San Antonio Family Heart Study, to identify genes whose expression showed evidence of polygenic genotype x duration of diabetes interaction (GxDoDI). We used as covariates sex, age, duration of diabetes, and the first 5 principal components derived from correlated gene expression, which appear to reflect (among other sources of correlation) sample-specific differences in relative abundance of PBMC species. Principal components correction substantially improved detection of GxDoDI: we found 74 transcripts with GxDoDI significant at a 1% false discovery rate, compared to 22 without inclusion of the principal components covariates. These transcripts represented genes involved in mitochondiral ribosome function, response to viral infection, and T-cell differentiation. The transcript of the pseudouridinylate synthase-like 1 gene *PUSL1* (polygenic GxDoDI p=3.3e-08) also showed evidence of cis-SNP GxDoDI, based on a panel of ~1M common variants (rs12410087, p= 1.9e-06; rs12402622, p=9.6e-06; rs6662635, p=1.2e-05). These results identify a core set of candidate genes for differential transcriptional response to duration of diabetes that may serve as a starting point for identifying molecular pathways associated with the development of diabetic complications, including kidney disease.

1038T

MS Risk Conferred by Obesity may be Independent of Predisposing Genetic Factors for Obesity: Results from the Kaiser Permanente MS Research Program. *M. Gianfrancesco[1], X. Shao[1], B. Rhead[1], L. Shen[2], H. Quach[1], A. Bernstein[3], C. Schaefer[2,4], L.F. Barcellos[1,2].* 1) School of Public Health, Dept of Epidemiology, UC Berkeley, Berkeley, CA; 2) Kaiser Permanente Division of Research, Oakland, CA; 3) Palm Drive Hospital, Sebastopol, CA; 4) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) [MIM 126200] is a demyelinating autoimmune disease affecting over 2.5 million people worldwide, thought to involve both genetic and environmental risk factors. Recently, childhood and adolescent obesity has been associated with a two-fold increased risk of MS. However, the relationship between obesity and disease may be confounded by lifestyle and socioeconomic characteristics that were not appropriately adjusted for in previous studies. We utilized Mendelian randomization to estimate the unconfounded causal relationship between obesity and MS using a weighted obesity genetic risk score (oGRS). The oGRS incorporates the cumulative effect of 32 SNPs associated with obesity identified from 16 published GWA studies of obesity phenotypes in European-descent samples (Belsky, 2013): *FTO, NEGR1, TNNI3K, PTBP2, SEC16B, FANCL, LRP1B, TMEM18, RBJ, CADM2, ETV5, GNPDA2, SLC39A8, POC5, ZNF608, TFAP2B, LING02, LMX1B, RPL27A, BDNF, MTCH2, FAIM2, MTIF3, PRKD1, NRXN3, MAP2K5, GPR5B, SH2B1, MC4R, KCTD15, QPCTL,* and *TMEM160*. A split-sample instrumental variable (IV) analysis was used by summing all minor alleles times the estimated effect of each minor allele on the phenotype as reported in the literature. We also examined the extent to which an obesity genetic risk score computed using supervised machine learning (Super Learner, R package) was associated with obesity in our sample, and whether instrumental variable results using this score differed from those generated by the published oGRS. Participants included non-Hispanic Caucasian female members of Kaiser Permanente (985 MS cases, 10,000 controls). Common and rare variant data for each candidate gene were obtained through genome-wide association profiling and imputation. Preliminary results show oGRS to be weakly correlated with childhood body size, body size in 20's, body mass index (BMI) in 20's and BMI in 30's ($r<0.10$). IV estimates demonstrated no association between oGRS and MS (causal odds ratio (OR) = 1.09, 95% CI 0.92, 1.29); however, the OR increased when restricting to individuals diagnosed with MS at age 30 or older (OR = 1.17, 95% CI 0.97, 1.42). MS risk conferred by obesity may be independent of predisposing genetic factors for obesity, suggesting that alternative mechanisms may mediate disease onset. Obesity acquired due to environmental factors rather than genetics may have greater influence on MS development, or interact with other risk factors to increase risk of disease.

Congenic analysis reveals a gene-stress interaction affecting obesity in mice. *S.M. Clee, C.L.K. Leung, J. Dong, S. Karunakaran, L. Innala, M. Wang, V. Viau.* Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada.

The BTBR T+ *Itpr3[tf]*/J (BTBR) inbred mouse strain is predisposed to obesity and pre-diabetes symptoms compared to the commonly studied C57BL/6J (B6) inbred strain. We have previously mapped loci affecting these traits and identified a locus, *Modifier of obese 1* (*Moo1*), on mouse chromosome 2 that accounts for the largest portion of the strain difference in body weight. Subsequently we localized this quantitative trait locus (QTL) to a congenic strain in which a ~6 Mb region of B6 genome had been transferred into the BTBR strain background. These congenic mice have reduced body weight, body fat, food intake and pre-diabetes compared to their pure BTBR littermates. Analysis of this congenic strain has revealed a significant gene-environment interaction that modifies the effect of this QTL. Here we show that under standardized phenotyping procedures the genotypic effect on body weight was markedly influenced by their housing environment (from a 0 to 17% difference in body weight between homozygous B6 and BTBR congenic mice across 3 facilities; $P_{geno} < 0.0001$, $P_{env} < 0.0001$, $P_{interaction}=0.006$). One major difference between facilities was ongoing construction nearby. This is known to cause stress in rodents and to affect food intake. In the facility with the most adjacent construction and where the genetic effect was completely overcome, the mice were never observed to be sleeping. In light of this, we examined the orexin (*Hcrt*) pathway. Orexin is a neuropeptide that promotes wakefulness and food intake and is known to be affected by stress. Orexin expression was 5 to 10-fold higher ($P < 0.001$) in mice housed in the facility with the most adjacent construction. We discovered a significant genotype-environment interaction in orexin receptor 1 (*Hcrtr1*) expression in the brain ($P=0.02$), consistent with the changes in body weight between genotypes and facilities and suggesting that genotype at this locus modifies the influence of stress on orexin signaling. When the effects of stress were directly tested in the congenic mice, we demonstrated a significant genotype-stress interaction ($P=0.02$) on body fat. Thus these studies have identified stress as a significant environmental modifier of obesity risk that is subject to genetic modulation. Discovery of the gene underlying the QTL will reveal a mechanism by which the orexin-mediated effects of stress on obesity can be modulated, which may prove useful for the design of novel strategies to aid weight loss.

Genetic Interactions in Developing of Rheumatoid Arthritis. *L.M. Diaz-Gallo, K. Shchetynsky, L. Padyukov.* Rheumatology unit, Department of Medicine, Karolinska Institute, Stockholm, Sweden.

Rheumatoid arthritis (RA) is a prototype of complex disease that involves multiple genetic and environmental factors. The individual effects of the known genetic risk factors are most often very moderate with highest impact for seropositive RA from the shared epitope (SE) alleles of the HLA-DRB1 gene. We previously have described significant interactions between the SE and some non-HLA genetic variants (i.e. PTPN22) in RA that indicated relatively strong effects in the susceptibility to seropositive RA. To provide more general view on gene-gene interactions in RA risk we tested the hypothesis regarding enrichment of the interactions between the SE alleles and previously shown genetic variants in association with RA. The study cohort includes 1151 seropositive RA patients and 1079 healthy controls from the Swedish EIRA study. Genome wide genotyping was performed using the IlluminaHumanHap300 BeadChip and subsequent imputation was done with the 1000 Genomes Phase I(α) Europeans as reference panel. All the individuals were genotype by low resolution SSP for the HLA-DRB1. Finally, 49 SNPs that previously were shown in association with RA and 48 SNPs selected from the study of genetic basis for reading and writing ability were analysed for interaction with SE alleles. SNPs from the HLA and PTPN22 loci and SNPs with MAF<0.01 were excluded from the analysis. The GEIRA algorithm provides measures of interaction including the attributable proportion (AP) due to interaction. We compared the distribution of the AP p-values observed in two groups of SNPs, using the Kolmogorov-Smirnov test. Overall 92 tests for interaction were valid in our study due to statistical constrains and we observed an enrichment of p-values <0.05 for AP in group of RA associated SNPs in comparison to control group of SNPs (10 vs. 3). Distribution analysis of p-values reveals significant difference between two groups ($p<0.05$). Additionally we noticed that only 17 out of 49 tested SNPs for RA exhibited a significant association in our study, but 7 of these SNPs (41%) were also in interaction with SE alleles. Our data indicate that the SE risk effect in RA could be in part attributed to its interaction with other non-HLA genetic risk factors to seropositive RA. The interaction between SE and others genetic variants can explain a significant fraction of the genetic background of RA.

Smoking-dependent genetic effects on obesity traits: the GIANT (Genetic Investigation of Anthropomorphic Traits) Consortium. *V.A. Fisher[1], A.E. Justice[2], T.W. Winkler[3], N.L. Heard-Costa[4,5], K.L. Young[2], J. Czajkowski[6], M. Graff[2], X. Deng[1], T.S. Ahluwalia[7], Q. Qi[8], L. Qi[9,10], A. Mahajan[11], D. Hadley[12], A.Y. Chu[13], L. Barata[6], J.S. Ngwa[1], R.A. Scott[14], L. Xue[1], T.O. Kilpeläinen[7], C-T. Liu[1], D.I. Chasman[13], K. Mohlke[15], R.J.F. Loos[16], I.B. Borecki[6], K.E. North[2], L.A. Cupples[1,4], GIANT Consortium.* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Genetic Epidemiology, Institute of Epidemiology and Preventive Medicine, University of Regensburg, Regensburg, Germany; 4) NHLBI Framingham Heart Study, Framingham, MA; 5) Boston University School of Medicine, Boston MA, USA; 6) Department of Genetics, Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO; 7) The Novo Nordisk Foundation Center for Basic Metabolic Research, Section of Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 8) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 9) Department of Nutrition, Harvard School of Public Health, Boston, MA; 10) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 11) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 12) Division of Population Health Sciences and Education, St. George's, University of London, London, UK; 13) Division of Preventive Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 14) MRC Epidemiology Unit, Institute of Metabolic Science, University of Cambridge, UK; 15) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 16) The Genetics of Obesity and Related Metabolic Traits Program, The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

Obesity and cigarette smoking (SMK) are important risk factors for cardiovascular disease. They are related: average body weight is lower among smokers and smoking cessation leads to weight gain, but central obesity is often higher in smokers. To investigate obesity as body size and distribution of body fat, we studied body mass index (BMI), waist circumference adjusted for BMI (WC), and waist/hip ratio adjusted for BMI (WHR). This builds on previous work of the GIANT consortium that identified 63 loci associated with WC in 42 cohort studies. Since then 46 additional studies have joined the consortium, nearly doubling the total sample size to 210,153 adults of European ancestry with genome-wide or Metabochip data. We performed genome-wide meta-analysis for each trait, considering association models stratified by SMK (current smoker: yes/no) and also adjusted for SMK. This analysis allows genetic effects to differ between smokers and non-smokers, equivalent to gene-environment interaction with SMK. A joint 2df test of the SMK-adjusted genetic main effect and gene-SMK interaction summarizes the influence of each SNP on trait outcomes, and stratified results allow us to distinguish between loci reaching genome-wide significance (GWS) because of strong effect in a specific population, and those with more consistent moderate effect. With a GWS threshold of 5E-8 and discarded weaker signals within 500kB of each selected SNP to avoid spurious associations due to LD, we identify 81 significant loci for WC of which 14 are novel in the extended sample, 68 loci (10 novel) for BMI, and 50 (9 novel) for WHR. Among the novel GWS main effect loci, WC associated with variants on chromosome 16 near the *AGRP* gene known for involvement in metabolism and eating disorders, and WHR associated with several intragenic SNPs between *NOTCH4* and the HLA D-antigen region on chromosome 6. Two variants near *ADAMTS7* showed GWS interaction with SMK, with lower BMI in minor allele carriers only among smokers. In addition, four loci previously associated with tobacco use disorder were also associated with WC and WHR (*COBBL1, DNM3, RSPO3, TBX15/WARS2*). We find several new loci associated with obesity by accounting for the influence of SMK, and continue to investigate biological function of these variants. Our results highlight the importance of appropriately modeling genetic associations by considering known relationships between phenotypes and environment.

1042S

Tomato consumption, an anecdotal trigger of gout flares, interacts with three urate transporters (*ABCG2*, *SLC22A12* and *SLC22A7*) in a non-additive fashion to influence serum urate. *T. Flynn[1], M. Cadzow[1], N. Dalbeth[2], L. Stamp[3], R. Topless[1], T. Merriman[1].* 1) Department of Biochemistry, University of Otago, Dunedin, Otago, New Zealand; 2) Department of Medicine, University of Auckland, Auckland, New Zealand; 3) Department of Medicine, University of Otago, Christchurch, Canterbury, New Zealand.

Raised urate levels, the main cause of gout, arise through a complex combination of genetic and environmental factors. Thirty genetic loci and several dietary exposures have well-established effects on urate levels. Interactions between these genetic and environmental factors have been reported. Urate is ideal for investigating gene-environment interactions as causal environmental exposures can be measured concurrently with phenotype. This study aimed to test two hypotheses: that tomato consumption, an anecdotal trigger of gout flares, is associated with urate levels and whether any of 7 genes encoding uric acid transporters interact with tomato consumption. 12,720 European individuals from the Atherosclerosis Risk In Communities (n=7517), Cardiovascular Health Study (n=2151) and Framingham Heart Study (n=3052) cohorts were used. All analyses were adjusted for confounding variables. There was association between tomato intake and urate levels (β=0.66 $\mu molL^{-1}$; P=0.01), which was modified by *ABCG2*: *rs2231142*, *SLC22A12*: *rs3825018* and *SLC22A7*: *rs4149178* genotypes (Pinteraction=0.04, 0.02 (in men) and 0.049, respectively). In the presence of the urate-increasing genotypes of *rs2231142* (TT) and *rs3825018* (GG) consumption of tomatoes showed a urate-lowering effect (β=-4.81 $\mu molL^{-1}$, P=0.01; β=-3.34 $\mu molL^{-1}$, P=0.02 (in men), respectively) converse to the urate-increasing effect shown when no genotypic stratification was performed. In the presence of the *rs4149178* urate-increasing genotype (GG) consumption of tomatoes showed a significantly higher increase in urate levels than in the un-stratified analysis (β=2.92 $\mu molL^{-1}$, P= 0.03). Subject to replication these data provide insight into the mechanisms involved in urate control and may lead toward personalised dietary advice in strategies to reduce urate concentrations.

1043M

Preliminary evidence of an interaction between a polymorphism in the *BDKR2B* gene and the dietary potassium intake on the systolic blood pressure in a sample of healthy adults. *J. Giovanella, J.P. Genro, S.M. Dal Bosco, V. Contini.* Postgraduate Program in Biotechnology, Centro Universitário UNIVATES, Lajeado, RS, Brazil.

Background: Studies have suggested significant associations between variants in the bradykinin receptor B2 gene (*BDKR2B*) and the development of hypertension. The bradykinin is one of the most important kinins involved in the modulation of the blood pressure (BP) and many of its physiological functions are mediated by the B2 receptors. In addition, high sodium and potassium intake has also been related to changes in the BP. **Objective:** The objective of this study was to investigate the interaction between the polymorphism rs1799722 of the *BDKR2B* gene and the environmental factors - sodium and potassium intake - on the variation in the BP in a sample of healthy adults from a private university in the South of Brazil. **Methods:** The participants were investigated for food consumption and BP by professional in the Nutrition Ambulatory from the university. The measurements of sodium and potassium intake were assessed by the 24-hour recall method (24-H-RQ), using the DietWin Professional software. BP values were determined by the mean of three measurements with the digital apparatus Omron. The polymorphism was genotyped using the TaqMan SNP genotyping assay. The allele frequencies were estimated by direct counting and the Hardy-Weinberg Equilibrium (HWE) calculated by the chi-square test. The gene-nutrient interactions were tested using multiple linear regressions with manual backward stepwise modeling. **Results:** The sample was composed by 267 women and 71 men. The average age of the sample was 25.5 years. Compared to women, men showed significantly higher values in the systolic BP (SBP) (men, 124.4 ± 11.0 mmHg; women, 113.7± 10.2 mmHg) and in the sodium (men, 2403.8 ± 1725.6 mg 24-H-RQ; women 1756.2 ± 1017.1 mg 24-H-RQ) and potassium intake (men, 2.343.7 ± 1089.9 mg 24-H-RQ; women 1758.5 ± 684.9 mg 24-H-RQ) (all p<0.001). The allele frequencies for the polymorphism were 0.59 (C) and 0.41 (T) and the genotype frequencies did not reveal a significant deviation from the expected values for the HWE. Our results did not show any main effect of the polymorphism in the investigated outcomes. However, we detected an interaction between the TT-genotype and the dietary potassium intake on the SBP (p<0,001). The increased consumption of potassium, in carriers of the TT-genotype, was associated with an increasing on the SBP. **Conclusions:** This study provides a preliminary indication of a gene-nutrition interaction on the BP in a sample of healthy adults.

The global obesity epidemic underscores the importance of gaining a deeper understanding of the biology of weight regulation to develop better preventive strategies. Obesity has a strong genetic component, but lifestyle factors, such as physical activity (PA), may modify the impact of genetic susceptibility. Recently, a candidate-gene-based meta-analysis confirmed that the body mass index (BMI)-increasing effect of *FTO* is attenuated by PA. To identify novel loci that interact with PA on BMI or waist-hip ratio adjusted for BMI (WHRadjBMI), we performed a meta-analysis of 64 studies with genome-wide or metabochip data, including up to 180,418 individuals of European descent. We standardized PA by categorizing it into a dichotomous variable (inactive vs. active) in each study. Overall, 23% of individuals were categorized as inactive. We pooled the results from individual studies using fixed effects meta-analysis of the SNP main effect in inactive and active strata, separately, and screened for SNPxPA interactions by testing for difference between the strata. To identify loci showing both main and interaction effects, we performed a joint meta-analysis of the SNP main effect and SNPxPA interaction. In the genome-wide meta-analysis of SNPxPA interaction alone, we identified a novel locus near *CDH12* ($P=3\times10^{-8}$) which showed a BMI-increasing effect in the inactive group, but a BMI-decreasing effect in the active group. In the joint meta-analysis, 69 loci reached $P<5\times10^{-8}$ (43 loci for BMI, 26 for WHRadjBMI), four of which have not been previously identified (near *FLJ30838* or *MRAS* for BMI; near *HHAT* or *PMS2P5* for WHRadjBMI). For each of the 69 loci, the joint test association was driven by the SNP's main effect, rather than by its interaction with PA. When we examined the SNPxPA interaction effects of the 69 loci, separately from main effects, the strongest interaction occurred at the *FTO* locus ($P=5\times10^{-4}$); the BMI-increasing effect was 29% smaller in the active than in the inactive group. In this sample of 180,418 individuals, we identify a novel locus near *CDH12* interacting with PA on BMI and replicate the PA-interaction of *FTO*. Furthermore, while accounting for PA in the model, we identify four novel loci associated with BMI or WHRadjBMI. We are currently performing a detailed follow-up of the loci to elucidate their potential functional roles. Our study may yield important novel insights into the role of gene-lifestyle interactions in the etiology of obesity.

1045S

Association of physical activity with lower type-2 diabetes incidence is weaker in those with high genetic risk. *Y.C. Klimentidis, Z. Chen, A. Arora, C. Hsu.* Epidemiology and Biostatistics, University of Arizona, Tucson, AZ.

We examined whether the association of physical activity (PA) with type-2 diabetes incidence differs according to several types of genetic susceptibility. In a large prospective cohort with 838 incident cases, we examined interactions of physical activity with 1) each of 65 type-2 diabetes-associated single nucleotide polymorphisms (SNPs), 2) a genetic risk score (GRS) comprised of all 65 SNPs, 3) two GRSs comprised of SNPs implicated in insulin resistance and insulin secretion, and 4) GRSs for fasting insulin and glucose. We find a significant interaction of physical activity and the type-2 diabetes GRS (p=0.019), suggesting a weaker protective effect of physical activity in those at high genetic risk. Based on the interactions observed with the insulin resistance GRS (p=0.044) and the fasting insulin GRS (p=0.060), it appears that this overall type-2 diabetes GRS interaction most likely occurs through genetic susceptibility to insulin resistance, as opposed to insulin secretion. Furthermore, this interaction was more pronounced in women (p=0.0046) than in men (p=0.47). No single SNP stood out as displaying a strong interaction with physical activity. We conclude that although physical activity appears to have an overall protective effect on type-2 diabetes, this putative effect is weakest in women with high genetic risk for type-2 diabetes and insulin resistance.

Genome-wide scan for context-dependent marker SNP effects in coronary heart disease. *S.M. Raj[1], C.F. Sing[2], G. Dyson[3], A.G. Clark[1].* 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI, USA; 3) Department of Oncology, Wayne State University, Detroit, MI, USA.

The existence of epistatic and genotype-environment interaction effects may limit the utility of genome-wide association studies (GWAS) to identify loci that are involved in determining the genetic architecture of a complex disease. We hypothesize that loci not detected by a GWAS may have allelic effects in the context of subgroups of the population who have the highest risk to disease. We have carried out the first genome-wide scan to detect such context-dependent locus effects.

We used a modified Patient Rule-Induction Method (PRIM) to assess which combinations of SNP marker and traditional risk factors identified subgroups with the highest cumulative incidence of coronary heart disease (CHD). The PRIM was applied to 840,000 autosomal SNPs and eight risk factors collected on 7,589 European-American adults from the Atherosclerosis Risk in Communities study. We also carried out a GWAS on this dataset to evaluate similarities and differences in the genetic signals captured by the PRIM.

The PRIM-based scan for context-dependent effects of marker SNPs identified approximately three times more hits than the GWAS, with females having a proportionately higher number of PRIM associations. These two approaches yielded very little overlap in associated genetic variants. We found that SNPs showing the strongest associations with CHD in a particular sub-group context defined by a traditional risk factor did not differ significantly between females and males, but did vary among contexts, with hypertension being the most common measure of context. These results suggest that consideration of context-based SNP associations with a complex disease may uncover new genetic pathways that contribute to disease pathogenesis. The role of context in determining the utility of genomic information has powerful implications for the clinical and population based management of the risk of a common disease having a complex multifactorial etiology.

1047T

Utility of the rhesus macaque (*Macaca mulatta*) as a novel genetic model for spontaneous human inflammatory bowel disease (IBD): sexual dimorphism and gene-by-sex effects on chronic diarrhea. *A. Vinson[1,3], M.J. Raboin[1], K.D. Prongay[2], E.R. Sunderhaus[3].* 1) Div. of Neuroscience, Oregon National Primate Research Center, Beaverton, OR; 2) Div. of Comparative Medicine, Oregon National Primate Research Center, Beaverton, OR; 3) Dept. of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR.

Inflammatory bowel disease (IBD) is one of the most prevalent gastrointestinal diseases in the U.S., and is known to have a strong genetic component. Moreover, recent studies support the role of female bias in genetic risk for IBD. However, no animal model of spontaneous IBD currently exists that will support genetic investigation of this disease, including sex-specific genetic effects. Based on our observation that the rhesus macaque displays chronic diarrhea at a high prevalence in captive colonies, our goal was to explore the utility of this species as a genetic model of spontaneous human IBD. Our aims were to assess the overall and sex-specific heritability of chronic diarrhea in a captive, pedigreed population of Indian-origin rhesus macaques. After clinical ascertainment of 233 animals affected with chronic diarrhea, we developed an extended pedigree of 5,328 relatives around these probands, using pedigree information available on ~23,000 macaques housed at the ONPRC since 1963. Using existing clinical veterinary records, we developed computational approaches to identify episodes of chronic diarrhea in all pedigree members. We then scored animals based on the number of days of diarrhea, per the total number of days present in the colony. After accounting for differences in housing, medication, and covariates of age and sex, we found low, but statistically significant heritability for this phenotype when both sexes were combined (h^2=0.12, P=1.61 × 10^{-8}). However, stratifying the pedigree by sex revealed substantial heritability among females (h^2=0.46, P=4.72 × 10^{-30}, N=1,676), and much lower, although statistically significant, heritability among males (h^2=0.16, P=5.40 × 10^{-4}, N=997). Consistent with the phenotypic sexual dimorphism suggested by covariate effects of sex (P-value=1.55 × 10^{-7}), initial tests of gene-by-sex interaction confirmed the significant effects of sex on genetic variance influencing chronic diarrhea in this pedigree (ρ_G = 0.02; test for ρ_G = 1.0 between males and females, P=5.37 × 10^{-4}). We conclude that genetic effects on chronic diarrhea in the rhesus macaque appear to play a larger role in females than in males, similar to observations in humans. These findings provide initial support for the utility of the rhesus macaque as a novel genetic model for sex-biased effects on spontaneous human IBD.

1048S

Genome wide gene-vitamin D interaction analysis suggests potential role for melanoma related genes in Parkinson disease. *L. Wang[1,2], L. Maldonado[1], J. Ritchie[3], M. Evatt[4], J.L. Haines[5], M. Pericak-Vance[1,2], G.W. Beecham[1,2], E.R. Martin[1,2], J.M. Vance[1,2], W.K. Scott[1,2].* 1) Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miller School of Medicine; 3) Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, GA; 4) Department of Neurology, Emory University School of Medicine, Atlanta, GA; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, School of Medicine, Cleveland, OH.

Despite extensive genome-wide association studies (GWAS) in Parkinson disease (PD), much of the estimated genetic risk has yet to be detected. One source of the "missing heritability" may be unaccounted-for gene-environment interactions. Vitamin D (Vit D) deficiency has been associated with increased PD risk in multiple studies. As Vit D regulates expression of a wide array of genes, we sought to identify genes involved in modifying the association between Vit D and PD by analyzing genetic interactions with vit D deficiency. We imputed up to 7.2 M SNPs in 477 PD cases and 430 controls, whose Vit D metabolites were measured in stored plasma samples using mass spectrometry. Vit D deficiency was defined as having plasma 25(OH)D concentration <20 ng/ml and was strongly associated with PD (Odds Ratio (OR)=2.7, P<0.0001). Joint tests of gene-environment interaction were conducted by comparing a full model containing SNP dosage, vit D deficiency, an interaction term, and covariates age, sex and sampling season to a restricted model with only vit D deficiency and covariates. While no joint tests produced genome-wide significant results at P< 5 x 10-8, the most significant interaction terms were detected with SNPs in two genes associated with melanin production and risk of melanoma. This is intriguing given that PD is characterized by a loss of melanin-positive, dopaminergic neurons in the substantia nigra and an increased incidence of melanoma in PD patients has been reported in several studies. The strongest evidence for interaction was found at rs7312710 in FBRSL1 (P=2×10 6). The effect of this SNP on PD depended on vit D status: the minor allele is associated with increased risk in vit D deficient individuals (OR=2.3, P=0.0004) and with decreased risk in vit D non-deficient individuals (OR=0.7, P=0.0036). The second strongest interaction was found in C10orf11 with a similar pattern. We hypothesize that PD and melanoma share biological pathways (e.g. melanin production) that when perturbed modify risk to both diseases. This is supported by our previous pathway analysis using GWAS and microarray data suggesting that variation in the melanogenesis pathway contributes to PD risk. Our study demonstrates vit D-gene interactions and nominates new genes that were not implicated in previous GWAS in PD. Our findings illustrate that examining gene-environment interactions can identify novel genes underlying the "missing heritability" in PD.

Smoking Then and Now: What Can the Aggregate of Genome-wide SNPs Tell Us About the Correspondence of Genetic Factors Influencing Cigarette Smoking Initiation Between Birth Cohorts. *A.G. Wills[1,2], G. Carey[1,2], M.C. Keller[1,2].* 1) Department of Psychology and Neuroscience, University of Colorado, Boulder, CO, USA; 2) Institute for Behavioral Genetics, University of Colorado, Boulder, CO, USA.

