The Autism Spectrum Disorders (ASDs) comprise a range of early-onset persistent neuro developmental conditions, characterized by significant impairments in reciprocal social interaction and communication, accompanied by repetitive restricted stereotyped behaviors. The core symptom of ASD typically coexists with other medical conditions such as Intellectual Disability (ID) and seizures. The involvement of rare (<1% frequency) copy number variations (CNV) of varying expressivity and penetrance as risk factors in ASD/ID phenotypes has been highlighted previously in large series of patients. The DLGAP2 (discs, large (drosophila) homolog-associated protein 2) gene, whose glutamatergic postsynaptic density product may play a role in synaptogenesis and plasticity, has been identified as a novel candidate gene on the basis of a de novo 8p23.3 duplication intersecting DLGAP2 observed in a sporadic nonsyndromic ASD male. Another patient with sporadic de novo duplication involving DLGAP2 and ASD/ID had been previously reported in the literature. It has also been suggested that increased DLGAP2 gene expression may contribute to the pathogenesis of schizophrenia. Based on these results and after fine phenotyping of another patient with a de novo 8p24.3p23.2 1.8 Mb duplication involving DLGAP2 and presenting with ASD intersecting schizophrenia, we gathered an international series of six additional cases via the Decipher database and diagnosed with array-CGH. This series comprised a family with 3 females in which the duplication segregated with mild ID but without ASD features, and 3 sporadic males with ID and ASD with a duplication inherited from an asymptomatic parent. This study supports the hypothesis that rare CNV encompassing DLGAP2 gene could predispose to ASD/ID, with the principle of incomplete penetrance and variable expressivity. It also further supports the existence of common predisposing factors to ASD, ID and schizophrenia.

Structural equation models of communication endophenotypes suggest that human vocalized speech has a polygenic basis. *C.M. Stein[1,2], A. Avrich Ciesla[1], Y. Song[1], L. Freebairn[3], B. Truitt[1], H.G. Taylor[5], B.A. Lewis[3], N.J. Morris[1], S.K. Iyengar[1,4].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Center for Proteomics & Bioinformatics, Case Western Reserve Univ, Cleveland, OH; 3) Psychological Sciences, Case Western Reserve University, Cleveland, OH; 4) Genetics, Case Western Reserve University, Cleveland, OH; 5) Pediatrics, Case Western Reserve University, Cleveland, OH.

The genetic basis of vocalized speech, hypothesized to be a human-limited trait, is unknown. We used extensive phenotype and genotype data from children and families with disordered speech to demonstrate that vocalized speech is set in a complex cognitive network connected through many endophenotypes. Speech sound disorder (SSD) is one of the most common types of communication disorders, with prevalence rates of 16% at 3 years of age, and an estimated 3.8% of children continuing to present speech delay at 6 years of age. SSD is manifested through several correlated endophenotypes, including phonological memory, phonological awareness, vocabulary, speed of processing, oral motor skill, reading decoding, spelling, and spoken language; many of these same domains are affected in language impairment and dyslexia. Several studies have identified promising genetic associations between communication disorders and specific genes, but have not accounted for the correlation among endophenotypes. Previously, we developed a structural equation model (SEM) that depicted how endophenotypes assessed at preschool age influenced endophenotypes at school-age (Lewis et al. 2011). However, that SEM did not explicitly model familial structure and also did not incorporate genetic effects. We have recently released 'strum' software, which implements the SEM framework for family data (Morris et al. 2010). Here, we have refined the speech sound SEM with strum, and identified significant polygenic influences on phonological awareness (p=0.02), phonological memory (p=0.04), and the correlation between phonological memory and phonological awareness (p=0.02) and between phonological awareness and speeded naming (p=0.03). Next, we incorporated candidate gene association data into the model, based on single gene associations we previously observed with DRD2, AVPR1A, and ASPM (Stein et al. 2014), and found that DRD2 has an independent influence on phonological memory (p=0.004) after accounting for polygenic and residual correlations among these phenotypes. By synthesizing comprehensive endophenotype and genetic data with SEM, these findings reveal the genetic complexity of SSD and other communication and learning disorders.

1131T

Second thought about 16p12.1 microdeletion syndrome: is two-hit a valid model? *F. Boyar[1], L. Ross[1], J. Kelly[2], J.C. Wang[1].* 1) Dept Cytogenetics, Quest Diagnostics, Nichols Inst, San Juan Capistrano, CA; 2) Dept Cytogenetics, Quest Diagnostics, Nichols Inst, Chantilly, VA.

The chromosome 16p12.1 deletion syndrome (520kb; OMIM #136570) was suggested to be associated with high incidence of carrying additional large copy-number variants (10 of 42, 24%) as per Girirajan, S et al, 2010. The presence of 16p12.1 microdeletion was considered to predispose patients to develop neuropsychiatric phenotypes, which were exacerbated by epigenetic, environmental or genetic abnormalities such as other large deletions or duplications. A cohort of 37 cases with 16p12.1 microdeletion was studied by oligo-SNP array (CaytoScan HD, Affymetrix) at Quest Diagnostics Nichols Institute. The patients' age ranges from newborn to 23 years old. A wide spectrum of phenotypic presentation was found, including intellectual disability, developmental delay, learning disability, cranio-skeletal anomalies, microcephaly, speech delay, seizures, endocrine abnormalities, and autism. All the deletions spanned the 520 kb commonly deleted region, varying from 478 kb to 909 kb. Four cases had small copy number variants of unclear clinical significance, and only two cases (2/37, 5%) had a large or clinical significant copy number variant. One case had a 1.7 Mb gain of 22q11.2 at the DiGeorge syndrome critical region (OMIM #608363), and another had a 580 kb loss involving multiple exons of the NRXN1 gene (OMIM #600565). Our findings are unable to confirm the two-hit model as previously proposed. The absence of other large or clinically significant microdeletions or microduplications in 95% (35/37) of cases from this cohort demonstrates that the loss at 16p12.1 microdeletion alone may give rise to neuropsychiatric phenotypes as a single event.

1132S

DUF1220 domain copy number is linearly associated with increased speech delay in individuals with autism. *J.M. Davis[1], T.E. Fingerlin[2], V.B. Searles[1], L. Dumas[1], M. O'Bleness[1], J.M. Sikela[1].* 1) Department of Biochemistry and Molecular Genetics, University of Colorado School of Medicine, Aurora, CO; 2) Department of Epidemiology, Colorado School of Public Health, Aurora, CO.

Purpose: Autism is a neurodevelopmental condition characterized behaviorally through social and communicative impairments and repetitive behaviors. DUF1220 protein domain copy number is dramatically increased specifically in the human lineage and has been implicated in brain growth and brain evolution. We previously demonstrated that, in individuals with autism, DUF1220 (subtype CON1) copy number is linearly associated, in a dose response manner, with increasing severity of each of the three core symptoms of autism. Given these findings we investigated associations of CON1 copy number and speech delay, a common marker of severity, in an additional independently assayed group of individuals with autism. Methods: DNA samples from an additional 50 non-Hispanic white unrelated individuals with autism were obtained from the Autism Genetic Resource Exchange (AGRE) and assayed by custom high density arrayCGH. Age of first meaningful word was obtained by the Autism Diagnostic Interview-Revised, a caregiver interview used by clinicians to assist with autism diagnostics. Initially age of first meaningful word was dichotomized where greater than 24 months was classified as delayed first word. Unequal variance t-tests were performed to assess mean differences in DUF1220 copy number between delayed first word and not delayed groups. This was followed with a linear model examining the relationship of CON1 with month of speech acquisition adjusted for sex, age and simplex vs multiplex status. Results: Age of first word in this group ranged from 10 to 66 months with a mean of 28.7 months. On average individuals with delayed first word had a 0.065 (p=0.030) higher CON1 copy ratio (copy number) than the group who did not have a delayed first word. Similarly a linear association was identified where increased copies of CON1 were progressively associated with greater speech delay (p=0.019). Conclusions: Using ddPCR we previously implicated the dosage of DUF1220 CON1 in the severity of the core symptoms of autism. Here we have extended these findings to include speech delay. This partially replicates our previous work in a group of individuals independently drawn from AGRE and assayed with different methods. Taken together, these findings lend further support to the view that DUF1220 CON1 dosage is an important contributor to autism severity, and that the same gene family implicated in human brain expansion is also involved in the symptoms of autism.

1133M

First report on a multiplex, consanguineous, family with autism and chromosome 15 duplication. *H. Mansour[1], D. Eltabei[2], O. Shahin[2], F. El-Chennawi[3], U. Urvashi[4], L. Hoffner[4], M. Sathanoori[4], V. Nimgaonkar[1,5].* 1) Department of Psychiatry, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 2) Department of Psychiatry, Cairo University, Cairo, Egypt; 3) Department of Psychiatry, Mansoura University, Mansoura, Egypt; 4) Pittsburgh Cytogenetics Laboratory, Department of Pathology, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 5) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania, USA.

BACKGROUND: Several genetic risk factors have been detected for Autism spectrum disorders (ASD), including copy number variations (CNVs) such as duplications of the chromosomal 15q region. Maternal deletions or inactivation of genes in this region leads to Angelman syndrome, but if paternal, will cause Prader-Willi syndrome. Consanguinity is reported to be associated with the risk as well. METHOD: We report on a consanguineous, first-cousin marriage, Egyptian family having 4 siblings with ASD. We also recruited parents, an unaffected sib and maternal grandfather. Diagnoses were made following structured interviews, including the ADI-R. Array Comparative Genomic Hybridization (aCGH), physical examination by clinical geneticist, IQ testing and EEG were conducted. Co-morbid seizure, intellectual disability or ADHD have been reported in affected siblings. RESULTS: aCGH indicates that 3 of the 4 affected children have maternally-inherited interstitial duplication 15q11.2-q13. The mother and 3 affected siblings have intellectual disability. Several facial dysmorphic features are shared between mother and affected children, including the autistic child who does not have the duplication. CONCLUSION: To our knowledge, this is the largest multiply affected, inbred family reported to date with 15q interstitial duplication. However, the duplication does not segregate completely with ASD in this family, suggesting the presence of other risk factors, possibly related to deleterious mutations unmasked by regions of homozygosity noted extensively. Further analyses, including phenotypic characterization and whole exome sequencing are warranted.

1134T

Screen for somatic mosaic mutations in unexplained Dravet syndrome patients. *CT. Myers[1], JM. McMahon[2], IE. Scheffer[2], HC. Mefford[1].* 1) University of Washington, Department of Pediatrics, Division of Genetic Medicine University of Washington, Department of Pediatrics, Division of Genetic Medicine, Seattle, WA, USA; 2) University of Melbourne, Department of Medicine, Florey Institute of Neurosciences and Mental Health, Austin Health, Melbourne, Australia.

Dravet syndrome is an infantile-onset epileptic encephalopathy characterized by refractory seizures, cognitive arrest or regression associated with ongoing epileptic activity, and a poor prognosis. 80% of Dravet cases are caused by heterozygous mutations in SCN1A, a gene that encodes the voltage-gated sodium channel alpha 1 subunit. Our lab has recently identified GABRA1 and STXBP1 as novel genetic causes of Dravet syndrome (Carvill et al, 2014), explaining a few additional cases. Despite these advances, in almost 20% of patients with Dravet syndrome, the molecular diagnosis is still unknown. Given the strong correlation between genotype and phenotype in solved Dravet cases, we hypothesize that somatic mutations in these known genes (SCN1A, GABRA1, and STXBP1) are causative in a subset of currently unsolved cases. Somatic mutations, well recognized as disease causing in cancer, are implicated in more than 30 monogenetic disorders. We propose to screen for somatic mutations in a cohort of 51 patients with unexplained Dravet syndrome that have already undergone candidate gene screening or exome sequencing. Targeted sequencing using single-molecule Molecular Inversion Probes (smMIPS) will be used to screen for low-level somatic mosaicism in DNA from blood and buccal swabs. The smMIPs technology has been used to detect allele frequencies as low as 0.2% (Hiatt et al., 2013) and searching for mutations in another tissue type such as buccal cells may yield additional mutations not detected in blood. We have collected 51 blood samples, 10 buccal swabs, and are actively collecting more samples. We are also in the process of testing the smMIPS capture protocol and analysis pipeline for variant calling. It is likely that these studies with identify previously undetected mutations that will explain a subset of Dravet diagnoses.

1135S

Genome-wide linkage analyses of non-Hispanic White families identifies several novel loci for familial late-onset Alzheimer's disease. *J. Jaworski[1], B.W. Kunkle[1], C. Reitz[2], A.C. Naj[3], L.S. Cantwell[3], A. Partch[3], G.W. Beecham[1], E.R. Martin[1], W. Raskind[4], R.P. Mayeux[2], J.L. Haines[5], L.A. Farrer[6], G.D. Schellenberg[3], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Taub Institute of Research on Alzheimer's Disease, Columbia University, New York, NY, USA; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 4) School of Medicine, University of Washington, Seattle, WA, USA; 5) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH USA; 6) School of Medicine, Boston University, Boston University, MA, USA.

While more than two dozen loci that contribute to late-onset Alzheimer disease (LOAD) have been identified, few high penetrance variants (e.g., PSEN2 mutations) that explain risk in families heavily burdened with LOAD have been found. Linkage/identity-by-descent (IBD) sharing analyses in large multiplex pedigrees represent a well-powered set of designs to isolate regions and loci of interest for sequencing studies. In order to identify highly-shared regions among multiply-affected pedigrees for prioritized follow-up in the Alzheimer's Disease Sequencing Project (ADSP), we performed extensive parametric and non-parametric multipoint linkage analysis on 386 individuals in 42 non-Hispanic white (NHW) families (5-15 cases per pedigree).The 42 NHW families selected met three criteria: 1) exhibiting dominant inheritance of LOAD; 2) no mutations at known familial AD loci; and 3) low occurrence of the APOEε4 allele. All were among families selected for whole genome sequencing (WGS) through the ADSP and had available genome-wide genotyping of common variants on either the Illumina HumanHap 550 or 1M arrays. Linkage analyses were performed using MERLIN, and follow-up analyses of multipoint loci with NPLall/NPLpairs>2 included IBD sharing with Olorin in order to narrow regions of interest.Two-point parametric linkage analysis identified 16 regions with suggestive linkage (HLOD>3.5), including four regions (Chr3q25, 3q28, 4q34.3, and 11q13.4) with HLOD>4. Non-parametric multipoint analyses found two additional loci at 14q32.2 (LOD= 3.73) and 1q24.1 (LOD=2.31), and supported the 4q34.3 two-point LOD score (LOD=2.51). Haplotype analysis supported segregation in the top families for these regions. 11q13.4 is a newly reported linkage region and includes the gene SHANK2 which has been linked to regulation of synaptogenesis. IBD analyses for the strongest multipoint signal (14q32.2) implicated the gene BCL11B, a transcription factor and regulator of BDNF signaling, a pathway associated with pathogenesis of several neurodegenerative diseases. While these analyses identified several regions of linkage previously observed in AD, including 1q24.1, 3q25, 3q28, 4q34.3, and 14q32.2, we produced new evidence for linkage at 11q13.4 and narrowed a previously reported signal at 14q32 to the candidate gene BCL11B. Prioritizing these regions for follow-up in the ADSP sequence data may provide opportunities to identify highly penetrant variants for familial LOAD.

1136M

Microsatellites in the 5' flanking region of AVPR1A were associated with social behavior scales of autism spectrum disorders in the Korean population. *J. PARK[1], S. Kim[3], H. Ghim[4], Y. Jung[1], H. Yoo[1,2].* 1) Seoul National University Bundang Hospital, Biomedical Research Institute, Gyeonggi-do, South Korea; 2) Seoul National University College of Medicine, Seoul, South Korea; 3) Department of Pharmacology, Eulji University College of Medicine, Daejon, South Korea; 4) Department of Psychology, Chungbuk University, Chungju, Korea.

Background: Impairment in social interaction and communication is core features in autism spectrum disorder (ASD). The arginine vasopressin receptor 1A gene (AVPR1A) is widely expressed in the brain and is considered to be a key mediator for regulation of social behavior. Evidence from numerous organisms implicates relationship between microsatellites of the 5'-flanking region in the arginine vasopressin receptor 1A gene (AVPR1A) and social behavior and genetic variation at AVPR1A has been reported to be associated with autism. The objective of this study is to evaluate the relationship between microsatellites in the 5' flanking region AVPR1A and specific social phenotypes of ASD. Methods: Two microsatellites (RS3 and RS1) in the 5' flanking region of AVPR1A were examined in 218 Korean family trios comprising children with ASD and their biological parents. Behavioral phenotypes are derived from comprehensive measures of the behaviors, using Social Communication Questionnaire (SCQ), Asperger Syndrome Diagnostic Scale (ASDS), Social Responsiveness Scale (SRS), Child Behavior Checklist (CBCL), Autism Diagnostic Observation Schedule (ADOS), Autism Spectrum Quotient (AQ), Empathy Quotient (EQ) and Systemizing Quotient (SQ). In the family-based association test and haplotype analysis using FBAT, we tested association between microsatellites and 28 quantitative traits related with social behaviors. Potential confounding effects, including age, sex and IQ, were controlled as covariates. Results: We found a statistically significant association ($P < 0.05$) between microsatellites and multiple scales related with social behaviors. RS1 is significantly associated with 18 phenotypes (p's = 0.049 - 0.004) and RS3 markers with 5phenotypes (p's = 0.043 - 0.012). Both markers are significantly associated with Social domain score in ASDS (RS1: $P = 0.004$; RS3: $P = 0.012$) and AQ (RS1: $P = 0.034$; RS3 = 0.022). Total seventeen phenotypes were significantly associated in haplotype association analysis (p's= 0.049 - 0.009). Conclusion: We observed significant relationship between microsatellites and specific social behaviors in Korean ASDs. Our results support that RS1 and RS2 microsatellite markers AVPR1A gene can be possible candidates for diagnosis for social behavioral dysfunction and autistic trait of ASD.

1137T

X-Chromosomal genetic and epigenetic factors in the etiopathogenesis of ADHD. *J. Kapalanga[1,3,4], D. Wong[2,3], A. Gandy[2,3], S. Cato[4], N. Nwebube[4].* 1) Pediatrics/Genetics, Western University/GBHS, London, ON, Canada; 2) Pediatrics, Dalhousie University, Halifax, NS, Canada; 3) Summerside Medical Centre, Summerside, PEI, Canada; 4) Grey Bruce Health Services, Owen Sound, ON, Canada.

ADHD is a common neurobehavioral disorder and genetic factors are known to play a critical role in its etiopathogenesis. Molecular, twin, family and adoption studies have led to the conclusion that genetic factors contribute 70 to 80 percent susceptibility for ADHD. While certain genes have been linked to ADHD, specific mutations in specific genes on specific chromosomal regions have not been conclusively implicated. In clinic settings it is not uncommon to see families with several affected members. Assessment of ADHD patients often involves genetic testing including fragile X testing, array based comparative genomic hybridization and karyotype analysis. We report on 5 patients who presented with severe clinical symptoms of ADHD and were subsequently found to have Klinefelter syndrome. Patients were identified from a large clinic population who underwent laboratory investigations to determine a genetic cause to explain their neurobehavioral symptoms. Selection clinical criteria for genetic testing included at least four of the following: onset before age 6 years, inattention, hyperactivity, learning disability, aggressive and violent behavior, impulsivity, social difficulties, significant comorbidity, poor response to treatment. A total of 557 patients fulfilled the clinical criteria and underwent genetic testing including molecular testing for fragile X syndrome, array based comparative genomic hybridization and karyotype analysis. Five patients were found to have an XXY karyotype, two were found to have tri-allelic mutation in FMR1. All five patients presented with inattention and learning disability. Marked hyperactivity and aggressive behavior were not observed in all five patients. All five patients required at least one stimulant medication change. Despite heightened intensity of inquiry, genome-wide association studies, meta-analyses and individual candidate gene studies have to date not identified strong and consistent association of a specific gene with ADHD. This suggests genetic heterogeneity and/or polygenic influences on symptomatology. Further, epigenetic mechanisms could also be implicated in ADHD. In all cases ecogenetic factors most likely play a critical role. The findings in this study suggest that genetic and/or epigenetic factors located on the X-chromosome are involved in the etiopathogenesis of ADHD in at least a subset of patients, and that a gene dosage effect is the underlying molecular mechanism in these cases.

1138S

Personality Genetics and Health in Super Seniors. *J.M.T. Nelson[1, 2], A.R. Brooks-Wilson[1, 2].* 1) Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, British Columbia, Canada; 2) Genome Science, Canada's Michael Smith Genome Sciences Centre, Vancouver, British Columbia, Canada.

Background: Few seniors are free of chronic disease and the genetic factors that contribute to long term good health are not well understood. We have established a study of super seniors, individuals who are over the age of 85 who have never reported being diagnosed with Alzheimer disease, cancer, diabetes, cardiovascular disease or pulmonary disease. It is important to determine why some individuals age with many comorbidities and others with none at all. Longevity and health are associated with specific personality traits. Personality consists of a person's emotional, attitudinal and behavioural responses, which are related to neurotransmission in the brain. Genes that encode neurotransmitters, their receptors or affect processes in their metabolism are candidates for study on the effects of personality. Genetic variation in personality-related genes may affect health by influencing behaviour and lifestyle. Hypothesis: Genetic variants in genes involved in neurotransmission or that underlie personality disorders influence healthy aging. Objective: To determine if genetic variation in personality-related genes is associated with the super senior phenotype. Methods: 1) A literature search has been conducted for genes involved in the physiology of personality and personality disorders. Five neurotransmitter-related candidate genes have been chosen. In addition, a literature search was conducted for genome wide association studies (GWAS) of personality traits and personality related disorders. Single nucleotide polymorphisms (SNP) have been selected and include tag SNPs, SNPs that meet genome-wide significance in GWAS of personality traits, and SNPs that were associated with personality traits in more than one study. 2) Genotyping of the SNPs will be performed using the Sequenom MassArray method. Variable number random repeats will also be genotyped using PCR and fragment analysis. 3) We will test for association with the super senior phenotype using a set of 493 European-ancestry super seniors and 431 European-ancestry controls. Identifying personality-related genetic variants that influence healthy aging may lead to pharmacological opportunities to improve long term health in our aging population.

1139M

Gene-based pleiotropy across five major psychiatric disorders. *D.R. Nyholt, H. Zhao.* QIMR Berghofer, Brisbane, QLD, Australia.

Background Studies have indicated genetic overlap between the five disorders in the Psychiatric Genomics Consortium (PGC): autism spectrum disorder (ASD), attention deficit-hyperactivity disorder (ADHD), bipolar disorder (BPD), major depressive disorder (MDD), and schizophrenia (SCZ). In this study, we aimed to identify specific genes overlapping the five psychiatric disorders utilizing a novel gene-based approach. **Methods** Optimized gene-based tests were performed utilizing genome-wide association (GWA) results from the PGC analysis of single-nucleotide polymorphism (SNP) data for the five disorders in 33332 cases and 27888 controls of European ancestry. After accounting for correlation (i.e., non-independence) of gene-based test results due to linkage disequilibrium we examined the significance of the proportion of genes nominally associated across the five disorders. Pathway and network based analyses were performed on the sets of genes significantly overlapping the disorders. **Results** We found highly significant overlapping genes between SCZ and BPD, moderate overlap between SCZ and MDD, SCZ and ASD, MDD and ASD, and ADHD and BPD. After combining disorders as discovery sets, we found significant overlap across SCZ, BPD and MDD, across SCZ, BPD, MDD and ASD, and across BPD, MDD and ASD/ADHD. No significant overlap was observed between the individual adult-onset disorders and ADHD. Pathways implicated by the genes overlapping the adult-onset disorders include MAPK signalling, calcium signalling, dorso ventral axis formation, chemokine signaling, and melanogenesis. Pathways for BPD and ASD include glycosphingolipd biosynthesis globo series, and pathogenic Escherichia coli infection. Pathways implicated by genes overlapping BPD and ADHD include glutathione metabolism, and arachidonic acid metabolism. Additionally, combining gene-based association results across disorders identified numerous genes surpassing our cutoff for genome-wide significance. **Discussion** Utilizing a novel approach, we identified numerous genes associated across multiple psychiatric disorders. Our results extend previous findings from single SNP-based genetic overlap analyses by providing important insight into the likely genes and biological mechanisms underlying the observed genetic correlation and co-morbidity between these major psychiatric disorders.

Fine mapping of schizophrenia risk locus CSMD1 (rs10503253) in Indonesian samples revealed association with indels. *D.B. Wildenauer[1], A.A.A. Kusumawardhani[2], D.M.B. Wildenauer[1], B. Benyamin[3], S.G. Schwab[4], Indonesian Schizophrenia Genetics Consortium.* 1) University of Western Australia, Perth, Australia; 2) Department of Psychiatry, University of Indonesia, Jakarta, Indonesia; 3) Queensland Brain Institute, Brisbane, Australia; 4) Department of Psychiatry, University of Erlangen-Nuremberg, Germany.

Schizophrenia is a devastating complex genetic disorder with a highly polygenic background. Recent GWAS findings in large combined Caucasian samples suggested rs10503253, located in the intronic region of the CUB Sushi and multiple domains 1 gene (CSMD1) on 8p23.2 as a risk locus for schizophrenia. We hypothesized that risk loci detected in Caucasian samples are also evident in samples from a different ethnic background. Our sample comprised 1067 individuals with schizophrenia and 1111 non-affected controls consecutively ascertained in five Mental State Hospitals in the area of greater Jakarta, Indonesia. Structured interviews (DIP in Bahasa translation) were performed in all cases and consensus diagnosis made according to the DSMIV criteria by psychiatrists. Using a test panel with 374 evenly spaced SNPs (Illumina) all samples were tested for genotyping quality and sampling errors. Principal component analysis revealed ethnical homogeneity of cases and controls with close relationship to East Asian populations (genomic inflation factor 1.02). Association of rs10503253 at 8p23.2 was confirmed (P =0.0086, same marker, same allele). For fine mapping, we selected 22 SNPs in the region (4.17-4.225Mb) and genotyped these using Taqman technology. Lowest P-value was obtained for rs10102283 (nominal p=0.00083, p=0.02 adjusted for multiple testing), which is 2.582kb apart from rs10503253. Next we analysed the region further by imputing with variants identified in this region in Asian individuals by the 1000 genome project. We selected 134 variants with info≥0.9. Four indels (MAF around 0.45) in the association peak (1.4kb) revealed nominal p-values from 10^{-4}-10^{-5} (P ~ 0.005 after adjusting for multiple testing). Odds ratios were in the range of 1.4. CSMD1 is expressed predominately in the brain. The protein plays a role in complement activation and has been found to be a binding site for micro RNAs. Even though the indels are intronic, they may affect structure of the gene with consequences for transcription and thus quantitatively influence the function of the protein in complement activation.

1141S

Transethnic HLA comparison in narcolepsy. *H.M. Ollila[1], J. Faraco[1], J. Ravel[1], F. Han[2], L. Lin[1], J. Hallmayer[1], E. Mignot[1].* 1) Stanford University, Palo Alto, CA., Select a Country; 2) Department of Pulmonary, Critical Care Medicine, Peking University People's Hospital, Beijing, China.

Narcolepsy is an autoimmune sleep disorder, which is characterized by severe daytime sleepiness. Recently, the onset of narcolepsy has been associated with the 2009 H1N1 influenza. In addition, it is strongly associated with Human leukocyte antigen (HLA) DQB1*06:02, and over 98 percent of narcoleptics carry this haplotype. However, the role of other HLA loci has remained unresolved. The aims of this study were to study the contribution of various HLA haplotypes to narcolepsy and clinical phenotypes related to narcolepsy. We used direct HLA genotyping and HLA imputation. The study was performed in Caucasian and Asian samples comprising altogether over 3000 cases and 10000 controls. Clinical phenotypes included age of onset, hallucinations, onset after vs. before 2009, absence of cataplexy, sleepiness and sleep paralysis. We found that DQB1*06:02 effect was strongly modulated by DQA1 genotype so that those carrying DQA1*01:02 had highest risk and those with DQA1*01 non 01:02 were protected from narcolepsy, suggesting allelic competition in narcolepsy. Analysis of clinical phenotypes revealed that cases carrying DQB1*03:01 had nearly two years earlier age of onset. DQB1*06:02 was rarer in individuals that got narcolepsy after 2009. The findings highlight the importance of HLA in the etiology of narcolepsy. Analysis of HLA-A, B, C and HLA-DP loci are ongoing.

Comparative sequencing of the *PARK2/PARCRG/QKI* locus in Early Onset Parkinson's disease. *W.C. Macedo[1,2], M.E.D. Sauer[1], H.A.G. Teive[3], R.P. Munhoz[4], C.M. Probst[5], M.T. Mira[1].* 1) Graduate program in health sciences, Pontifícia Universidade Católica do Paraná - PUCPR, Curitiba, Paraná, Brazil; 2) Department of Genetics, Universidade Federal do Paraná - UFPR, Curitiba, Paraná, Brazil; 3) Department of Neurology, Hospital de Clinicas - UFPR, Curitiba, Paraná, Brazil; 4) Associação Paranaense dos Portadores de Parkinsonismo - APPP, Curitiba, Paraná, Brazil; 5) Department of Genomic and Bioinformatics, Instituto Carlos Chagas - FIOCRUZ-PR, Curitiba, Paraná, Brazil.

Early Onset Parkinson's disease (EOPD [MIM 600116]) is a neurodegenerative disorder characterized by death of midbrain dopaminergic cells and clinical outcome before 45 years of age. EOPD is under strong genetic control; mutations in the *PARK2* gene have been consistently associated with familial and non-familial autosomal recessive EOPD cases. Interestingly, an attempt to reproduce PD in *Park2* knockout mouse strain has failed. On the other hand, the Qk^{v} mice, which develops vigorous limb shaking a few days after birth, are carriers of a spontaneous, recessive deletion of Quaking (*Qk*), *Pacrg* and *Park2* neighboring genes located at *chr17A*. In humans, these three genes are also adjacent to each other and located at *chr6q25-q27*, homologous to the murine *chr17A*. We hypothesized that mutations in human *QKI* and/or *PACRG*, together or not with *PARK2* mutations, are necessary or sufficient for the development of EOPD. To investigate this hypothesis, we performed comparative sequence analysis of the coding sequences of *QKI*, *PACRG* and *PARK2*, seeking for potentially pathogenic variants. Study sample was composed by two DNA pools: one including 36 EOPD cases and the other, 17 individuals with age higher than 65 years, free of any neurodegenerative disease. Sequencing was conducted as implemented at the Ion PGM platform. Primary data was subjected to a filtering protocol designed to eliminate sequencing artifacts; variants approved by the quality filters were subjected to *in silico* prediction analysis, searching for changes in regulatory sites of mRNA, splicing sites and polypeptide sequence. A total of 82 variants were identified and 38 were validated by the quality criteria (seven new and 31 known). From this set, functional high impact variants were only found in *PARK2*; two of them were selected for further investigation: a nonsense c.1198C>T and a frameshift c.1277delA. These novel mutations, located on exon 11, were found only in the patient pool. In both cases, the functional predicted impact was of complete abolishment of enzyme activity. To validate these mutations, Sanger sequencing was conducted on an expanded sample of 55 controls and 41 patients. As a result, the c.1198C>T mutation was validated in two heterozigous patients. Our findings reveal a novel mutation that may predispose humans to non-familial EOPD, corroborating the evidence that suggests that *PARK2* variants alone are responsible for the role of the *6q25-q27* locus in the pathogenesis of EOPD.