Twin studies have drawn attention to the importance of birth cohort when examining the genetic etiology of cigarette smoking behavior. For the smoking phenotype of initiation, we used whole-genome SNP data from a combined sample of 9189 European Americans that had participated in the Atherosclerosis Risk in Communities Study (ARIC) and the Multi-Ethnic Study of Atherosclerosis (MESA). The majority of these individuals were born between 1920 and 1950. Using Genome-wide Complex Trait Analysis[1], we estimated the SNP heritability for individuals born before (SNP h^2 = .16) and after (SNP h^2 = .23) the combined sample's median birth year of 1934. In the bivariate analysis, the correlation between the set of SNPs that explained variance in those born before 1934 and those born after was moderate (r_g = .40) and significantly different from 1 (p = .048). Further, in a model that allowed for a gene x cohort interaction parameter, we found a marginally significant interaction (.11, p = .06) between birth year and the conglomerate of SNP effects. To better understand the differing genetic contribution based on year of birth, we divided our sample into birth decades, and the largest genetic effect was found for those born in the late 1930s. Due to disparity in sample sizes and the potential for unexamined gender effects, we remain cautious in interpreting this result. However, these findings highlight the potential for etiological heterogeneity among smokers of different eras.

Risk prediction and Type II Diabetes. *N. Furlotte, S. Dandekar, R. Smith, N. Eriksson, D. Hinds.* 23andMe, Mountain View, CA.

As the prevalence of Type II Diabetes (T2D) continues to increase worldwide, the ability to accurately assess the risk for developing this disease is becoming increasingly important in clinical practice. Accounts vary as to the clinical utility of genetic risk prediction models for T2D. Estimates of heritability vary widely, but it is generally accepted that environmental factors such as food consumption, exercise frequency and body mass index play a much larger role in the development of this disease than the genetic variations implicated through genome-wide association studies. Furthermore, the effects of genetic variations may only be apparent under particular environmental conditions - so called gene-by-environment interactions. We explore these issues in a cohort of over 300,000 23andMe customers. We evaluate the predictive power of the most recent and robust genetic variations implicated in the etiology of T2D through association analysis and compare their predictive ability with environmental predictors related to individual behavior. In addition, we search for genetic variations exhibiting environmentally specific genetic effects and quantify the proportion of the total trait variation attributed to these gene-by-environment interactions.

Investigate cytokine levels of cord blood samples in related to maternal allergic status. *H. Tsai[1,2,3], Y. Huang[2], Y. Tsai[2], Y. Ho[4], W. Hsiao[4], J. Wang[4,5].* 1) Dept Pediatrics, Northwestern Univ Sch Med, Chicago, IL; 2) Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Taiwan; 3) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Department of Pediatrics, National Cheng Kung University Hospital, Tainan, Taiwan; 5) Institute of Basic Medical Sciences, College of Medicine, National Cheng Kung University Hospital, Tainan, Taiwan.

Introduction: The increasing prevalence of early childhood allergic traits such as eczema, wheezing, asthma and allergic rhinitis has been a substantial public health burden in Taiwan and worldwide. Previous studies have reported certain kinds of cytokines and chemokines are involved in the pathophysiology of asthma and/or atopy. Based on our previous work, we hypothesize that maternal allergic status during pregnancy may play an important role influencing cytokine levels of their fetus, that is, may have an effect of immune dysregulation in-utero. Methods: A total of 55 maternal participants was recruited in this study. In addition to maternal biospecimen, we also collected their cord blood samples. We stimulated cord blood mononuclear cells (CBMCs) with lipopolysaccharide (LPS) and specific allergen from Der. Pteronyssinus (Derp), separately, and measured cytokine levels, specifically, IL-6, IL-8, IL-10, IL-23 and Tumor necrosis factor alpha (TNF-alpha), from the stimulated cord blood samples. We then applied Student's t test and Wilcoxon rank sum test, separately, to examine whether examined cytokine levels differed related to maternal allergic status. Results: We examined 5 different cytokine levels in medium (not stimulated), LPS and Derp stimulated CBMCs in related to maternal allergic status. We only observed that there was borderline significance in TNF-alpha between maternal subjects with and without allergy (p=0.06). Beyond that, the results indicated that there was no difference in the examined cytokine levels between maternal subjects with and without allergy, no matter medium, LPS or Derp stimulated cord blood samples. Conclusions: The present study indicated cytokine levels of IL-6, IL-8, IL-10 and IL-23 in cord blood were not different in related to maternal allergic status. Further investigation will be warranted to better understand maternal influence on TNF-alpha levels in -utero.

Estrogen-dependent upregulation of *IRF5* in human immune cells. *S.E. Lofgren[1], J. de Azevedo Silva[2], M.E. Alarcon-Riquelme[3], S.V. Kozyrev[4].* 1) Department of Cell Biology, Embriology and Genetics, Federal University of Santa Catarina, Florianopolis, Brazil; 2) Department of Genetics, Federal University of Pernambuco, Brazil; 3) GENYO; Centre for Genomics and Oncological Research; Pfizer; University of Granada; Andalusian Regional Government; Granada, Spain and Arthritis and Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 4) Department of Medical Biochemistry and Microbiology, Uppsala University, Uppsala, Sweden.

Background: Systemic lupus erythematosus (SLE) as well as other autoimmune diseases show a strong gender bias, where the great majority of patients are women. Although controversial, the effect of estrogen has been implicated with SLE in several ways. However, the mechanism on how estrogen contributes to the development of SLE is still largely unknown. Objective: To contribute to the knowledge of the mechanisms behind the strong sex-biased prevalence of SLE, we investigate the role of estrogen on the expression of one of the strongest associated gene with SLE, the interferon regulatory factor 5 (*IRF5*), in human immune cells. Material and methods: *IRF5*, as well as *IRF3*, *IRF4*, *IRF7* and *IRF9* expression was measured in PBMCs, LCLs, monocytes and monocyte-derived macrophages from both male and female origin. Cells were treated with different concentrations of estrogen and gene expression was measured by quantitative PCR. Results: We found that the initial levels of *IRF5* in PBMCs were almost 2-fold higher in women that in men, although not reaching statistical significance. After 12 h in culture the *IRF5* levels became roughly equal in both sexes, and further stimulation with estrogen lead to up-regulation of *IRF5* levels in both PBMCs and monocytes in both women and men. No difference was seen for *IRF3*, *IRF4*, *IRF7* and *IRF9* expression, and none of the genes analyzed was up-regulated in LCLs, upon estrogen treatment, regardless of the gender. The later could be explained by the fact that we could not detect any expression of estrogen receptor *ESR1* on those cell lines. Conclusions: We could show that in human PBMCs and monocytes from healthy individuals *IRF5* expression can be regulated by exogenous estrogen. The effect in PBMCs was seen in both gender but was more pronounced in women. This feature might be specific to *IRF5* since four other *IRF* genes tested did not show any up-regulation in these cells. This data could to some extent explain the sex bias in the development of SLE as well as other autoimmune diseases.

1053T

Genetic and early life environmental influences on body mass index. *A. Smith[1], K. Jensen[1], C. Sartor[2], J. Kaufman[2], H. Kranzler[3,4], J. Gelernter[1,5].* 1) Div Human Genetics, Dept Psychiatry, Yale School Medicine, New Haven, CT; 2) Dept Psychiatry, Yale School of Medicine, New Haven, CT; 3) Dept Psychiatry, University of Pennsylvania, Philadelphia, PA; 4) Philadelphia VAMC; 5) West Haven VAMC.

Introduction: The public health consequences of overweight and obesity include risk for a range of metabolic and cardiovascular disorders. Early life adversity has been shown to exert lasting effects on body mass index (BMI) and related health outcomes throughout adulthood. Improved understanding of the pathogenesis of obesity may therefore require examination of the interplay between genetic and early life environmental risk factors. Methods: We recruited a heavily substance-dependent (SD) adult sample of >9,000 European- and African-American (EA and AA) subjects with BMI data and careful diagnosis of SD and other psychiatric traits via the semi-structured assessment of drug dependence and alcoholism (SSADDA). Severe childhood adversity (CA) (e.g., child abuse, violent crime, or death of a parent in early childhood) was also assessed; 30.2% of men and 31.2% of women reported at least one such event. We conducted in this sample a study of how both genetic variation and early life stress influence BMI in a single group of subjects. Results: In our combined sample (AA and EA), after adjusting for SD diagnoses, age, race/ ethnicity, and household income in a linear regression model, we found a consistent relationship between a CA sum score and log transformed BMI (Pmales = 1.9 x 10-4, beta = 0.01, n = 5,095; Pfemales = 2.0×10-10, beta = 0.03, n = 4,175). Large consortia have previously carried out GWASs of BMI that were restricted to European-ancestry populations. In the EA sub-sample of our dataset, we generated genetic risk scores (GRSs) for each individual using effect size estimates for 32 loci with known genome-wide significant BMI associations. GRSs fell on a continuous scale from 3.3 to 10.0. After incorporation of GRSs into the regression model, in both male and female EAs significant associations were observed between CA and BMI (Pmales = 1.5 x 10-2, beta = 0.02, n = 1,482; Pfemales = 6.8×10-5, beta = 0.04, n = 931), and between GRS and BMI (Pmales = 2.3 x 10-10, beta = 0.03; Pfemales = 3.9×10-7, beta = 0.04). In males, but not females, we observed a significant interaction between GRS and CA (P = 7.6 x 10-3), which reflected an increase in the influence of GRS on adult BMI as the CA sum score increased. Conclusion: These sex-specific findings represent an initial step in understanding how genetic variation and the developmental environment individually and jointly may exert lasting effects on metabolism and health.

A new GATK framework for RNA-seq variant discovery identifies differential A-to-I RNA editing in autistic brains. *A. Eran[1,2], A. Levy-Moonshine[2], R. Anner[3], N. Milo[3], E. Bachmat[3], R. Zhang[4], J.B. LI[4], D.M. Margulies[1], L.M. Kunkel[5], I.S. Kohane[1].* 1) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 2) Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Department of Computer Science, Ben Gurion University, Beer Sheva, Israel; 4) Department of Genetics, Stanford University, Stanford, CA; 5) Department of Genetics, Boston Children's Hospital and Harvard Medical School, Boston, MA.

Adenosine-to-inosine (A-to-I) RNA editing is an epigenetic mechanism that fine-tunes synaptic function in response to environmental stimuli. Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental disorder commonly associated with synaptic dysfunction. Targeted RNA sequencing studies have identified consistent A-to-I editing alterations of candidate genes in ASD, suggesting that A-to-I RNA editing may play a role in the disorder. However, transcriptome-wide editing profiles of individuals with ASD are still unknown, and the overall contribution of A-to-I editing alterations to the ASD phenotype remains to be discovered. Here we present a comprehensive framework for accurate SNP and indel detection in RNA-seq data, and apply it to conduct a first transcriptome-scale survey of A-to-I RNA editing in postmortem prefrontal cortex and cerebellum from individuals with ASD. The Genome Analysis Toolkit's RNA-seq variant analysis framework is based on local de-novo assembly of RNA haplotypes. It begins with RNA-seq data pre-processing, including spliced alignments, duplicate marking, splicing and indel realignment, and the recalibration of base and mapping scores. It continues with de-Bruijn assemblies of variable regions, their likelihood calculations, and identification of variants on the most likely haplotypes. It ends with variant filtering and the production of a SNP and indel call set in a VCF file. We evaluated the performance of this approach using whole exome sequences from the same tissues, and applied it for a first genome-wide comparative survey of A-to-I RNA editing in autistic brains. We compared cerebellar to prefrontal cortex editing levels, in synaptic vs. non-synaptic transcripts, across isoforms, genes, and gene families. We identified differential editing of bona fide autism genes and pathways, and characterized their relations to expression and splicing patterns. We then validated these findings using an independent deep targeted sequencing approach, mmPCR-seq. These results improve our understanding of the role of A-to-I editing in ASD and demonstrate the effectiveness of the GATK's RNA-seq variant analysis framework.

Risk Prediction for Age-Related Macular Degeneration Using Genetic and Environmental Factors. *W. Wu[1,2], F. Wu[1,2], L. Zhao[1,2], H. Luo[1,2], C. Wen[1,2], N. Sfeir[1,2], S. Patel[1,2], M. Goldbaum[1], H. Ferreyra[1], K. Zhang[1,2].* 1) Department of Ophthalmology and Shiley Eye Center, University of California, San Diego, La Jolla, CA; 2) Institute for Genomic Medicine, University of California, San Diego, La Jolla, CA.

Purpose: To determine the individual and composite effects of genetic factors and smoking on the development of age-related macular degeneration (AMD), including the early form of AMD, which is characterized by the presence of confluent drusen in the retina, as well as the advanced forms of AMD, which include geographic atrophy (GA) and choroidal neovascularization (CNV). Methods: DNA samples from 522 patients without AMD, 239 patients with confluent drusen, 271 patients with GA, and 1159 patients with CNV were analyzed for four genetic variants known to be associated with advanced AMD. Patients were also asked about their smoking status. Logistic regression was performed to generate a predictive model for AMD risk, and odds ratios were calculated based on individual and composite factors. Results: Odds ratios (ORs) for CNV were 5.26 (95% CI: 3.51-8.13) for HTRA1/ARMS2 rs10490924 TT, 2.15 (95% CI: 1.41-3.28) for CFH rs1061170 CC, 3.71 (95% CI: 2.31-6.00) for CFH rs2274700 CC, and 1.33 (95% CI: 1.05-1.68) for C3 rs2330199 CG when compared to individual reference genotypes. Smoking status alone was associated with an OR for CNV of 1.55 (95% CI: 1.24-1.95). ORs for GA were 3.85 (95% CI: 2.21-6.79) for HTRA1/ARMS2 rs10490924 TT, 1.89 (95% CI: 1.07-3.38) for CFH rs1061170 CC, 6.83 (95% CI: 3.10-16.21) for CFH rs2274700 CC, and 2.97 (95% CI: 1.61-5.52) for C3 rs2330199 GG when compared to individual reference genotypes. Smoking status alone was not associated with an increased risk of GA. For smokers carrying a minimum of six out of eight possible risk alleles, the OR for CNV was 15.83 (95% CI: 6.06-45.19), and the OR for GA was 15.39 (95% CI: 3.47-110.84). For smokers carrying five risk alleles, the OR for drusen was 6.97 (95% CI: 2.13-27.86). The composite effect of all four genotypes combined with smoking was significant for CNV ($p < 2*10^{-16}$), GA ($p < 2*10^{-16}$) and drusen ($p = 8.1*10^{-12}$). Conclusions: Combined genetic and environmental factors influence the risk of AMD significantly. CFH rs2274700 and C3 rs2330199 conferred greater risk for GA than for CNV. Because the onset of AMD can be insidious, it is important to develop predictive models to target high-risk individuals. Monitoring and early interventions may improve clinical outcomes in these patients.

Study of genetic polymorphism and oxidative stress markers analyses in psoriasis patients from Indian. *S. Chettiar[1], S. Desai[1], D. Gimhre[1], D. Umrigar[6], J. Dattani[4], A. Patel[3], D. Jhala[2], R. Uppala[5].* 1) Department of Biotechnology, SRICEAS, surat, Gujarat, India; 2) Department of Zoology, Gujarat University, Ahmedabad, India; 3) Genexplore Diagnostic and Research Centre, Ahmedabad, India; 4) Regional Office for Health and Family Welfare, GOI, Ahmedabad, India; 5) Green cross Pathology and Molecular Biology laboratory, Paldi, Ahmedabad, India,; 6) Department of Dermatology, New Civil Hospital, Surat.

Psoriasis (PSORS) is a common, immune-mediated, genetically determined long-lasting (chronic) skin disease that usually presents after puberty. It is characterized by red, scaly patches, papules, plaques usually inflamed skin lesions and patches can show up in most parts of the body. The prevalence varies widely, depending on the ethnicity and geographic location of the population, ranging from 1 to 11%. In India, it affects ~ 3% of adults and is the most common among skin diseases. Various genetic studies of different populations provided evidence of several loci / genes on various chromosomal regions contributing to PSORS, including HLA-Cw6 gene, which has strong association with PSORS. We have studied 53 clinically proven PSORS patients from Gujarat, India and an equal number of age matched controls from the same geographic origin. After informed consent, detailed dermatological evaluation was conducted for each patient included in the study and genetic polymorphism analysis for all the subjects. It was found that 88% of affected subjects were with plaque type psoriasis. Serum oxidative stress markers for example TBARS assay GSH quantification and catalase activity revealed significant difference as compared to normal controls. The ACE genotype with deletion allele frequencies were significantly higher in PSORS patients as compared to normal controls. The present study suggests that the ACE gene polymorphism confers susceptibility to PSORS in the population of Gujarat.

Multiscale Analysis of Chronic Fatigue Syndrome. *N.D. Beckmann[1,2], G.E. Hoffman[1,2], C. Becker[3], E.E. Schadt[1,2].* 1) Genetic and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

Chronic Fatigue Syndrome (CFS, or Myalgic Encephalomyelitis) is a disease that afflicts between 1 and 4 million people in the United States. Yet the etiology is poorly understood. CFS affects several body systems and is characterized by a severe fatigue or exhaustion that does not improve with rest. A wide variety of symptoms are often exacerbated by physical or mental activity. Here we perform a multiscale analysis of RNAseq and genotype data from 15 patients and 15 controls matched for age and gender to characterize the molecular signature of CFS. The RNAseq data is comprised of 6 cell types (whole blood, monocytes, natural killer cells, granulocytes, B-cells and T-cells) over 4 time points in order to assess the differential response to moderate exercise between patients and controls. The first time point characterizes the baseline level, before exercise; the following time points represent, respectively, one, two and three days after exercising. We consider differential expression of RNAseq data between patients and controls in order to identify genes playing an important role in CFS, in a cell-type or time-specific manner. We construct coexpression networks to identify interpretable subsets of genes that could be perturbed by the disease status and interpret differentially expressed genes in terms of these coexpressed gene modules. Integrating these RNAseq data with genotyping data, we identify expression quantitative trait loci (eQTLs) specific to the disease for each cell type and time point. Our multiscale approach to disease biology elucidates relevant genes, pathways, and cell types, and is a first step toward better understanding CFS.

Genetic influences common to bronchial asthma and pulmonary tuberculosis present targets for intervention. *R.C. McEachin[1], M.B. Freidin[2], E. Bragina[2], V. Puzyrev[2], L.A. Koneva[1,2].* 1) DCM&B, Univ Michigan, Ann Arbor, MI; 2) Research Institute of Medical Genetics, SB RAMS, Tomsk, Russia.

Purpose: Bronchial asthma and pulmonary tuberculosis (TB) are both serious health issues worldwide. Though asthma is an allergic disease and TB is an infectious disease, both show evidence of genetic influences on susceptibility. Interestingly, epidemiological data show their co-occurrence is rare, relative to the expected. Historically, TB caused more deaths in industrialized countries than any other disease during the 18th to early 20th centuries. While TB is now rare in the progeny of survivors of this epidemic, asthma is prevalent. Equally, in populations that currently have high rates of TB, asthma is rare. One explanation for these observations is that differences in hygiene may influence differential TB and asthma rates. We hypothesize that there are also genetic influences shared across asthma and TB, including risk variants for one disease that are protective for the other. In this work, we test this hypothesis and develop a model that a) places the results into biological context and b) presents gene/drug targets for intervention. Methods: Gene expression is a primary cellular response to the environment, so we looked for genes differentially expressed (DE) in both asthma and TB, but in opposite directions. We assessed DE in T-cells from asthma patients vs controls, and from TB patients vs controls, as well as in lungs of non-infected TB-resistant vs TB-susceptible mice (fold change $\geq \pm 2.0$ AND FDR ≤ 0.05). We used GeneGo to model interactions among DE genes that responded in opposite directions in human TB and asthma, emphasizing transcriptional regulation as the mechanism of action. We used DAVID to assess enrichment of annotation for DE genes in the mouse TB model. Results: Consistent with our hypothesis, 14 human genes were DE in opposite directions in asthma and TB. The network shows how these 14 genes interact, and how a given variant could be a risk factor for one disease and protective for the other. Two genes in the network are known targets for 35 drugs currently in use for a wide range of disorders, including lung disorders. The mouse TB model also yields results consistent with the hypothesis, with “asthma” as the most significantly enriched annotation for the set of DE genes (FDR 1.17E-08). Conclusions: The proposed model presents a novel hypothesis on how TB and asthma responsive genes could have opposite effects in predisposing the two diseases and presents immediate targets for follow on testing in asthma and/or TB.

1059T

Identification of a Common Pathogenesis for Chronic Kidney Disease: Perspectives from Gene Ontology analysis. *W. WU[1], J. Guo[3], R. Yenchek[2], J. Abraham[2], A. Cheung[2], L. Jorde[2].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Division of Nephrology, Department of Internal Medicine, University of Utah, Salt Lake City, UT, United States; 3) Department of Oncological Sciences, University of Utah, Salt Lake City, UT, United States.

Background: Chronic kidney disease (CKD) affects more than 13% of people in the United States, and is one of the leading causes of death. Genetic studies have provided molecular insights into CKD, but there is substantial locus heterogeneity. Yet the clinical manifestations of CKD are often shared across various etiologies. Is there a common pathogenesis that may explain these heterogeneous diseases? Here we employed a bioinformatics approach to identify one or a few common groups of genes for CKD pathogenesis. Methods: We first identified known causative genes associated with CKD curated by the Online Mendelian Inheritance in Man (OMIM). These genes were mapped to the Gene Onotology (GO) networks, and we traversed these trees to trace back to the root nodes. The GO terms hit by these genes and their parent-child relationships were parsed. A statistical hypothesis test with theoretical hypergeometric distribution was carried out to test if the genes are significantly over-represented in each GO node. Simulation was performed to correct for multiple comparisons. These GO terms and their relationships were structured and further visualized for grouping for possible common pathogenesis. Results: From OMIM, we identified 84 causative genes for CKD. When mapping back to the GO networks, 2728 GO terms were hit, among which 2159 were in the biological process (BP) domain, 263 in the cellular component (CC) domain, and 306 in the molecular function (MF) domain. However, after testing for over-representation and correction for multiple comparisons for all terms, only 141 GO terms were statistically significant, among which 117 were in the BP domain, 23 in the CC domain, and 1 in the MF domain. Structure and visualization of these GO nodes and edges showed a diverse pattern across the network. Conclusions: We have derived both positive and negative lists of ontologies to be ruled in or ruled out for future studies of CKD. We also provided a quantitative prior probability for each GO term that can be integrated into a computational model for pathogenesis prediction.

1060S

Pathway Burden Analysis Identifies Genes Underlying Complex Human Limb Disorders. *D. Alvarado[1], G. Haller[1], P. Yang[1], C. Cruchaga[2], M. Harms[3], M. Dobbs[1,4], C. Gurnett[5].* 1) Orthopaedic Surgery, Washington Univ, St Louis, MO, USA; 2) Psychiatry, Washington Univ, St. Louis, MO, USA; 3) Neurology, Washington Univ, St. Louis, MO, USA; 4) Shriners Hospital for Children, St. Louis, MO, USA; 5) Pediatrics, Washington Univ, St. Louis, MO, USA.

Clubfoot, vertical talus and hip dysplasia are congenital birth defects with complex inheritance patterns. The genetic and morphological basis of all three lower limb disorders is poorly understood. Although each disorder describes a different clinical phenotype, their common occurrence within individuals and families suggests a common genetic developmental etiology. To identify the genetic risk factors associated with complex human limb disorders, we performed exome sequencing and genome-wide rare variant pathway burden analysis on 119 patients (88 families) with human lower limb malformations and 298 (249 families) unaffected controls. Using famSKAT, we calculated a collapsed gene burden analysis for all novel coding variants not previously identified in dbSNP137. An enrichment of muscle development, extracellular matrix, hindlimb morphogenesis and chondrocyte differentiation GO term genes was found using the top 100 rank ordered genes. Genome-wide collapsed pathway burden analysis of novel coding variants for all non-redundant GO term gene pathways revealed an association of lower limb malformation cases with collagen catabolism/metabolism and hindlimb morphogenesis GO term genes ($p=1.22\times10^{-5}$ and $p=1.39\times10^{-5}$). Based on these results, candidate genes associated with collagen or hindlimb morphogenesis GO terms with collapsed famSKAT p-value < 0.05 were selected for re-sequencing in a larger cohort. Using Multiplexed Direct Genomic Selection (MDiGS), a newly described BAC capture approach for CNV and SNP/INDEL detection, we sequenced candidate genes in an additional 400 cases. Overall, these results suggest that clubfoot, vertical talus and hip dysplasia are highly heterogeneous disorders related to each other through an increased frequency of novel variants in genes responsible for hindlimb morphogenesis and extracellular matrix organization.

1061M

Integrative Analysis of Transcriptomic and Epigenomic Data to Reveal Regulation Patterns for Osteoporosis. *J.G. Zhang[1, 2], L.J. Tan[3], C. Xu[1, 2], Q. Tian[1, 2], H.W. Deng[1, 2, 4].* 1) Center of Genomics and Bioinformatics, Tulane University, New Orleans, LA, 70112, USA; 2) Department of Biostatistics, Tulane Univ Sch Public Health & Tropical Medicine, New Orleans, LA. 70112, USA; 3) Laboratory of Molecular and Statistical Genetics and Key Laboratory of Protein Chemistry and Developmental Biology of the Ministry of Education, Hunan Normal University, Changsha, Hunan, 410081, China; 4) Center for Systems Medicine, Shanghai University for Science and Technology, Shanghai, 200093, China.

Multiple profiling studies have uncovered a number of risk factors/genes for human complex diseases but are less informative of protein-protein interactions, post-transcriptional modifications and regulation of functional networks. Integration of genomic data and construction of functional gene networks may provide additional insights into the molecular mechanisms of complex diseases. Osteoporosis is a worldwide public health problem characterized by low BMD (bone mineral density) and has strong genetic determination. With the advent of high-throughput technologies, the increasing multi-omics data has created an opportunity for a comprehensive understanding of osteoporosis. In this study, we analyzed gene expression microarray, miRNA microarray and methylation sequencing data of peripheral blood monocytes (PBM) from 5 high hip BMD subjects and 5 low hip BMD subjects. Through integrating the transcriptomic and epigenomic data, we firstly identified BMD-related genetic factors, including 9 protein-coding genes and 2 miRNAs, of which 3 genes (FAM50A, ZNF473 and TMEM55B) and one miRNA (hsa-mir-4291) showed the consistent association evidence from both expression and methylation data, and 3 genes (TMEM55B, RNF40 and ALDOA) were confirmed in the meta-analysis of 7 GWAS samples and GEnetic Factors for OSteoporosis consortium (GEFOS) summary results. Secondly in network analysis we identified an interaction network module with 12 genes and 11 miRNA including AKT1, STAT3, STAT5A, FLT3, hsa-mir-141, hsa-mir-34a and hsa-mir-302b which were proved to be associated with BMD in previous studies. This module revealed the crosstalk among miRNAs, mRNAs and DNA methylation and showed four possible regulatory patterns of gene expression to influence the BMD status, including regulation by gene methylation, by miRNA and its methylation, by transcription factors and co-regulation by miRNA and gene methylation. In conclusion, the integration of multiple layers of omics can bring more evidence than analysis of single layers alone. Integrative analysis from transcriptomics and epigenomic data improves the ability to identify the causal genetic factors, and more importantly uncover the regulation pattern of multi-omics for osteoporosis.