1143T

Strategies for identifying new genes in autosomal recessive Parkinson's disease. *S. Lesage[1,6], A. Nicolas[1], M. Sabahtou[2], V. Drouet[1], C. Pujol[1], F. Cormier[1,3], E. Lohmann[4], M. Tazir[5], A. Dürr[1,6], O. Corti[1], E. Kabashi[1], A.L. Leutenegger[2], A. Brice[1,6], French PDG group.* 1) U1127, INSERM, Paris, Paris, France; 2) Inserm UMR_S946, Fondation Jean Dausset, Paris, France; 3) Centre d'Investigation Clinique Pitié Neurosciences, CIC-1422, Paris, France; 4) Behavioural Neurology and Movement Disorders Unit, Department of Neurology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; 5) Faculté de Médecine, Université d'Alger, Algier, Algeria; 6) AP-HP, Pitié-Salpêtrière Hospital, Department of Genetics and Cytogenetics, Paris, France.

BACKGROUND: In recent years, understanding of the genetics and the physiopathological mechanisms underlying molecular defects in Parkinson's disease (PD) has greatly advanced, since 10 genes are now confirmed to cause monogenic forms of PD, including 4 (Parkin, PINK1, DJ-1 and ATP13A2) associated with early-onset (EO) PD cases with autosomal recessive (AR) inheritance that account for only ~40% of AR EO PD cases. Thus, a significant proportion of cases with inherited PD remain unexplained genetically. AIM: To identify novel genes implicated in AR forms of PD. PATIENTS AND METHODS: 1) Subjects: We selected 140 EO (<55 years) PD families or isolated cases with known or suspected consanguinity, excluded for Parkin, PINK1, DJ-1 and the LRRK2 G2019S mutation and fulfilled quality and quantity controls; 2) Genome-wide SNP genotyping and homozygosity mapping: SNP genotyping was performed using Illumina HumanCytoSNP-12 BeadChip. Inbreeding coefficients F estimated by FEstim and multipoint genetic linkage analyses were computed with FLOD; 3) Search for rare rearrangements using the same DNA microarrays and the Illumina cnvPartition module; 4) Whole exome sequencing was performed in a subset of 60 PD families with confirmed consanguinity, using Agilent technologies and Illumina Hiseq2000; 5) Validation of 10 best candidate genes by functional testing candidate genes in zebrafish. Morphans are phenotyped for lethality, abnormalities in the body axis, touched-induced and spontaneous motor behaviour and loss of TH+ cells; 6) Replication in an independent set of 200 EO AR PD families and 400 patients with apparently sporadic EO PD using medium-throughput sequencing and establishment of the mutational spectrum and frequency of each new gene and phenotype/genotype correlations. RESULTS: We looked for rare homozygous mutations that are assumed to affect the protein sequence and fell within identified regions of homozygosity. Preliminary analyses of exome data from consanguineous families have led to the identification of deleterious mutations in ATP13A2, FBXO7 in 2 affected sibpairs and a list of 40 best candidate genes. Zebrafish testing for one of them showed a phenotype. CONCLUSION: As a proof of concept, we identified a list of known and novel candidate genes for PD which validation is in progress. The identification of new genes involved in AR PD will represent a major advancement that will permit the development of new molecular diagnostic strategies.

1144S

Could somatic copy number alterations contribute to sporadic Parkinson's disease? *C. Proukakis[1], K. Gancheva[2], C. Grace[2], D. Pease[1], D. Brazma[2], E. Kara[1], J.W. Taanman[1], H. Houlden[1], A.H. Schapira[1], E. Nacheva[2].* 1) Institute of Neurology, University College London, London, United Kingdom; 2) 2Academic Department of Haematology, University College London, United Kingdom.

Objective: to determine feasibility and sensitivity of detecting somatic copy number alterations (CNAs) in Parkinson's disease brain. Background: Parkinson's disease (PD) is usually sporadic, and despite heritability estimates of around 30%, the majority of the cases are unexplained. Alpha-synuclein (SNCA) protein is central to pathogenesis, but *SNCA* missense mutations and copy number variants (CNV) are rare. We have recently hypothesised that mosaicism due to post-zygotic somatic mutations in early embryogenesis in the neuronal cell lineage could contribute to pathology. We have already screened over 500 brain samples for somatic coding *SNCA* mutations, without detecting any. There is, however, recent clear evidence of somatic CNAs in brain, which are methods would not have detected, but their role in diseases remains unknown. Methods: We have designed a custom Agilent CGH array with dense spacing of probes for PD-related genes, including *SNCA* and *PARK2*. Dilution of DNA from a *SNCA* duplication carrier with wild-type to give various levels of increased *SNCA* DNA (thus creating artificial mosaics for CNAs) allows determination of the sensitivity, and comparison of different analytical methods. To determine if interphase cell FISH (fluorescent in situ hybridization) can allow reliable detection of lower level mosaicism, probes for *SNCA* and *PARK2* will first be tested on fibroblasts with known CNVs. Results: Our array can detect 7.5-15% increase of *SNCA* genomic DNA, depending on the analytical settings used. FISH probes for *SNCA* and *PARK2* have been verified in both normal and positive control fibroblasts. Reproducible data can be obtained by FISH analysis of substantia nigra. Conclusions: We have developed methods and tools to allow us to further investigate our hypothesis of somatic CNAs in sporadic PD cases.

1145M

Whole-genome sequencing to identify genes implicated in Familial Parkinsonian Tauopathy. *M. Sanchez-Contreras[1], S. Fujioka[1], C. Pottier[1], A.J. Strongosky[2], B.F. Boeve[3], J.E. Parisi[3], P.M. Tacik[1], N. Aoki[1], M. Baker[1], V. Sossi[4], D.W. Dickson[1], A.J. Stoessl[5], O.A. Ross[1], Z.K. Wszolek[2], R. Rademakers[1].* 1) Department of Neuroscience, Mayo Clinic Jacksonville, FL; 2) Department of Neurology, Mayo Clinic Jacksonville, FL; 3) Department of Neurology, Mayo Clinic, Rochester, MN; 4) Department of Physics and Astronomy, University of British Columbia, BC, Canada; 5) Pacific Parkinson's Research Centre, Division of Neurology, University of British Columbia & Vancouver Coastal Health, BC, Canada.

Tauopathies are a group of neurodegenerative disorders characterized by the pathological inclusions of phosphylated tau protein. In some entities, as Alzheimer's disease, genetic variants have been proposed to contribute to tau pathology. However, genetic causes of other less common tauopathies, as Progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD), are poorly understood. To identify novel causal genes implicated in tauopathies, we provide a detailed study of a large family of 64 individuals with 8 affected patients with an inherited tauopathy that is likely autosomal dominant with reduced penetrance. The index case developed progressive speech and language difficulties at age 64 years. Examination 4 years later disclosed non-fluent aphasia, word-finding difficulties, circumlocution, frontal release signs, and right-sided bradykinesia, rigidity, and pyramidal signs. She died 5 years after the symptomatic onset. Neuropathologic features included numerous ballooned neurofilament-positive neurons, tau-positive astrocytic plaques, and oligodendroglial coiled bodies, all typical of CBD. Two other family members were diagnosed clinically with Parkinsonism and behavioral problems, 2 with Parkinson's disease, 1 with amyotrophic lateral sclerosis, 1 with dementia, and 1 with progressive gait and speech problem. DNA was available from the proband and one first-degree cousin, clinically diagnosed with dementia and Parkinsonism at the age of 54. After exclusion of mutations in MAPT, PGRN and LRRK2 in these affecteds, we performed whole-genome sequencing. Analysis of the genomes of these patients resulted in a list of novel and rare variants that were shared among the affecteds and follow an autosomal dominant inheritance pattern. This list of potential tauopathy variants was confirmed by Sanger sequencing and subsequently screened in a series of >750 population controls which resulted in a total of 6 confirmed-variants which were absent or very rare in controls: SCN10A, OPRK1, CAPRIN2, UBN1, NEURL4 and CCDC9. The presence of additional variants in these candidate tauopathy genes currently is being studied in a series of pathologically-confirmed CBD and PSP cases as well as in 3 additional tauopathy families. This approach provides a select list of potential tauopathy genes by whole-genome sequencing in a family with pathologically confirmed CBD that may help identify novel pathways involved in pathological tau aggregation.

1146T

Distinct genetic variants in Alzheimer's disease, Parkinson's disease and type 2 diabetes. *S.J. Chung[1], S.Y. Kim[2], J. Kim[1], M.J. Kim[3], Y. Kim[1], J.H. Lee[1].* 1) Neurology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea; 2) Psychiatry, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea; 3) Neurology, Bobath Memorial Hospital, Seongnam, South Korea.

Insulin and insulin-like growth factor contribute to normal brain function. Recent experimental and clinical studies demonstrated the possible link between T2DM and Alzheimer's disease (AD). Experimental evidence also indicates that T2DM and Parkinson's disease (PD), both age-related chronic diseases, share similar dysregulated pathways. Epidemiological researches also demonstrate that T2DM is associated with an increased risk of PD. We aimed to investigate whether genome-wide significant loci of type 2 diabetes mellitus (T2DM) are associated with AD and PD. Study subjects were 400 AD cases, 500 PD cases, and 500 unrelated controls without the evidence of any cognitive impairment or neurological diseases. All subjects were ethnic Koreans. We selected 32 genetic variants from 10 genes (*CDKAL1, CDKN2B, FTO, GLIS3, HHEX, IGF2BP2, KCNJ11, KCNQ1, SLC30A8,* and *TCF7L2*) and intergenic regions based on results of the recent genome-wide association studies (GWAS) in T2DM. These variants were reported to be T2DM-susceptibility loci and were replicated by other independent studies. Two *APOE* SNPs (rs429358 and rs7412) were also genotyped to adjust the *APOE* ε4 status in association analyses using AD cases. All association analyses were performed using logistic regression models, adjusting for age, sex. There was no significant association of each genetic variant of GWAS-linked loci in T2DM with AD or PD. The *KCNQ1* SNP rs163182 showed nominal significance (P = 0.0084) in unadjusted analysis using AD cases and controls, but it did not remain significant after the adjustment for age, sex, and *APOE* ε4 status. Two *APOE* SNPs showed significant associations with AD. Our results suggest that genome-wide significant loci of T2DM have no major role in AD or PD. Further studies are needed to confirm these findings.

1147S

Defects of *ARHGAP36* in patients with developmental delay and autism. *S. Fan[1], L. Dukes-Rimsky[1], R.C. Rogers[1], A. Chaubey[1], C. Skinner[1], L. Wang[2], A.K. Srivastava[1,2].* 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC.

Rho family GTPase activating proteins (GAPs) are known to regulate physiological processes including embryogenesis, neurodevelopment, cytokinesis and differentiation and act as negative regulators of Rho GTPases. Several genes implicated in intellectual disability (ID) and autism spectrum disorders code for proteins that function as regulators or effectors of Rho GTPases. ARHGAP36 is one of approximately 70 Rho family GAPs in human with uncharacterized biological functions. Using the Affymetrix Genome-wide SNP 6.0 Microarray system, we identified a copy number loss of approximately 770 kb on chromosome Xq25q26.1 in a 5-year-old male patient with mild fine motor and speech delay, macrocephaly, hypothyroidism, autism, and significant ADHD. The deletion included the *ENOX2*, *ARHGAP36*, and *IGSF1* genes. The proband's normal mother carried the deletion and showed a random X inactivation pattern. We found the identical deletion in the proband's 28-month-old brother with speech delay and macrocephaly. Furthermore, the NCBI ClinVar database lists a copy number loss located in a similar genome region encomapssing *ARHGAP36*, *IGSF1*, and *OR13H1* genes in a patient with hearing impairment and language delay. We screened the *ARHGAP36* gene for mutations in approximately 249 male patients with ID and 245 male patients with developmental delay/autism and identified a novel missense alteration, c.1316G>A (p.R439H), in a 16-year-old male patient with absent speech, hyperactivity and autism. The alteration was absent in 6500 individuals in the NHLBI dataset. Defects of *IGSF1* have been reported in male patients with congenital central hypothyroidism. Thus, the deletion of the *IGSF1* gene is likely responsible for hypothyroidism in the proband and we speculate that his younger brother is also likely to develop hypothyroidism. To understand the physiological function of *ARHGAP36*, we further determined *ARHGAP36* expression in several tissues including human fetal brain. We identified and analyzed genes that are co-expressed with *ARHGAP36*. On the basis of probe-to-probe correlation coefficient calculated from an integrated set of 2,968 microarray expression profiles of healthy human tissue samples, we found that *ARHGAP36* was co-expressed with genes significantly enriched with Gene Ontology terms including synapse, postsynaptic membrane, synaptic transmission and neurogenesis. Altogether, our findings suggest a potential role for the *ARHGAP36* gene in developmental delay and autism.

1148M

HIV-related cognitive impairment shows association with polymorphisms within the dopaminergic system in substance dependent and independent populations. *M.M. Jacobs[1], M. Pizzirusso[1], J. Murray[1], S. Morgello[1,2,3].* 1) Neurology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Pathology, Icahn School of Medicine at Mount Sinai, New York, NY.

It has been postulated that drugs of abuse act synergistically with HIV, leading to increased neurotoxicity and neurocognitive impairment. The CNS impacts of HIV and drug use converge on the mesocorticolimbic dopamine (DA) system. Using an advanced-stage HIV+ population, previous studies in our laboratory have implicated a role of polymorphisms of two receptors within this system (DRD1 and DRD2) and neuropsychological performance as well as opiate and cocaine dependence. To replicate and expand these studies, we have increased our sample size and added additional polymorphisms within several genes of the dopaminergic system (DRD1-5, COMT, DAT). We observed that polymorphisms of DRD2 are associated with opiate and cocaine dependence in our population. In Caucasian subjects, we observe significant associations for opiate and cocaine dependence with polymorphisms within DRD2 and COMT genes, while a significant association within the DRD1 gene was observed in African-American individuals. Using linear regression analysis, we next examined these polymorphisms for associations with neuropsychological performance in global and cognitive domain T-scores (Motor, Processing Speed, Verbal Fluency, Learning, Memory, Executive Functioning, Working Memory) while controlling for opiate and cocaine dependency. While significant associations were observed in nearly every domain across both populations for multiple polymorphisms, the most significant effects in Caucasian subjects were observed in the motor domain with several DRD2 polymorphisms while African-American subjects had its most significant associations in working memory (COMT and DRD3) and memory (DRD1) domains. For all of these associations, the effects differed for substance dependence groups as the direction of the correlations were opposite to what was seen in subjects without dependency. Future studies will focus on increasing the sample size of the population as well as increasing the number of genes within the dopaminergic circuitry. We conclude that studies to examine genetic risk for HAND must carefully account for substance dependence patterns when assaying dopaminergic systems, as the neurobiological substrates of cognition in HIV populations may vary with tonic alterations secondary to chronic substance exposures.