The Brainstorm project; a cross-phenotype analysis of 14 brain disorders by heritability-, constraint- and pathway-based methods, using genome-wide association data from 500,000 samples. *V. Anttila[1,2,3], S. Ripke[1,2], R. Malik[4,5], T.H. Pers[2,6], K.-H. Farh[2,7], L. Duncan[1,2,3], A. Biffi[2,8,9,10], P. Lee[7], K. Kendler[11,12], J. Scharf[7], J. Smoller[7], A. Palotie[2,7,13], M. Daly[1,2], J. Rosand[8,9,10], B. Neale[1,2,3].* 1) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Harvard Medical School, Boston, MA; 4) Institute for Stroke and Dementia Research, Klinikum der Universität München, Ludwig-Maximilians-University, Munich, Germany; 5) Munich Cluster for Systems Neurology (Synergy), Munich, Germany; 6) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Boston, MA; 7) Psychiatric and Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, MA; 8) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 9) Division of Neurocritical Care and Emergency Neurology, Department of Neurology, Massachusetts General Hospital, Boston, MA; 10) J. Philip Kistler Stroke Research Center, Massachusetts General Hospital, Boston, MA; 11) Departments of Psychiatry and Human Genetics, Virginia Commonwealth University, Richmond, VA; 12) Virginia Institute for Psychiatric and Behavior Genetics, Richmond, VA; 13) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland.

Many neurological and psychiatric diseases have considerable co-morbidity, and the strength of the etiological boundaries is a topic of active debate. However, studying these co-morbidities in the real world has proven difficult, and new approaches are needed. To this end, hypothesis-free methods using large genetic datasets may provide a way to study these co-morbidities by examining the genetic correlation through orthogonal approaches. Our aim is to provide insight into the molecular basis of these phenotypic co-morbidities and leverage large-scale genome-wide association data to reveal more of the underlying pathophysiology of an array of brain disorders in a statistically robust fashion. To this end, we have set up collaborations with a number of disease-specific genetics consortia, to obtain summary statistics from roughly 150,000 cases from 14 different diseases and corresponding controls. Meticulous efforts have been applied to identify overlapping studies and samples, using algorithmically generated identifiers where possible, as well as using a novel statistical approach to account for overlapping summary statistics where needed. In addition to successfully replicating and expanding on the previous cross-disorder results from the Psychiatric Genetics Consortium, we report the first comprehensive look into the genetic co-morbidity of common neurological diseases, as well as cross-over analyses between each. Using a novel uni- and bivariate heritability estimation method, we report the total observed heritability for each disease and genetic correlations between each disease pair. In addition, we report some tissue-of-effect analyses using ENCODE and GTEX data, as well as analysing pairwise correlations through pathway membership of the associated loci in existing in silico data. In this study, we set out to integrate the best available neurological and psychiatric genome-wide association results, and to use them to explore cross-disorder analyses of common genetic risk factors using large-scale genetic data.

1063S

RAI1 is a multi-hit regulator of obesity gene expression networks. *J.T. Alaimo[1], S.V. Mullegama[1], R. Tahir[2], J. Beach[2], J. Cruz[2], E. McMullen[2], B. Burns[2], S.H. Elsea[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA.

Smith-Magenis syndrome (SMS, OMIM 182290) is a complex neurobehavioral disorder characterized by a deletion of chromosome 17p11.2 and due to haploinsufficiency of *retinoic acid induced 1* (*RAI1*). Affected individuals have an array of phenotypic features that include sleep disturbance, varying degrees of intellectual disability, skeletal and craniofacial abnormalities, neurological and behavioral issues, and obesity. A majority of individuals with SMS are obese by early adolescence, and SMS mouse model work has further implicated *Rai1* in both obesity and diet induced obesity. We used a three-pronged approach to identify obesity-related gene networks and tested whether these networks were dysregulated in SMS. First, we utilized Human Phenotype Ontology and identified 156 genes that are known to cause a significant increase in body weight. Second, we took a global genomics approach and identified 723 RAI1-regulated genes by performing gene expression microarrays using HEK293 cells haploinsufficient for *RAI1* generated by siRNA knockdown. Third, we narrowed our focus to genes that are neuronally regulated by RAI1 and performed an additional gene expression microarray using neuroblastoma cell lines haploinsufficient for *RAI1* generated by siRNA knockdown and found 549 differentially expressed genes. Using Ingenuity Pathway Analysis, we analyzed and integrated all three gene lists to generate obesity-related co-expression gene networks. Expression analysis of genes within each network in both SMS patient fibroblasts and across multiple SMS mouse model tissues (brain, liver, abdominal fat, subcutaneous fat) found that *RAI1* haploinsufficiency causes the dysregulation of multiple nodes, including *MC4R*, *POMC*, *CMKLR1*, *BBS4*, and *BMP2K*. Bioinformatics analyses revealed multiple RAI1 consensus binding sites amongst the dysregulated genes, suggesting possible regions of direct regulation. To test one of the genes for responsiveness to RAI1 transcriptional regulation, we employed a luciferase assay using the putative binding region in *CMKLR1*. Reporter assays revealed that RAI1 acts as an enhancer of *CMKLR1* expression, confirming expression data in both SMS cells lines and mouse tissues and the physical interaction of RAI1 at the consensus site. These data support RAI1 as a regulator of multiple obesity-related gene networks and implicate RAI1 as a contributor to early onset obesity.

1064M

Uncovering the pairs of tissue-epigenetic mark which are relevant for a trait. *T. Bigdeli, D. Lee, B.P. Riley, A.H. Fanous, K.S. Kendler, S-A. Bacanu.* Virginia Commonwealth University, Richmond, VA.

Background: For many phenotypes there is a strong working assumption regarding which tissues are biologically relevant to the underlying pathophysiology (e.g. brain tissues for psychiatric disorders). While network and gene-set methods often support these a priori expectations, they largely analyze each tissues univariately. However, only a multivariate analysis of all tissues can empirically assess the likelihood of these assumptions being true. Moreover, such a joint analysis might provide much stronger evidence for other-perhaps even unexpected-tissues as being relevant for the investigated trait. **Method:** We develop a method based only on summary statistics from genome-wide association studies (GWAS), which evaluates the significance of the multivariate (partial) effect on a given trait for all tissue-mark pairs provided by the Roadmap Epigenomics and ENCODE projects. The statistical procedure consists of a regression approach based on the estimated correlation matrix between signals from GWAS and tissue-mark pairs. Given the high levels of correlation (i.e. linkage disequilibrium) between adjacent GWAS SNPs, we divide these into 1,000 disjoint sets, thus ensuring an average spacing of at least 300Kb between variants in the same set. Upon the analysis of each such set of quasi-independent SNPs, for each tissue-mark pair, the ordered series of 1,000 correlated coefficients is statistically tested for a non-zero mean assuming a circular ARMA (1,1) model. **Results:** Application of the proposed method to more than 25 publicly available datasets suggests new and surprising etiological pathways, while maintaining false discovery rates at nominal levels. Among those psychiatric disorders we considered, only for bipolar disorder were brain tissues relevant at statistically significant levels. For schizophrenia, epigenetic marks for certain lymphocyte types yielded much larger signals compared to those for brain tissues. Perhaps unexpectedly, the exact lymphocyte-mark pairs are also the most prominent in rheumatoid arthritis. However, maybe even more unexpectedly, cortical epigenetic marks seem to be the most important tissue-mark pair for some seemingly unrelated phenotypes, such as body-mass index. **Discussion:** The identification of novel, putatively relevant tissues has the potential to inform our as yet incomplete understanding of these disorders, and, in some instances, could even suggest possible treatments.

1065T

Network analysis to identify human genes influencing susceptibility to Mycobacterium tuberculosis and Nontuberculous mycobacteria infection. *E.M. Lipner[1,2], M. Strong[2].* 1) University of Colorado, School of Medicine, Department of Pharmacology, Aurora, CO, 80045, US; 2) National Jewish Health, Integrated Center for Genes, Environment, and Health, Denver, CO 80206, US.

Mycobacterial diseases, including tuberculosis (TB) and nontuberculous mycobacterial (NTM) infections, result in over 1.4 million deaths per year. In order to investigate and identify human genes that may influence control or susceptibility to mycobacterial disease, we compiled gene-disease relational information from several databases. We then performed network and enrichment analysis to identify relevant and enriched human genes and pathways. We hypothesized that such an approach would provide a more comprehensive understanding of the biological pathways involved in mycobacterial infection, and facilitate the identification of novel, candidate genes that have not been previously identified via conventional genetic analytic methods. In order to identify genes associated with TB and NTM phenotypes, we searched three publically available databases; OMIM, HuGE Navigator, and CTD. Our search identified 50 TB-associated and 15 NTM-associated genes, with literature support. Based on these genes, we employed network and functional enrichment analysis using bioinformatic tools including Ingenuity Pathway Analysis (IPA) and DAVID in order to build and examine networks of TB-associated genes, NTM-associated genes, and combined TB and NTM gene sets. For TB, the highest ranking network included 14 query genes in a 35 gene network, including *IL12B* (MIM 161561), *TLR1* (MIM 601194), *TLR4* (MIM 603030), *TLR6* (MIM 605403), *TLR9* (MIM 605474), *TIRAP* (MIM 606252), as well as the putatively associated genes *IRAK* (MIM 300283) and *Akt* (164730). For NTM, the highest ranking network included 14 query genes in a 35 gene network, including *IL12B* (MIM 161561), *TLR2* (MIM 603028) and *STAT1* (MIM 600555), and putatively associated genes *NFkB* complex (MIM 1644011), *ERK1/2* (MIM 176948) and *MAPK14* (MIM 600289). We also investigated the intersection and union among these gene sets, which identified *NFkB* complex (MIM 1644011), *Vegf* (192240), *CSF2* (MIM138960) and *Fcer1* (MIM 147140) as potential candidate genes for further investigation in the role pertinent to mycobacterial disease. Our approach places previously identified and new TB and NTM associated genes in a systems biology framework, where we can investigate the overlap of genes and pathways that may imply similar susceptibility and control mechanisms for TB and NTM. Additionally, these networks suggest candidate genes that may have biological relevance to TB and NTM infection susceptibility for further study.

Reevaluating the clinical delineation of inflammatory bowel disease using genetic and subphenotype data. *L. Jostins[1,2], International IBD Genetics Consortium.* 1) Statistical Genetics, Wellcome Trust Centre Human Genetics, Oxford, United Kingdom; 2) Medical Genomics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Inflammatory bowel disease (IBD) is generally considered to consist of two major diseases, Crohn's disease (CD) and ulcerative colitis (UC). However, both show significant clinical heterogeneity, and the delineation between the diseases remains the subject of significant controversy. Recent developments in IBD genetics (with >160 loci described to date) may help shed light on the clinical characteristics of this heterogeneous disorder.

Clinicians across 54 centers collated IBD subphenotypes on 34,819 patients (19,713 CD, 14,683 UC) according to the Montreal Classification. All subjects had genotypes generated by Immunochip and data was QC'd and collated at a central data coordinating center. The clinical data recapitulated known epidemiological results, such as the static nature of CD location (colonic vs ileal) over time, and the dependence of disease progression on location at diagnosis.

We confirmed known subphenotype loci (at *NOD2* for CD location, $p<10^{-34}$, and MHC for multiple traits, $p<10^{-22}$), and identified a novel signal (at *MST1* for age of onset, $p<10^{-11}$). Aggregate risk scores of other IBD risk loci showed association with all subphenotypes (e.g. CD vs UC score with CD location, $p<10^{-17}$), suggesting a role for most or all IBD risk loci in disease subphenotype. Reverse regression suggested that the majority of the outcome subphenotypes associations in CD were explained by factors that are present at diagnosis (the location of the disease and the age of onset).

Different risk variants and scores predict different aspects of disease subphenotype (including age of onset and disease outcome), but the dominant axis appears to separate progressive, restricted ileal disease from more stable colonic disease. UC and ileal CD are on opposite ends of this axis, and colonic CD has a genetic profile that is distinct from, and intermediate between, the two. Blind rephenotyping by clinicians of outlying patients (e.g. CD patients with UC-like genetic profiles) demonstrated diagnostic blur at the extremes of this axis. 27% of outlying patients had a doubtful or incorrect diagnosis, compared to 8% of randomly selected patients ($p<0.001$). These results, combined with epidemiological data, suggest that IBD should be considered a spectrum of disorders, with Crohn's colitis as a distinct disease intermediate between UC and ileal CD.

Integration of diverse genomic datasets identifies novel pathways and key regulatory networks for type 2 diabetes and related traits. *L. Shu, V. Mäkinen, X. Yang.* Department of Integrative Biology and Physiology, University of California Los Angeles, Los Angeles, CA.

Type 2 diabetes (T2D) is a highly prevalent metabolic disease and is among the top leading cause of death in developed countries. Recent genome-wide association studies revealed a number of susceptible loci associated with T2D and its relevant traits. However, the molecular mechanisms underlying many of these loci remain unclear and together these loci only explain ~10% of the genetic heritability. In this study, we utilized an integrative genomics approach to leverage tens of existing, diverse genetic and genomic datasets from humans and mouse including 1) GWAS of T2D and related traits such as HbA1c and beta-cell function indices from DIAGRAM and MAGIC consortium, 2) knowledge-driven biological pathways, 3) data-driven, tissue-specific gene co-expression networks, and 4) data-driven, tissue-specific Bayesian networks. The integration of these diverse datasets allowed us to identify tissue-specific gene subnetworks (i.e., specific parts of gene regulatory networks) that are enriched for risk variants of T2D and relevant traits, as well as the key regulators of these subnetworks. Our results confirmed that subnetworks for beta-cell regulation and glucose transport are shared among the different T2D traits. More interestingly, we captured multiple trait-specific subnetworks such as incretin, adipocytokine and vesicle budding subnetworks for T2D, amyloid, nitric oxide metabolism and protein folding subnetworks for HbA1c trait, and bile acids and iron transport subnetworks for beta-cell function traits. Finally, by utilizing the gene network topology of the subnetworks, we pinpointed various tissue-specific key regulators, both known (e.g. ACSL1 in adipose and FASN in liver for T2D; ATF3 in islet for beta-cell function) and novel (e.g. BIRC5 and GLO1 in adipose and RGS12 in muscle for T2D; ZBTB10 in islet for beta-cell function). Our integrative analysis provides deeper insights into the mechanisms underlying T2D development and reveals novel key regulators, which could serve as potential targets for T2D intervention when experimentally validated.

Using random forests to identify genetic links between Alzheimer's disease and type 2 diabetes. *B. Darst[1], C. Yao[2], R. Koscik[3,4], B. Bendlin[3,5], B. Hermann[3,4], A. La Rue[3,4], S. Johnson[3,4,5], M. Sager[3,4], C. Engelman[1].* 1) Department of Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 2) Department of Dairy Science, University of Wisconsin, Madison, WI, USA; 3) Alzheimer's Diseases Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 4) Wisconsin Alzheimer's Institute, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 5) Geriatric Research Education and Clinical Center, Wm. S. Middleton Memorial VA Hospital, Madison, WI, USA.

Background: Increasing evidence suggests that type 2 diabetes (T2D) is a risk factor for Alzheimer's disease (AD), but the genetic mechanism linking these conditions is unknown. Purpose: The purpose of this study was to use random forest to investigate whether interactions between single nucleotide polymorphisms (SNPs) in the vacuolar protein-sorting pathway, linked to both AD and T2D, and risk factors for T2D, influence cognition in a cohort of middle-aged adults enriched for a parental history of AD. Methods: Participants from the Wisconsin Registry for Alzheimer's Prevention were included with data on age, gender, homeostasis model assessment-estimated insulin resistance index (HOMA-IR), waist-hip ratio (WHR), physical activity, *APOE* status, 30 SNPs in the *SORL1* and *SORCS1* genes, and 4 cognitive factors (Immediate Memory, Verbal Learning & Memory, Speed & Flexibility, and Visual Learning). These variables were input into random forest, a machine-learning algorithm that calculates importance scores based on the variance explained by each variable in a model while allowing for interactions. Because random forest does not specifically identify interacting variables, we used a novel approach that explicitly identifies potential interactions by determining how often a pair of variables descends together in a random forest. Results: Utilizing a sample of 836 individuals, our findings strongly suggest that rs7907690 within *SORCS1*, and rs2282649 and rs1010159 within *SORL1*, interact with known predictors of insulin resistance to influence cognition. Rs7907690 appeared in the top 25 descendant pairs for all 4 cognitive factors, consistently paired with WHR, HOMA-IR, age, and physical activity. Rs2282649 and rs1010159 also appeared in the top 25 for all cognitive factors paired with the same traits, although not quite as consistently. Many of the interactions identified with the descendant pair method consisted of discordantly ranked pairs, with one variable having a high importance score and the other having a low importance score. Conclusion: These results suggest that interactions between SNPs associated with AD and T2D and strong risk factors for T2D may contribute to the relationship between AD and T2D. Further, the observed discordant descendant pairs indicate that this method captures interactions that the standard random forest method does not.

Clusters of urate transporter genes as genetic biomarkers in the early detection, diagnosis and prediction of gout. *C. Chung[1,2], H. Tu[3], A. Ko[4], S. Lee[5], H. Lai[6], C. Lee[7], C. Lee[8], C. Huang[9], Y. Ko[1,2].* 1) Graduate Institute of Clinical Medical Science, China Medical University, , Taichung, Taiwan; 2) Environment-Omics-Disease Research Center, China Medical University Hospital, Taichung, Taiwan; 3) Department of Public Health and Environmental Medicine, School of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig D-04103, Germany; 5) Division of Plastic Surgery, Department of Surgery, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Division of Rheumatology, Allergy and Immunology, Department of Internal Medicine, Chang Gung Memorial Hospital-Kaohsiung Medical Center, Kaohsiung, Taiwan; 7) Department of Public Health, Kaohsiung Medical University, Kaohsiung, Taiwan; 8) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 9) Division of Immunology and Rheumatology, China Medical University Hospital, Taichung, Taiwan.

Objective: Gout is the most prevalent inflammatory arthritis in men. We aimed to evaluate the contribution of clusters of urate transporter genes and environmental factors to provide predictive biomarkers for gouty arthritis progression. Methods: We took a pathway based candidate gene approach to investigate the association between genetic variants in clusters of urate transporter genes and gout. Four single nucleotide polymorphisms (SNPs) in urate transporter pathway (rs2231142 in ABCG2 gene, rs3733591 and rs1014290 in SLC2A9 gene, and rs475688 in SLC22A12 gene) were genotyped in 558 male Taiwanese Hans. Results: Per copy increment in the Q141K [T], rs1014290 [A] and rs475688 [C] independently predicted risk of tophaceous gout (OR=3.33, P=9.76×10-7; OR=2.18, P=1.08×10-2; OR=2.50, P=3.87×10-4, respectively). Multifactor dimensionality reduction identified interaction of Q141K, rs1014290 and rs475688 locus had OR=14.01 (95% confidence interval [CI] 6.52-30.11) the risk of developing tophaceous gout. Higher genetic scores of high risk alleles at three genes were associated with hyperuricemia (OR=1.83, P=1.63×10-2), non-tophaceous gout (OR=5.12, P=7.18×10-10) and tophaceous gout (OR=14.03, P=5.86×10-11) and decreased with earlier onset age in tophaceous gout patients (p-trend=2.88×10-3). The calculated attributable fraction indicates that 7.07% of hyperuricemia patients, 20.5% of non-tophaceous gout and 39.3% of tophaceous gout progression can attribute their disease to the detrimental effects of higher genetic risk scores Conclusion: Our results provide additional insight into genetic mechanisms underlying gout arthritis.

Identification of novel predisposing genes in neural tube defects by whole exome sequencing in multiplex families. *P. Lemay[1], A. Dionne Laporte[2], D. Spiegelman[2], E. Henrion[2], O. Diallo[2], P. De Marco[3], E. Merello[3], G.A. Rouleau[2], V. Capra[3], Z. Kibar[1].* 1) CHU Ste-Justine, Montreal, Canada; 2) Montreal Neurological Institute, Mcgill University, Montreal; 3) Gaslini hospital, Genova, Italy.

Neural tube defects (NTD), including anencephaly and spina bifida, are among the most common and severe birth defects affecting nearly 1 in 1000 births. They are caused by partial or complete failure of neural tube closure in the rostro-caudal axis during embryogenesis. The etiology of NTD is complex including genetic and environmental factors that remain largely unknown. While preconceptional intake of folic acid protects against 50-70%; of NTDs, they still affect thousands of families urging the need for novel preventive and counseling strategies. Here we suggest and approach prioritizing highly pathogenic variants and biological processes burdened by a high amount of rare coding mutations to better understand the etiology of NTDs. The main goal of our study is to identify new candidate pathways or genes implicated in NTD development. Our hypotheses are: (1) rare coding mutations are an important part of the NTD etiology and (2) whole exome sequencing in multiplex affected families and prioritization based on highly pathogenic mutations and biological process enrichment will identify new NTD related genes. To date, 11 multiplex families with at least 2 affected individuals were recruited. Exome sequencing data obtained on 32 individuals from 8 families was treated by a bioinformatics pipeline using BWA, GATK v2.7 and ANNOVAR. The output was filtered for rare (>5% in public databases) and high quality mutations resulting in a list of 200 to 300 mutations per family. The list was then screened for enrichment of biological processes and highly pathogenic mutations. Candidate processes or genes are then validated in a cohort of 87 control families. Out of the 8 families already sequenced, three families were enriched for mutations in certain biological processes using both the DAVID 6.7 program and our control cohort. Our results suggest that whole exome sequencing combined to a hypothesis free gene enrichment approach may offer new insights in the complex etiology of NTDs. Identification of new genetic factors will lead to better clinical management of affected families and may identify novel protective supplements.

1071T

The Genetic Architecture of Age-Related Macular Degeneration in the Amish. *J.D. Hoffman[1], J.N. Cooke Bailey[2], R.J. Sardell[4], A.C. Cummings[1], L.N. D'Aoust[1], W.K. Scott[4], M.A. Pericak-Vance[4], J.L. Haines[2,3].* 1) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 4) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

The Amish are a genetically and culturally isolated founder population descended from Swiss and German Anabaptists who emigrated from Western Europe to North America in the 1700 and 1800s. The Amish also live a more homogeneous lifestyle, thus reducing the variability of environmental factors typically seen in complex diseases. Previous work demonstrated that the cumulative genetic risk across known age-related macular degeneration (AMD) loci is significantly lower in Amish AMD cases as compared to non-Amish European American cases, although the prevalence of AMD is similar. In this study we perform a pathway analysis using data from an Affymetrix 6.0 SNP chip to explore the potential role of functional pathways in AMD in the Amish population. Single-variant association analysis corrected for relatedness was performed on 92 Amish cases and 640 Amish controls using the MQLS program. Pathway analysis was performed on the results of the single variant tests using the Pathway Analysis by Randomization Incorporating Structure (PARIS) algorithm, and restricted to the Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway database, which contains 199 defined pathways. Results of the AMD pathway analysis showed nominal associations with the heparan sulfate biosynthesis (HSBS; $p=8.0*10^{-4}$), MAPK signaling (p=0.0002) and FC∈ R1 Signaling (p=0.003) pathways. Somewhat surprisingly, the complement and coagulation signaling cascade (CCSC) pathway was not significant (p=0.47). We compared these results to a non-Amish European-American dataset of 534 cases and 379 controls. In the non-Amish dataset, the p-values for the HSBS, MAPK, and FCER1 pathways were 0.995, 0.10, and 0.91 respectively while the CCSC pathway was highly significant ($p<5.0*10^{-5}$). The results for the HSBS pathway are interesting since heparin sulfate plays a role as an inactivator in the complement alternative pathway through cleavage of C3b, also a target of complement factor H (CFH). From this preliminary analysis we observe signals in pathways previously shown to be associated with AMD. Interestingly, the complement pathway is not significant in this analysis; a major genetic risk factor for AMD. These data further support the hypothesis that the genetic architecture in the Amish is different than in the general European-descent population.

1072S

Genome-wide profiling of gene expression and DNA methylation changes in Alzheimer's disease brains. *M. Allen[1], D. Serie[4], Z. sun[3], S. Baheti[3], M. Walsh[4], F. Zou[1], H.S Chai[3], C.S Younkin[1], J. Crook[4], V.S Pankratz[3], M.M Carrasquillo[1], A. Nair[3], S. Middha[3], S. Maharjan[3], T. Nguyen[1], L. Ma[1], K. Malphrus[1], S. Lincoln[1], G. Bisceglio[1], R.C Petersen[6], N.R Graff-Radford[2], D.W Dickson[1], S.G Younkin[1], T. Ordog[5], Y.W Asmann[4], N. Ertekin-Taner[1,2].* 1) Dept Neuroscience, Mayo Clinic Florida, Jacksonville, FL; 2) Department of Neurology, Mayo Clinic Florida, Jacksonville, FL; 3) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Department of Health Sciences Research, Mayo Clinic Florida, Jacksonville, FL; 5) Department of Physiology and Biomedical Engineering, Mayo Clinic, Rochester, MN; 6) Department of Neurology, Mayo Clinic, Rochester, MN.

Late-Onset Alzheimer's disease (LOAD) is a complex neurodegenerative disease with a substantial genetic component. Despite the success of GWAS studies, much of the heritability of LOAD remains unexplained. We hypothesize that evaluation of the genetic and epigenetic mechanisms that influence gene expression in the brain will lead to identification of novel LOAD genes and improved understanding of vulnerable molecular pathways. We previously performed a gene expression GWAS that assessed genome-wide genotypes and mRNA levels of ~24,000 transcripts in two brain regions (temporal cortex and cerebellum) for ~ 200 AD subjects and ~200 subjects with other pathologies (Non-AD). Gene expression levels were measured using Illumina's WG-DASL array and genotypes were generated using the Illumina Hap300 chip. We have now performed transcript profiling analysis comparing gene expression levels in AD vs. non-AD subjects in both brain regions, using linear regression carried out in R, and conducted pathway enrichment analysis on these data using the functionalities in Metacore. In addition, we have collected CpG methylation data (methylome), using reduced representation bisulfite sequencing, on a subset of the temporal cortex samples (55AD, 55 NonAD) to evaluate the influence of DNA methylation on gene expression in the brain. DNA methylation levels at promoter regions were tested for association with gene expression levels using linear regression carried out in R. Transcript profiling analysis identified 743 targets in the cerebellum and 2839 targets in the temporal cortex (un-corrected pdiff <0.01) that were selected for pathway analysis. In the temporal cortex the most significant pathway identified was oxidative phosphorylation. Many of the top differentially expressed genes replicated across both brain regions and represent the most robust observed changes. DNA methylation-gene expression analysis identified more significant associations than expected by chance alone. Many of the top genes identified in this analysis were also found to be differentially expressed in the transcript profiling study indicating that epigenetic changes that influence gene expression may be associated with disease status. Further integrative analysis of genome-wide genotype, methylation and expression data in this cohort provides an opportunity to enhance our understanding of the role of genetic and epigenetic changes on brain gene expression and risk for LOAD.

1073M

Heterogeneous Network Link Prediction Prioritizes Disease-Associated Genes. *D. Himmelstein[1], S. Baranzini[1,2].* 1) Biological and Medical Informatics, University of California, San Francisco, San Francisco, CA; 2) Department of Neurology, University of California, San Francisco, San Francisco, CA.