1149T

HLA-DRA is strongly associated with Parkinson's disease in Iranian population. *J. Jamshidi[1], H. Darvish[2], B. Emamalizadeh[2], A. Movafagh[2].* 1) Department of Biochemistry, Fasa University of Medical Sciences, Fasa, Iran; 2) Department of Medical Genetics, Faculty of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Background and Objective: Parkinson's disease (PD) is a progressive neurodegenerative disorder which impairs the patient's motor skills. The rs3129882, a noncoding variant in HLA-DR, was found to be associated with PD using several genome-wide association studies (GWAS). The aim of this replication study was to explore the relationship between this variant and PD in Iranian population Materials and methods: The study was performed on 520 unrelated patients and 520 healthy controls. The mean age of patients was 59.5±14.5 years and were composed of 278 men and 242 women. The diagnostic criteria for PD were based upon the UK Parkinson's disease Society Brain Bank Clinical Diagnostic Criteria. Genomic DNA was extracted from peripheral blood using a standard salting out method. The rs3129882 variant was genotyped through polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP). We examined the association of rs3129882 (A/G) with the risk of PD, under four models (codominant (G/G vs. G/A vs. A/A), dominant (A/A or G/A vs. G/G), recessive (G/G or G/A vs. A/A) and overdominant (G/G or A/A vs. G/A) using SNPassoc package of R version 3.0.1. Odds ratio (OR) together with 95% confidence interval (CI) was Estimated; and a $p < 0.05$ was considered as statistically significant for the tests. Results: Distributions of the rs3129882 (A/G) polymorphism in both PD and control group were in Hardy-Weinberg equilibrium. The alleles frequencies of rs3129882 (A/G) were distributed differently in PD group and control group ($\chi 2 = 4.641$, OR=1.209, 95% CI: 1.017-1.436, $P = 0.035$), and under codominant, dominant and overdominant models the association of the SNP with PD risk was significant, where the A allele was observed to be protective. Discussion: HLA is associated with numerous neurologic disorders and association of HLA with Parkinson's disease was recently revealed. Our result suggests that the rs3129882 (A/G) polymorphism may be a risk factor for PD in Iranian population. It is assumed that the intronic variant plays a role as a cis-acting regulatory element which correlates significantly with overexpression of DR antigens in substantia nigra. The finding is not so far beyond expectation because of the previous evidences for involvement of neuroinflammation and adaptive immunity in PD pathogenesis. This association emphasizes an important biological pathway in the etiology of the disease and points to a potential target for new therapies.

1150S

Ancestral haplotypes of BHLHE40 in non-24-hour rhythms and bipolar disorder. *D.F. Kripke[1], S.A. Ament[2], C.M. Nievergelt[1], J.R. Kelsoe[1].* 1) Psychiatry, UCSD, La Jolla, CA; 2) Institute for Systems Biology, Seattle, WA.

A previous study (Kripke et al., Psychiatry Investigation, in press, 2014) demonstrated a haplotype group in the circadian gene BHLHE40 that was associated with patients displaying non-24-hour free-running circadian rhythms. This haplotype group and several of its SNVs were also nominally associated with bipolar disorder. The only exonic variant of the 16 in the haplotype group, rs908078, is a synonymous variant which may alter splicing. Also, several of the variants may alter transcription binding sites. With further study of the haplotypes, we now found that 7 of the 16 key minor variants were identical with the chimpanzee reference, and 6 matched the reference allele of the majority of 9 non-human primates. Each of these 7 variant alleles was also reported at least once in available early sequencing data from 3 Neanderthals and the Denisovan, so they likely have an ancestral primate origin. According to 1000 Genome data (Phase 1), 5 of the 7 minor alleles are distinctly more common among Africans than Europeans or Asians. In sum, current data suggest that these 7 SNVs are of ancestral origin but have been negatively selected in modern humans, particularly outside the tropics. Perhaps altered circadian dynamics were favored after the discovery of fire and especially after migration to more northern latitudes where more time must be spent inside shelters. This would not be surprising, since Drosophila and several small mammals have recognized genetic variability among populations related to adaptations to latitude and photoperiod. Whole-genome sequencing of BHLHE40 was now examined 325 members of multiplex bipolar disorder pedigrees, among whom 74 individuals displayed these SNVs, but the sequenced pedigrees are not yet sufficient to examine association powerfully. Recent PGC GWAS analyses have given no support to any BHLHE40 variant association with bipolar disorder, but Seifuddin et al. (2013) found a nominally-significant association with down-regulated brain BHLHE40 by summarizing studies of bipolar disorder. Since the ancestral haplotype group has not been well represented in GWAS studies, further replication of expression studies and expanded studies with whole-gene-region sequencing will be needed to clarify the import of BHLHE40 for circadian and affective disorders.

1151M

***MAPT* non-coding variation in neurodegenerative disorders.** *C. Labbé[1], M. Heckman[2], K. Ogaki[1], O. Lorenzo-Betancor[1], A. Ortolaza[1], R. Walton[1], D. Serie[2], R. Uitti[3], Z. Wszolek[3], O. Ross[1].* 1) Neuroscience, Mayo Clinic Florida, Jacksonville, FL; 2) Section of Biostatistics, Mayo Clinic, Jacksonville, FL; 3) Neurology, Mayo Clinic, Jacksonville, FL.

Genome-wide association studies have identified over 20 loci associated with increased risk to sporadic Parkinson's disease (PD). The *MAPT* gene is in one of the most systematically replicated locus in PD. The gene encodes protein tau which aggregate in brain inclusions and define the neurodegenerative diseases called tauopathies. A common non-recombining *MAPT* haplotype (*MAPT* H1) has been associated to several tauopathies including progressive supranuclear palsy (PSP); yet *MAPT* H1 has also been implicated in the risk to Parkinson's disease (which is not a traditional tauopathy). Preliminary sub-haplotype analyses suggest that different genetic variants on the *MAPT* H1 haplotype associate with each of these disorders. To date it remains unclear which variant(s) at the *MAPT* locus is(are) responsible for the risk and what is the underlying pathomechanism of disease. We set out to identify causal variants for PD and PSP within the *MAPT* region using next generation sequencing technologies. We captured the entire *MAPT* gene and 10kb on each side, a 154kb genomic region that was sequenced in 300 patients with PD, 300 patients with PSP, and 300 controls using a pooling strategy (10 DNA samples/pool). We designed 4248 amplicons using the Haloplex platform followed by Illumina sequencing for a total coverage of 96.3%. We identified over 4000 variants in the coding, intronic and surrounding region of the *MAPT* gene. Among these variants 39% are singletons, 19% have a minor allele frequency between 1% and 5%, and 42%, over 5%. We identified 43 variants located within 25 base pairs of an intron/exon boundary, some of which map to boundaries of the well-known excised exons 2, 3, 4a, 6, 8 and 10. We selected SNPs for stage 2 based on association tests and are using the OpenArray platform to genotype the variants in our replication series consisting of a total of 4500 independent samples. We will present results using the latest sequencing and genotyping technologies to comprehensively define the *MAPT* locus associated with PD and PSP and thus identify novel targets for both neuroprotective and symptomatic therapies.

1152T

9.6% of mouse gene knockouts show abnormal neuroanatomy: a resource to identify genes related to intellectual disability in human. *A. Mikhaleva[1], A. Baud[2], V. Vancollie[3], A. Edwards[4], M. Kannan[5], H. Whitley[5], C. Wagner[5], A. Duret[5], I. Herr[1], K. Navarro[1], A. Delay[1], S. Jayaram[1], J. Estabel[3], D. Wright[6], D. Fairley[6], C. Lelliott[3], J. White[3], D. Adams[3], D. Keays[7], J. Flint[4], Y. Herault[5], A. Reymond[1], B. Yalcin[1,5].* 1) Center for Integrative Genomics, University of Lausanne, Switzerland; 2) EMBL-European Bioinformatics Institute, Hinxton, Cambridge, CB10 1SD, UK; 3) Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1HH, UK; 4) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN, UK; 5) Institute of Genetics and Molecular and Cellular Biology, Illkirch, 67404, France; 6) HistologiX Ltd, Biocity, Nottingham, NG1 1GF, UK; 7) Research Institute of Molecular Pathology, 1030 Vienna, Austria.

Although intellectual disability affects 1-3% of the population, it is one of the least understood health problems. It is estimated that genetic lesions account for half of the currently undiagnosed cases. Despite recent successes in identifying some of the mutations responsible, it has been suggested that up to 1,000 more genes remain to be uncovered. The large number of intellectual disability syndromes is due to many causal pathophysiological mechanisms. The diversity of mechanisms results in an array of quantifiable neuroanatomical abnormalities. To identify genes related to intellectual disability, we are collaborating with the Sanger Mouse Genetics Project (MGP), allied to the International Mouse Phenotyping Consortium (IMPC), to systematically study the neuroanatomy of the MGP/IMPC knockout mouse strains using a standardized set of 78 brain parameters. So far, we have assessed brain defects in 425 knockout mouse mutants (this number will double by the end of 2014). These preliminary data yielded success with the identification of 20 known intellectual disability genes including Ap4e1, Cenpj, Chd7, Mcph1, Sc4mol and Ube3b demonstrating the pertinence of our approach. We also discovered 21 other genes including Mta1, Ccdc104, Caprin2 and Dusp3, which when disrupted caused modification of brain structures. Our study is the largest screen of brain morphology from the MGP/IMPC. It shows that we can detect abnormalities in about 10% of knockout mouse mutants, and that these translate into human pathology. This offers a complementary resource to human genetic studies.

1153S

Homozygous deletions of non-coding transcriptional control sites in autism spectrum disorder. *K. Schmitz-Abe[1,2,3,4,7], M. Chahrour[1,2,3,4,5], S. Hill[1,2,3], G. Sanchez-Schmitz[1,3], J. Partlow[1,2,3], B. Mehta[1,2,3], S. Servattalab[1,2,3], A. Lam[1,2,3], E. Morrow[8], T. Yu[1,2,3,4,5,6], C. Walsh[1,2,3,4,5], K. Autism spectrum disorder (ASD) is characterized by extensive genetic heterogeneity. A subset of ASD has been linked to disruptions of gene coding regions by de novo copy number variants (CNVs), de novo single nucleotide variants (SNVs), or inherited biallelic SNVs but most cases remain unexplained. We analyzed CNVs in 183 consanguineous families with ASD and found that individuals affected with ASD have significantly more homozygous deletions compared to unaffected siblings [22% vs. 15%]. This excess suggests that homozygous deletions might account for up to 7% of ASDs in our cohort. In contrast to most de novo CNVs and SNVs, we found that the homozygous deletions often did not include exons, but were enriched for DNA regulatory regions, with 12 of 16 disrupting ENCODE regulatory elements, a rate much higher than expected by chance (bootstrap $p<0.05$). Specifically, we cross-referenced the 16 deletions with histone modification marks from the ENCODE project. We selected H3K4Me1, H3K4Me3, and H3K27Ac as three of the best characterized histone modifications corresponding to states of gene transcription and enhancer activity, and then examined ChIP-Seq data gathered from 7 cell lines (GM12878, H1-hESC, HSMM, HUVEC, K562, NHEK, NHLF). Our data suggest an important new mechanism of ASD, and highlight the importance of patterned gene activation in cognitive and social function.

VGF as a potential target for Night Eating Syndrome. *G.J. Wyckoff, S.B. Mullegama.* MBB, SBS, University of Missouri- Kansas City, MO.

In recent years, clinicians and researchers have realized that a significant number of individuals with eating disorders did not fit into DSM categories of anorexia nervosa and bulimia nervosa. By default, many received a diagnosis of “eating disorder not otherwise specified.” Nonetheless Eating Disorders(ED) have biochemical indicators such serotonin, norepinephrine, dopamine. Deeper analyses of EDs in recent years have shown that there are genes that may play a role in ED. Night Eating Syndrome is specifically characterized as a “delayed circadian pattern of food intake”, and it may be part of a broader spectrum of sleep-related eating disorders. Identification of genes that may be related to Night Eating syndrome should be undertaken to help determine treatment and diagnosis options. To gather preliminary data for this question, we collected data from the Gene Expression Omnibus (GEO). The GEO website has a feature named GEO2R that does some analysis of datasets. The GEO2R does a normalization of data with a log2 transformation along with a Benjamini & Hochberg (False discovery rate) plus adding annotation. GEO2R provides the R script of the online process that GEO2R performed for the particular dataset. In order for the GEO2R to perform analysis, experimental groups must be assigned. The datasets that were selected for the most part had the design of control versus experimental group. Thirteen relevant datasets from GEO were passed through the GEO2R online application. Following analysis, genes of interests were selected by using the criterion of $|z| \geq 5.5$, which is well above $|z| \approx 5$ that corresponds to a Bonferroni-corrected P value of 0.001. The analysis of the datasets resulted in 44 genes that are possible candidates for further studies. An extensive literature search and further review suggests that the most interesting of the 44 genes collected is the gene VGF, which is associated with biological processes such as glucose homeostasis, insulin secretion, response to dietary excess, and has been shown to be under the control of the circadian clock in mammals.

Background: Our aim was explore the role of HTR2C gene in pathogenesis of suicidal behavior through a study association in Mexican population and to get a more comprehensive data we conducted a meta-analysis and a systematic-review with up-do-date outcomes. Methods: A number of 192 suicide attempters and 207 healthy volunteers were included. Regarding to meta-analysis and systematic review was collected 1,604 cases and 2,143 controls for them study. Results:In Mexican population we found a significant association in the allelic distribution of the polymorphism ($p=0.03$ and $X2= 4.34$) and also in the common haplotype AACGC ($p = 0.01$ and $X2= 5.51$). In the meta-analysis not associatión was observed between HTR2C variant gene and allelic, additive, dominant and recessive models. Conclusions: Even we did not find an association in the meta-analysis, in Mexican population it could be suggest a possible role of the HTR2C gene that collaborate in the pathology of suicidal behavior. The lack association of the meta-analysis it could be because may be the expression of this gene could depend of the ethnic.

Replicative association analysis of schizophrenia in Russian population of Siberian region. *A. Bocharova, A. Marusin, V. Stepanov.* Research Institute of Medical Genetics, Tomsk, Russian Federation.

Introduction. Schizophrenia is a common neuropsychiatric disorder. The etiology of schizophrenia as presently defined is not well understood. It is a complex disease with genetic, environmental and lifestyle factors. Common psychiatric and neurological disorders including schizophrenia are the subject of intensive genetic research based on genome-wide association studies (GWAS) and targeted resequencing of genomic regions of interest. Genetic variants associated with cognitive impairments, which are an important endophenotypes for schizophrenia, also have been revealed by GWAS. The aim of this study was to analyze associations of 15 SNPs reported in GWAS with schizophrenia in Russian population of Siberian region. **Subjects and Methods.** 15 SNPs strongly associated with schizophrenia and cognitive performance according to recent GWA studies were genotyped by real-time PCR in Russian patients with schizophrenia (N = 114) and in healthy control group (N = 285). DNA samples were genotyped using TaqMan® SNP Genotyping Assays (Applied Biosystems) under condition recommended by the manufacturer. Allele-specific ORs and associated p values were calculated. **Results.** The association of rs2616984 located in the region of CUB and Sushi multiple domains 1 (*CSMD1*) gene, previously reported in GWAS by Cirulli et al. (2010), was confirmed in Russians (OR = 1.4, p = 0.04). This gene is of unknown function but has been implicated in multiple neurodevelopmental disorders. Genetic markers in loci for *VRK2, SLCO6A1, NOTCH4, TCF4, ZNF804A, AGBL1, TLR4, RELN, ZFP64P1, KCNB2, CPVL, NRGN* and *NRIP1* previously reported in GWAS were not associated with the disease in Russian population of Siberian region. **Conclusions.** Our findings replicate association of schizophrenia with rs2616984 at *CSMD1* gene and demonstrate that genetic variability in cognitive performance and schizophrenia have overlapping genetic background. This work is partially supported by RFBR grant #12-04-00595.