The first decade of Genome Wide Association Studies (GWAS) has uncovered a wealth of disease-associated variants. Two important tasks will be translating this information into a multiscale understanding of pathogenic variants, and increasing the power of existing and future studies through prioritization. We show that link prediction on heterogeneous networks—graphs with multiple node and edge types—accomplishes both tasks. Given a heterogeneous network comprised of diverse information sources, our technique elegantly learns the importance of each connection type. We demonstrate the method's distinctive performance and apply it to infer influential genes in a complex disease phenotype, multiple sclerosis (MS). First we constructed a network with 18 node types—genes, diseases, tissues, pathophysiologies, and 14 MSigDB collections—and 19 edge types from high-throughput publicly-available resources. From this network we extracted features describing the topology between specific genes and diseases. Using a machine learning approach that relied on GWAS-discovered associations as positives during model training, we predicted the probability of association between each protein-coding gene and each of 23 diseases. These predictions achieved a testing AUROC of 0.814 and a 285-fold enrichment in precision at 10% recall. We quantified the performance of each network component and identified pleiotropy, transcriptional signatures of perturbations, pathways, and protein interactions as the most predictive domains. The full model greatly outperformed any individual domain, highlighting the benefit of integrative approaches. We created an interactive prediction browser, available at http://het.io, that decomposes a prediction to show the contribution of each component. Since the entirety of GWAS knowledge is incorporated into every prediction, our method performed well for diseases with few seed genes—where most existing methods fail. We masked the largest MS GWAS from our network leaving only 15 MS-associated genes. Nonetheless, our method predicted the 36 genes discovered by the masked study with an AUROC of 0.78. Finally, we predicted 5 novel susceptibility genes for MS, 4 of which (JAK2, REL, TNFAIP3, RUNX3) achieved Bonferroni validation on the 9,772-case masked GWAS. Regions containing two of these genes were uncovered in a recent MS ImmunoChip-based study, highlighting our ability to identify the causal gene within a locus.

Expression pathway analysis for genes associated with rheumatoid arthritis. *K. Shchetynsky, L. Diaz, L. Klareskog, L. Padyukov.* Department of Medicine Solna, Karolinska Institutet, Stockholm, Sweden.

Background: Whole-transcriptome RNA expression analysis provides new insight into disease mechanisms. Interpretation of data from studies of differential gene expression in complex human diseases based on RNA-seq data is sensitive to study design and require rigorous verification. Integration of genetic association data with transcriptome analysis facilitates cross validation of expression and GWAS data and may provide additional clue for identification of new candidate genes and gene-networks. We performed this analysis in a common autoimmune disease, rheumatoid arthritis (RA). **Materials and methods:** RNA-seq was performed on whole-blood RNA samples from 12 healthy controls, 6 untreated RA patients, and 6 patients receiving standard treatment with Methotrexate. RNA-seq was done on the Illumina HiSeq 2000 platform with TruSeq library construction and selection for polyadenylated mRNA, with 28 M paired-end reads per sample. TopHat and Cufflinks software packages were used for RNA-seq data analysis. Pathway analysis was carried out with Ingenuity Pathway Analysis software. **Results:** We address the expression of genes containing markers previously associated with RA in GWAS. Out of 109 genes, 39 genes were differentially expressed (DE) between any two of the three groups (Cuffdiff $p<0.05$) - naïve RA patients, treated RA patients and healthy controls. These DE genes were grouped by pathway analysis into 4 functional protein networks, involving 75 additional "connector" molecules. Out of these 75 corresponding genes suggested by pathway analysis, the information for 37 were present in our RNA-seq data, and 15 were differentially expressed (Cuffdiff $p<0.05$). The majority of these new candidate genes (9/15) coded for proteins from a single network, where tumor protein p53 (TP53) was a hub, directly connected with other 8 genes. Clustering samples based only on the expression of the 9 members of the TP53 network produced reasonable grouping of healthy controls and patients in our data. **Conclusion:** An integration of RNA-seq data with prior information from association studies allowed us to infer new candidate genes for rheumatoid arthritis using pathway analysis. Our data implies, that TP53 could be a hub in the network that could contribute to the molecular pathological mechanisms behind rheumatoid arthritis.

1075S

Stratified enrichment test for dissecting colocalized genomic annotations to fine-map complex trait variants. *G. Trynka[1,2], B. Han[1,2], K. Slowikowski[1,2], HJ. Westra[1,2], H. Xu[3,4], M. Daly[5,2], XS. Liu[3,4], R. Klein[6], S. Raychaudhuri[1,2,7].* 1) BWH, Harvard Medical School, Boston, MA; 2) Broad Institute of Harvard and MIT, Boston, MA, USA; 3) Dana-Farber Cancer Institute, Boston, MA, USA; 4) Harvard School of Public Health, Boston, MA, USA; 5) Massachusetts General Hospital, Boston, MA, USA; 6) Icahan School of Medicine at Mt. Sinai, New York NY USA; 7) University of Manchester, Manchester, UK.

Motivation: Enrichment tests offer the opportunity to translate genetic associations to biological mechanisms by integrating trait-associated variants with genomic annotations. However, genomic annotations highly colocalize with each other: regulatory elements cluster in the proximity of genes, DNase hypersensitive sites (DHS) colocalize with exons and transcription factors co-occur with enhancers. This is a critical issue because, if the colocalization of annotations is not accounted for, the observed enrichment might reflect inappropriate annotations rather than the most biologically relevant annotations. This might obscure fine-mapping efforts. Method: We developed a stratified enrichment test (*GoShifter*) that uses a local annotation shifting method to robustly quantify the enrichment of a given annotation while taking into account co-localized background annotations. Results: (1) We tested *GoShifter* using simulated GWAS SNPs, where associated SNPs tag loci at exons or DHS, as these are known to colocalize. Standard test that does not correct for colocalization between these annotations resulted in 48% higher enrichment, while *GoShifter* reported enrichment in only 10% of time, reflecting appropriate false positive rate. (2) We applied *GoShifter* to SNPs influencing gene expression (eQTL) in whole blood. The unstratified test resulted in significant enrichment for DHS, genes, proximity to transcription start (TSS) ($p<10^{-4}$) and histone marks (H3K4me3, H3K9ac and H3K4me1, $p<0.01$), many of which colocalize. Stratified analysis with *GoShifter* revealed that the DHS enrichment best explains eQTL associations. (3) Finally, we applied *GoShifter* to NHGRI GWAS Catalog variants and observed that DHS were the most strongly enriched annotation ($p<10^{-4}$) above and beyond TSS proximity or genes. H3K4me3 and H3K4me1 showed less significant, but independent signals, from DHS enrichment ($p<0.05$). We estimate that 20-40% of GWAS Catalog loci capture causal variants in DHS, a much lower proportion than the widely reported 80%. Conclusions: *GoShifter* can dissect colocalized annotations to distinguish the true driving annotations from spuriously enriched annotations due to annotation correlations. We expect that it will be widely used to understand the molecular mechanisms underlying common traits associations.

Transcriptional Analysis of Sepsis Patients Reveals Differential Expression Patterns. *D.L. Dinwiddie[1], E.L. Tsalik[2,3], J.C. van Velkinburgh[4], C.W. Woods[3,5], N.A. Miller[6], S.F. Kingsmore[6], R.J. Langley[7].* 1) Department of Pediatrics and Clinical Translational Science Center, University of New Mexico Health Sciences Center, Albuquerque, NM; 2) Research Service and Emergency Medicine Service, Durham Veterans Affairs Medical Center, Durham, NC; 3) Duke Institute for Genome Sciences & Policy and Department of Medicine, Duke University School of Medicine, Durham, NC; 4) National Center for Genome Resources, Santa Fe, NM; 5) Medicine Service, Durham Veterans Affairs Medical Center, Durham, NC; 6) Center for Pediatric Genomic Medicine, Children's Mercy Hospitals and Clinic, Kansas City, MO; 7) Department of Respiratory Immunology, Lovelace Respiratory Research Institute, Albuquerque, NM.

The Community-Acquired Pneumonia and Sepsis Outcomes Diagnostics (CAPSOD) project is a multidisciplinary observational collaboration to understand sepsis pathophysiology and identify biomarkers. This study was designed to identify biomarkers that differentiate sepsis from systemic inflammatory response syndrome (SIRS) of other causes, define the biology of sepsis progression, and understand the molecular predictors of sepsis mortality. To this end, we conducted transcriptome sequencing of 132 patients with SIRS suggestive of possible sepsis at emergency department presentation, t0. We conducted expression analysis with TopHat and Cufflinks pipeline using HTseq-Tools. A distinct transcriptional response was identified in sepsis survivors, sepsis nonsurvivors, and controls. Differentially expressed genes were analyzed to determine related biological pathways and functions. Expression patterns were also analyzed based on pathogenic organism (gram negative vs gram positive). Finally, we investigated the ability to use variant calls from RNA-seq to examine genomic variation that might impact RNA expression using STAR alignment and variant calling with VQSR by the GATK v3.1. In summary, we provide an in depth transcriptional analysis of patients with SIRS, sepsis survivors, and sepsis deaths and provide evidence of differential gene expression patterns capable of delineating the three groups.

1077T

Analysis of Endosomal Trafficking and Protein Recycling Genes in Parkinsonism. *E.K. Gustavsson[1,2,3], J. Trinh[1], I. Guella[1], H.E. Sherman[1], C. Szu-Tu[1], S. Appel-Cresswell[4], A.J. Stoessl[4], A. Rajput[5], A.H. Rajput[5], J.O. Aasly[2,3], M.J. Farrer[1].* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Neuroscience, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Neurology, St. Olav's Hospital, Trondheim, Norway; 4) Pacific Parkinson's Research Centre, Department of Medicine (Neurology), University of British Columbia Vancouver, BC, Canada; 5) Division of Neurology, University of Saskatchewan and Saskatoon Health Region, Saskatoon, SK, Canada.

Pathogenic mutations in genes involved in endosomal protein recycling, trafficking and lysosomal autophagy have been implicated in autosomal dominant late-onset Parkinson's disease (PD). One key component of protein recycling and trafficking is the retromer complex, which consists of SNX-BAR dimers (SNX1, SNX2, SNX5 and SNX6), and a cargo recognition trimer (VPS26, VPS29 and VPS35). DNAJC13 also regulates endosomal trafficking and protein recycling by coating and uncoating clathrin-coated vesicles. In this study, we aim to assess rare missense variants (MAF<0.01) in these genes. Next Generation Sequencing (NGS) of *VPS26A/B*, *VPS29*, *VPS35*, *SNX1*, *SNX2*, *SNX5* and *SNX6* and *DNAJC13* were performed in 411 patients with PD, 224 atypical parkinsonism patients and in 371 controls. Patient and control subjects are unrelated and of multi-ethnic background. Identified rare missense variants (MAF<0.01) were Sanger sequenced and subsequently genotyped in two PD cohorts (Canada, 970 cases and 470 controls; Norway, 950 cases and 660 controls). For carriers with family history segregation analysis was performed when DNA was available. Seven variants were observed across *VPS26A*, *VPS29* and *VPS35*, five of which were not seen in the control population. Furthermore, 22 variants were observed across the sorting nexin genes (*SNX1*, *SNX2*, *SNX5* and *SNX6*), twelve of which only within patients. Eighteen mutations were identified in *DNAJC13*, eleven of which were only seen in patients. Segregation analyses in families were unequivocal for these variants. Subsequent genotyping of *DNAJC13* mutations revealed p.Glu1740Gln and p.Leu2170Trp to be more frequent in patients (OR=7.65, p=0.041 and OR=4.12, p=0.007, respectively), and p.Pro336Ala, p.Val722Leu, p.Nsn855Ser, p.Arg1266Gln and p.Thr1895Met were not seen in any control subjects. Deficits in endosomal protein recycling, trafficking and lysosomal autophagy are highlighted by the discovery of pathogenic mutations in *VPS35* and *DNAJC13* (*VPS35* p.Asp620Asn and *DNAJC13* p.Nsn855Ser). The missense mutations within *DNAJC13* and the retromer subunits, in PD and atypical parkinsonsm cases, converge with membrane-protein recycling and endosome-trans-Golgi trafficking as a central component of PD pathogenesis. Further evaluation of components within membrane-protein recycling and endosome-trans-Golgi trafficking in parkinsonism is warranted.

Transcriptome analyses of patient-specific induced pluripotent stem cell (iPSC) derived neural stem cells implicate neurodevelopmental pathways involved in Tourette Syndrome. *N. Sun[1,2], J. Xing[1,2], L. Deng[1,2], M. Moreau[3], M. Sheldon[1,2,3], JC. Moore[1,2,3], RP. Hart[2,3,4], GA. Heiman[1,2], JA. Tischfield[1,2,3].* 1) Genetics, Rutgers University, Piscataway, NJ; 2) Human Genetics Institute of New Jersey, Piscataway, NJ; 3) RUCDR Infinite Biologicals NIMH Stem Cell Resource, Piscataway, NJ; 4) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ.

Tourette Syndrome (TS) is a childhood onset neurodevelopmental disorder of unknown etiology characterized by the presence of waxing and waning motor and vocal tics. Family and twin studies showed that TS segregates within families and across multiple generations. However, the transmission pattern of TS is unclear and no common genetic factors and biological pathways are reported to be responsible for all TS patients. In order to look at the manifestation of TS at the gene expression level and to identify critical biological pathways which could be universally affected in all TS patients during early neurodevelopment, we conducted an expression study (RNA-seq) using iPSCs from TS patients and controls. The study included 1) TS patient-specific iPSCs (TS-iPSCs), 2) control iPSCs, 3) TS-iPSC derived neural stem cells (TS-NSCs), and 4) control NSCs. Based on the RNA-seq data, we will determine which genes are differentially expressed in the TS cells compared with control cells. By clustering these differentially expressed genes under co-expression and/or interaction criteria, we aim to unveil biological pathways affected during the neurodevelopmental process of TS patients and further to understand the molecular mechanisms of the etiology of TS.

1079M

Liver-specific long non-coding RNAs and its association with liver disease. *J. Fu[1], B. Atanasovska[1,2], M. van der Sijder[1], S. Rensen[3], P. Deelen[1], D. Zhernakova[1], L. Franke[1], V. Kumar[1], S. Withoff[1], C. Wijmenga[1], M. Hofker[2].* 1) Dept Genetics, UMCG, University of Groningen, Groningen, Netherlands; 2) Department of Paediatrics, Molecular Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 3) Department of Surgery, University Hospital Maastricht and Nutrition and Toxicology Research Institute (NUTRIM), Maastricht University, Maastricht, The Netherlands.

Introduction: Long noncoding RNAs (lncRNAs) have been shown to cover a significant portion of the noncoding transcriptome in mammalian genome. Recently, an increasing number of studies have shown that lncRNAs can be involved in various biological processes and their dysregulation can underlie a number of complex human diseases. However, the role of lincRNAs in liver pathology and overall mechanism remain largely unknown. Here, we investigated the role of lncRNA in the nonalcoholic steatohepatisis (NASH) using expression data and the cis-regulation of lncRNA expression by genetic variants (cis-eQTL). Methods: Whole-transcriptome expression in four different tissue types was simultaneously determined in 93 severely obesity individuals with BMI> 35 kg/m2 and with varying degrees of NASH. We focused on the expression of 2,359 microarray probes that co-localize with lncRNA and assessed their correlation with NASH phenotypes. We further validated the correlation using quantitative RT-PCR (qRT-PCR) in subset of 34 samples and investigated the association between lncRNA expression and genetic variation. Results: The correlation analysis based on microarray data identified 15 significant correlations for 12 lncRNAs at P<2.1×10-5, corresponding to Bonferroni-corrected 0.05 level. We observed that one liver-specifically expressed lncRNA probe was correlated with four different NASH phenotypes: ALAT (r=0.50, P=3.00×10-6); Kleiner score steatose (r=0.47, P=7.02×10-6); Lobular inflammation (r=0.56, P=1.39×10-7) and Large lipoglanulomas (r=0.52, P=7.22×10-7). The further qPCR analysis validated its association in NASH and a large-scale public RNA-seq data in over 3,000 samples confirmed its liver specificity. Cis-eQTL analyses identified liver-specific eQTL for 3 out of 4 liver-specific lncRNA. Conclusion: Our study identified 15 significant correlations between lncRNA expression in multiple human tissues and NASH. Further validation analysis confirmed the association of some liver specific lncRNAs. Our finding indicates the potential role of lncRNAs in liver metabolism and development of NASH and they can be subjected to genetic regulation. Further functional studies are warranted.

1080T

The Effects of Genetic Perturbation on Networks of Phenotypes in Complex Diseases. *J. Chu[1,2], P.J. Castaldi[1,2], M.H. Cho[1,2,3], B.A. Raby[1,2,3], E.K. Silverman[1,2,3].* 1) Channing Division of Network Medicine , Brigham & Women's Hospital, Boston, MA; 2) Department of Medicine, Brigham & Women's Hospital, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA.

Complex diseases are often assessed using an array of disease-related phenotypic variables, which may have subtle, hidden relationships not captured by standard epidemiological analyses. Investigation of the potentially nonlinear relationships among phenotypes and between phenotypes and specific genetic variants is a challenging problem. To examine the effects of genetic perturbations on the relationships between disease-related phenotypes, we developed a novel network-based approach using the Gaussian graphical model (GGM) to infer the connections between each pair of phenotypic variables and create a phenotypic network based on partial correlations. First, for each SNP we constructed GGM phenotypic networks for groups of subjects defined by their genotypes. Then, for each pair of phenotypic variables, we test for differences in the network connectivity between different genotypes. We applied this method to COPDGene, a large, well-characterized set of smokers from a study of chronic obstructive pulmonary disease (COPD). We selected 10 key quantitative COPD-related phenotypes to build the phenotypic networks, and the effects of perturbations at 467 top loci (P < 0.001) from previous case-control studies of COPD populations were tested on 5,471 non-Hispanic White subjects. Although most SNPs have little or no effect on the phenotypic networks, there are many SNPs with significant effects on multiple interactions, disrupting a large part of network (15-20 out of 45 possible edges), and these SNPs may provide clues regarding underlying mechanisms by which genetic variant influence disease susceptibility and outcome. For example, in the networks characterized by rs7671167 (near *FAM13A*), which was previously associated with COPD in genome-wide association studies, we found that measures of lung function and emphysema were negatively correlated in the group with COPD-protected alleles but not correlated in the group with COPD-associated alleles, which suggests that *FAM13A* may lead to reduced lung function through mechanisms other than increased emphysema. Our results are based on the genetic effects on networks of multiple quantitative phenotypes within one complex disease and would not have been observed using traditional multivariate approaches. More importantly, the results can help understand the relationships between these disease-related phenotypes and provide novel insight into disease susceptibility, disease severity, and genetic mechanisms.

Mediation effect of eQTLs reveals trans-regulation of gene expression in complex disease traits. *C. Yao[1,2], R. Joehanes[1,2,3], T. Huan[1,2], B.H Chen[1,2], X. Zhang[1,2], C. Liu[1,2], A.D. Johnson[1,2], P. Courchesne[1,2], P. Munson[1,2,3], D. Levy[1,2].* 1) The National Heart, Lung and Blood Institute; the NHLBI's Framingham Heart Study, National Institutes of Health, Bethesda, MD, USA; 2) Population Sciences Branch, National Institutes of Health, National Heart, Lung, and Blood Institute, Bethesda, MD, USA; 3) Mathematical and Statistical Computing Laboratory, Center for Information Technology, National Institutes of Health, Bethesda, MD, USA.

Expression quantitative trait locus (eQTL) analyses have shed light on transcriptional regulation in numerous complex diseases. An eQTL can be classified as cis or trans acting, based on its association with nearby or remote gene expression, respectively. Compared to cis-eQTLs, the underlying regulatory mechanisms responsible for remote effects of trans-eQTLs are still largely unknown. We hypothesize that expressed genes of cis-eQTLs can act as trans regulators. Using 11,672 published trait- or disease-associated SNPs for 427 complex traits, we explored the gene expression associations of trait-associated SNPs from GWAS that are eQTLs in 5,257 individuals from the Framingham Heart Study. At a false discovery rate (FDR) <0.05 (p<10-6), we identified 177 trans-eQTLs that are associated with expression of 546 genes representing 1162 eQTL-gene pairs. Among these eQTLs, 131 (associated with 231 genes, and representing 589 eQTL-gene pairs) also have cis associations with genes residing within 1 megabase. Mediation testing suggested that for 116 of these 131 eQTLs, the disease-associated SNPs may alter expression of remote (i.e. trans) genes via their cis associations with genes near the eQTL (p<0.005 for 1,000 permutations). Examples of cis mediated effects on remote genes include 1) a trans-effect of rs174546 (a lipid-associated SNP from GWAS) on LDLR and SREBF2 that appears to be mediated by cis effects of the eQTL on FADS1 and FADS2 expression, and 2) trans-effect of rs3184504 (associated in GWAS with type 1 diabetes and blood pressure) on STAT1 that is mediated by expression of nearby TCTN1. We conducted functional enrichment analysis of the eQTLs and the trans-genes potentially mediated by them. For the 90 eQTLs that are annotated in RegulomeDB, we found that 56 (62%) affect transcription factor binding. For the 196 trans-regulated genes annotated in the Database for Annotation, Visualization and Integrated Discovery (DAVID), we found that 20% to 26% were previously reported to be associated with disease phenotypes in OMIM or GWAS studies, providing supportive evidence of a mediation mechanism linking trans-eQTLs to complex diseases.

Beyond GWAS: Probing the landscape between pathway associations, genome-wide associations and protein-protein interaction networks in Chronic Obstructive Pulmonary Disease. *M. McDonald[1], M. Mattheisen[1,2], M. Cho[1,3], Y. Liu[1], B. Harshfield[1], C. Hersh[1,3], P. Bakke[4], A. Gulsvik[4], C. Lange[5], T. Beaty[6], E. Silverman[1,3] on behalf of the GenKOLS, COPDGene and ECLIPSE study investigators.* 1) Channing Division of Network Medicine, Brigham & Women's Hosp/Harvard Sch Med, Boston, MA,USA; 2) Department of Biomedicine and Centre for integrative Sequencing (iSEQ), Aarhus University, Aarhus, Denmark; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) Department of Clinical Science, University of Bergen, Bergen, Norway; 5) Harvard School of Public Health, Boston, MA, USA; 6) Johns Hopkins School of Public Health, Baltimore, MD, USA.

In a traditional genome-wide association study (GWAS), thousands to millions of markers are tested; however, only a small fraction of markers reaches a level of genome-wide significance (GWS). As such, we sought to apply a traditional pathway approach and an integrative systems biology approach to maximize information from GWAS results to gain insight into Chronic Obstructive Pulmonary Disease (COPD). Specifically, we performed gene-based and gene-set associations, defined from gene-sets in the molecular signatures database (MSigDB), with FORGE software. For discovery, we analyzed GWAS results from two well-characterized COPD cohorts, COPDGene and GenKOLS. As replication, we used a third well-characterized COPD case-control cohort (ECLIPSE). Next, we used an integrative systems biology approach that integrates GWAS results with protein-protein interactions (PPI) to identify COPD disease modules with the R library dmGWAS. Using the traditional pathway approach, no gene-sets reached experiment-wide significance in either discovery population. Using the systems biology approach, we identified a consensus network of 10 genes identified in modules by integrating GWAS results with PPI that replicated in COPDGene, GenKOLS, and ECLIPSE. We found enrichment of members of four gene-sets among these 10 genes: (i) lung adenocarcinoma tumor sequencing genes, (ii) IL7 pathway genes, (iii) kidney cell response to arsenic, and (iv) CD4 T cell responses. Further, several genes, including KCNK3 and NEDD4L, have also been associated with pathophysiology relevant to COPD. In particular, KCNK3 has been associated with pulmonary arterial hypertension, a common complication in advanced COPD. Thus, we report a set of new genes that may influence the etiology of COPD that would not have been identified using traditional GWAS and pathway analyses alone. This project was supported by NIH R01 HL089856, R01 HL089897, P01 HL105339, and R01 HL111759. GenKOLS and ECLIPSE (SCO104960, NCT00292552) were funded by GlaxoSmithKline.

Systemic effects of genetic variation on gene expression. *D. Plichta[1], T. Esko[2, 3, 4, 5], H.B. Nielsen[1, 6], T.H. Pers[1, 2, 3], J.N. Hirschhorn[2, 3, 4].* 1) Center for Biological Sequence Analysis, Technical University of Denmark, Kgs. Lyngby, Denmark; 2) Division of Endocrinology and Center for Basic and Translational Obesity Research, Children's Hospital, Boston, MA, USA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 4) Department of Genetics, Harvard Medical School, Boston, MA, USA; 5) Estonian Genome Center, University of Tartu, Tartu, Estonia; 6) Novo Nordisk Foundation Center for Biosustainability, Technical University of Denmark, Kgs. Lyngby, Denmark.

Expression quantitative trait locus (eQTL) analysis is a well-established approach to discover novel biological mechanisms underlying genome-wide association study (GWAS) associations. Recent studies have shown that eQTLs may affect expression levels of multiple nearby and distal genes indicating that eQTLs may impact the transcriptional regulation of biological pathways. To search for common variants with systemic effects on expression levels, we developed an approach to identify eQTLs that regulate modules of co-expressed genes (transcriptional components). We used whole blood expression data from 814 genotyped, Caucasian individuals to construct 775 transcriptional components using independent component analysis (ICA). We annotated each transcriptional component by assessing enrichment of highly loading genes in a diverse set of pre-defined gene sets, including canonical pathways from the REACTOME database, Gene Ontology terms, and sets of genes that upon knock-out in mice result in the same phenotype. We then used individuals' scores on each of the transcriptional components as phenotypes in an eQTL association analysis based on 2,933 independent SNPs that have previously been associated with diseases and complex traits at genome-wide significance. Finally, we applied our approach on Framingham Heart Study expression and genotype data from 2,324 unrelated individuals to replicate our findings. We identified 152 significant eQTLs, which associated with 106 independent transcriptional components (at false discovery rate <10%). Majority of them exerted systemic effects on multiple genes. The strongest eQTL was between a variant previously associated with inflammatory bowel disease (rs1363907; Spearman r=0.8, $P<10^{-100}$) and a transcriptional component enriched for telomere maintenance and respiratory electron transfer genes ($P<0.05$). The variant was in high linkage disequilibrium with a splice site variant (rs2248374), which previously has been reported to result in non-sense mediated decay of the immune system related ERAP2 gene transcripts. The ERAP2 gene was the highest loading gene on the associated transcriptional component but more than 250 other genes loaded high as well (removal of the ERAP2 gene from the transcriptional component did not abolish the association). We replicated this association along with 33 other eQTLs in the Framingham data. Our work supports the idea that genetic variants can have broad biological effects.

1084S

Pathway analyses of extreme age-related macular degeneration phenotypes using whole exome sequencing data. *R.J. Sardell[1], W.K. Scott[1], G. Wang[1], W. Cade[1], J.N. Cooke Bailey[2], M.D. Courtenay[1], S.G. Schwartz[3], J.L. Kovach[3], A. Agarwal[4], M.A. Brantley[4], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Department of Ophthalmology and Visual Sciences, Vanderbilt University School of Medicine, Nashville, TN.

Age-related macular degeneration (AMD) is a leading cause of vision loss among older adults in the US. Although multiple common genetic variants as well as several environmental risk factors for AMD have been identified, a substantial portion of the variance in disease risk and heritability remains unexplained and may reflect rare variants, gene-gene or gene-environment interactions. We used whole exome sequencing of 74 phenotypically extreme individuals to identify rare AMD related risk variants. We hypothesized that these extreme affected AMD individuals are more likely to carry variants of large effect. A genetic risk score was calculated based on 16 common (≥1% minor allele frequency) single nucleotide variants (SNVs) known to be associated with risk of advanced AMD. We then selected 38 individuals with bilateral neovascular AMD, the lowest genetic risk score, and youngest age at examination, and 36 unaffected controls with no or very few small drusen, the highest genetic risk score, and oldest age at examination for sequencing. Variants were annotated for predicted function using SeattleSeq. We used a pathway based analysis approach to combine information on multiple genes within biological pathways using WebGestalt (WEB-based GEne SeT AnaLysis Toolkit). P-values from gene-based tests run using SKAT were used to identify genes of interest for input (those with $p<0.05$). The Kyoto Encyclopedia of Genes and Genomes (KEGG) was used to identify pathways. Genes that contained SNVs used to define the risk score were excluded from analyses. Considering all common and rare SNVs, we did not identify any pathways significantly associated with the extreme phenotype. Considering rare (minor allele frequency <5%), damaging variants only, we identified one enriched pathway that remained significant after Bonferroni correction ($p=0.02$); the Glycosphingolipid biosynthesis lacto and neolacto series. This pathway contained four genes with $p<0.05$ in our original SKAT analysis: *FUT2*, *FUT3*, *FUT7* and *ABO*. Sphingolipid metabolism has been linked to retinal pigment epithelium cell inflammation and death, suggesting this pathway may be relevant to the AMD disease process. Although *FUT3* is nearby the previously identified AMD-associated gene, *C3*, variants at these two loci were not in strong linkage disequilibrium. These initial results highlight a pathway that may be associated with extreme AMD phenotypes and support the validity of this approach to identify new risk genes.

1085M

Exome variants underneath linkage peaks in multiplex Sardinian multiple sclerosis pedigrees implicate genes with roles in autoimmunity and neuroinflammation. *A. Hadjixenofontos[1], L. Foco[2], A. Ticca[4], P. Bitti[5], R. Pastorino[2], L. Bernardinelli[2,3], J.L. McCauley[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Department of Public Health, Neurosciences, Experimental and Forensic Medicine, Medical Statistics and Epidemiology Unit, University of Pavia, 27100 Pavia, Italy; 3) Statistical Laboratory, Centre for Mathematical Sciences, Wilberforce Road, Cambridge CB3 0WA, UK; 4) Divisione di Neurologia, Ospedale S. Francesco, Nuoro, Italy; 5) Immunohaematology and Blood Transfusion Department, Ospedale S. Francesco, Nuoro, Italy.

Multiple sclerosis (MS) is an autoimmune, demyelinating disease of the central nervous system that affects 2 million people worldwide. The prevalence of MS in the isolated population of Sardinia, Italy is unusually high (143 to 262 per 100,000). We sequenced the exomes of 31 affected individuals from 5 Sardinian multiplex families and examined the genes implicated by the currently established list of 110 MS-associated SNPs. Two genes (*MANBA* and *IKZF1* at 7p12) in two regions shared identical-by-descent in one family carry missense variants that are predicted to be probably damaging, highly conserved, and that are rare in outbred Europeans, but have a 5 to 10-fold higher frequency in Sardinia. Both of these are present in at least 6 out of 7 affecteds in the same family. In further examining these exomes for rare, missense variants we performed non-parametric linkage analysis in a dataset of 19 multiplex, extended pedigrees with 75 affected individuals, using a linkage map created from the variation tiled on the custom Illumina beadchip dubbed the “Immunochip”. Five regions reached a LOD* > 1, on chromosomes 4, 6, 7, 12 and 18. Multiple genes that were previously implicated in autoimmune diseases and some that were explored as drug targets in experimental autoimmune encephalomyelitis are located in these regions; one example is the serpin cluster on 18q21-22. Interestingly, the 12p13 peak spans the natural killer cell gene complex at that locus. The 7p15-12 peak replicates previously reported linkage peaks from Sardinian datasets. One of the currently established MS-associated loci also overlaps this region. We then performed fine-mapping family-based tests of association using CAPL, in the regions defined by the support intervals of the five linkage peaks. Four regions produced nominally significant ($p\leq0.05$) results. The implicated genes are *JAF1* (7p15), *CD226* (18q22), *EPHA7* (6p21) and *KLRC2* (12p13). Interestingly, the literature reports upregulated expression of both *EPHA7* and *KLRC2* in active MS lesions, while variation in *JAZF1* and *CD226* has previously been implicated in MS. Of particular interest, our exome sequencing data shows that multiple affecteds from all families carry the alternative alleles for many, primarily rare variants in the *CD226* gene. The overall functional themes in our results in this population highlight genes important in natural killer cell activity and transmigration of lymphocytes across the blood-brain barrier.

1086T

Family-Based Linkage Analysis of Coding Variants with Cardiometabolic Traits in the Diabetes Heart Study. *L.M. Raffield[1,2,3], J.N. Hellwege[2,3], A.J. Cox[2,3,4], C.D. Langefeld[5,6], J.J. Carr[7], B.I. Freedman[8], N.D. Palmer[2,3,4,6], D.W. Bowden[2,3,4].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 6) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 7) Department of Radiology, Vanderbilt University Medical Center, Nashville, TN; 8) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

In contrast to Mendelian disorders, family-based linkage analysis has had limited success in identifying genetic variants relevant to complex traits such as cardiovascular disease and type 2 diabetes (T2D). Current efforts to identify high effect, low frequency coding variants have renewed interest in linkage methods. Data from an Illumina Infinium HumanExome BeadChip array, designed to assay less common coding variants, was available in the Diabetes Heart Study (DHS), a study of subclinical cardiovascular disease in T2D-enriched families (T2D prevalence 83.7%). Two-point linkage analysis was performed in 1190 European-American individuals from 468 families (1318 sibpairs). We hypothesized that linkage analysis might highlight variants and regions of interest for cardiometabolic traits, including measures of vascular calcified plaque, dyslipidemia, inflammation, renal function, and adiposity, and could be aligned with single variant association analysis results. Both two-point linkage and association analyses were performed using the Sequential Oligogenic Linkage Analysis Routines (SOLAR) program adjusting for age, sex, and T2D status. Across 26 traits, 174 LOD scores over 3.0 were observed; the highest was located intergenically on chromosome 4 (rs10939444, LOD=5.69, minor allele frequency (MAF)= 0.35) with plasminogen activator inhibitor-1 levels. Notable evidence of linkage was observed for several traits on chromosome 6, including C-reactive protein (max LOD=3.97, rs2395730, MAF=0.43), high-density lipoprotein cholesterol (max LOD=3.53, rs4413654, MAF=0.23), albumin/creatinine ratio (max LOD=3.14, rs927332, MAF=0.48), adiponectin (max LOD=2.94, rs9370418, Ser387Pro in GFRAL, MAF=0.24), and waist circumference (max LOD=3.72, rs1264344, MAF=0.47). These variants were distributed over a 9 to 49 Mb region, depending on the traits included, suggesting a possible pleiotropic influence on related cardiometabolic traits. Linkage and association analyses also highlighted a variant in cadherin 13 (rs72807847, Asn39Ser, MAF= 0.006) with evidence for both association ($p= 6.23 \times 10^{-6}$) and linkage (LOD=2.62) with abdominal aortic calcification; cadherin 13 has previously been associated with blood pressure, adiponectin levels, and myocardial infarction risk. A combined linkage and association analysis approach may be effective for identifying loci, including loci for late onset diseases such as cardiometabolic traits, in sibpair studies without parental data.

1087S

Identification of Juvenile Myoclonic Epilepsy Loci in Chromosomes 16p13.3, 13q31.1 and 4q35.2 in Honduran Families: Linkage to Epilepsy and Encephalography Traits. *Y. Lin[1, 2], J.E. Wight[1, 2], V.H. Nguyen[1, 2], M.T. Medina[2, 4], R.M. Duron[2], C. Patterson[1, 2], M. Tanaka[1, 2, 3], D.S. Bai[1, 2, 3], S. Aftab[1, 2, 3], Y. Molina[2, 4], J.N. Bailey[1, 2, 5], A.V. Delgado-Escueta[1, 2, 3].* 1) Epilepsy Genetics/Genomics Laboratories, VA GLAHS - West Los Angeles, Los Angeles, CA; 2) GENESS International Consortium; 3) Department of Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) School of Medical Sciences, National Autonomous University of Honduras, Tegucigalpa, Honduras; 5) Fielding School of Public Health at UCLA, Los Angeles, CA.

Juvenile myoclonic epilepsy (JME), the most common genetic generalized epilepsy, accounts for 3% to 11% of all epilepsies. Because JME is the most common cause of a life-long burden of devastating grand mal convulsions, researchers search for JME causing genes. We ascertained three multigenerational families from Honduras through a proband diagnosed with JME, and validated the clinical and EEG phenotypes of all family members. After genotyping with 6500 SNPs by CIDR, we performed two-point parametric and multipoint linkage analyses, as well as haplotype analysis. Analyses used four different diagnostic models based on epilepsy diagnoses of family members and presence of clinically asymptomatic members with polyspike wave EEG traits. Analyses were performed for each family and for all three Honduran families pooled together. Two-point parametric linkage analysis assumed autosomal dominant inheritance with 0.7 penetrance, gene frequency of 0.01 and penetrance of the homozygote non-disease allele of 0.001. With three families pooled together, and all persons with clinical epilepsy as well as all asymptomatic persons with EEG spike waves considered affected, Zmax passed threshold for significance with LOD of 4.29 for rs1203974 and 3.77 for rs1211375 ($\theta m=f$ 0.00) in chromosome 16p13.3. A third SNP, rs3127540, in 13q31.1 also reached significance (Zmax=3.72). With asymptomatic family members with EEG polyspike waves not considered affected and only members with epilepsy considered affected, Zmax was 3.20 at rs6553022 ($\theta m=f$ 0.00) in chromosome 4q35.2 Analyses for individual families did not produce Zmax >3.3. Haplotype analyses confirmed segregation in all clinically affected and asymptomatics with EEG polyspike waves in 4q35.2 and 13q31.1 in all three Honduran families, and in two families linked to 16p13.3. Linkage and haplotype analyses identified two linkage areas where epilepsy genes have not been previously found (13q31.1 and 4q35.2) and confirmed a previously determined linkage region in 16p13.3. Whole exome sequencing (WES) narrowed our search to a handful of genes within linkage areas 13q31.1 and 4q35.2 in two of these families. Combining linkage analyses with WES can identify genes that share disease pathways and lead to finding cures.

1088M

Candidate high-penetrance locus for myopia identified on chromosome 7 using linkage and family-based association analyses of exome chip data in 3 U.S. populations. *J.E. Bailey-Wilson[1], C.L. Simpson[1], L. Portas[1,2], F. Murgia[1,2], S.S. Yee[3], E.B. Ciner[4], D.D. Stambolian[3].* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 2) Institute of Population Genetics, National Research Council of Italy, Sassari, Italy; 3) Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA; 4) Pennsylvania College of Optometry, Salus University, Elkins Park, PA.

Myopia, the most common cause of visual impairment worldwide, is one of several related refractive error traits and is thought to have both environmental and genetic causes. Current understanding of the genetic basis of myopia, based on genetic linkage and genome-wide association studies suggest that there are many genetic loci that influence variation of mean spherical equivalent (MSE) and risk for myopia (MSE ≤ -1Diopter). Some of these loci appear to have common risk alleles with smaller effects on trait heritability while other loci may have rarer variants with higher penetrance and larger effects on trait heritability. The current study analyzed Exome Chip (Illumina WGHum-ExomePlus) data in extended pedigrees from Ashkenazi Jewish (64 families), Old Order Amish (40 families), and African American (103 families) ethnic groups where multiple individuals were diagnosed with myopia, in a search for higher penetrance susceptibility alleles. This genome-wide chipset includes a set of 4761 GWAS tag SNPs with common minor allele frequencies (MAF), 3468 ancestry informative SNPs, > 230,000 SNVs (some with more rare MAFs) that occur in exons and 30,000 custom SNVs that were chosen to provide denser coverage of chromosomal regions that had been previously reported to show linkage or association to myopia and/or MSE. After extensive quality control procedures, allele frequencies of all variants were estimated from pedigree founders in each ethnic group separately. Parametric linkage and family-based association analyses were performed in each ethnic group separately using the PARAMLINK and FBAT programs, respectively. All three sets of families showed evidence of linkage of myopia to the same region of chromosome 7p (maximum two point LOD scores were 3.38 at 54.9cM, 2.45 at 56.9cM and 4.35 at 44.1cM in the Ashkenazi, Amish and African-American samples). Both the Ashkenazi and Amish families showed evidence of association in this linkage region to variants in the gene *Homo sapiens oxysterol binding protein-like 3*, *OSBPL3*, (different variants in each population, p=2.51E-6 at 42.32cM and 2.76E-6 at 42.18cM respectively). *OSBPL3* encodes a protein that is involved in the regulation of cell adhesion and organization of the actin cytoskeleton. These results give strong evidence of a myopia susceptibility locus on chromosome 7p15. Follow-up of variants in the linkage regions is ongoing to determine which variants best explain the linkage signal in each linked family.

Linkage-based Analytical Approaches with GWAS Data to Localize Variants Underlying Complex Traits. *N.D. Palmer[1,2], J.N. Hellwege[2], K.D. Taylor[5], J.M. Norris[3], C. Lorenzo[4], J.I. Rotter[5], C.D. Langefeld[6], D.W. Bowden[1,2].* 1) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Aurora, CO; 4) Department of Medicine, University of Texas Health Science Center, San Antonio, TX; 5) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; 6) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC.

In the era of Next Generation Sequencing, novel approaches will be needed to assess the contribution of low frequency, functional variants postulated to explain the missing heritability in common complex disease. We have computed two-point linkage analysis of genome-wide association study (GWAS) and exome chip data in the IRAS Family Study Hispanic American cohort in an effort to map low frequency, high impact variants contributing to novel, diabetes-related phenotypes. This approach reduces the stringent multiple comparison penalty in association testing by highlighting linked genomic regions for focused association and burden testing, with the advantage of being easily aligned. Analysis of 687,095 SNPs across six diabetes-related quantitative traits in 88 families (1034 individuals) revealed 1170 nominal (LOD>3) and 19 significant (LOD>5) signals. Consistent evidence of linkage was observed for acute insulin response (AIR; beta-cell function) on 1q24.3-25.2 (LOD=5.1-6.4). Among the genes implicated in association of common and rare variants was *RALGPS2*/*ANGPTL1* (rs6693283, $P=4.2\times10^{-4}$) although family-based burden testing did not enhance the evidence of association (P=0.20). A more defined interval on 2p13.1 was also linked to AIR (LOD=5.3) encompassing *ALMS1* which underlies Alstrom Syndrome; an autosomal recessive syndrome including insulin resistance, hyperinsulinemia, and type 2 diabetes. Analysis of common and rare variants revealed association with a missense SNP (S2027P, P=0.0042). Family-based burden testing weighted for rare variants more significantly supported these results ($P=1.5\times10^{-7}$). Among other phenotypes, insulin sensitivity (S_I) was linked to 7q11.22 (LOD=5.1). Regional evaluation of candidates in the interval using association analysis revealed signals in *CALN1*, a member of the calmodulin family. Association analysis revealed common variants associated with S_I (rs844762, P=0.0091) while only a single rare variant was captured by the exome chip. Family-based burden testing at this locus revealed nominal association (P=0.048) likely due to down weighting of common variants. Family-based linkage is a powerful approach in contemporary array-based genetic datasets to prioritize genomic intervals for association analysis and burden testing. Whole genome sequence data should add to the power of this approach. Thus, a combined linkage and association testing framework using high density genetic data has the potential to reveal novel loci.

1090S

Meta-analysis of birth weight genome-wide association studies identifies five novel loci extending links between early growth and adult metabolic diseases. *M. Horikoshi[1,22], M.N. Kooijman[2], J.P. Lower birth weight (BW) is associated with increased risk of future type 2 diabetes (T2D) and cardiovascular disease. Based on HapMap 2 imputed European genome-wide association (GWA) studies, we previously reported 7 loci associated with BW, of which two (*ADCY5*, *CDKAL1*) have been implicated in T2D and one (*ADRB1*) in hypertension. Here we report analyses based on an increased sample size (55,729 full term singletons) from multiethnic groups (22 European and 6 non-European of African-Americans (AA), Philippines, Moroccan, Surinamese, Turkish and Chinese descent) and imputation up to 20.8M SNPs from the more dense 1000 Genomes Project reference panel. Using inverse-variance fixed-effects meta-analysis, GWA summary statistics between standardized sex-specific Z-scores of BW (gestational week adjusted) and each SNP were combined across studies in sex-combined and sex-stratified manner. We detected five novel loci at genome-wide significance: near *EPAS1* ($p=2.4\times10^{-9}$), *YKT6* ($p=1.2\times10^{-8}$), *SREBF2/CENPM* ($p=3.5\times10^{-8}$) and *MAFB* ($p=4.1\times10^{-8}$) from sex-combined meta-analysis and *KIAA0907* (pmale=0.22, pfemale=2.8×10^{-8}, pheterogeneity=0.0023) from sex-stratified meta-analysis. There was no heterogeneity between ethnicities at any of the novel loci (Cochran's Q $p > 0.05$). All loci were common variant loci except for *YKT6* (MAF EUR:1%, AA:0.2%). Other variants in the *MAFB* locus have been implicated in hyperlipidemia. We then fine-mapped established and novel loci by constructing credible sets of variants with 99% overall posterior probability of being causal. The 99% credible sets included fewer than 20 SNPs at 7 loci. At *ADRB1*, the credible set consisted of just 5 variants, including missense G389R (posterior probability 0.13, r^2 with index SNP in EUR:0.85, AA:0.47 and East Asian:0.95). Approximate conditional analysis showed that *ADRB1* signal could be explained by G389R (*ADRB1* index SNP $p_{unconditional}=6.1\times10^{-10}$, $p_{conditional\ on\ G389R}=0.22$). Collectively, we have extended the number of BW associated signals from 7 to 12 at both common and low-frequency loci, of which 4 loci provide genetic links between BW and T2D, hypertension and hyperlipidemia, highlighting complex non-linear relationships between genetic variation, early growth and later metabolic disease.

Runs of homozygosity reveal inbreeding depression on cognitive function and stature. *P.K. Joshi[1], T. Esko[2], H. Mattsson[3,4], N. Eklund[3], I. Gandin[5], A.U. Jackson[6], T. Nutile[7], C. Schurmann[8], O. Polasek[1], J.F. Wilson[1,9], ROHgen consortium.* 1) Centre for Population Health Sciences, University of Edinburgh, Edinburgh, United Kingdom; 2) Estonian Genome Centre, University of Tartu, Tartu, Estonia; Boston Children's Hospital and Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 5) Department of Medical Sciences, University of Trieste, Italy; 6) Department of Medical Sciences, University of Trieste, Italy; 6) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI 48109, USA; 7) Institute of Genetics and Biophysics 'Adriano-Buzzati Traverso', CNR, Naples, Italy; 8) The Genetics of Obesity and Related Metabolic Traits Program, The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 9) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Edinburgh, EH4 2XU, Scotland.

The effect of inbreeding on fitness traits in plants and animal populations has been studied since the time of Darwin. Close inbreeding is also associated with increased risk of Mendelian diseases in humans, however the effect of the distant inbreeding found in present day populations on complex traits is less well understood. Our study analysed 16 health-related quantitative traits in up to 350,000 individuals from multiple continental ancestries in 102 cohorts. Within each ethnically homogeneous sub-cohort, we modelled the effect on each trait of increased inbreeding as measured by the sum of lengths of runs of homozygosity in base pairs (SROH), with covariates of age, sex, and at least 3 principal components of genetic variation. We then used fixed effect inverse-variance meta-analysis to combine results. We found that SROH is associated with reduced stature (as measured by height and reflected in a measure of lung function), and reduced cognitive function (as measured by educational attainment and the general cognitive factor, g). In all four cases the effect sizes were small (-0.00075, -0.00112, -0.00126, -0.00160 phenotypic standard deviations per megabase of SROH, respectively), but statistically very significant (Nominal p <1e-16, 5.2e-6, 2.5e-12, 4.7e-9 respectively, with 16 traits and only one genetic effect tested). These effect sizes correspond to a decrease in height of 0.0068 cm and decrease of 0.0043 years in education for each 1Mb increase in SROH. Offspring of first cousins are thus predicted to be 1.1 cm shorter and complete 8 months less education. Contrary to earlier reports in much smaller samples, no evidence of an association was seen for the burden of homozygosity on blood pressure traits or LDL cholesterol, or on other cardiovascular risk factors tested (classical lipid, glycaemic and adiposity traits). Even for the traits where we observed an effect, we estimate the proportion of phenotypic variance explained in an outbred European population to be less than 0.001%. We therefore consider it unlikely that population cardiovascular health or the Flynn effect can be materially explained by background inbreeding or secular changes in the level of outbreeding. Inbreeding depression is predicted to arise in evolutionary fitness-related traits. Thus, our study suggests that increased stature and cognitive function may have been positively selected in human evolution, while many risk factors for late onset complex diseases have not.

1092T

Population-wide linkage screen for successful aging in the Amish. *J.E. Hicks[1], J.R. Gilbert[1], L. Caywood[1], L. Reinhart-Mercer[1], D. Fuzzell[2], R. Laux[2], M.L. Cuccaro[1], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland OH.

As the population of industrialized nations ages, the health problems associated with aging will become a major public health concern. The Amish of Indiana and Ohio provide an ideal population to study aging because of their geographic stability and cultural isolation that minimizes environmental variability. The pedigree of the Amish is too large and complex for conventional linkage (e.g. lod score) analysis. For linkage analysis in the Amish, the pedigree must be cut into smaller pedigrees, which may result in false negative results. An alternative approach is to use long range chromosomal phasing (LRP), which allows the detection of segments shared identical-by-descent (IBD) derived from dense SNP genotypes; this avoids the computational complexity of conventional linkage analysis approaches. Population-based linkage using LRP was assessed for successful aging (SA), a composite phenotype consisting of lack of cognitive impairment, lack of depression (as determined by the Geriatric Depression Scale), high performance on the EPESE lower extremity performance battery, and unimpaired performance on four scales: Activities of Daily Living, Instrumental Activities of Daily Living, Nagi (a test of musculoskeletal function), and Rosow-Breslau (a test of lower-extremity function). 74 individuals met all of these criteria and formed primarily cousin-pair relationships. Amish participants (n=813) were genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0. Missing genotypes were imputed in BEAGLE, and IBD segments of at least 250kb were identified using the GERMLINE unphased algorithm. The configuration of these IBD states was quantified for each as the proportion of affected pairs IBD for the marker. Statistical significance for each marker was determined by repeated sampling without replacement of an equivalent number of individuals from the population and assessing their IBD configuration. The p-value was the proportion of samples where the IBD configuration was as or more extreme than that of the successfully aged individuals. Suggestive evidence of linkage ($p<1.7\times10\text{-}3$; Lander and Kruglyak 1995) was detected on chromosomes 4, 6, 9, and 16. The interval providing the most extreme evidence of linkage ($p=1.2\times10\text{-}4$, hg18 coordinates: chr6:109,186,957-109,761,180) was shared by 12.8% of SA pairs and contained the single gene SESN1, which involved in the cellular response to oxidative stress, making it an excellent candidate gene in the aging process.

1093S

Simple Linkage-Based Methods to Identify Cardiometabolic Risk in Families. *J.N. Hellwege[1,2], L.M. Raffield[1,2,3], N.D. Palmer[1,2,4,5], A.J. Cox[1,2,4], J.M. Norris[6], C. Lorenzo[7], Y.-D.I. Chen[8], J.I. Rotter[8], C.D. Langefeld[5,9], B.I. Freedman[5,10], D.W. Bowden[1,2,4].* 1) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 6) Department of Epidemiology, Colorado School of Public Health, University of Colorado Denver, Denver, CO; 7) Department of Medicine, University of Texas Health Science Center, San Antonio, TX; 8) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute at Harbor-UCLA, Torrance, CA; 9) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 10) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

Linkage-based approaches in family studies were abandoned by investigators with the advent of genome-wide association studies (GWAS) due to diminished enthusiasm or lost funding. With contemporary genetic datasets of high density arrays coupled with imputations, it seems relevant to revisit linkage methods. Family-based cohorts vary dramatically in size and complexity from very large families through nuclear families and sib pairs. We evaluated cardiometabolic traits using conventional two-point linkage analysis from exome chip data in combination with genetic association data with potentially interesting implications. Two-point analysis has the advantage of being easily aligned with simple association, and meta-analysis is equally straightforward by simple addition of LODs (assuming $\theta=0$). Two-point linkage analysis was performed separately in three diverse cohorts (African Americans (n=596) and Hispanics (n=1414) from the Insulin Resistance Atherosclerosis Family Study (large pedigrees, average family size 14-15 individuals) and European Americans (n=1190) from sibships from the Diabetes Heart Study) for 24 traits using SOLAR. SNPs present in all three cohorts were collated (n=46,420), and linkage meta-analysis performed for each trait by adding the two-point LOD scores across all sample groups to identify variants with substantial contributions to evidence of linkage by all three cohorts. LOD_{cohort} scores up to 5.69 were observed. Combining all three LOD scores for overlapping SNPs across all traits resulted in a total of 502 LOD_{sum} scores greater than 3, including 59 which were greater than 4. Of these, 282 were contributed to by more than one cohort ($LOD_{cohort}<3$). Just one SNP, rs2398162, had a LOD_{cohort} score greater than 1 with adiponectin levels in all three cohorts ($LOD_{sum}=4.27$). The maximal LOD_{sum} score with no LOD_{cohort} >3 was 5.20: rs1073525 (*MARCH8*) with plasminogen activator inhibitor-1 levels. This LOD score was contributed to by LOD_{cohort} scores of up to 2.63. Further evidence of multi-cohort contribution to linkage was seen with rs11708014 and HDL levels (*MCF2L2*; $LOD_{sum}=4.99$), rs250853 with C-reactive protein levels *(FSTL4*; $LOD_{sum}=4.72$), and rs8068318 with waist circumference (*TBX2*; $LOD_{sum}=4.66$), among 9 additional LOD_{sum} scores >4 with no LOD_{cohort} >3. Overall, these SNPs and regions are relevant for functional follow-up due to consistent support for linkage across multiple ethnic groups and with a variety of cardiometabolic phenotypes.

1094M

Linkage and association mapping for osteoarthritis progression in the Genetics of Generalized Osteoarthritis Study. *M.S. Yau[1], L.M. Yerges-Armstrong[1], J.R. O'Connell[1], R.D. Jackson[2], M.C. Hochberg[1], B.D. Mitchell[1], V.B. Kraus[3].* 1) University of Maryland, Baltimore, MD; 2) The Ohio State University, Columbus, OH; 3) Duke University, Durham, NC.

Osteoarthritis (OA) is the most common form of arthritis and is a major cause of morbidity. To identify genetic risk factors associated with structural knee OA progression, we undertook a genome-wide linkage scan using data from the longitudinal component of the Genetics of Generalized Osteoarthritis (GOGO) study (N=1,245, 79% women). We defined knee OA progression as worsening of Kellgren-Lawrence (KL) grade, osteophyte grade, or joint space narrowing grade in individuals with radiographic evidence of OA (KL grade=2 or 3) at baseline (N=703). Individuals who progressed to total joint replacement were also considered cases. We have previously reported linkage of OA progression to two chromosomal regions, Xq21-25 (LOD=4.3, P<0.01) and 18q21 (LOD=2.0, P<0.01). To fine map these regions, we conducted association analyses using markers genotyped on the Illumina 550K platform and replicated our most significant associations in the Osteoarthritis Initiative (OAI), a multi-center natural history study of knee OA (N=1,682, 58% women). Within the X chromosome linkage region, the most significantly associated SNP was rs437033 (OR=1.6, P=9.6E-5), which is located in *SLC25A43*. This did not replicate in the OAI, although the most significant SNP across the chromosome (rs6528082; OR=1.8, P= 9.5E-5) located on Xp22 between *SMS* and *PHEX* showed nominal association with OA progression in the OAI (OR=1.5, P=0.03). Within the chromosome 18 linkage region, the most significantly associated SNP was rs470497 (OR=1.6, P=6.1E-4), located near *CDH7*. This SNP did not replicate in the OAI, although the most significant SNP across the chromosome on 18q12 was rs660959 (OR=1.7, P=5.8E-5), which is closest to *GAREM*. Interestingly, though not in LD with rs660959, another SNP in this gene, rs76800900, was one of the most highly associated SNPs with OA progression in the OAI (OR=0.2, P=3.2E-7). *GAREM* encodes a GRB2 associated regulator of MAPK1 that is involved in the epidermal growth factor receptor-mediated signaling pathway. In summary, while our association studies did not identify any replicated SNPs that could potentially explain the linkage to OA progression, they did provide an interesting lead for a novel OA progression gene on chromosome 18, i.e., *GAREM*. Further bioinformatics analyses will be needed to determine the contribution of these association SNPs to the linkage regions and the specific role that these genetic markers may play in the pathogenesis of OA progression.