1157M

GABAergic interneuron origin of Schizophrenia - a genetic association analysis in South Indian population. *KR. Saradalekshmi[1], Balan. Shabeesh[1], Sathyan. Sanish[1], NV. Neetha[1], Nair. Indu[2], Nair. Chandrasekharan[3], Moinak. Banerjee[1]*. 1) Rajiv Gandhi Centre for Biotechnology, Thiruvananthapuram, India; 2) Mental Heath Centre, Thiruvananthapuram, India; 3) Nairs Hospital, Cochin, India.

Schizophrenia is one of the most debilitating disorders affecting about 1% of the world population. The etiology is complex involving a major genetic contribution as well as environmental factors interacting with the genetic susceptibility. Several lines of evidence from post-mortem and brain imaging in schizophrenia patients suggest that Gamma-amino butyric acid (GABA) deficits may contribute to the pathophysiology of schizophrenia. Changes in GABA receptors in schizophrenic brain may represent a primary pathogenesis, such that modifications to GABA receptor subunit assembly and/or structure contribute to the symptoms of schizophrenia. The GABA receptors are a class of receptors that respond to the neurotransmitter gamma-aminobutyric acid (GABA), the chief inhibitory neurotransmitter in the vertebrate central nervous system. Brain-derived neurotrophic factor (BDNF) is one of the most important modulators of glutamatergic and GABAergic synapses. BDNF can play a permissive role in shaping synaptic networks, making them more susceptible for the occurrence of plastic changes. Reelin(RELN), a neuromodulator secreted by GABAergic interneurons regulates the synaptic plasticity. Together, these genes play an important role in regulation of neurotransmission and synaptic plasticity .The objective of the study was to investigate the association of polymorphisms in GABA (A) receptors, BDNF and RELN genes with schizophrenia in a south Indian population. DNA was isolated from 300 patients and 300 healthy controls after obtaining informed consent. Only patients suffering from schizophrenia diagnosed by DSM-IV/ICD 10 have been enrolled for this study. Symptom severity was rated using BPRS-E and PANNS. Age, sex and ethnicity matched controls were recruited for the study. We investigated the association of 10 single-nucleotide polymorphisms: rs2279020 (GABRA1), rs3219151 (GABRA6), rs2229944 (GABRB2), and rs211037 (GABRG2), BDNF -270C/T, rs6265(BDNF), rs727531(RELN), rs7341475(RELN), rs6951875(RELN), rs362719 (RELN)with predisposition to schizophrenia. Samples were genotyped using allele specific amplification followed by fluorescence detection (KASPar), PCR-RFLP and PCR sequencing. Allele and genotypic frequencies were calculated for patients and controls and association with predisposition to schizophrenia was tested.

The major histocompatibility complex (MHC) has emerged as a region of major interest in schizophrenia genetics. Large-scale genome-wide association studies (GWAS) in schizophrenia have converged to demonstrate that the MHC contains the strongest association signal for illness susceptibility. However, prior GWAS have been unable to precisely localize the source of this signal, due to the extensive long-range linkage disequilibrium throughout the MHC; different studies have identified top SNPs ranging across a nearly 10Mb extent (coordinates ranging from 25-35Mb on Chromosome 6). A subcommittee within the PGC SCZ working group has been formed to parse the signal within the MHC using HLA imputation and conditional analysis. Methods: Of the 52 PGC-SCZ cohorts, raw genotype data were available for 38 cohorts of European ancestry, with a total n = 64,631 (29,148 cases and 35,483 controls). Imputation of classical HLA alleles was performed using SNP2HLA (Jia et al. 2013) applied to raw genotype data from each cohort. A total of 267 HLA alleles were successfully imputed. Regression and conditional regression analyses, covarying for top 10 PCAs and study site, were performed in PLINK. Results: Six HLA alleles that form the so-called 8.1 ancestral haplotype (AH8.1) attained genomewide significance (10^{-15} < all p-values < 10^{-9}) and were protective (frequencies in cases ~10.5-11% vs ~12-12.5% for controls; OR~0.87). Notably, these associations were much less strong than those observed for individual SNPs across the extended MHC, and conditional analyses covarying for AH8.1 components revealed genomewide significant SNPs remaining throughout the region, with top signals at rs34661691 (an eQTL for BTN3A2) and rs2523721 (an eQTL for HLA-A and VARS2). Additional conditional analyses, covarying for top individual SNPs rather than HLA alleles, are ongoing and results will be presented at the meeting. Discussion: Initial results demonstrate a pattern that is markedly different from that observed for autoimmune disorders. In most autoimmune disorders, AH8.1 is associated with risk; whereas in schizophrenia, the opposite relationship is observed. . Moreover, in autoimmune disorders, SNP effects in the MHC are entirely accounted for by HLA alleles and corresponding amino acid changes. By contrast, SNP effects in schizophrenia are likely to play a significant independent role, probably regulatory in nature, and potentially implicating non-HLA genes.

Common and rare genetic risk factors converge in protein interaction networks underlying schizophrenia. *X. Chang[1], L. Lima[1], Z. Wei[2], J. Li[1], P. Sleiman[1], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ, USA.

Schizophrenia is an idiopathic brain disorder with profound genetic heterogeneity. The major forms of genetic risk factors in schizophrenia are common single nucleotide polymorphisms (SNPs) and rare copy number variants (CNVs). Recent studies have shed new light on the genetic basis of schizophrenia that de novo mutations play a prominent part in sporadic form of schizophrenia. However, the underlying genetic mechanisms remain unclear. We first performed a network-based pathway analysis on our previous meta-analysis of GWAS in schizophrenia and bipolar disease, which contains 13,394 cases and 34,676 controls from 16 cohorts. The largest connected component (LCC) identified in our PPI network is significantly enriched in many pathways relevant to synaptic plasticity, neural development and signaling transduction such as long-term potentiation, RAP1 signaling pathway, GnRH signaling pathway. We also observed the proteasome pathway and ubiquitin mediated proteolysis pathway to be significantly enriched. Dysfunction of the ubiquitin-proteasome pathway has been implicated in the pathology of various neurodegenerative diseases. However, growing evidence revealed that schizophrenia patients have aberrant gene expression patterns in the UPP suggesting the UPP may also contribute to the deficits in schizophrenia. In order to add more genetic pieces to the schizophrenia puzzle, we collected literature reported genes disrupted with CNVs and de novo mutations in schizophrenia patients for the network analysis. We found the size of LCC were significantly increased, bigger than 10000 simulation based on genes randomly selected. To pinpoint a small group of interacted genes with a significant combined effect to schizophrenia, we developed an edge-based network search algorithm for detecting casual gene modules in PPI networks. The most significant module is comprised by DISC1 connectors and N-methyl-D-aspartate (NMDA) receptor associated genes. We then combined the top three modules and constructed a small sub-network of 47 nodes and 76 edges, which is highly enriched in long-term potentiation and Calcium signaling pathway. In summary, we demonstrated that multiple types of genetic risk variants converge on a PPI network enriched with schizophrenia susceptibility genes involved in synaptic plasticity and neural development. We also provided evidence that de novo mutations and common variants are likely to influence same genes or functionally interacted genes.

Alzheimer's Disease: Analyzing the Missing Heritability. *K.L. Hoyt, P.G Ridge, K. Boehme, L.A. Staley, H. Smith, J.S.K. Kauwe, Alzheimer's Disease Genetics Consortium.* Biology, Brigham Young University, Provo, UT., USA.

Alzheimer's disease (AD) is a complex disorder influenced by genetic and environmental factors. We previously analyzed the phenotypic and genetic variance explained by SNPs known to be associated with AD, APOE alone, and by ~2 million genotyped or imputed SNPs from the Alzheimer's Disease Genetics Consortium (ADGC), using the Genome-wide Complex Trait Analysis (GCTA) software. We found that 33% of total phenotypic variance is explained by common SNPs (n=~2 million), 6% by APOE alone (including the e2 and e4 alleles), and 2% by other known markers—meaning 25% of phenotypic variance remains unexplained by known AD markers. In this study we follow-up our previous work using an expanded version of the ADGC dataset. In this expanded version, SNPs were imputed using the 1000 Genomes dataset, resulting in more complete imputation of both common and rare variation. In the present analysis we estimate phenotypic and genetic variance explained by the SNPs. Additionally, while our previous study included only APOE and nine other loci, the present study includes all the IGAP and previously known AD SNPs (n=23, includes APOE e4 and e2). In addition we will evaluate the contribution of SNPs in genes known to harbor rare variants for AD (APP, PSEN1, PSEN2, TREM2, PLD3, ADAM10). We discuss the current state of known AD heritability and suggest where resources should be focused to identify the remaining undiscovered AD SNPs.

1161T

Probing the shared polygenic underpinnings of anorexia nervosa and five other major psychiatric disorders. *L.M. Huckins[1], K.S. Mitchell[2], L. Thornton[3], D. Collier[4], P.F. Sullivan[3], C.M. Bulik[3], E. Zeggini[1], WTCCC3 Consortium; GCAN Consortium.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Boston University, MA, USA; 3) University of North Carolina at Chapel Hill, NC, USA; 4) King's College London, London, UK.

Anorexia nervosa (AN) is marked by extremely low body weight and intense fear of gaining weight. Comorbidity with other psychiatric disorders (PsyD) is common (up to 56.2%) We evaluated shared genetic determinants of AN and comorbid PsyD by testing whether polygenic risk scores derived from genome-wide data of other PsyD can predict AN status. We obtained allele risk scores for major depressive disorder (MDD), bipolar disorder (BPD), autism (AUT), attention deficit hyperactivity disorder (ADHD) and schizophrenia (SCZ), and a set of cross-disorder risk alleles, from the Psychiatric Genomics Consortium (PGC). We divided each of these sets into 10 Pt significance level thresholds. The test set comprised AN cases and controls from a published WTCCC3 AN GWAS study. For every sample in this test set, we produced a polygenic risk score as a weighted sum of risk allele scores. Logistic regression was used to assess whether each of the five polygenic scores predicted AN case-control status. We computed pseudo R^2 values, and compared these to the values obtained when randomly permuting case-control status to measure the proportion of variance in AN explained by each PsyD risk score. Our pseudo R^2 values were ~0.5-1%, comparable to pseudo R^2 values found by the PGC in a recent cross-disorder polygenic score analysis of five PsyD [1]. We used the baseline results to compute an empirical p-value for every significance threshold and found significant pseudo R^2 values at the lowest Pt threshold (Pt< 0.001) for AN vs AUT (p=0.0009), MDD (p=0.009), and SCZ (0.0008), and at the second lowest Pt threshold (Pt <0.01) for BPD (p=0.0004). We demonstrated for the first time a shared genetic etiology between AN and other PsyD using genome-wide data. Cross-disorder analyses may prove to be a powerful approach to identifying overlapping susceptibility loci across PsyD. [1] Cross-Disorder Group of the Psychiatric Genomics Consortium (2013) "Identification of risk loci with shared effects on five major psychiatric disorders: a genome-wide analysis" The Lancet 381:1371-1379.

1162S

Genes regulated by epigenetic mechanisms in determining general intelligence (g) are over-represented in disorders that affect cognition. *P. Cha[1], K. Kobayashi[1], Y. Ando[1], K. Takao[2], T. Miyakawa[2,3], T. Toda[1,4].* 1) Division of Molecular Brain Science, Kobe University Graduate School of Medicine, Kobe, Hyogo, Japan; 2) Center for Genetic Analysis of Behavior, Section of Behavior Patterns, National Institute for Physiological Sciences, 38 Aza-Nishigonaka, Myodaiji-cho, Okazaki, Aichi 444-8585, Japan; 3) Division of Systems Medical Science, Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Aichi 470-1192, Japan; 4) Division of Neurology, Kobe University Graduate School of Medicine, 7-5-1 Kusunoki-chou, Chuo-ku, Kobe 650-0017, Japan.

General intelligence (g) is a common core shared by cognitive tasks. Despite the high heritability of "g" that increases with age, molecular mechanisms that underlie "g" remains poorly understood. To study epigenetic regulation of "g", we conducted 5 mouse behavioral studies on 41 inbred mice and identified mice with high, medium, and low cognition. Through subsequent genome-wide gene expression profiling by using hippocampal RNAs of these cognitively discordant mice followed by gene-set enrichment analysis (GSEA), we identified 17 genes and several pathways that expressed differentially between mice with high and low cognition. Since inbred mice are genetically homogeneous, we expect most of the differences that we observed are resulting from epigenetic mechanisms. In addition to memory and learning, the role of epigenetic mechanisms in cognition and neurological disorders has recently come to lights. To investigate if genes implicated in our study provide insights into mechanisms underlying "g" and disorders that affect cognition, we evaluated enrichment of genes reported to be associated with each of the cognitive function/intelligent quotient (IQ), intellectual disability (ID), autism, Parkinson's disease (PD), Alzheimer's disease (AD), Rett Syndrome, and Schizophrenia in the top 100 genes, as well as their interacting proteins, identified in our study. Information on genes reported to be associated with IQ, ID and each of the aforementioned disorders was retrieved from published studies or disease-related databases (AutDB, AlzGene etc), whereas interacting proteins were identified from Protein Interaction Network Analysis (PINA) platform. Overlap enrichment analysis indicated that the 100 genes or genes encoding their interacting proteins are significantly enriched with candidate genes reported to be associated with IQ, ID, PD and AD (p<0.05 in 100,000 permutation test). Subsequent investigation of the commonly shared genes may shed light on common mechanisms and pathways that underlie "g" and the aforementioned disorders.

1163M

Novel Locus in 15q23 Implicated in Recovery after Severe Traumatic Brain Injury. *Y.P. Conley[1,2], D. Ren[1,4], S. Beers[5], A. Puccio[3], D. Okonkwo[3], D.E. Weeks[2,4].* 1) School of Nursing, Univ Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh PA; 3) Department of Neurological Surgery, University of Pittsburgh, Pittsburgh, PA; 4) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Traumatic Brain Injury (TBI) often results in chronic disability, however there is great variability in symptom development and severity of disability with little knowledge to date to explain the biological underpinnings for this variability. Genomics, though rarely used in the context of recovery following injury, provides a toolbox for assessment of the underlying biology that may explain the variability in phenotypes post-TBI. This project utilized a cohort of subjects recruited immediately after a severe TBI and followed for up to 24 months post injury using the neurobehavioral rating scale (NRS) to conduct a genomic evaluation using the Illumina Human Exome Beadchip. After data quality checks and filtration using the GWASTools R package, 386 subjects were analyzed and six SNPs within a 414kb region in 15q23 were implicated in NRS scores at six months post-TBI (p=3.8×10-7 through p=4.6×10-5) after controlling for age, sex, and extent of initial injury. This region has been implicated previously with rate of progression in subjects with mild cognitive impairment and contains several novel, biologically relevant candidate genes. This is the first study to conduct a non-candidate driven association study to identify genes potentially implicated in recovery after TBI.

1164T

Long non-coding RNAs associated with synapse are differentially expressed in autistic bloods. *W. Ju[1], Y. Wang[2], X.L. Zhao[3], M. Flory[1], E.C. Jenkins[1], W.T. Brown[1], N. Zhong[1,2,3].* 1) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Shanghai Jiaotong University Children's Hospital, Shanghai, China; 3) Peking University Center of Medical Genetics, Beijing, China.