1095T

Using monogenic phenotypes to identify mechanisms of GWAS variants associated with insulin resistance. *H. Yaghootkar[1], R.A. Scott[2], C.C. White[3,4], W. Zhang[5], E. Speliotes[6], P.B. Insulin resistance is linked to high risk of type 2 diabetes, hypertension and coronary artery disease but the underlying mechanisms are poorly understood. Studies of monogenic forms of insulin resistance, however, established mechanistic paradigms of potential relevance to the common form of the disease. Genome wide association studies (GWAS) have found 19 common genetic variants associated with fasting insulin based measures of insulin resistance but the variants have subtle effects and most have unclear mechanisms. We aimed to combine the distinct characteristics of monogenic forms of insulin resistance and findings of GWAS to get mechanistic insights. We used results from GWAS of 8 metabolic traits that can distinguish between different forms of monogenic insulin resistance and used hierarchical clustering to group the 19 insulin resistance variants. We analysed the effect of each group against type 2 diabetes (12,171 cases), coronary artery disease (40,365 cases) and blood pressure (69,828 individuals). Hierarchical clustering identified a group of 11 variants among 19 insulin resistance variants associated with a metabolic profile resembling rare form of insulin resistance secondary to lack of adipose tissue under the skin - lipodystrophy. Collectively the 11 insulin resistance risk alleles were associated with higher triglycerides (β=0.018; p=4×10^{-29}), lower HDL-C (β=-0.020; p=7×10^{-37}), greater hepatic steatosis (β=0.021; p=3×10^{-4}), higher alanine transaminase (β=0.002; p=3×10^{-5}), lower SHBG (β=-0.010; p=9×10^{-13}) and lower adiponectin (β=-0.015; p=2×10^{-26}). The same risk alleles were associated with lower BMI (per-allele β=-0.008; p=7×10^{-8}), and increased visceral-to-subcutaneous adipose tissue ratio (β=-0.015; p=6×10^{-7}). Individuals carrying >= 17 fasting insulin raising alleles were slimmer (0.30 kgm-2) but at increased risk of type 2 diabetes (odds ratio [OR] 1.46, per-allele p=5×10^{-13}), coronary artery disease (OR 1.12, per-allele p=1×10^{-5}), and increased blood pressure (systolic and diastolic blood pressure of 1.21 mmHg (per-allele p=2×10^{-5}), and 0.67 mmHg (per-allele p=2×10-4), respectively, compared to individuals carrying <=9 risk alleles. Our results provide genetic evidence for an association between reduced fat under the skin and the risk of insulin resistance and metabolic traits. Our study gives an example of how monogenic studies can complement GWAS to understand mechanisms underlying complex traits/diseases.

Copy number of the salivary amylase gene *AMY1* modulates serum amylase levels and is associated with the metabolic profile. *J.S. El-Sayed Moustafa[1], T. Martin[2], M. Beaumont[2], L. Yengo[3,4,5], P. Maboudou[6], C. Menni[2], T. Brousseau[6], T.D. Spector[2], P. Froguel[1,3,4,5], M. Falchi[1,2].* 1) Department of Genomics of Common Disease, Imperial College London, London, United Kingdom; 2) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 3) CNRS UMR 8199, Lille Pasteur Institute, Lille, France; 4) Lille 2 University, Lille, France; 5) European Genomics Institute for Diabetes (EGID), Lille, France; 6) CHRU de Lille, Pôle de Biologie-Pathologie-Génétique, UF Biochimie automatisée, Lille, France.

We have recently shown low *AMY1* copy number to be strongly associated with increased body mass index (BMI) and risk of obesity (Falchi *et al*, *Nature Genetics*, 2014), suggesting that salivary amylase copy number may play an important role in energy balance and metabolism. We have measured both *AMY1* genomic copy number and salivary serum amylase levels in 219 female twins from the UK TwinsUK cohort. Salivary amylase levels were highly heritable (h^2 = 0.81) and were strongly correlated with *AMY1* copy number (R^2 = 0.32; $P < 2.2 \times 10^{-16}$). BMI was negatively associated with salivary amylase levels (β = -0.062; $P = 4.15 \times 10^{-3}$) and also inversely associated with fasting insulin levels (β = -0.08; P = 0.02). Association analysis with blood metabolomic profiles generated using mass spectrometry in the TwinsUK sample suggest that genetically-determined low salivary amylase levels are accompanied by dysregulation of lipid and glucose metabolism. Alterations observed in lipid metabolism, bile acids and amino acid catabolism may also reflect changes in the gut microbiome. Salivary amylase is a digestive enzyme involved in the metabolism of dietary starch. Our analysis of serum amylase levels suggests low salivary amylase levels to be a genetic trait associated with increased risk of metabolic abnormalities. In order to further investigate its role in human metabolism, we are currently expanding our sample size by measuring serum amylase levels in a further 1,500 subjects from the TwinsUK cohort as well as over 2,000 subjects from the French DESIR cohort for whom *AMY1* copy number measurements and metabolomics data are also available.

Accurate molecular prediction in inflammatory bowel disease. *H. Huang[1,2], J.B. Essers[3], B.M. Neale[1,2], S. Ripke[1,2], M. Vu[4], R. Xavier[5], A. Ananthakrishnan[5], P. Fleshner[6], M. Dubinsky[7], T. Harituniains[6], S.R. Targan[6], D.P.B. McGovern[6], M.J. Daly[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, The Broad Institute of MIT and Harvard, Cambridge, MA; 3) Inflammatory Bowel Disease Center, Children's Hospital Boston, Boston, MA; 4) Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Gastrointestinal Unit, Massachusetts General Hospital, Boston, MA; 6) F. Widjaja Family Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 7) Department of Pediatrics, Cedars-Sinai Medical Center, Los Angeles, CA.

Inflammatory bowel diseases (IBD) are chronic inflammatory diseases of the gastrointestinal system. Ulcerative colitis (UC) and Crohn's disease (CD) are two major types of IBD. While some IBD therapies are universally effective, others show greater clinical efficacy in either CD or UC. Accurate classification of IBD can lead to optimal treatment choices and reduce disease complications and relapses. Due to the heterogeneous presentation of IBD, diagnosis can be challenging in up to 20% of patients using the conventional classification. Here we propose a molecular based risk model as a novel clinical tool to discriminate CD from UC by aggregating genetics, serology and tobacco smoking information.

The genetics component includes polygenic risk scores for CD and UC using independently associated SNPs from 163 IBD loci [Jostins et al]. IBD-associated serum immune responses to ASCA, ANCA, anti-Cbir1, anti-OMPC and anti-I2 were generated by ELISA. Smoking status at diagnosis was uniformly collected and categorized as never, ex-smoker and current. The study cohort, including 1363 CD and 501 UC patients, was split evenly into training and validation groups. The overall risk model achieved an area under the curve (AUC) of 0.80 for discriminating CD from UC. Individually: genetics AUC=0.72; serology AUC=0.79; and smoking AUC=0.55. This genetics model outperformed the genetics component of the commercially available IBD sgi diagnostic by PROMETHEUS (AUC=0.55). Serology alone showed the best AUC but is uninformative in over half of patients. Importantly genetics performs similarly well when serology is uninformative (AUC=0.69), establishing that genetics and serology provide independent information. We identified 42 patients who developed 'denovo' CD after surgery with a UC diagnosis. We assigned our CD risk scores to these patients and correctly classified 26 (62%) of them. We achieved the same success in other cohorts using only the genetics component. Out of 31 patients whose diagnoses changed from UC to CD, our model gave correct diagnoses to 24 (77%). In addition to diagnosis, the risk score from our model was also associated with a younger age of onset in CD (p=3E-12).

In conclusion, we have shown that our molecular-based model combining genetics, serology and smoking information could complement current diagnostic strategies and is particularly useful when conventional diagnosis of IBD is challenging.

Improving the Power of Genetic Association Tests with Imperfect Phenotype Derived from Electronic Medical Records. *J.A. Sinnott[1], W. Dai[1], K.P. Liao[2], S.Y. Shaw[3], A.N. Ananthakrishnan[4], V.S. Gainer[5], E.W. Karlson[2], S. Churchill[6], P. Szolovits[7], S. Murphy[5,8], I. Kohane[6,9], R. Plenge[10], T. Cai[1].* 1) Biostatistics, Harvard School of Public Health, Boston, MA; 2) Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Boston, MA; 3) Center for Systems Biology, Massachusetts General Hospital, Boston, MA; 4) Division of Gastroenterology, Massachusetts General Hospital, Boston, MA; 5) Research Computing, Partners Healthcare, Charlestown, MA; 6) i2b2 National Center for Biomedical Computing, Boston, MA; 7) Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, MA; 8) Laboratory of Computer Science, Massachusetts General Hospital, Boston, MA; 9) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 10) Merck Research Laboratories, Boston, MA.

To reduce costs and improve clinical relevance of genetic studies, there has been increasing interest in performing genetic studies in hospital-based cohorts by linking phenotypes extracted from electronic medical records (EMRs) to genotypes assessed in routinely collected medical samples. A fundamental difficulty in implementing such studies is extracting accurate information about disease outcomes from large numbers of EMRs. Recently, many algorithms have been developed to infer phenotypes from EMRs, and although these algorithms are quite accurate, they typically do not provide perfect classification due to the difficulty in inferring meaning from text. Some algorithms produce for each patient a probability that the patient is a disease case. This probability can be thresholded to define case-control status, and this estimated case-control status has been used to replicate known genetic associations in EMR-based studies. However, using this dichotomized outcome (denoted DO) in place of the true disease status results in outcome misclassification, which can diminish test power and bias odds ratio (OR) estimates. We propose to instead directly model the algorithm-derived probability of being a case. We demonstrate how our approach (denoted p_D) improves test power and OR estimation in simulation studies: improvements in test power are small but consistent, but improvements in odds ratio estimation are dramatic (e.g., a bias of 34% using DO vs. 3% using p_D). We also demonstrate our method's performance in an EMR-based study of rheumatoid arthritis (RA). For some SNPs, our approach recovers the OR observed in a recent meta-analysis: e.g., for rs6457620 in *HLA*, the meta-analysis OR is 2.35 and the p_D OR is 2.28, while the DO OR is 2.03. For other SNPs (e.g., rs6679677 in *PTPN22*), both EMR-based estimates differ from the meta-analysis estimate. We discuss possible causes for these discrepancies, which may impact other EMR studies: our cases are likely to have more severe disease than a random sample of RA cases, while our controls are likely to have more comorbidities than typical "healthy controls." We also provide power and sample size calculations in terms of algorithm accuracy measures for use in planning future studies. Our work provides an easily implemented solution to a major practical challenge that arises when using EMR data, which can facilitate the use of EMR infrastructure for more powerful, cost-effective, and diverse genetic studies.

Kho[1].* 1) Northwestern University Feinberg School of Medicine, Chicago, IL; 2) Marshfield Clinic, Marshfield, WI; 3) Mayo Clinic, Rochester, MN; 4) Vanderbilt University, Nashville, TN; 5) Geisinger Health System, Danville, PA; 6) Group Health Research Institute, Center for Health Studies, Seattle, WA; 7) University of Washington, Seattle, WA; 8) Penn State University, State College, PA.

Diverticulosis is defined by small outpouchings formed through weakening of the colonic mucosal wall muscles that when inflamed (diverticulitis) can cause significant abdominal pain and morbidity. As part of the electronic Medical Records and Genomics (eMERGE) network, we identified diverticulitis and diverticulosis cases and controls for GWAS using data captured through routine clinical care across six institutions with different electronic medical record systems. All participants had to have an abdominal CT scan or a colonoscopy to be included. Using natural language processing of these procedure reports, cases had a positive mention of diverticula, diverticulosis or diverticulitis; while controls had ≥1 colonoscopy and no mention of any type of diverticula. This approach yielded an 88-100% positive predictive value and an 89-100% negative predictive value for identification of diverticular cases and controls compared against clinician review when validated across three eMERGE sites. We identified 5,285 cases and 3,761 controls for diverticulosis and 569 cases and 8,477 controls for diverticulitis, all of European ancestry. Previously genotyped data associated with these participants were collaboratively quality-controlled, merged, and imputed to 1000Genomes reference across all six institutions. Logistic regression analyses were performed for case-control status under an additive model, adjusting for age, sex, BMI, smoking status, study site, and the first two principal components for ancestry from the genotype data. For diverticulosis, we observed a robust association signal spanning *CAV1*/*CAV2* on 7q31.2 lead by rs76633992 that nearly reached genomewide significance ($p=1.2\times10^{-7}$). Another association signal approaching genomewide significance was observed (chr3:168780737:d; $p=1.7\times10^{-6}$) near *EVI1*. For diverticulitis we observed a genome-wide significant association with rs148547269 ($p=4.4\times10^{-8}$) on 12q22. This variant occurs ~20 kb upstream of *CLLU1*, in a highly conserved region containing a CTCF zinc finger transcription factor binding site. Multiple association signals approaching genome-wide significance were also observed including rs28646272 ($p=1.1\times10^{-6}$) in *PALLD* on 4q32.3, rs4584511 ($p=1.4\times10^{-6}$) in *HPS1* on 10q24.2, and rs12347739 ($p=1.7\times10^{-6}$) in *DENND4C* on 9p22.1. Our results identify a number of novel associations for follow-up fine-mapping in order to elucidate the genetic architecture of diverticular disease in European ancestry populations.

Comparative Analysis of Electronic Health Record (EHR)-driven and Conventional Cohort-driven Genomic Research. *V. Thaker[1], T. Lingren[2], B. Namjou[2], C. Perry[1], N. Crimmins[2], C. Brady[2], I. Solti[2], G. Savova[1], I. Kohane[1], J. Harley[2].* 1) Boston Childrens Hospital, Boston, MA; 2) Cincinnati Childrens Hospital and Medical Center, Cincinnati, OH.

BACKGROUND: Cost-effective and time-efficient systems to perform genetic research require phenotypic data extraction from EHRs. Within the eMERGE network (electronic MEdical Records and GEnomics, an NHGRI funded initiative), Boston Children's Hospital (BCH) and Cincinnati Children's Hospital Medical Center (CCHMC) collaborated to develop an algorithm for Early Childhood Obesity. We describe the process of case selection, gaps identified, logistical and cost analysis of potential solutions. METHODS: The phenotypic identification of cases and controls was performed using a validated algorithm with structured and unstructured data using Natural Language Processing (NLP). Biorepository databases were searched for identified cases and controls. New systems targeted for biological sample collection were defined to bridge gaps in availability. BCH established the conventional method of cohort-driven biorepository. CCHMC used EHRs for subject recruitment. RESULTS: Both institutions are recruiting subjects at weight management and primary care clinics. BCH is recruiting a cohort for family study including probands and first-degree relatives. Using a study algorithm, 194 unique study subjects have been approached with an enrollment of 35 (18%). The IRB approval required 7 months. The cost of recruitment of each subject is ~$400.00 including permission from physician and patients, enrollment, sample collection at Clinical Study Unit. After IRB approval (12 months), CCHMC is recruiting new cases using EHRs. Clinical research coordinators evaluate patient data with the algorithm and flag cases. Flagged patients are approached during the visit for consent. Consented patients provide saliva for DNA extraction. The cost of recruitment is ~$53 per subject including screening, approach and enrollment. Current consent rates (73.9%, 17/23) indicate support of previous claims made about the advantages of EHR-based recruitment.1 CONCLUSION: The selection of a common phenotype does not guarantee availability of DNA samples for genetic studies. For genomic studies using EHR, the burden of development of a phenotype algorithm, identifying cases, collecting samples, satisfying regulatory considerations can be substantial. Augmentation of institutional biorepositories to enhance cost effective genomic research using EHR is recommended. 1 Kohane, Isaac S. "Using electronic health records to drive discovery in disease genomics." Nature Reviews Genetics 12.6 (2011): 417-428.

UK BiLEVE, the first genetic study in UK Biobank, identifies novel regions associated with airway obstruction phenotypes using a custom genome-wide array in 50,000 individuals. *L.V. Wain[1], N. Shrine[1], I. Ntalla[1], J.P. Cook[1], A.P. Morris[2], E. Zeggini[3], J. Marchini[4,5], P. Deloukas[6], A. Hansell[7], R. Hubbard[8], I. Pavord[9], N.C. Thomson[10], D.P. Strachan[11], I.P. Hall[12], M.D. Tobin[1,13].* 1) Department of Health Sciences, University of Leicester, Leicester, United Kingdom; 2) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom; 3) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 4) Department of Statistics, University of Oxford, Oxford, United Kingdom; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University London, London, United Kingdom; 7) Faculty of Medicine, School of Public Health, Imperial College London, London, United Kingdom; 8) Faculty of Medicine and Health Sciences, School of Medicine, University of Nottingham, Nottingham, United Kingdom; 9) Respiratory Medicine, University of Oxford, Oxford, United Kingdom; 10) Institute of Infection, Immunity and Inflammation, University of Glasgow, United Kingdom; 11) Population Health Research Institute, St George's University of London, London, United Kingdom; 12) Division of Therapeutics and Molecular Medicine, University of Nottingham, Nottingham, United Kingdom; 13) National Institute for Health Research (NIHR) Leicester Respiratory Biomedical Research Unit, Glenfield Hospital, Leicester, United Kingdom.

UK Biobank recruited 500,000 UK individuals aged 40-69 years (95% European ancestry), collecting detailed health and lifestyle information, DNA, and physical measures, including spirometry. In the UK Biobank Lung Exome Variant Evaluation (UK BiLEVE) we undertook nested case-control studies in European ancestry UK Biobank subjects with high-quality spirometry measures. Among heavy smokers, we selected groups defined by low percent predicted forced expiratory volume in 1 second (%FEV_1, n=10,000), normal %FEV_1 (n=10,000) and high %FEV_1 (n=5,000). Similarly, among never smokers, we sampled low %FEV_1 (n=10,000), normal %FEV_1 (n=10,000) and high %FEV_1 (n=5,000) groups. Genome-wide genotyping was undertaken using a custom designed Affymetrix array that included 130K rare missense and loss of function variants (selected to be polymorphic in UK populations based on currently available "exome chip" data), 642K variants selected for optimal imputation of common variation and improved imputation of low frequency variation (MAF 1-5%), and 9000 variants selected for improved coverage of known and candidate respiratory regions. Nested case-control analyses were undertaken, using genotyped and imputed variants within the heavy-smoking and never-smoking strata. We reconfirmed associations at previously identified loci and identified additional novel signals of association, notably a large ~1.5Mb region of association on chromosome 17 centred on a directly genotyped SNP, rs2696671, upstream of *KANSL1* (in never smokers, airway obstruction phenotype (low %FEV_1) versus high %FEV_1, $P=7.20\times10^{-10}$). This signal spans a number of genes in a well characterised inversion (17q21.31) and overlaps previously identified signals of association for multiple traits including idiopathic pulmonary fibrosis and Parkinson's disease. We will compare the genetic architecture of extreme lung function phenotypes in smokers to that in non-smokers, and report other emerging novel findings from UK BiLEVE. The genotype data for the UK BiLEVE study will be made available to the scientific community via UK Biobank from 2014, as will subsequent genome-wide genotyping from a similar array in the remaining UK Biobank participants as this becomes available from 2015. This research has been conducted using the UK Biobank Resource.

***APOL1*-associated kidney disease risk and hypertension management in primary care - A project of the IGNITE Network (Implementing GeNomic medicine In pracTicE).** *N.S. Abul-Husn[1,2], R. Negron[3], K. Ferryman[4], G. Nadkarni[1], S.B. Ellis[1], S. Sanderson[1,2], E. Madden[5], H. Junkins[5], S.E. Kimmel[6], E. Bagiella[3], D. Hauser[7,8], N. Calman[7,8], C.R. Horowitz[3], E.P. Bottinger[1].* 1) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Health Evidence and Policy, Icahn School of Medicine at Mount Sinai, New York, NY; 4) The New School, New York, NY; 5) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 6) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 7) The Institute for Family Health, New York, NY; 8) Department of Family Medicine and Community Health, Icahn School of Medicine at Mount Sinai, New York, NY.

African Americans are more likely to develop kidney disease than European Americans and are at higher risk for progression to kidney failure. Two alleles in the last exon of the *APOL1* gene confer a five-fold increased risk for kidney disease in hypertensive, non-diabetic individuals of African ancestry: the missense variants S342G and I384M (in almost complete linkage disequilibrium; referred to as the G1 allele) and the 6 base pair deletion N388/Y389 (referred to as the G2 allele). Approximately 14% of African Americans carry two *APOL1* risk alleles (vs. < 0.5% of European Americans), contributing to the high burden of kidney disease in this population. Management of hypertension in African Americans with high risk *APOL1* genotypes constitutes an important opportunity for genome-guided medicine. Here, we describe a randomized controlled trial studying the effects of incorporating *APOL1* genotype information into the primary care management of African ancestry patients with hypertension. We will recruit hypertensive, non-diabetic adults with no kidney disease and self-reported African ancestry from ten primary care practices in New York City and randomize them to undergo genetic testing for the *APOL1* G1 and G2 variants at baseline (intervention) or at one year (control). We will educate providers about genome-guided medicine and *APOL1* risk alleles in kidney disease through training sessions, electronic medical records-enabled decision support, and educational materials. Guided by genetic counselors, trained staff will return results to tested patients, and provide them with educational materials suitable for a range of literacy levels. During patient encounters, providers will receive point-of-care clinical decision support to alert them of their patients' *APOL1* genotype and risk status, and to provide recommendations. At three and twelve months, we will assess primary outcomes (blood pressure reduction and appropriate renal surveillance) and secondary, psycho-behavioral outcomes, comparing three patient groups: increased genetic risk, no increased genetic risk, and genetic risk not yet assessed. This study will help to establish the effective implementation of *APOL1* risk-informed management of hypertension in African Americans who are at high risk of kidney disease, and will provide a framework for future endeavors to implement genome-guided medicine in clinical practice.

1103M

Mendelian Randomization study of body mass index/waist hip ratio-associated SNPs and five cancer types. *C. Gao[1], C. Patel[2], S. Lindstrom[1], B. Pierce[3], P. Kraft[1] on behalf of the Genetic Mechanisms in Oncology (GAME-ON) initiative.* 1) Program in Genetic Epidemiology and Statistical Genetics, Harvard School of Public Health, Boston, MA; 2) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 3) Department of Health Studies, The University of Chicago, Chicago, IL.

Body mass index (BMI) has been shown to be associated with multiple cancer types, but whether the observed associations are causal is unclear due to possible confounding and reverse causality. Mendelian Randomization is a technique that uses genetic predictors of a putative causal factor to eliminate reverse causality and reduce confounding bias. Here, we carried out Mendelian Randomization analyses to assess the causal relationship between BMI and waist-hip-ratio (WHR) and risk of breast, ovarian, prostate, colorectal and lung cancers. BMI and WHR genetic risk scores were derived from 32 GWAS-significant BMI-associated variants and 14 WHR-associated variants. We also derived sex-specific scores based on twelve GWAS significant WHR-associated SNPs for women and four GWAS significant WHR-associated SNPs for men. We tested the association between these genetic scores and risk for each of the five cancers using summary statistics from the Genetic Associations and Mechanisms in Oncology (GAME-ON) Consortium, which conducted GWAS meta-analyses involving between 7,272 and 62,528 cases and controls (depending on cancer type). The test was performed by calculating a weighted average across SNPs of the allelic log odds ratio for cancer, where the weights were defined using the allelic effect on BMI (or WHR) and the standard error of the estimated log odds ratio.

We found that the genetic risk score of BMI was significantly associated with decreased risk of breast cancer (OR=0.89; 95%CI: 0.85, 0.93; pvalue= 3.37×10-7); conversely, the genetic risk score for BMI was associated with increased risk of ovarian cancer (OR=1.08, 95%CI: 1.00, 1.15; pvalue= 0.047). Positive associations, though not significant, were observed between the genetic score for WHR and risk of all cancer types except breast cancer. We observed a significant association between the male-specific genetic score for WHR and decreased risk of breast cancer (OR=0.41; 95%CI: 0.24, 0.72; pvalue=0.002). Our findings implicating opposite risk profiles between adiposity and breast/ovarian cancers may reflect the complex relationship between menopausal status, adiposity, and cancer. By presenting BMI-associated risks across five different cancer types, findings from this study provide additional insights to help understand the relationships between adiposity and cancer risk.

1104T

Distinct differences in HLA genotypes for latent autoimmune diabetes in adults (LADA) and type 1 diabetes within the same extended pedigree. *K.J. Basile[1], V. Guy[1], S. Schwartz[2], D.S. Monos[3], S.F.A. Grant[1,4].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Main Line Health System, Wynnewood, PA; 3) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, PA; 4) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Latent autoimmune diabetes in adults (LADA) shares characteristics of both type 1 diabetes (T1D) and type 2 diabetes (T2D), thus often referred to as "type 1.5 diabetes". According to the World Health Organization, LADA is a slowly progressing form of T1D resulting from autoimmune destruction of pancreatic beta-cells. However, LADA also shares characteristics with T2D, such as adult age onset, non-insulin dependence and strong association with variants in the T2D-implicated locus, TCF7L2. Symptoms of LADA are often indistinguishable from early stage T2D, and it has been estimated that 8-10% of patients diagnosed with T2D are in fact positive for specific circulating auto-antibodies. In order to further clarify differences between these forms of diabetes, we performed HLA genotyping of members of a large family consisting of four LADA cases (age of onset >25 yrs), four T1D cases (age of onset <15 yrs) and eight unaffected members, all derived from the National Disease Research Interchange. Of particular note was the generational split for the two diseases, with LADA being all in one generation and T1D all occurring in the next generation. We elected to perform HLA class I and II genotyping (HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, HLA-DQA1) for all DNA samples obtained from this family using next-generation sequencing tools. Interestingly, the HLA genotypes of the family members with T1D were distinctly different, while the HLA genotypes of the family members with LADA were more similar to unaffected family members. All the LADA cases had HLA genotypes that were identical to at least one unaffected family member. However, none of the family members diagnosed with T1D had any genotypes in common with an unaffected family member and exhibited more classical HLA genotypes (e.g. one T1D case exhibited DRB1*0401 homozygosity, DQB1*0302 homozygosity and DQA1*0301 heterozygosity while two other cases had a distinct DRB1 heterozygous combination of 0401 and 1301, with the latter DRB1 genotype not being present in any other nuclear family member). Based on our results from this somewhat unique family, we conclude that the development of T1D resulted from key HLA alleles being concentrated into the latter generation via incomers to this family. We therefore hypothesize that LADA may have, at least in part, arisen from genetic influences beyond the HLA locus in this family and may reflect a more general mechanism underpinning the genetic etiology of this disease.

Like Mother, Like Daughter: Analysis of Parent-Child Phenotypic Correlations for Hundreds of Medical and Behavioral Traits. *E. Pierson[1], D. Hinds[1], A. Kleinman[1], N. Eriksson[2].* 1) 23andMe, 1390 Shorebird Way, Mountain View, CA; 2) Coursera, 381 E Evelyn Ave, Mountain View, CA.

We examined correlations between the phenotypes of parents and children in 15,683 trios for 2,235 medical and behavioral phenotypes. While parent and child phenotypes were almost always positively associated, and no phenotypes showed significant negative associations, for most traits that showed significant parent-child associations (58%) the mother's phenotype was more strongly associated with the daughter's than was the father's. There was no disparity for sons. We observed this effect regardless of whether we examined the correlation between parent and child phenotype or used a regression model that controlled for the age, sex, and genetic principal components of the child and included the mother's and father's phenotypes as covariates. When we filtered for phenotypes in which the disparities in parental effect sizes were especially significant ($p < .05$), the mother-daughter effect became more pronounced: the mother showed a stronger association with the daughter than did the father for 35/40 traits. We observed the opposite effect, to a weaker degree, in sons: the father showed a stronger association with the son than did the mother for 24/35 traits. We found specific phenotypes for which children showed significantly more association with one parent after multiple hypothesis correction. Standardized BMI in daughters showed a stronger association with mother's standardized BMI, consistent with previous results; there was no disparity for sons. Smoking behavior in sons (as measured by years smoked) was more strongly associated with father's smoking behavior. We estimated the proportion of these disparities that were attributable to genetics as opposed to environment using SNPs previously associated with the phenotypes and compared parent-sibling correlations with heritability estimates from distant relatives.

ROBUST MicroRNA EXPRESSION UPREGULATION EXISTS IN INFLAMMATORY BOWEL DISEASE. *S. Ben-Shachar[1], H. yanai[2], L. Baram[2], H. Elad[2], H. Sherman Horev[2], E. Brazowski[3,6], H. Tulchinsky[4,6], M. Pasmanik-Chor[5], N. Shomron[6], I. Dotan[2,6].* 1) Genetic Institute, Tel Aviv Medical Center, Tel Aviv, Israel; 2) IBD Center, Department of Gastroenterology and Liver Diseases, Tel Aviv Medical Center, Tel Aviv, Israel; 3) Department of Pathology, Tel Aviv Medical Center, Tel Aviv, Israel; 4) Proctology Unit, Department of Surgery, Tel Aviv Medical Center, Tel Aviv, Israel; 5) Bioinformatics unit, G.S.W. Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel; 6) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Introduction: The etiology of inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC) is yet unknown. Similarly, it is not clear why some patients with UC undergoing large bowel resection and creation of ileal pouch (pouch surgery), develop small intestinal inflammation (pouchitis) reminiscent of CD. We have previously shown that gene expression profiles are associated with ileal inflammation and disease behavior in patients with CD and pouchitis. As microRNAs (miRNAs) regulate gene and protein expression, we hypothesized that miRNAs may have a major role in IBD. **Methods:** Patients with CD ileitis, UC (unoperated and after pouch surgery) and normal controls (NC) were recruited. Pouch patients were stratified according to disease behavior into three groups: normal pouch (NP), chronic pouchitis (CP), and Crohn's-like disease of the pouch (CLDP). miRNAs expression in Ileal and pouch biopsies was analyzed using parallel massive sequencing (next generation sequencing-NGS). Effect of inflammation on miRNAs expression was evaluated in Caco-2 and HCT-116 epithelial cell lines after stimulation with IL1β, INFγ, and TNFα. miRNAs expression as well as validation in biological replicates was performed using real time PCR. **Results:** Fifty-Six subjects: 10 CD, 12 NP, 16 pouchitis (12 CP and 4 CLDP) and 11 unoperated UC as well as 7 NC were recruited. The ileum of unoperated UC patients was comparable to NC. Eight, 25 and 124 significant miRNAs alterations (fold change ≥ 2, corrected p-value ≤ 0.05) were noticed in NP, CP, and CLDP patients compared to NC, respectively, with high overlap between pouch subgroups. The magnitude of change correlated with pouch disease behavior. Only two alterations were noted in CD. The validation study confirmed the results. Interestingly, the expression of more than 95% of the altered miRNAs was increased. Most miRNAs with increased expression target mRNA transcripts that were significantly decreased in pouchitis, suggesting an effect of miRNAs on mRNA expression. Inflammatory stimulation of Caco-2 and HCT-116 cells resulted in an expression upregulation of 8/13 (62%) of tested miRNAs. **Conclusions:** The robust increase in miRNAs expression may result from the inflammatory process in IBD. The consequence may be down regulation of mRNA transcripts and proteins, further affecting disease course.

The application of genome-wide association analysis to diverse sample cohorts has revolutionised our understanding of the common genetic variants influencing complex diseases and their risk factors. However, as the development of low cost sequencing facilitates greater focus on rarer genetic variants, the particular characteristics of population resources become more important. Specifically populations with increased kinship - across a spectrum spanning nuclear families in a cosmopolitan setting to isolated populations - stand apart from collections of unrelated individuals in different ways: 1. Decreased genetic heterogeneity, 2. Alleles can sometimes rise via drift to tractable frequencies, 3. Increased genomic sharing, 4. Increased linkage disequilibrium, 5. Increased homozygosity, 6. Possibility of parent-of-origin and segregation-based analyses. 7. Availability of deep pedigrees. KinGen is a new partnership of 24 population-based cohorts with high kinship including over 100,000 research subjects, which aims to leverage the special population structure to deliver insights into architecture of complex traits that are difficult to achieve in other settings. Subsets of the KinGen sample have variously whole genome sequence, whole exome sequence, exome and genome-wide chip genotyping, together with very rich phenotyping, some of which is harmonised across cohorts. Here we present a number of analyses of identity-by-descent (IBD) sharing. The predominantly isolated populations in KinGen vary dramatically in the amount and type of kinship observed between pairs of individuals. The number and sum length of runs of homozygosity and of segments shared IBD are greatly enriched over and above typical outbred populations. Analyses of surrogate parents with long range phasing methods reveal striking variation from cohort to cohort in the degree of surrogacy. Drift in allele frequencies has been compared to related cosmopolitan populations, summarizing how often otherwise rare alleles have increased significantly in frequency versus how many alleles have been lost. The population genetic characteristics translate into more accurate imputation of rare and low frequency variants and whole genome sequences and also result in concomitant gains in association power for a subset of variants.

Meta-Analysis of Glaucoma Genome-Wide Imputed Datasets. *J.N. Cooke Bailey[1], S.J. Loomis[2, 3], M.A. Hauser[4,5], L.R. Pasquale[2,3], J.H. Kang[3], R.R. Allingham[4], R.N. Weinreb[6], J.L. Wiggs[2], J.L. Haines[1], NEIGHBORHOOD Consortium.* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Ophthalmology Duke University Medical Center, Durham, NC; 5) Department of Medicine, Duke University Medical Center, Durham, NC; 6) Department of Ophthalmology, Hamilton Eye Center, University of California, San Diego, SD, CA.

Glaucoma is a phenotypically and genetically complex neurodegenerative disease that is the second leading cause of blindness worldwide. Although genetic factors are known to contribute to glaucoma and to endophenotypes associated with it (e.g., intraocular pressure, cup-to-disc ratio, optic nerve parameters, and central corneal thickness), identified risk loci fail to fully account for the genetic component of glaucoma. To extend the proportion of the genome testable for association with glaucoma as well as the power to detect associations at numerous loci, we evaluated imputed genome-wide data in the NEIGHBORHOOD Consortium dataset, which consists primarily of individuals of European descent. Eight datasets, typed on different genome-wide SNP arrays, were imputed to the March 2012 version of the 1000 Genomes data using IMPUTE2 and/or MaCH/miniMaC. Each dataset was individually evaluated for genomic inflation and then filtered for minor allele frequency (MAF≥0.05) and imputation quality (r2 or info metric ≥ 0.7). We then performed study-specific dosage analysis (using ProbABEL) evaluating the estimated genotypic probabilities from the imputation step. The study-specific logistic regression models included as covariates, age, gender, and significant Eigenvectors, along with, in some cases, study-specific covariates. These study-specific results were meta-analyzed applying the inverse variance weighted method in METAL and applying genomic control correction. The meta-analyzed dataset includes 3,873 POAG cases and 33,642 controls, and a total of 7,301,525 variants that passed quality control parameters in at least one dataset. Significant associations were found for genomic regions previously associated with POAG (TMCO1, CDKN2BAS, SIX6) as well as novel regions on 6p and 14q. Imputation of genome-wide array data extends the genomic coverage beyond what can be interrogated by a single or multiple arrays. Meta-analyzing multiple imputed datasets can successfully be implemented to study common diseases with complex inheritance, such as glaucoma, and will help fully define the underlying genetic architecture.

1109M

Influence of BMI- and lipid-associated variants on longitudinal phenotypes. *R.M. Salem[1,2,3], J.N Hirschhorn[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Department of Endocrinology, Boston Children's Hospital, Boston, MA.

Genome-wide association studies (GWAS) have allowed geneticists to gain significant insights into the genetic architecture of many polygenic traits and diseases of public health importance. However, these studies have tended to focus on a single quantitative or dichotomous phenotype at a single time point. While informative, these simple characterizations disregard important complexities of polygenic traits. Most polygenic traits, such as BMI or lipid levels, change over time, and genetic influences in these traits may be exerted at different stages in the life cycle. By considering more informative phenotypes, study designs and analytical approaches that take time into account, it may be possible to shed light on new or different aspects of biology. Methods: We assessed the longitudinal influence of 187 genetic variants known to be associated with BMI (GIANT 2010) or one or more lipid traits (HDL, LDL, total cholesterol (TC) and triglycerides (TG), Global Lipids Consortium 2013). We analyzed data from 10,950 European Ancestry subjects from the ARIC and MESA cohorts downloaded from dbGaP. The longitudinal analysis was performed using a mixed model analysis implemented in SAS, optimized for faster run time. Lipid phenotypic measures with prevalent or incident diabetes or concurrent statin medication use were excluded from analysis. SNPs were considered significant if SNPxAGE p-value was <0.05 in both cohorts. Results: None of the 31 BMI-associated SNPs influenced longitudinal change in BMI (SNP x Age p<0.05). For the lipids traits, two loci were identified that influenced longitudinal change in HDL and TG. Decreasing longitudinal HDL level was significantly influenced by the HLD decreasing G allele of rs4148008 in locus *ABCA8* (SNPxAge, ARIC p=0.016 and MESA p=0.013). The TC decreasing C allele of rs7515577 in locus *EVI5* was associated with decreasing TG levels across time (SNPx AGE, ARIC p=0.028 and MESA p=0.041). Additional large longitudinal samples or methods to utilize cross-sectional data may be required to validate results. Conclusions and future directions: Using a mixed-model approach and longitudinal data, we showed that two lipids associated variants influence longitudinal change in HDL and TG. Genome-wide application of these and other approaches may reveal SNPs whose longitudinal effect is more prominent than or independent of main effects.

Background and objectives Gout is a common disease which results from hyperuricemia. We have reported that the decrease in extra-renal (intestinal) urate excretion by ABCG2 dysfunction induced renal urate overload (ROL) hyperuricemia. This mechanism, however, does not give a sufficient explanation for all ABCG2 dysfunction cases as a major cause of hyperuricemia and gout, because renal underexcretion (RUE) hyperuricemia is the most prevalent subtype of hyperuricemia. In this study, we focus on the involvement of ABCG2 dysfunction in RUE hyperuricemia. **Design, setting, participants & measurements** We performed genotyping for 2,267 Japanese male participants, who consisted of 644 hyperuricemia cases (SUA>7.0 mg/dl) and 1,623 controls. Their functional ABCG2 activities were estimated from their genotype combinations of its two dysfunctional missense variants, Q126X (rs72552713) and Q141K (rs2231142). All participants were divided into four groups by ABCG2 function, and all cases are classified into RUE hyperuricemia or ROL hyperuricemia by the patients' fractional excretion of urate (FE_{UA} < 5.5%) and urinary urate excretion (UUE > 25.0 mg/hr/1.73m^2), respectively. **Results** The association analysis revealed that ABCG2 dysfunction significantly raised the risk of both RUE and ROL hyperuricemia. The risk of hyperuricemia was increased as the ABCG2 function decreased. When hyperuricemia was divided into three distinct types, all but RUE type with the severe ABCG2 dysfunction showed the significant risk for hyperuricemia. Nevertheless, moderate and mild dysfunction still contributed to increase the risk of RUE type hyperuricemia. These data imply that ABCG2 dysfunction under certain conditions causes renal urate underexcretion and leads to hyperuricemia even without renal urate overload. **Discussion** Our study show that ABCG2 plays physiologically important roles in renal urate excretion as well as extra-renal urate excretion, and its dysfunctional mutations are involved in all types of hyperuricemia as their major genetic causes. *ABCG2* genotyping in combination with FE_{UA} and UUE tests is sufficient for screening high-risk individuals with hyperuricemia and gout. Our findings will therefore serve to build up the health of people predisposed to hyperuricemia and gout.

1111S

Coherent Somatic Mutation in Autoimmune Disease. *K.A. Ross.* Computer Science, Columbia University, New York, NY.

Many aspects of autoimmune disease are not well understood, including the specificities of autoimmune targets and patterns of co-morbidity and cross-heritability across diseases. We hypothesize that many autoimmune diseases are triggered by immune responses to proteins whose DNA sequence mutates somatically in a coherent, consistent fashion. Simple tandem repeat (STR) sequence is highly mutable, both somatically and in the germ-line, and somatic STR mutations are observed under inflammation. Protein-coding genes spanning STRs having markers of mutability, including high total length, high repeat count, high repeat similarity, and germ-line variability, are evaluated in the context of autoimmunity. For the initiation of autoimmune disease, antigens whose autoantibodies are the first observed in a disease, termed primary autoantigens, are informative. Known primary autoantigens include thyroid peroxidase (TPO) in Hashimoto's thyroiditis, phogrin (PTPRN2) in type-1 diabetes, and filaggrin (FLG) in rheumatoid arthritis. The genes encoding these three autoantigens include STRs that are among the eleven longest STRs spanned by protein-coding genes. This association of primary autoantigens with long STR sequence is highly significant ($p<3.0\times10^{-7}$). Long STRs within twenty genes are associated with sixteen common autoimmune diseases and atherosclerosis. The TTC34 gene is an outlier in terms of repeat length and count, and is proposed as a candidate gene for autoimmune induction in systemic lupus erythematosus. The results support the hypothesis that many autoimmune diseases are triggered by immune responses to somatically mutated proteins. Other autoimmune diseases may be caused by coherent somatic mutations in immune cells. The coherent somatic mutation hypothesis, in which similar somatic mutations happen both within and across individuals, has the potential to be a comprehensive explanation for the initiation of many autoimmune diseases.

1112M

Secular change in 13 metabolic phenotypes: A Chinese longitudinal twin study. *S. Li[1], Z. Pang[2], D. Zhang[3], H. Duan[2], Q. Tan[4], J. Hjelmborg[4], T. Kruse[1], K. Kyvik[5].* 1) Human Genetics, Institute of Clinical Research, University of Southern Denmark, Odense, Odense, Denmark; 2) Qingdao Center for Disease Control and Prevention, Qingdao, China; 3) Dept. of Public Health, Qingdao University Medical College, Qingdao, China; 4) Epidemiology, Biostatistics and Biodemography, Institute of Public Health, University of Southern Denmark; 5) Institute of Regional Health Research, University of Southern Denmark, Odense, Denmark.

Aims: The genetic and environmental influences on metabolic phenotypes have been intensively studied by twin modeling in different populations. However, twin studies on secular change in metabolic phenotypes have been rare due to high expenses, losses of follow up, and long waiting time in prospective investigations. Based on Chinese twin data collected from Danish-Chinese collaboration research, we perform twin modeling on 13 metabolic phenotypes (total cholesterol; triglyceride; high density lipoprotein (HDL); low density lipoprotein (LDL); urine acid (UA); glucose; weight; body mass index (BMI); waist and hip circumstance and ratio (WHR); systolic blood pressure (SBP); diastolic blood pressure (DBP)) measured longitudinally in a period of 7 years in 254 middle aged Chinese twins (126 monozygotic; 128 dizygotic twins). **Methods:** Univariate ACE, ADE models and their nested models were fitted to the secular changes in each of the 13 phenotypes with best fitting model selected based on model performance. Age and sex were included as covariates in the models to adjust for their effects on secular trend. **Results:** Variations in secular change in 3 lipids (total cholesterol; triglyceride; LDL), weight and blood pressure (SBP, DBP) have AE model as the best fitting model with low to moderate (a^2: 0.25 - 0.46) genetic control. Variations in secular change in the rest of the phenotypes have CE model as the best fitting model with low to moderate (c^2: 0.21 - 0.55) control by shared environmental factors. Secular changes in all phenotypes are under moderate to high (e^2: 0.45 - 0.79) control by unique environmental factors. **Conclusions:** Variations in secular change in the 13 metabolic phenotypes show limited genetic control. Our results emphasize the special importance of unique environment in determining individual change in metabolic phenotypes in adult Chinese.

Latent variable adjustment of NIH Epigenomics Roadmap ChIP-seq data for utilization in tissue-specific polygenic analysis of type II diabetes in the DIAGRAMv3 GWAS meta-analysis. *A.L. Dobbyn[1], B.F. Voight[2], P. Roussos[1,6], A. Morris[3], S. Raychaudhuri[4,5], M. McCarthy[3], E.A. Stahl[1,5,6], the DIAGRAM consortium.* 1) Icahn School of Medicine at Mount Sinai, New York City, NY; 2) Departments of Pharmacology and Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 4) Partners HealthCare Center for Personalized Genetic Medicine, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 5) Broad Institute, Cambridge, MA; 6) Division of Psychiatric Genomics, Icahn School of Medicine at Mount Sinai, New York, NY.

INTRODUCTION: Previous analyses have shown that tissue specific chromatin marks can be used to inform association studies in order to dissect the genetic architecture of complex disease. Enrichment for the H3K4me3 chromatin mark in GWAS identified variants has implicated causal tissues in the etiology of complex disease, including both Liver and Pancreatic Islets for type II diabetes (Trynka 2013). However, we have detected similar levels of enrichment in non-causal tissues in separate analyses, and observe a lack of correlation between H3K4me3 peaks from samples of the same tissues, consistent with the presence of latent confounding variables. We outline a method for the normalization of ChIP-seq data that adjusts for confounders, allowing for improved detection of enrichment signal in downstream analyses, and then utilize the normalized data in polygenic risk score analysis of T2D. METHODS: We constructed a matrix of the union of all peaks in all samples from the NIH Epigenomics Roadmap Project (82 samples, 44 tissues/cell types), merging peaks with any overlap, resulting in a total of 214,704 peaks. We then conducted surrogate variable analysis (Leek & Storey, 2007) using this matrix in order to identify and adjust peak fold enrichments for latent variables. We will make publicly available our normalized adjusted Epigenomics Roadmap data. We used H3K4me3 ChIP-seq peaks to define tissue-specific H3K4me3 enriched sets of genes, and selected SNPs within 20kb of each gene's transcription start site for use in polygenic analysis. We then conducted polygenic risk score analysis of T2D using discovery SNPs from the DIAGRAMv3 GWAS meta-analysis (Morris 2012; 12,171/56,862 cases/controls), and tested polygenic risk scores in the WTCCC (2007; 1,924/2,938 cases/controls). RESULTS: After normalization, maximum enrichment (observed/expected variance explained) for Liver and Pancreas SNP sets, based on a small number of tissue-specific peaks, increased from 4.37 and 7.08 to 38.6 and 17.5, respectively. Liver and Pancreas within-tissue correlations increased from R_{Liver}=0.785 and R_{Panc}= 0.570 to R_{Liver}=0.858 and R_{Panc}=0.859. CONCLUSIONS: We have implemented surrogate variable analysis for the normalization and adjustment of ChIP-seq data, reducing the effects of hidden covariates and improving detection of tissue-specific compartments of polygenic signal. The adjustment used is applicable to all downstream analyses that utilize tissue specific ChIP-seq data.

1114S

Excess of Runs of Homozygosity is associated with severe cognitive impairment in Intellectual Disability. *I. Gandin[1], F. Faletra[2], F. Faletra[2], M. Carella[3], V. Pecile[2], G.B. Ferrero[4], E. Biamino[4], P. Palumbo[3], O. Palumbo[3], P. Bosco[5], C. Romano[6], C. Belcaro[1], D. Vozzi[2], A.P. d'Adamo[1].* 1) Medical Sciences, University of Trieste, Trieste, Trieste, Italy; 2) Institute for Maternal and Child Health, IRCCS "Burlo Garofolo", Trieste, Italy; 3) Medical Genetics Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo (FG), Italy; 4) Department of Pediatrics, University of Torino, Torino, Italy; 5) Oasi Institute for Research on Mental Retardation and Brain Aging (IRCCS), Troina, Italy; 6) Unit of Pediatrics and Medical Genetics, IRCCS Associazione Oasi Maria Santissima, 94018 Unit of Pediatrics and Medical Genetics, IRCCS Associazione Oasi Maria Santissima, 94018 Troina (EN), Italy.

The harmful effect of inbreeding is well known by geneticists and several studies have already reported cases of Intellectual Disability (ID) in consanguineous families caused by recessive variants. Nevertheless, despite the recent findings for other neurological disorders like Alzheimer disease, Parkinson disease and schizophrenia, the effect of inbreeding on ID is still poorly investigated in outbred populations. Here we present a Runs of Homozygosity (ROHs) study performed in a 612 individual cohort of ID patients. We first investigated the ROHs distribution considering the complexity of the phenotype (presence of malformations, seizures, micro/macrocephaly, etc.), and we didn't find a different amount of homozygosity comparing syndromic and non-syndromic ID patients. In a second stage, we focused on the effect of ROHs on the ID degree, starting from the IQ. Our data revealed the presence of significantly larger ROH stretches in severe ID cases compared to non-severe ID ones (p=7.1×10-3), together with an increase of the percentage of genome covered by ROHs (p=3.0×10-2). According to the recent findings on ID in autism, this study reveals that autosomal recessive variants have an important role in ID and that they mainly and specifically affect the cognitive impairment modulation, in spite of the ID cause. This is not surprising, since ID degree is a highly complex trait whose overall variability is likely not determined by a single pathogenic mutation. Other environmental and genetic factors modulate the phenotype and one of the most important seems to be accounted for by ROHs.

1115M

Impact of genetic burden on the age at onset in bout-onset and progressive multiple sclerosis. *M. Sorosina[1], F. Esposito[1,2], C. Guaschino[1,2], F. Clarelli[1], N. Barizzone[3,4], S. Lupoli[5], V. Martinelli[2], M. Leone[3], G. Comi[2], S. D'Alfonso[3,4], F. Martinelli Boneschi[1,2], PROGEMUS group, PROGRESSO group.* 1) Laboratory of genetics of Neurological complex disorders, Institute of Experimental Neurology (INSPE), San Raffaele Scientific Institute, Milan, Italy; 2) Department of Neurology, San Raffaele Scientific Institute, Milan, Italy; 3) Interdisciplinary Research Center of Autoimmune Disease IRCAD, University of Eastern Piedmont, Novara, Italy; 4) Department of Health Sciences, University of Eastern Piedmont, Novara, Italy; 5) Department of Health Sciences, University of Milan and Genomics & Bioinformatics Unit, c/o Fondazione Filarete, Milan, Italy.

Multiple sclerosis (MS [MIM 126200]) is an inflammatory disease of the central nervous system (CNS) characterized by myelin damage and neurodegeneration. It is a highly heterogeneous disorder and two main clinical courses exist: the bout onset MS (BOMS) and the progressive onset MS (PrMS). While the susceptibility to the disease has been widely explored from the genetic point of view, conflicting evidence exist on the role played by genetic risk factors in influencing the clinical features. We calculated a weighted genetic risk score (wGRS) in 1450 Italian multiple sclerosis patients using 107 MS-associated genetic risk variants recently reported by the IMSGC consortium to explore the influence of genetic burden on the age at onset (AAO) in the two MS disease courses. By analysing the entire MS cohort, no effect of wGRS was detected on AAO (rho=-0.04, p=0.15; comparison of patients stratified according to the median age at progression: p=0.13), although the trend was toward a negative correlation. After stratification based on the clinical course we observed an opposite relationship between the wGRS and AAO in the two groups: negative in BOMS (n= 796; correlation: rho=-0.1; $p=5\times10^{-3}$; comparison of patients stratified according to the median AAO: $p=9.5\times10^{-3}$), while positive in PrMS (n=474) and in Secondary Progressive MS (SPMS, n=94) referring to the onset of the progressive phase (correlation: rho=0.08; p=0.07; comparison of patients stratified according to the median age at progression: p=0.01). In SPMS females this association seems to be due to a longer inflammatory phase preceding the progressive phase (correlation: rho=0.26, p=0.047; survival analyses comparing patients stratified according to the wGRS: p=0.043), instead to the age of progression itself. While the relationship between wGRS and AAO seems to be mediated also by the non-HLA loci, the effect on age at progression seems to be mediated mainly by HLA. Our results suggest that the MS-associated risk variants differentially influence the onset of the inflammatory and progressive phases in multiple sclerosis.

Association of Mitochondrial DNA levels with Frailty and All-Cause Mortality. *F.N. Ashar[1], A. Moes[1], A.Z. Moore[2], M.L. Grove[3], P.H.M. Chaves[4], J. Coresh[2], A.B. Newman[5], A.M. Matteini[6], K. Bandeen-Roche[7], E. Boerwinkle[3], J.D. Walston[6], D.E. Arking[1].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD., USA; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA; 3) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 4) Benjamin Leon Center for Geriatric Research and Education and Department of Medicine, Florida International University, Miami, USA; 5) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, USA; 6) Division of Geriatric Medicine and Gerontology, Johns Hopkins University School of Medicine, Baltimore, USA; 7) Department of Biostatistics, Johns Hopkins University, Baltimore, USA.

Age-related declines in mitochondrial function have long been hypothesized to underlie multiple biological changes that increase vulnerability to multiple disease states, functional and cognitive decline, and ultimately, mortality. Evidence to support this comes from the fact that specific variants in mitochondrial DNA (mtDNA) have been shown to modulate risk for several age-related disease states. While the association of mitochondrial variants with age-related disorders is well-established, the effect of mtDNA copy number, which reflects energy reserves and oxidative stress, on aging and mortality in the general population has not been addressed. To address this gap, we examined mtDNA copy number in two large multi-center prospective studies—the Cardiovascular Health Study (CHS) and the Atherosclerosis Risk in Communities (ARIC) study—with a total of 16,401 samples of European and African descent focusing on two primary phenotypes—prevalent frailty in CHS, and all-cause mortality in ARIC and CHS. In race-stratified meta-analyses, we demonstrate a significant inverse association of mtDNA copy number with age, with a reduction of 0.12 standard deviation units with a 10 year differences in age ($P=2.78 \times 10^{-25}$), and higher mtDNA copy number in women relative to men (meta-analysis OR=1.33, 95% CI 1.14-1.51, $P=6.91 \times 10^{-45}$). Furthermore, we show that lower mtDNA copy number is significantly associated with prevalent frailty in 4,109 self-identified white participants from CHS (OR=0.91, 95% CI, 0.85-0.97, P=0.005). Finally, mtDNA copy number is a strong predictor of all-cause mortality in an age and sex-adjusted, race-stratified analysis of 16,401 participants from both cohorts with a pooled hazard ratio of 1.47 (95% CI 1.33-1.62, $P=4.24 \times 10^{-14}$) for the lowest quintile of mtDNA copy number relative to the highest quintile. Based on the association with mortality and observation of a higher mtDNA copy number in women relative to men, we tested whether a mito-protective effect may be related to the differences in life expectancy between men and women. We estimate that mtDNA copy number is associated with 3-10% of the effect of sex on mortality, suggesting that mtDNA copy number may be a contributing factor to the disparity of the phenotype. In summary, we report that a single, easily implemented measure of mtDNA copy number, isolated from whole blood decades before the event of interest (death), is predictive of all-cause mortality.