Autism spectrum disorders (ASD) are characterized by significant impairments in reciprocal social communication and the presence of repetitive and/or restricted behaviors. The most recent surveillance data showed that ASD affects as many as 1 in 68 children within the United States. The increased incidence of ASD may reflect environmental exposures interaction(s) with genetic factor(s). Several studies have demonstrated that noncoding RNAs may involve in the development of ASD and the long noncoding RNA (lncRNA) may be differentially expressed in ASD brains and contributes to ASD risk. We have studied 25 pairs of blood samples collected from ASD vs. controls to investigate the lncRNA in the ASD bloods. We identified both up-regulated and down-regulated lncRNAs from ASD bloods. Among the up-regulated 2,329 lncRNAs, 1,053 were intergenic, 210 exon sense-overlapping, 69 intron sense-overlapping, 592 natural antisense, 392 intronic antisense, and 13 bidirectional. Among the 1,408 down-regulated lncRNAs, 644 were intergenic, 129 exon sense-lapping, 96 intron sense-overlapping, 443 intronic antisense, and 96 bidirectional with no natural antisense. Six pathways, constructed with three up-regulated lncRNAs involved in long-term depression, long-term potentiation, and synaptic vesicle cycling and three in down-regulated lncRNAs involved in Huntington's disease, Alzheimer diseases, and Parkinson's disease, showed neurological lncRNAs may be differentially expressed in peripheral bloods. Among the lncRNAs identified, 27 (11 up-regulated and 16 down-regulated) were found as the synapse associated. Functionally, they are localized at the loci of gene SYT (synaptotagmin), SYN (synapsin), STX (syntaxin), SV2C (synaptic vesicle glycoprotein 2C), SDCBP2 (syntenin), SYNM (synemin), SYNRG (synergin gamma), and SYNPO2L (synaptopodin 2-like protein). Accordingly, a subset of synaptic mRNAs, transcribed from genes SYT, SYN, STX, SYNGR, SDCBP2, SYNPO2L, SNAP25, SYDE1, STXBP6, SYNJ2BP, SYNCRIP, SNCA, SDC2, SYCP3, SYPL2, SYBU, and SYCE1, were identified. Identification of synapse-associated lncRNAs that were differentially expressed in the ASD peripheral bloods may have opened a new avenue to investigate the epigenetic mechanisms underlying ASD and to explore the potential of applying the differentially expressed lncRNA as a biomarker for early detection of ASD clinically.

Evidence pointing to abnormal energy metabolism in two genetic animal models of epilepsy. *A.H.B. Matos[1], A.S. Vieira[1], V.D.B. Pascoal[1,3], C.S. Rocha[1], M.F.D. Moraes[2], C.V. Maurer-Morelli[1], D.R. Nascimento[2], S. Martins[2], A.S. Martins[2], A.C. Valle[4], A.L.B. Godard[2], I. Lopes-Cendes[1].* 1) UNICAMP, Campinas, Brazil; 2) UFMG, Belo Horizonte, Brazil; 3) UFF, Nova Friburgo, Brazil; 4) USP, Sao Paulo, Brazil.

Background: Wistar audiogenic rat (WAR) is a genetic epilepsy model susceptible to audiogenic seizures, after high-intensity sound stimulation. Another genetic model we have recently identified is the generalized epilepsy with absence seizures (GEAS) rat. The aim of this study was to determine the molecular pathways involved in the susceptibility to seizures of these two strains using gene expression analysis. Methods: We obtained total RNA from five susceptible WAR [hippocampus and corpora quadrigemina (CQ)], five control Wistar and five WAR naive (without stimulation) as well as from hippocampus and somatosensory cortex (SC) of five GEAS rats and five control Wistar. Gene expression analysis was performed using microarray technology, and analyzed in R environment using the Affy and RankProd packages from Bioconductor, as well as the MetaCore® platform to identify molecular networks, gene ontology categories and gene interactions. Genes with differential expression and a possible biological role in epileptogenesis were validated by qRT-PCR. Results: In WAR, expression profileshowed a total of 1624 differentially expressed transcripts in the CQ and 1351 differentially expressed in the hippocampus compared with controls, with 616 upregulated and 1008 downregulated in CQ and 660 upregulated and 691 downregulated in the hippocampus. Enriched gene ontology categories identified in WAR were involved in oxidative phosphorylation, neurophysiological process GABA-A receptor life cycle. Genes validated by qRT-PCR were Grin1, Nedd8, Il18 and Slc1a3. The comparison of these genes between WAR naive and WAR showed that overall these genes are upregulated in WAR. In GEAS rats expression profile showed a total of 2307 differentially expressed transcripts in the hippocampus and 2282 differentially expressed in the SC compared with controls, with 1039 upregulated and 1268 downregulated in hippocampus and 991 upregulated and 1291 downregulated in the SC. The top enriched gene ontology categories included: oxidative phosphorylation, LRRK2 in neurons in Parkinsons disease. Genes validated by qRT-PCR were Grin1, Gabbr1 and Slc6a1. Conclusion: Interestingly, among the gene ontology categories abnormally expressed in both models (WAR and GEAS rats) we found oxidative phosphorylation, indicating that an abnormal energy metabolism in the central system may be an important mechanism leading to epileptogenesis in these two genetic models of epilepsy. Supported by FAPESP, BRAZIL.

Genetic influences on metabolite levels in Alzheimer's Disease. *P. Proitsi[1], M. Kim[2], L. Whiley[2], P. Sham[3], S. Lovestone[4], J. Powell*[1], C. Legido-Quigley*[2], R. Dobson*[5], AddNeuroMed Consortium.* 1) King's College London, Institute of Psychiatry, De Crespigny Park, London, UK; 2) King's College London, Institute of Pharmaceutical Science, London, UK; 3) Department of Psychiatry, The University of Hong Kong, Hong Kong; 4) Department of Psychiatry, University of Oxford, Warneford Hospital, Oxford, UK; 5) NIHR Biomedical Research Centre for Mental Health and Biomedical Research Unit for Dementia at South London and Maudsley NHS Foundation Trust.

A better understanding of the biological mechanisms underlying Alzheimer's Disease (AD) is required. AD is one of the major challenges for healthcare in the 21st century and with estimated longer life expectancy, the worldwide numbers of demented patients are expected to reach 81.1 million in 2040. Studies have now demonstrated the promise of using associations with blood metabolites, the repertoire of small molecules present in cells and tissue, as functional intermediate phenotypes in biomedical and pharmaceutical research. In AD, a number of non-targeted blood metabolomic studies have been performed highlighting the role of lipid compounds in disease initiation and progression. In addition, recent studies investigating the genetics of the human metabolome have identified genetic variants in metabolism-related genes that lead to clearly differentiated metabolic phenotypes, termed 'genetically influenced metabotypes' (GIMs), which provide new insights into the role of inherited blood metabolic variation. The aim of this study was to investigate genetic influences on human plasma metabolites in a sample of >400 AD patients and controls, in a two stage approach (Stage 1 N=102, Stage 2 N=315), in order to survey regions of the genome associated with metabolic traits and identify AD specific associations. We performed a comprehensive untargeted lipidomic analysis, using Ultra-Performance Liquid Chromatography/Mass Spectrometry generating >600 features and a Genome Wide Association (GWA) study followed by imputation (>6 million SNPs). Following genetic and metabolomic data quality control, linear regression analyses were run to identify genetic influences on each metabolic feature. Results were pooled together by inverse-weighted meta-analysis. We report novel and previously reported associations between genetic loci and metabolites. We identified >30 associations at p<1*10-6 and 3 associations at p< 5*10-8 in stage 1, as well as evidence for associations between loci and two metabolites previously shown to be altered in AD (p<5*10-8). Results of stage 2 and meta-analysis will be reported. This is the first study to investigate the genetic influences on metabolite levels in an AD cohort and allow us to gain further insights into the genetic control of metabolites in plasma related to AD pathogenesis, which lead to a greater understanding of disease processes and help identify potential new opportunities for drug development.

Genome-wide meta-analysis identifies three loci for common forms of epilepsy. *J.P. Bradfield, The International League Against Epilepsy Consortium on Complex Epilepsies.* Center for Applied Genomics, Childrens Hospital of Philadelphia, Philadelphia, PA.

Epilepsy is a common complex disorder characterized by recurrent seizures of different etiology. While genome-wide association studies have been successful in identifying associations in a number of complex diseases, they have had limited success in identifying risk loci in epilepsy due in part to relatively small sample sizes and lack of power. To search for common variants associated with this disorder, we performed a meta-analysis of genome wide association studies of common forms of epilepsy. Here we report three meta-analyses conducted for all epilepsy and the two largest clinical subgroups - genetic generalized epilepsy (GGE) and focal epilepsy. We combined 9 different GWAS's comprising a total of 8,696 (2606 GGE/5310 Focal) cases and 26,157 controls that were imputed to the 1000 Genomes Phase I (interim), using the June 2011 reference. Each genome wide association was carried out using linear mixed models to control for potential population stratification and meta-analyzed with METAL. Meta-analysis of the "all epilepsy" phenotype identified 2 loci at genome wide significance ($P<1.66\times10^{-8}$). The locus at 2q24.3 (rs6732655, $P=8.7\times10^{-10}$) contained numerous genes with the strongest association coming from within *SCN1A*, while the locus at 4p15.1 (rs28498976, $P=5.44\times10^{-9}$) harbored just one gene (*PCDH7*). For the GGE cohort, a single locus passing genome wide significance was observed at 2p16.1 (rs2947349, $P=9.99\times10^{-9}$), which contained the genes *VRK2* and *FANCL*. Even though the focal epilepsy cohort was more powered than the GGE cohort, no genome wide significant SNP's were observed. *SCN1A* is a voltage gated sodium ion channel that has been implicated in numerous monogenic forms of epilepsy such as Dravet syndrome and genetic epilepsy with febrile seizures plus (GEFS+). *PCDH7*, a protocadherin gene, would be a novel candidate locus for epilepsy but another gene in this family (*PCDH19*) is a known cause of epilepsy and mental retardation limited to females (EFMR). The region at 2p16.1 that was associated in the GGE cohort was previously reported by another GWAS that is a constituent of our meta-analysis.

1168S

Investigating polygenic contributions of common hippocampal variants to epilepsy predisposition. *C.D. Whelan[1], D.P. Hibar[2], J. Stein[2], D. Speed[3], S. Sisodiya[4], M. Johnson[5], D. Goldstein[6], N. Delanty[7], S.E. Medland[1], P.M. Thompson[8], G.L. Cavalleri[2], The International League Against Epilepsy Consortium on Genetics of Complex Epilepsies.* 1) Molecular and Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin, Leinster, Ireland; 2) Imaging Genetics Center, Keck School of Medicine, University of Southern California; 3) UCL Genetics Institute, University College London; 4) Institute of Neurology, University College London; 5) Division of Brain Sciences, Imperial College London; 6) Duke Centre for Human Genetic Variation, North Carolina; 7) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 8) Departments of Human Genetics and Psychiatry, Radboud university medical center, Nijmegen, The Netherlands.

Hippocampal sclerosis (HS) is a common feature of localisation-related epilepsies (LREs), present in 50-75% of all surgical resections in the disorder. The underlying cause of HS is debated. Animal models and post-mortem cell counts suggest that HS can result from epileptogenesis, and some MRI investigations have highlighted a familial component to HS and concomitant neuronal loss within hippocampal regions. Recently, the Enhancing Neuro Imaging Genetics through Meta-Analysis (ENIGMA) consortium identified genome-wide significant signals correlating with hippocampal volume, in a study of 29,037 individuals. We tested the hypothesis that variants predisposing to changes in hippocampal volume may, as a group, contribute to epilepsy predisposition. To investigate this, we summarised variation across nominally-associated ENIGMA SNPs into quantitative 'risk' scores, weighted for local linkage disequilibrium and effect size, and related these scores to disease state in (i) a phenotypically mixed sample of epilepsy patients (n=2,502), (ii) four epilepsy 'subtypes', including LREs (n=1,801), lesional epilepsies (n=280), nonlesional epilepsies (n=614) and idiopathic generalised epilepsies (IGEs; n=194) and (iii) an independent sample of healthy controls (n=5,191). Results did not reveal a significant association between disease state and risk score: observed scores only explained a small fraction (0-0.2%) of total variance in our risk model. Our findings suggest that being genetically predisposed to having smaller hippocampal volume may not be a strong risk factor for epilepsy. However, further analyses in additional epilepsy patients and healthy control cohorts are required to conclusively confirm or reject this position.

1169M

Using polygenic risk scores of psychiatric disorders to predict Neuroticism. *L. Colodro Conde[1,2], K. Verweij[3], E. Byrne[4], R.A. Power[5], N. Martin[1], S. Medland[1].* 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) University of Murcia, Spain; 3) Vrije Universiteit Amsterdam, The Netherlands; 4) University of Queensland, Australia; 5) SGDP Centre, Institute of Psychiatry, King's College London, United Kingdom.

Neuroticism is conceived of as an endophenotype for major depressive disorder (MDD). Neuroticism and MDD are moderately heritable and 45-55% of the genetic liability of MDD is shared with Neuroticism. To test if Neuroticism provides an index of the risk for MDD, we examined the extent to which Neuroticism can be predicted by a polygenic risk score (PRS) derived from the Psychiatric Genomics Consortium MDD analyses. Additionally, we sought to determine if including the PRSs for ADHD, Autism (AUT), bipolar disorder (BP) and schizophrenia (SCZ) accounted for additional variation in Neuroticism. Phenotypic information was obtained from four studies undertaken at the QIMR Berghofer Medical Research Institute. Phenotypes were available for 20702 individuals, of whom 5295 were genotyped. Personality data were collected using the Eysenck Personality Questionnaire. Scale scores in Neuroticism were transformed by taking the arcsine of the square root, corrected for age and sex effects and standardised. After selecting one individual per family, data were available for 2549 individuals (36.2% males, mean age = 35.83, SD = 12.14). PRSs were calculated using the PLINK profile score method A multiple regression on the profile scores of Neuroticism was performed controlling for ancestry (using three principal components). Preliminary analyses found no effects of ancestry on Neuroticism (p=.55). PRSs were calculated for clumped SNPSs using thresholds of $p \leq 0.001$, 0.01, 0.1, 0.5 or 1. As hypothesised, the MDD PRSs predicted Neuroticism explaining 0.17, 0.31, 0.49, 0.48 and 0.45% of the variance (p= 0.04, 0.005, 4.2×10-4, 5.0×10-4 and 7.2×10-4 respectively). However, adding the corresponding PRSs for ADHD, AUT, SCZ and BP did not result in a significant improvement in fit. To determine if BP PRSs could predict Neuroticism in the absence of the MDD PRS, we repeated this sequence of analyses using the BP risk scores. While nominally significant at a $p \leq 0.001$, 0.01 and 0.1 thresholds, these results did not survive correction for multiple testing. These results confirm the findings of previous studies which have shown a moderate genetic correlation between MDD and Neuroticism. However, adding the PRSs for ADHD, AUT, SCZ and BP did not improve the prediction of Neuroticism. Although limited by the power of both the PRS analysis and the original PGC GWAS, the present analyses support the use of Neuroticism as a specific endophenotype for MDD.

1170T

Machine Learning Derived Disease Risk Prediction for Anorexia Nervosa. *Y. Guo[1], Z. Wei[2], B. Keating[1,3], H. Hakonarson[1,3], GCAN, WTCCC3.* 1) The Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ 07102, USA; 3) Department of Pediatrics, School of Medicine University of Pennsylvania, Philadelphia, PA 19104, USA.