Significant role of height-associated variants in the variation of intracranial volume. *R. Shafee[1,2], G. Genovese[2], A.J. Holmes[3], P.H. Lee[4], L. Germine[4], J.L. Roffman[5], J.W. Smoller[4], R.L. Buckner[6,7], S.A. McCarroll[1,2].* 1) Genetics, Harvard Medical School, Boston, MA; 2) Stanley Ctr. for Psychiatric Res., Broad Inst. of Harvard and MIT, Cambridge, MA; 3) Dept. of Psychology, Yale University, New Haven, CT; 4) Psychiatric and Neurodevelopmental Genet. Unit, Massachusetts Gen. Hosp., Boston, MA; 5) Psychiatry, Massachusetts Gen. Hosp., Boston, MA; 6) Athinoula A. Martinos Ctr. for Biomed. Imaging, Dept. of Radiology, Massachusetts Gen. Hosp., Charlestown, MA; 7) Psychology and Ctr. for Brain Sci., Harvard Univ., Cambridge, MA.

Height and intracranial volume (ICV) are both highly heritable traits as shown by twin studies. Additionally, it has been observed that the two quantities are positively correlated. We investigated the contribution of height-associated variants to the heritability of ICV and tested whether height-increasing alleles also increase ICV using 963 18-35 year old healthy Caucasian subjects. ICV was measured from the magnetic resonance imaging (MRI) scans of the subjects. The genotype data of these subjects comprised of ~531,000 SNPs after standard quality control. The height-association p-values of these SNPs were acquired from the publicly available results of the GIANT consortium. First, using GCTA we estimated the SNP-heritability of ICV due to all the genotyped SNPs to be $h_g^2 \sim 0.29 - 1$ (95% CI, LRT p-value = 0.0002). Next, we categorized the SNPs as height-associated (HA) or not-height-associated (NHA) based on varying GIANT association p-value thresholds and estimated heritability contributions from each component for each case using a joint model in GCTA. For a threshold of $p = 0.5$, 49% of the genotyped SNPs were HA ($p < 0.5$) and 51% of the SNPs were NHA ($p \geq 0.5$) with the HA SNPs showing a trend of enrichment (1.9X enrichment, $p = 0.18$, 95% CI of $h_g^2 = 0.3 - 1$) over the NHA SNPs. Lowering the GIANT p-value threshold for defining HA/NHA SNPs strengthened the trend. For a threshold of $p = 10^{-4}$ HA SNPs (0.6% of all SNPs) showed statistically significant enrichment (20X, $p = 0.0042$, $h_g^2 = 0.1 - 0.8$) over the NHA SNPs in explaining the SNP-heritability of ICV. Next, we performed association tests of ICV using all genotyped SNPs and investigated whether the height-increasing alleles of the SNPs also increased ICV in our sample. We tested whether the average ICV association test regression coefficient (β) of the height-increasing alleles of the genotyped SNPs was positive. Once again, we divided the SNPs as HA (GIANT p-value <0.5) or NHA (GIANT p-value ≥ 0.5) and found the mean β of the height-increasing alleles to be 96.4 ± 14.5 mm^3/allele (mean ± SEM; permutation p-value = 0.04 for mean ≥ 96.4) for the HA SNPs and 15.2 ± 15.2 mm^3/allele (with permutation p-value = 0.4 for mean ≥ 15.2) for the NHA SNPs indicating high probability of the mean positive β arising by chance in the latter case. Together these results indicate that height-associated SNPs possibly play an important role in determining ICV.

MultiBLUP: Improved Prediction for Complex Traits. *D. Speed, D.J. Balding.* UCL Genetics Institute, University College London, London, United Kingdom.

Prediction of phenotype from genome-wide SNPs is challenging. It is now well established that for many complex traits, in addition to a handful of individually-significant SNPs, substantial heritability is carried in a polygenic component that is tagged by a much larger set of SNPs. However, there are currently no statistical tools for prediction that can exploit this genetic architecture and remain computationally tractable. BLUP (Best Linear Unbiased Prediction) is a classic prediction tool widely used in plant and animal breeding. It is computationally fast, but is suited only to simple polygenic traits, and not to complex genetic architectures. We therefore introduce MultiBLUP, which generalises BLUP in a way that retains its good computational properties while increasing its flexibility so that it can perform well for a wide range of genomic architectures. In tests on many disease traits, it consistently achieves better risk prediction than rival methods, while being many times faster than the next best method and able to handle much larger datasets. For example, applied to imputed data for inflammatory bowel disease (13,000 individuals, 1.5M SNPs), MultiBLUP runs in a few hours, and achieves better prediction performance than BLUP or genetic risk scores (AUC 0.68 compared to 0.58 and 0.61, respectively). Similar improvement is achieved for Celiac Disease (AUC 0.86 compared to 0.79 for both BLUP and genetic risk scores). MultiBLUP can also be used for predicting continuous traits (we demonstrate this for cholesterol phenotypes), and for non-human data (we consider 139 mice phenotypes). The low prevalence of most diseases means that prediction in a general population remains difficult, but there are many settings in which subgroups of patients can be identified using classical risk factors. For example, the prevalence of Type 2 diabetes among obese individuals is almost 50%, while the chance of developing epilepsy following a single seizure is about 45%, which are both much higher than the population prevalences. SNP-based prediction using MultiBLUP can be very powerful for such subgroups. Moreover, with meta-analysis consortia established for many major diseases, MultiBLUP can take advantage of the very large sample sizes now available. The MultiBLUP software will be freely available at www.ldak.org after publication.

Hair e-QTLs - delineating the genetic basis of gene-expression in human hair follicle and its implication for the interpretation of hair loss disorders. *S. Heilmann[1,2], H. Schulz[3], N. Karbalai[4], A. Hofmann[1,2], L.M. Hochfeld[1,2], F.A. Degenhardt[1,2], S. Herms[1,2,5], J. Becker[1,2], T. Kätzel[1,2], F.F. Brockschmidt[1,2], A.M. Hillmer[6], P. Hoffmann[1,2,5,7], B. Müller-Myhsok[4], M.M. Nöthen[1,2].* 1) Institute of Human Genetics, University Bonn, Bonn, Germany; 2) Department of Genomics, Life & Brain Center, University of Bonn, Germany; 3) Cologne Center for Genomics (CCG), University Cologne, Cologne, Germany; 4) Max-Planck-Institute of Psychiatry, Munich, Germany; 5) Division of Medical Genetics, Department of Biomedicine, University of Basel, Basel, Switzerland; 6) Cancer Therapeutics and Stratified Oncology, Genome Institute of Singapore, Singapore, Singapore; 7) Institute of Neuroscience and Medicine (INM-1), Research Center Juelich, Juelich, Germany.

The human scalp hair plays an important role in our social and cultural life and its undesirable loss is often perceived as psychologically stressful in affected individuals resulting in a reduced quality of life. This has provoked many studies on the genetic and biological causes of hair loss. Candidate gene and genome-wide association studies have been successful in the identification of genetic risk factors that predispose to hair loss disorders such as alopecia areata and male-pattern baldness. However, the biological context in which these genetic risk factors exert their biological effect is often unknown. Although the functional annotation of the human genome is becoming increasingly detailed, further experiments are still warranted to elucidate the often tissue- and cell-specific biological contexts. Here, the analysis of genetic variants that influence gene expression (eQTLs) has gained major importance. The aim of our study therefore was to systematically map eQTLs in human hair follicle. For this purpose we performed genome-wide genotyping of blood-DNA samples and transcriptome profiling of hair follicle RNA samples from 100 healthy male donors using the Illumina OmniExpress v1.1 and HT12v4 array. After quality control, a total of 562,176 autosomal SNPs (MAF≥5%, call rate≥95%) and 21,696 expression probes (quantile normalized, detection P-value<0.05 in at least one sample, no SNP with MAF>1% within probe) for 97 individuals remained for eQTL analysis. A total of 5,438 SNPs were found to regulate expression of 856 transcripts in cis or trans, corresponding to almost 1% of all SNPs analyzed. Among the top cis-regulated genes are *CHURC1*, *KCTD10*, *WDR41*. Top trans-regulated genes include *RPS26L*, *PEX16* and the long-non-coding RNA *MGC57346*. Elaborate data analysis is currently underway and the results will be presented at the meeting. The present hair-eQTL data set will help to further elucidate the underlying biological mechanisms of hair loss disorders such as male-pattern baldness and alopecia areata and hair morphological traits such as hair thickness or curliness. Promising strategies include the interpretation of GWAS findings using the hair-eQTL data, tests for association of the limited set of functionally relevant hair-eQTLs in case-control samples for hair related traits and disorders as well as pathway- and score-based approaches.

Cerebellar Ataxias (CA) and Hereditary Spastic Paraplegias (HSP) are neurodegenerative diseases, which belong to the family of Spinocerebellar Degenerations (SCD). They are characterized by major clinical and genetic heterogeneity, which renders both the molecular diagnosis and the phenotype-genotype correlations really complex. As of today, only 60% of SCD cases are genetically elucidated even though more than 150 causal genes have been described. Aiming at the identification of new causative genes, we gathered the strengths of Next Generation Sequencing technologies (NGS), and the SPATAX network with its cohort of more that 10000 SCD patients. Whole Exome Sequencing (WES) was performed in 54 families (1-3 patients/family). Along with classical criteria based on database frequencies and effect on the encoded protein, variants were sorted with linkage analysis data in the most informative families, or with gene network analysis in the smaller ones. In 9 families, variants in genes previously involved in SCD were described (FTL, SCA14, C10orf2, SETX, ATM, COL6A3, PIK3R5). Another noteworthy family presented with both heterozygous and homozygous mutations of the same gene, leading to interesting intra-familial genotype-phenotype comparison. In yet another family, a heterozygous mutation of a gene already described in an autosomal recessive heavier neurocutaneous phenotype shed the light on the putative broadening of phenotypes that will be brought along by NGS. Two new genes in autosomal recessive CA are published (Synofzik et al., Brain 2014) or submitted. In the remaining families, we isolated 41 candidate genes in autosomal dominant CA, one of which is involved in 2 families; 7 in HSP, again with mutations of one gene in 2 separated families; and 4 in autosomal recessive CA with associated hypogonadism. We designed targeted gene panels aimed at screening our extended cohort for these genes. Functional analyses are already ongoing for 6 of these genes. In conclusion, we report results from WES in a cohort of 54 families with SCD, with clues on frequency of already known genes, novel elements on the complexity of phenotype-genotype correlations, as well as several promising candidate genes. We furthermore demonstrate how high-throughput and medium-throughput sequencing may be used efficiently in novel genes identification and validation. Further results on extended cohorts will finally be available shortly.

1121M

Homozygosity mapping and candidate gene screening in Attention Deficit/Hyperactivity Disorder (ADHD) in Highly Inbred Saudi Arabian Families. *F. Alnaemi[1], D. Abebe[2], A. Adi[1], A. Almagrashi[1], A. Tahir[1], S. Qasem[1], M. Ghaziuddin[2], N. AlTassan[1].* 1) King Faisal Specialist Hospital & research Center, Riyadh, Saudi Arabia; 2) Psychiatry Department, King Faisal Specialist Hospital& research Center.

Attention Deficit/Hyperactivity Disorder (ADHD) is the most common neurodevelopmental disorder affecting at least 7% of all children in Saudi Arabia. ADHD, is not considered to have a single genetic cause but rather a complex interaction of genetic and environmental factors. Association studies have identified a number of susceptibility loci on 4q13.2, 5q33.3, 7p, 11q22,14q12 and 17p11. Moreover, meta-analysis of candidate genes has implicated genes for dopamine, norepinephrine, and serotonin neurotransmitter systems in the etiology of ADHD. The objective of this study is to identify ADHD susceptibility in highly consanguineous and inbred families of Saudi Arabia. To achieve this goal genotyping using high-resolution chip array and candidate gene sequencing has been performed. Regions of homozygosity on chromosomes 3,4,5,6, 7,11,10,13,17 and 18 were identified in different families . Subsequent bidirectional sequencing of candidate genes in these regions identified a number of novel and previously reported single nucleotide variants (SNV's) in *DDR1*, *GAB2*, *INTS4*, *ALG8*, *GDPD4*, *NRM* and *BTNL2* genes. None of these variants segregated with the autosomal recessive inheritance in these families. The large number of LOH regions identified and the lack of segregation of variants identified in candidate genes reinforces the complex genetics of ADHD, and points to other possible genetic mechanisms as an explanation to the phenotypes observed.

1122T

Linkage analysis, homozygosity mapping and whole exome sequencing to identify new genes in consanguineous families with juvenile myoclonic epilepsy. *B. ouled amar bencheikh[1,2,3], F. Lahjouji[2], K. Khaldi[2], H. Lamghari[2], D. Spiegelman[3], A. Dionne Laporte[3], H. Belaidi[2], P. Dion[3], R. Ouazzani[2], G. Rouleau[3], P. Cossette[1].* 1) Centre de Recherche du Centre Hospitalier de l'Université de Montréal, Notre Dame Hospital, University of Montreal, Montreal, Quebec, Canada; 2) Clinical Neurophysiology Department, Speciality Hospital, CHU Ibn Sina, Rabat, Morocco; 3) Montreal Neurological Institute and Hospital, Department of Neurology and Neurosurgery, McGill University, Montréal, QC, Canada.

Background. The genetic (idiopathic) generalized (GGEs) epilepsies account for 40 to 60% of the etiologies of epilepsy. Most of these syndromes have a complex transmission, with phenotypic and genetic heterogeneity as well as incomplete penetrance of the causative genes. However, despite this complexity, many genes and loci responsible for epilepsies have been identified. The identification of these loci and genes has been possible by genetic linkage studies and recently by whole exome sequencing. Methods. To identify new genes of GGEs, we characterized clinically three consanguineous families from Morocco with juvenile myoclonic epilepsy (JME) and autosomal recessive transmission. Genotyping of each family subjects was done by Illumina Omni-express SNP chips for the linkage mapping. The Multipoint linkage analysis was carried out with Merlin by using an autosomal-recessive model with complete penetrance. The homozygosity mapper was used to identify intervals of homozygosity. Then, the exome sequencing was performed for 8 patients from the three families. The exome capture was done by the Agilent SureSelect V4 and the sequencing on Illumina HiSeq2000. The annotation and the calling of the variants was done by using an in-house data pipeline using the GATK software. Resutls. We identify one locus in each family confirmed by homozygosity mapper. Then, we prioritize the variants identified by exome sequencing within these intervals of homozygosity. We filtered the variants considering the frequency of the disease at 1% and excluded all variants with frequency greater than 1% in public and in our In-house database (2000 exomes). We have identified a total of 328869, 281434 and 325231 shared variants in family 1, 2 and 3 respectively. Some of these variants segregate well with the disease. All the variants filtered were validated by Sanger sequencing. Conclusion. The use of Linkage analysis and homozyosity mapping, combined to whole exome sequencing in consanguineous families with juvenile myoclonic epilepsy have great potential to identify the causative genes of this disease and provide us novel therapeutic issue for epilepsy.

1123S

Genetic characterization of a homozygous 9p deletion in a patient with hyper IgE syndrome and progressive multifocal leukencephalopathy supports deficiency of DOCK8 as a causal factor for both diseases. *C. Sun[1], A. Day-Williams[1], H. McLaughlin[1], I. Jelcic[2], T. Harris[1], R. Martin[2], J. Carulli[1].* 1) Translational medicine, Biogen Idec, Cambridge, MA; 2) Department of Neurology, University Hospital Zurich, Frauenklinikstrasse 26, Zurich, Switzerland.

A 30 year old male Caucasian patient with eczematoid dermatitis since early childhood was found having massively elevated serum immunoglobulin E (IgE) level (26'800 kU/L), and slightly increased peripheral blood eosinophiles (1.6 x 109/L). Therefore, he was diagnosed with hyper IgE syndrome (HIES). In fall 2008, the patient developed progressive neurological deficits caused by large intracerebral lesions as detected by MRI, suggestive of progressive multifocal leukencephalopathy (PML), an infection of the brain caused by JC virus (JCV). CSF analysis showed presence of JCV DNA (500 copies/mL), proving PML. HIES-associated CD4+ and CD8+ T cell lymphopenia was detected repeatedly. Family history revealed that the parents of the patient are first cousins.

Whole genome sequencing and microarray analysis revealed large deletions on both copies of chromosome 9, near the p telomere. The sequence at 9ptel as determined by NGS technology (Complete Genomics Incorporated) is somewhat ambiguous due to the existence of multiple copies of chromosome 9p paralogous sequences in the human genome, and the repetitive sequence nature near telomere. Therefore, we defined the breakpoint using focused molecular genetic assays. Using WGS and whole genome SNP array data as guidance, we PCR-tested multiple chromosome 9ptel-specific SNPs near the potential telomeric end of the break points, on this PML patient and controls. Analysis showed that he has a homozygous deletion and that the breakpoint is very close to telomere repetitive sequence. Cloning and dideoxy sequencing of a long range PCR product from primers flanking the hypothetical centromeric and telomeric breakpoints defined them unambiguously at the nucleotide level (10,047-586751). This interval includes 7 known genes: WASH1, FAM138C, FOXD4, CWBD1, C9orf66, KANK1, and DOCK8, with DOCK8 being the primary candidate for causing immune dysfunction in this patient. DOCK8 deficiency causes a pleiotropic combined T and B cell immunodeficiency characterized by recurrent cutaneous viral infections, susceptibility to cancer and elevated serum levels of IgE. Additionally, cases of PML in DOCK8 deficiency have been described elsewhere. Our data provide further evidence that DOCK8 deletion is causal to HIES and predisposes to PML development.

Next-generation sequence analysis of neurodegeneration on Guam. *I. Guella[1], J. Steele[2], C. Szu-Tu[1], M.K. Lin[1], C. Thompson[1], D.M. Evans[1], H.E. Sherman[1], C. Vilariño-Güell[1], K. Gwinn[3], H. Morris[4], D.W. Dickson[5], D.S. Fenton[6], M.J. Farrer[1].* 1) Djavad Mowafhagian Centre for Brain Heath, University of British Columbia, Vancouver, BC, Canada; 2) Guam Memorial Hospital, Tamuning, Guam; 3) National Institute of Neurologic Disorders and Stroke, National Institutes of Health, Bethesda, Maryland, USA; 4) Institute of Neurology, Queen Square, University College London, London, England; 5) Department of Neuroscience, Mayo Clinic Jacksonville, Florida, USA; 6) Anthropology Program, University of Guam, Mangilao, Guam.

The amyotrophic lateral sclerosis (ALS)/Parkinsonism-dementia complex (PDC) is a progressive, age-associated neurodegenerative disorder that has been described in Guam, Western Papua and the Kii peninsula of Japan. The etiology and pathogenesis of this complex syndrome remains enigmatic despite decades of research. In this study we have used next-generation targeted sequencing to evaluate the contribution of genetic variability in the pathogenesis of Guamanian ALS/PDC. Thirty-two genes previously linked and/or associated with parkinsonism, dementia, ALS and related neurodegenerative syndromes were sequenced in 101 indigenous Chamorro Islanders including patients with ALS, parkinsonism and/or dementia, and neurologically normal subjects. Pathogenic mutations identified include HTT (42 CAG repeats), homozygous PINK1 (p.L347P), heterozygous DCTN1 (p.T54I) and FUS (p.P431L). The findings help explain the clinical, pathologic and genetic heterogeneity observed in some multi-incident families and contribute to the excess incidence of neurodegeneration reported.

1125T

Sex differences in neuropsychiatric expression of rare deletions overlapping schizophrenia susceptibility gene ZNF804A. *C. Lowther[1,2], A.C. Lionel[3,4], C.R. Marshall[3,4], S.W. Scherer[3,4], A.S. Bassett[1,2,5].* 1) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) The Centre for Applied Genomics and Program in Genomics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 5) Department of Psychiatry, University of Toronto and University Health Network, Toronto, Ontario, Canada.

Intellectual disability (ID), autism spectrum disorder (ASD), and schizophrenia each have a strong genetic component and significant sex differences. There is a 4:1 male sex bias in ASD, an excess of males institutionalized for ID, and men with schizophrenia tend to have a more severe course of illness compared to females. X-linked disorders have long been posited to contribute in part to the observed sex bias in ASD and ID and new studies suggest males manifesting these disorders may be more susceptible to the damaging effects of copy number variations (CNVs). Few studies as yet have investigated sex bias in the expression of a rare autosomal CNV. We recently identified two distantly related probands ascertained for schizophrenia with a very rare 790 kb deletion overlapping ZNF804A, a top candidate gene for schizophrenia. Using family history and locally available census data we were able to trace the origin of this inherited deletion. We performed in-depth phenotyping of several relatives of these probands including comprehensive medical, psychiatric, and physical assessment to identify major lifetime features and illnesses. DNA samples for ZNF804A deletion testing were collected. We report on results from a large extended family within which two nuclear families could be distinguished. Of the nine adults (6 females, 3 males) tested, six (5 females, 1 male) were found to have the ZNF804A deletion: two females were unaffected with respect to neuropsychiatric conditions while the remaining three had schizophrenia and intellectual disability, personality disorder, and major depressive disorder, respectively. The one male proband with the ZNF804A deletion was diagnosed with schizophrenia and learning difficulties. A second male without the deletion was also diagnosed with schizophrenia. To our knowledge this is the first study to report on the broader neuropsychiatric phenotypes associated with rare deletions overlapping ZNF804A. It appears that the deletion increases the risk for a range of neuropsychiatric conditions in females, though not all females manifest disease. The recurrence of schizophrenia in two males (one without the deletion) in this family suggests that additional factors are likely contributing to the variable expression and incomplete penetrance. Further study, including next generation sequencing, will be critical for understanding the sex related differences in neuropsychiatric expression associated with the ZNF804A deletion.

Clinically Relevant Candidate and Known Genes for Alcoholism with Representation on High Resolution Chromosome Ideograms. *A.M. Manzardo, A. McGuire, M.G. Butler.* Psychiatry & Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS., USA.

Alcoholism arises from the combined effects of multiple biological factors including a wide range of possible genetic variations and/or abnormalities, as well as non-genetic causes including interpersonal and psychosocial relationships, and gene/environmental interaction (epigenetics) with the risk of development strongly related to family history, childhood behavioral problems and the presence or absence of life stressors particularly in childhood. The interface of these relationships are complex and involve overlapping and competing effects of possibly hundreds of genes impacting brain development, structure, and function, as well as, alcohol processing and sensitivity. Years of research on alcoholism has generated a wide range of data linking various genes and pathways to the causation and pathophysiology of alcoholism. The list of alcoholism-related genes has significantly increased recently due to better awareness and advances in genetic technology along with expanding searchable genomic databases. Candidate genes for alcoholism related to neurotransmitter pathways are associated with brain reward processes including the dopaminergic (e.g., *DRD2, MAOA*, and *COMT*), serotoninergic (e.g., *HTR3A, HTR1B, HTR3B*, and *SLC6A4*), GABAergic (e.g., *GABRA1, GABRA2*, and *GABRG1*), glutaminergic (e.g., *GAD1, GRIK3*, and *GRIN2C*) and opioid (e.g., *OPRM1, OPRD1*, and *OPRK1*) pathways. These genes presumably influence the reinforcing properties of alcohol and drive the motivation to seek and use alcohol to excess. We have compiled the latest list of highly validated and clinically relevant alcoholism genes from the medical literature and related websites dedicated to gene discovery and characterization. Our list of over 160 genes consisted of the most clinically relevant with symbols placed on high resolution human chromosome ideograms enabling researchers, physicians, and counselors to have a convenient visual image of the location of a particular alcoholism gene and the flanking alcoholism genes therein. Meaningful correlations of the observed phenotype with the suspected/detected alcoholism gene(s) at the chromosome region/breakpoint defect can be used to inform diagnosis, treatment and improve outcomes with gene-based personalized genetic counseling risk assessments and information for families.

Association analysis of *HLA-DQB1* gene with narcolepsy without cataplexy and idiopathic hypersomnia. *T. Miyagawa[1], H. Toyoda[1], H. Kojima[2], T. Futagami[2], SS. Khor[1], A. Hirataka[1], M. Yamasaki[1], H. Saji[2], Y. Honda[3], M. Honda[3, 4], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) HLA Foundation Laboratory, Kyoto, Japan; 3) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 4) Sleep Disorders Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Narcolepsy without cataplexy (NA w/o CA) is a lifelong disorder characterized by excessive daytime sleepiness and rapid eye movement (REM) sleep abnormalities, but does not exhibit cataplexy. Several studies have reported that NA w/o CA is associated with human leucocyte antigen *HLA-DQB1*06:02* similar to narcolepsy with cataplexy (NA-CA). The sample sizes of the studies were relatively small because NA w/o CA is an infrequent condition, which makes it difficult to find a large number of samples. We have therefore formed a collaborative research group to promote the study in Japan. In the present study, we examined *HLA-DQB1* in 146 Japanese patients with NA w/o CA and 1,418 control subjects. The frequency of *DQB1*06:02* in the patient group was significantly higher than that in the control group (allele frequency: 16.8% vs. 7.6%, $P = 1.6\times10^{-7}$, OR = 2.40; carrier frequency: 31.5% vs. 14.7%, $P = 1.5\times10^{-7}$, OR = 2.68). After controlling for the effect of *DQB1*06:02*, distributions of *HLA-DQB1* alleles were compared between NA w/o CA and NA-CA to assess whether the genetic backgrounds of the two diseases have similarities. The distribution of *HLA-DQB1* alleles in *DQB1*06:02*-negative NA w/o CA was significantly different from that in NA-CA ($P = 8.4\times10^{-7}$). On the other hand, the patterns of the *HLA-DQB1* alleles were similar between *DQB1*06:02*-positive NA w/o CA and NA-CA. *HLA-DQB1* analysis was also performed in 171 Japanese patients with idiopathic hypersomnia (IHS). No significant associations were observed between IHS and *HLA-DQB1* alleles. We found a significant difference in *HLA-DQB1* allele distribution between IHS and NA-CA ($P = 2.0\times10^{-8}$). The findings suggest that *DQB1*06:02*-positive NA w/o CA has an autoimmune pathogenesis in common with NA-CA, but *DQB1*06:02*-negative NA w/o CA and IHS might be unique from NA-CA.

Targeted Sequencing of Candidate Genes Identified with Exome sequencing in Multiplex Autism Families. *A. Patowary, I. Stanaway, R. Nesbitt, W. Raskind, D. Nickerson, Z. Brkanac.* University of Washington, Seattle, WA.

Autistic disorder is a severe neuropsychiatric disorder with strong genetic component. Recent large scale exome sequencing studies have demonstrated the importance of de-novo mutations in Autism. For familial autism, the contribution of rare highly penetrate genetic variants is not well understood. Identification of genes responsible for familial autism is important as genetic architecture of familial autism might differ from de-novo autism. To identify the contribution of rare variants to familial autism we performed whole exome sequencing in 25 NIMH and University of Washington autism families that include affected cousins and thereby minimizing variant sharing between affected family members. We define candidate variants as variants that are private (not present in dbSNP132, 1000 genomes or ESP6500) and functional (coding, missense, stop-gain, stop-loss, splice). For each family between 2 and 25 variants met our selection criteria. Based on overlap with de-novo variants and literature searches we have selected 25 candidate genes for further evaluation. To establish the association of the identified candidate genes with autism we have performed a large gene-based case control study. For all candidate genes whose protein coding sequence encompasses more than 50 Kbp, we have performed Molecular Inversion Probe (MIP) capture and targeted sequencing in 960 NIMH and 288 UW familial autism cases and 960 NIMH unscreened controls. The variant calling and annotation were performed in the same manner as for exome sequencing with modifications due to MIP capture and multiplexing to ensure comparative coverage representations of the genes in both case and control samples. Enrichment of rare variants in the affected subjects was evaluated using plink/seq tools. Our preliminary analysis has identified one novel gene for which rare functional variants are more common in cases as compared to controls ($P<0.01$). Detail analysis of the of the case-control study and analysis will presented.