Anorexia nervosa (AN) is a serious complex psychiatric disease with a strong contribution from the patients' genetic background. In addition to identifying signals through genome wide association (GWA) studies, researchers have been using genetic information and machine learning methods to predict risk of diseases in which genetics play an important role. In this report we collected whole genome genotyping data on 3,940 AN cases and 9,266 controls from the Genetic Consortium for Anorexia Nervosa (GCAN), the Wellcome Trust Case Control Consortium 3 (WTCCC3) and the Children's Hospital of Philadelphia (CHOP), and applied machine learning methods for predicting AN disease risk. The prediction performance is measured by area under the receiver operating characteristic curve (AUC), indicating how well the model distinguishes cases versus controls. Logistic regression model with the lasso penalty technique generated an AUC of 0.693, while Support Vector Machines and Gradient Boosted Trees reached AUC's of 0.691 and 0.623, respectively. Our results of different sample sizes also suggested that larger datasets are required to optimize the machine learning models and achieve higher AUC values. To our knowledge, this is the first attempt to assess AN risk by incorporating genetic data, and it will pave the way for improved AN risk evaluation, eventually benefitting AN patients and families.

1171S

Genome-wide Association Study of Quantitative Autistic Traits in the General Population. *T. Nishiyama[1], S. Hosono[2], M. Watanabe[2], I. Oze[2], H. Ito[2], H. Tanaka[2], H. Kishino[3], T. Kawaguchi[4], F. Matsuda[4], K. Matsuo[5].* 1) Department of Public Health, Aichi Medical University School of Medicine, Nagakute, Japan; 2) Division of Epidemiology and Prevention, Aichi Cancer Center Research Institute, Nagoya, Japan; 3) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo, Tokyo, Japan; 4) Center for Genomic Medicine, Kyoto University, Kyoto, Japan; 5) Department of Preventive Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Copy number variations and single nucleotide variants, many of which are highly penetrant, are increasingly identified to confer susceptibility to autism spectrum disorder (ASD). In contrast, only a modest number of common variants associated with ASD have been reported through genome-wide association studies (GWAS) (Weiss LA 2009, Wang K 2009, Anney R 2010, Xia K 2013). These common variants have weak effects on ASD susceptibility, and thus sample size would be prohibitively large in practice. Recent studies both of the general population and of twins have shown that quantitative autistic traits are continuously distributed with no natural boundary between normality and ASD (Baron-Cohen 2001, Constantino & Todd 2003), leading to the notions that the extreme of quantitative autistic traits represents the clinical syndrome of autism. Based on this dimensional conceptualization, we conducted GWAS of quantitative autistic traits in the general population, instead of relying on case-control sample of ASD. This methodology seems promising because of easy sampling.

In this study, we used non-cancer participants in the Hospital-based Epidemiological Research Program II at Aichi Cancer Center Hospital (HERPACC-II) (Hamajima N 2001). Quantitative autistic traits were measured using the Japanese version of the Subthreshold Autistic Traits Questionnaire (SATQ) (Nishiyama T 2014) in the second wave of surveys. The sample was genotyped on an IlluminaHuman 610 Quad BeadChip with 576,736 SNP markers. The present study was approved by the Ethics Committee of Aichi Cancer Center and informed consent was obtained from all participants.

After removing SNPs that failed the quality control criteria a priori defined, 488,823 markers were used for the analysis. The snpStats package in R was used to test the association between SNP genotypes and the SATQ score, using additive models adjusted for gender. Using only 358 subjects currently available (we have a plan to increase up to around 1000 in this year), we found four SNPs (rs11577575, rs10071163, rs11862060 and rs10446439) significant at p-value $< 1 \times 10^{-5}$. These four SNPs are located in/near ARHGAP29, PDE4D, ABAT and LSM3-SLC6A6, respectively, and were reported to be associated with ASD in some way. This result suggests potential advantages of the methodology using quantitative autistic traits in the general population.

1172M

Diagnostic exome sequencing of patients with Autism Spectrum Disorder overwhelmingly detects mutations in newly characterized genes, which supports a *de novo* paradigm and the convergence of disrupted pathways in neurodevelopmental disease. *Z. Powis[1], C. Mroske[1], K. Radtke[1], D. Shinde[1], K.F. Gonzalez[1], L. Shahmirzadi[1], D. El-Khechen[1], B. Tippin[1], E. Chao[1,2], R. Baxter[1], S. Tang[1].* 1) Ambry Genetics, Aliso Viejo, CA., Select a Country; 2) University of California Irvine, Irvine, CA 92697.

Diagnostic exome sequencing (DES) is an increasingly effective tool for diagnosis in intractable cases where the underlying cause is believed be genetic. Autism Spectrum Disorders (ASDs) have traditionally been thought to be highly heritable but often the exact genetic origin has been difficult to elucidate. It is estimated that the positive rate for ASD patients is around 15% with the three first tier tests (karyotyping, CMA, and fragile X). However, the diagnostic yield for the other identifiable etiologies for ASD remains unknown. Of the first 500 unselected cases referred for DES to Ambry Genetics (Aliso Viejo CA), 50 (10%) were reported to have an ASD. All of these individuals had additional features such as seizures, intellectual disability, dysmorphic features or other organ involvement, and 40 (80%) had previous uninformative results in at least one of the three first-tier tests. For these 50 ASD patients, trio DES analyses were performed for 41 families. Among them, mutations in characterized genes have been detected in 12 (24%) (*ANK2, CDKL5, CHD8, ELP2, FHL1, IQSEC2* (2 cases), *KMT2A, PANK2, SET5D, SHANK3*, and one individual with mutations in both *ANO3* and *NALCN*). 10 of these cases (83%) were *de novo* alterations. In addition, 7 patients (14.0%) had an uncertain result (*SYP, KDM6B, MTRR, PIGA, ZBTB20, ADCY5*, and *SHROOM4*). 6 of these 7 cases were inherited (85.7%). 62 (4%) of these cases had a novel result (*HDAC1* and *MTOR*), and 29 (58%) had a negative result. Interestingly, among the remaining 450 patients without ASD as an indication for testing, de novo loss-of-function mutations in recently discovered high-confidence autism genes were identified in 7 cases: *ADNP* and *ARID1B*, 2 cases each, *CHD2, DYRK1A, GRIN2B*). These observations indicated that 24% of syndromic ASD patients received a definitive molecular diagnosis via DES after negative first-tier genetic testing. The vast majority of the associated genes were newly identified, non-classical ASD genes and thus might evade traditional sequential or panel testing. The rapid progress being made to the understanding of ASD genetics accentuates the great potential and continuing challenges for genotype-phenotype correlation in the clinical setting. Our clinical data also strongly support the *de novo* paradigm as well as the convergence of disrupted pathways in neurodevelopmental disorders.

1173T

Common polygenic variation and risk for childhood-onset schizophrenia. *K. Ahn[1], S. An[2], J. Rapoport[1].* 1) Child Psychiatry Branch, National Inst Mental Health, NIH, Bethesda, MD; 2) Department of Environmental Health Sciences, Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD.

Childhood-onset schizophrenia (COS) is a rare and severe form of the disorder, with more striking abnormalities in brain development and more striking uneven prepsychotic development compared to later onset disorder. We previously documented that COS patients, compared with their healthy siblings and with adult-onset patients (AOS), carry substantially more rare (0.1% in control) chromosomal copy number variations (CNVs), spanning large genomic regions (> 100kb). (Ahn et al. in press). Here we interrogated the contribution of common polygenic variation to the genetic susceptibility for schizophrenia. We examined the association between a direct measure of genetic risk of schizophrenia in 126 COS probands and 98 healthy siblings. Using data from the schizophrenia and autism GWAS of the Psychiatric Genomic Consortia, we selected risk related sets of SNPs from which we conducted polygenic risk score comparisons for COS probands and their healthy siblings. COS probands had higher genetic risk scores of schizophrenia and autism than their siblings ($P<0.05$). These initial results show that childhood onset schizophrenia shares common risk alleles with autism. Finally, these findings suggest that COS patients may have more salient genetic risk than do adult onset patients.

1174S

A psychometric GWAS finds specificity of variants associated with level and change in immediate and delayed verbal memory after age 60. *T.E. Arpawong[1], J.J. McArdle[1,2], C.A. Prescott[1,2].* 1) Psychology, University of Southern California, Los Angeles, CA; 2) Gerontology, University of Southern California, Los Angeles, CA.

Substantial individual differences exist in memory ability and the rate of age-related memory decline among older adults. Phenotypically, there is a strong association between immediate recall (IR) and delayed recall (DR), but candidate gene findings suggest that genetic influences on IR and DR may be partially distinct, with stronger genetic influence on initial level of recall than on rate of decline. However, this may be due to measurement error; with limited measurement occasions, there is greater precision for estimating level than change. Our goal was to combine a psychometric approach with GWAS to identify whether unique genetic variants are associated with level and change in IR and DR in older age. The sample comprised 12,326 participants (mean age=66.7, range of 50 to107) in the Health and Retirement Study (HRS) who provided DNA and cognitive data (77,693 data points) and were assessed up to 8 times between 1996 through 2012. IR and DR were assessed with an auditory learning task in which individuals were read a list of 10 nouns, asked to immediately recall the list, then asked to recount them after a several-minute delay. Genetic data comprised 2.4 million SNPs from the Illumina Human Omni-2.5 Quad beadchip. We used the following analytical steps: (1) Applied a two-spline mixed effects models to estimate each individual's: level at age 60 and rate of change after 60 in both IR and DR; (2) Conducted four GWAS for IR and DR level and decline, adjusting for sex and ancestral informative markers; (3) Examined whether the same SNPs associated with level and slope of IR were similarly associated with level and slope of DR. The results await replication; however, several SNPs were strongly associated with each outcome (P<5.0×10e-6), and the implicated regions for IR and DR level and decline were mostly non-overlapping.

1175M

GWAS analysis of Insight into illness in Schizophrenia. *V. De Luca, A. Bani-Fatemi, A. Graff, P. Gerretsen.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

Impaired insight into illness is a core feature of schizophrenia characterized by a failure to recognize the presence of a mental illness, symptom misattribution, and unawareness of the need for treatment or negative consequences associated with the disorder. Impaired insight is associated with treatment non-adherence and poor clinical outcomes. The degree of insight impairment tends to remain stable over the illness course, improving modestly with age, but can fluctuate with illness exacerbations, i.e. psychotic episodes. Impaired insight is associated with a number of premorbid factors, such as lower functioning, education, IQ, and personality traits. In particular, impaired insight into illness is consistently associated with illness severity, global cognitive impairment, lower premorbid intelligence (i.e. IQ), executive dysfunction, and memory deficits. A number of genes are implicated in schizophrenia, including DISC1 and NRG1. Yet, despite the high heritability of schizophrenia (81%), few genes are reliably replicated and together explain only a small proportion of the disorder's variance. Due to the heterogeneity of schizophrenia and the overlap between susceptibility genes for schizophrenia and related conditions, it is possible that these genes may contribute more substantially to certain clinical subtypes, such as schizophrenia with impaired insight. As such, the aim of this study was to perform an exploratory genome wide association study (GWAS) to identify candidate genes for impaired insight into illness in a sample of 123 schizophrenia patients. No variants passed the genome-wide significance threshold. However, insight can be used as valuable tool to identify subtype of schizophrenia with higher genetic susceptibility.

1176T

Genetic influences of language development in typically developing children and children with autism spectrum disorders. *J.D. Eicher[1], J.R. Gruen[1,2], Pediatric Imaging Neurocognition Genetics study.* 1) Department of Genetics, Yale University, New Haven, CT; 2) Departments of Pediatrics and Investigative Medicine, Yale University School of Medicine, New Haven, CT.

The ability to effectively communicate is an essential milestone of child development, particularly in social interaction and academic achievement. Deficits in communication skills severely hamper development and lead to long-term negative consequences. One of these vital communication skills is receptive vocabulary, the ability to comprehend and respond to written/verbal language. Children with various language disorders, including dyslexia, language impairment, and autism spectrum disorders, have deficits in receptive vocabulary. As each of these disorders is a complex trait with a significant genetic component, we examined the genetics of receptive vocabulary skills in typically developing children and in children with autism spectrum disorders. First, we performed a genome wide association study (GWAS) of receptive vocabulary in 440 typically developing children in the Pediatric Imaging Neurocognition and Genetics (PING) study. There were associations with markers in *MAGI-1* ($p=3.66\times10^{-8}$) and *BMP7* ($p=8.25\times10^{-7}$). *MAGI-1,* a scaffolding protein important in cell-cell junctions, has previously been implicated with bipolar disorder, schizophrenia, associative learning, and modulation of AMPA synaptic behavior. *BMP7* is important in neural development and was recently identified as a prospective candidate gene for language related disorders (Boeckx and Benitez-Burraco 2014). Next, we assessed whether genes previously associated with language—including *MAGI-1*, *BMP7*, *DCDC2*, *KIAA0319*, *MRPL19*/*GCFC2*, *ATP2C2*, *CMIP*, and *KIAA0319L*, among others—were associated with receptive vocabulary in a meta-analysis of two autism spectrum disorders cohorts: the Autism Genome Research Exchange (AGRE) and Simons Simplex Collection (SSC). We found evidence of associations with *ATP2C2* ($p=4.89\times10^{-6}$), *KIAA0319L* ($p=1.00\times10^{-5}$), *MAGI-1* ($p=3.00\times10^{-5}$), and *MRPL19* ($p=3.91\times10^{-5}$), indicating that genes previously associated with other language disorders (such as dyslexia and language impairment) also influence communication skills in children with autism spectrum disorders. These studies identify genes that influence childhood communication development and indicate that disorders with language-associated deficits share genetic etiologies. Future studies should further examine to what extent these disorders are related using human-based and model-based approaches.

Genome-wide meta-analysis reveals significant association between CHRNA4 variants and nicotine dependence in cohorts of European ancestry. *N.C. Gaddis[1], D.B. Hancock[1], G.W. Reginsson[2], N.L. Saccone[3], S.M. Lutz[4], S. Steinberg[2], P. Kraft[5], J.E. Hokanson[4], L.J. Bierut[3], T.E. Thorgeirsson[2], E.O. Johnson[1], K. Stefansson[2].* 1) RTI International, Research Triangle Park, NC; 2) deCODE Genetics, Reykjavik, Iceland; 3) Washington University, St. Louis, MO; 4) University of Colorado Anschutz Medical Campus, Aurora, CO; 5) Harvard University School of Public Health, Boston, MA.

Cigarette smoking is a major contributor to cancer, vascular disease, and lung disease and is the leading cause of preventable mortality worldwide. Previous genome-wide studies of smoking-related phenotypes have convincingly demonstrated associations with the nicotinic acetylcholine receptor genes on chromosome 15q25 (CHRNA5-CHRNA3-CHRNB4) and chromosome 8p11 (CHRNB3-CHRNA6). To identify novel genetic loci associated with smoking, we conducted a genome-wide association study (GWAS) and meta-analysis of nicotine dependence (ND) in five cohorts of European ancestry totaling 16,244 subjects: the largest GWAS meta-analysis of ND to date. We defined ND using the Fagerstrom Test of Nicotine Dependence (FTND), which is a multi-dimensional measure of physiological dependence to nicotine. After completing standard quality control and 1000 Genomes imputation for each of the five cohorts, we tested approximately 10 million genetic variants for association with a three-level FTND-based phenotype (mild, moderate, and severe ND), separately by cohort, using a linear regression model adjusted for age, sex, eigenvectors to correct for population stratification, and other cohort-specific covariates as needed. We then combined the results from the five cohorts in an inverse variance-weighted meta-analysis with genomic control applied to each cohort. As expected, variants in the CHRNA5-CHRNA3-CHRNB4 region displayed the strongest association with FTND, with p-values as low as 10^{-17}. We also observed genome-wide significant association for a variant in the 3' untranslated region of CHRNA4 ($p = 3.60\times10^{-8}$), with odds ratios for the five cohorts ranging from 1.05-1.20 and 1.11-1.43 for moderate and severe ND compared to mild ND, respectively. This variant is predicted to alter a microRNA binding site that may regulate CHRNA4 expression. In total, we found 22 CHRNA4 variants with p-values less than 10^{-5}, all of which had consistent directions of association across the five cohorts: their minor alleles (frequency range 4-20%) being associated with an increased risk of ND. CHRNA4 is known to have high affinity for nicotine, and our findings build on the evidence from several smaller studies suggesting that CHRNA4 variants contribute to smoking-related phenotypes.

1178M

Identification of novel candidate genes in canine noise phobia -a model for human panic disorder. *O. Hakosalo[1,2], K. Tiira[1,2], R. Sarviaho[1,2], M. Sillanpää[3], J. Kere[4,5], H. Lohi[1,2].* 1) Department of Veterinary Biosciences and Research Programs Unit, Molecular Neurology, University of Helsinki, P.O.Box 63, 00014 University of Helsinki, Helsinki, Finland; 2) The Folkhälsan Research Center, Helsinki, Finland; 3) Department of Biology and Mathematical Sciences, University of Oulu; 4) Department of Biosciences and Nutrition, Karolinska Institutet, and Center for Biotechnology, Sweden; 5) Research Programs Unit, University of Helsinki.

Noise phobia (NP), a fear of loud noises, is a severe anxiety disorder in dogs, which may result in panic attacks. It provides a natural animal model for human panic disorder. NP is common (20-40%) in many breeds with high heritability (h^2 0.56) estimates but its genetic background remains unknown. We aimed to discover the genetic cause by a genome wide association analysis. We focused on German Shepherds because the breed is popular and presents sufficient phenotypic variation in NP. We used our validated owner-completed anxiety questionnaire to create a categorical NP phenotype and genotyped altogether 310 German Shepherds (GS) (86 cases and 224 controls) to map the NP locus. We found a genome widely significant association in a 4 Mb region at CFA20 harboring several interesting candidate genes. Targeted capture and resequencing of the associated region from 39 dogs revealed several disease segregating variants that were enriched in three promising candidate genes. Further validation and functional characterization of variants in a larger GS cohort and other breeds should implicate the causative gene. This study will improve the understanding of the genetic background of noise phobia, and at best reveal a new candidate gene for human anxiety and help in developing a model for potential therapeutic approaches.

1179T

Core-Exome Chip study of low-frequency variants identifies genome-wide significant hits associated with anorexia nervosa. *K. Hatzikotoulas[1], L.M. Huckins[1], L. Thornton[2], L. Southam[1], D. Collier[3], P. Sullivan[2], C.M. Bulik[2], E. Zeggini[1], GCAN Consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) Department of Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, King's College London, London, UK.

Anorexia nervosa (AN) is a neuropsychiatric disorder presenting with extremely low body weight, and a marked fear of gaining weight. AN has the highest mortality of any psychiatric disorder, and affects roughly 0.9% of women. Very little is known about the biological mechanisms which underlie AN; two GWAS have been completed and have yet to identify genome-wide significant hits. No effective medications are available, and treatment outcome for AN remains unacceptably poor. Our study comprises 2,376 female AN cases and >22,000 controls, genotyped on the Core-Exome Chip. Samples derive from eight different populations; cases and controls are ancestrally matched. The CoreExome Chip enables us to study both common and low-frequency variants simultaneously; our study is the first to examine the role played by low-frequency and rare variants in AN. Analysis is currently complete across three of the eight contributing populations: Norway, 87 cases, 100 controls; Finland, 163 cases, 5,300 controls; and the UK, 181 cases and 10,034 controls. We have performed a meta-analysis across these three populations and thus far have identified four genome-wide significant signals: exm370124, exm462797, exm464785, exm2116552. These four variants are all low frequency, missense variants. We looked at the frequency of these SNPs in both cases and controls. All SNPs were extremely low frequency in the control populations, with highest MAF between 0.005 and 0.01. SNPs were also low frequency in the cases, with highest MAF between 0.01 and 0.10. Effect sizes for each SNP were high, and the same direction of effect was noted for every SNP in at least 2/3 populations. Maximum effect sizes for each SNP were between 6.6 and 74.5. One of these associated variants (exm464785) lies in RASGRF2, a gene that has previously been associated with eating disorders (Wade et al. 2013), albeit not at a genome-wide significant level. This is the first genome-wide significant variant that has been associated with AN. We hope that this will enable further studies into the functional mechanisms underlying AN, and perhaps be a first step towards establishing effective medications and treatment. Further, all four hits that have been identified are very low frequency and could not possibly have been identified in previous GWAS studies. This may be a good indication that low-frequency, Core-Exome chip type studies have potential to reveal new associated variants across a range of psychiatric disorders.

1180S

Multi-ethnic meta-analysis in a cohort of 110,266 individuals identifies novel shared and sex-specific loci associated with smoking initiation. *E. Jorgenson[1], L. Shen[1], A. Hamidovic[2], H. Choquet[3], T. Hoffmann[3], Y. Banda[3], M. Kvale[3], N. Risch[3], C. Schaefer[1], L. Sakoda[1].* 1) Kaiser Permanente Division of Research, Oakland, CA; 2) Departments of Pharmacy and Psychiatry University of New Mexico, Albuquerque, NM; 3) Institute for Human Genetics University of California, San Francisco San Francisco, CA 94143.

Smoking is a major public health problem in which both genetic and environmental factors play an important role. Genome-wide association studies have identified six loci influencing smoking behavior, and additional investigation is needed to clarify how these and other genetic factors affect the chronology of smoking behavior, specifically smoking initiation, persistence, and cessation. Family and twin studies have suggested that significant sex differences exist in smoking behavior, with the heritability of smoking initiation being higher in women than in men. We conducted a genome-wide association meta-analysis of smoking initiation across race/ethnicity (non-Hispanic white, Latino, Asian, and African American subjects) and sex strata in the Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort. Over 6.6 million SNPs were imputed with imputation r2>0.8 and minor allele frequency > 0.05 using the 1000 Genomes reference panel. We identified four loci that exceeded a genome-wide significance level of 5×10-8. An intergenic locus near TMEM182 on chromosome 2 (p=2.65×10-8) and SNPs in SDK1 (p=2.52×10-8) were associated with smoking initiation in both men and women. Additionally, SNPs in BDNF (p=3.48×10-8) and NCAM1 (p=9.20×10-9) were associated with smoking initiation in women but not in men. While BDNF was previously reported to be associated with both smoking initiation and persistence, our other findings are novel. We examined additional evidence for the association of these loci with smoking initiation in the combined-sex association results among European populations made publicly available by the Psychiatric Genomics Consortium. Those results provided support for both BDNF (p=2.01×10-5) and NCAM1 (p=6.76×10-3), but not for the other two loci (p>0.05), indicating both a need for additional replication in large, multi-ethnic samples and the power of combining evidence across race/ethnicity groups to provide additional insights into the genetics of smoking behavior.

1181M

Genome-Wide Association Study in *APOE* ε4 Negative Subjects Identifies a Novel Locus in 17q21.31 for Alzheimer Disease. *G. Jun[1,2,3], C. Ibrahim-Verbaas[6], C. Bellenguez[7,8,9], M. Vronskaya[11], J. Chung[1], J.C. Bis[12], J. Williams[11], S. Seshadri[5], G.D. Schellenberg[13], K.L. Lunetta[2], P. Amouyel[7,8,9,10], P. Holmans[11], C.M. van Duijn[6], L.A. Farrer[1,2,3,4,5], International Genomics of Alzheimer's Project (IGAP) Consortium.* 1) Medicine, Boston University, Boston, MA, USA; 2) Biostatistics, Boston University, Boston, MA, USA; 3) Ophthalmology, Boston University, Boston, MA, USA; 4) Epidemiology, Boston University, Boston, MA, USA; 5) Neurology, Boston University, Boston, MA, USA; 6) Epidemiology, Clinical Genetics and Neurology, Erasmus MC University Medical Center, Rotterdam, the Netherlands; 7) Inserm, U744, Lille, France; 8) Université Lille 2, Lille, France; 9) Institut Pasteur de Lille, Lille, France; 10) CNR-MAJ, Centre Hospitalier Régional Universitaire de Lille, Lille, France; 11) Institute of Psychological Medicine and Clinical Neurosciences, MRC Centre for Neuropsychiatric Genetics & Genomics, Cardiff University, UK; 12) Medicine, University of Washington, Seattle, WA, USA; 13) Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, USA.

APOE ε4 is the most significant genetic risk factor for Alzheimer disease (AD) and may mask effects of other loci. We re-analyzed genome-wide association study (GWAS) data from the International Genomics of Alzheimer's Project (IGAP) Consortium in *APOE* ε4-positive (10,246 cases and 11,924 controls) and *APOE* ε4-negative (7,231 cases and 19,603 controls) subgroups as well as in the total sample allowing for interaction between a SNP and *APOE* ε4 dosage. Suggestive associations ($p<1\times10^{-4}$) in the discovery sample were evaluated in an independent replication sample containing 4,474 subjects (ε4-positive: 1,250 cases and 536 controls, ε4-negative: 718 cases and 1,699 controls). In the discovery set, we observed suggestive associations from 15 loci in either ε4-positive or ε4-negative subjects (5 novel loci in ε4-negative subgroup: *SOX/CLDN18*, *CDC42SE2/ACSL6*, *PFDN1/HBEGF*, *KANSL1/LRRC37A*, and *CDR2L*) and two novel loci in the total sample for interaction (*THSD7A/TMEM106B* and *ABCA13/CDC14BL*). Of these, five distinct loci from 4 known (*CR1*, *BIN1*, *CLU*, and *MS4A* cluster) and one novel locus (*KANSL1/LRRC37A*) were genome-wide significant ($p<5\times10^{-8}$) in meta-analysis of the discovery and replication in either ε4-positive or ε4-negative subjects. Among the loci previously identified by AD GWAS, SNPs in *BIN1* were genome-wide significant in both *APOE* subgroups. SNPs in *CR1* and *CLU* were genome-wide significant in ε4-positive subjects, whereas SNPs in the *MS4A* cluster region (*MS4A6A/MS4A4A/MS4A6E*) were genome-wide significant in ε4-negative subjects. Novel associations among ε4-negative subjects were observed in the *MAPT* region covering approximately 100 kb including *KANSL1* and *LRRC37A* (best SNP, rs2732703, ε4-positive: OR=0.86, CI=0.76-0.98, p=0.02; ε4-negative: OR=0.73, CI=0.65-0.81, $p=5.8\times10^{-9}$). Although 17 SNPs in this region initially showed genome-wide significant p-values, analyses conditioned on the lead SNP (rs2732703) revealed no additional independent associations. However, despite these findings, no SNPs showed statistical evidence of genome-wide significant interaction by ε4 status in the meta-analysis of discovery and replication. Association of variants in the *MAPT* region with AD may represent a novel genetic risk factor among individuals who do not carry the ε4 risk allele. Further examination of this region is warranted to identify functional determinants of AD risk among persons lacking the ε4 allele.

1182T

First GWAS in DBH confirms strong cis-acting variants and lends support for its role as an intermediate phenotype in post-traumatic stress disorder. *A.X. Maihofer[1], M. Mustapic[1,2,4], D.G. Baker[3], D.T. O'Connor[2], C.M. Nievergelt[1,3].* 1) Department of Psychiatry, University of California at San Diego, La Jolla, CA; 2) Department of Medicine, University of California at San Diego, La Jolla, CA; 3) VA Center of Excellence for Stress and Mental Health (CESAMH), VA San Diego Healthcare System, La Jolla, CA; 4) Division of Molecular Medicine, Ruđer Bošković Institute, Zagreb, Croatia.

Dopamine beta-hydroxylase (DBH) catalyzes formation of norepinephrine. DBH is expressed in noradrenergic nerve terminals of the central and peripheral nervous systems, as well as in chromaffin cells of the adrenal medulla. DBH is present in cerebral spinal fluid and plasma as stable heritable trait. Differences in DBH expression or activity might reflect a role in the pathogenesis of cardiovascular and neuropsychiatric disorders. The genetic mechanisms underlying DBH activity and its secretion have been only partially explained. Thus we conducted a genome-wide association search for loci contributing to human plasma DBH (pDBH) activity. In a population sample of European ancestry, we identified 3 common trait-determining variants (top hit rs1611115, $p=7.2\times10^{-51}$) in the proximal DBH promoter. Each of the 3 variants had an effect on transcription and acted additively on gene expression. We replicated the associations in a population sample of Native American descent (top hit rs1611115, $p=4.1\times10^{-15}$). Additionally, we identified yet another genome-wide significant SNP at the LOC338797 locus on chromosome 12 as potential trans-quantitative trait locus (QTL) (rs4255618, $p=4.62\times10^{-8}$). Analysis conditioned on 3 DBH promoter variants identified a third genomic region on chromosome 9q contributing to pDBH variation: a likely cis-QTL adjacent to DBH in SARDH (rs7040170, $p=1.31\times10^{-14}$). The identification of SNPs with such strong effects on pDBH opens the possibility of utilizing Mendelian randomization (MR) approaches to test causal effects of this intermediate trait on disease. Therefore we performed an exploratory MR analysis in a sample of participants recruited from the Marine Resiliency Study (MRS), a large, prospective study of post-traumatic stress disorder (PTSD) involving active-duty United States Marines bound for deployment to Iraq or Afghanistan. The SNP rs1611115, which explained 50% of the variability in pDBH, was employed as a genetic instrument to test for a causal effect of plasma DBH on PTSD symptoms. The MR estimate of the association of pDBH and re-experiencing symptoms was significant (beta = 0.21, p = 0.002), indicating the possibility that pDBH is a causal component in the development of re-experiencing symptoms.

1183S

Genome-wide association study of sensory disturbances in the inferior alveolar nerve after bilateral sagittal split ramus osteotomy. *D. Nishizawa[1], D. Kobayashi[1,2,3], Y. Takasaki[4], S. Kasai[1], Y. Aoki[1,2], J. Hasegawa[1], T. Kakizawa[5], K. Ikeda[1], K. Fukuda[2].* 1) Psychiatry and Behavioral Science (Addictive Substance Project), Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Dental Anesthesiology, Tokyo Dental College, Tokyo, Japan; 3) Department of Dentistry and Oral surgery, Tokyo Metropolitan Tama Medical Center, Tokyo, Japan; 4) Department of Dentistry and Oral surgery, National Hospital Organization, Takasaki General Medical Center, Gunma, Japan; 5) Department of Oral Health and Clinical Science, Division of Oral and Maxillo-facial Surgery, Tokyo Dental College, Tokyo, Japan.

Background: Bilateral sagittal split ramus osteotomy (BSSRO) is a common orthognatic surgical procedure. Sensory disturbances in the inferior alveolar nerve, including hypoesthesia and dysesthesia, are frequently observed after BSSRO, even without distinct nerve injury. The mechanisms that underlie individual differences in the vulnerability to sensory disturbances have not yet been elucidated. **Methods**: The present study investigated the relationships between genetic polymorphisms and the vulnerability to sensory disturbances after BSSRO in a genome-wide association study (GWAS). A total of 304 and 303 patients who underwent BSSRO were included in the analyses of hypoesthesia and dysesthesia, respectively. Hypoesthesia was evaluated using the tactile test 1 week after surgery. Dysesthesia was evaluated by interview 4 weeks after surgery. Whole-genome genotyping was conducted using Illumina BeadChips including approximately 300,000 polymorphism markers. **Results**: Hypoesthesia and dysesthesia occurred in 51 (16.8%) and 149 (49.2%) subjects, respectively. Significant associations were not observed between the clinical data (i.e., age, sex, body weight, body height, loss of blood volume, migration length of bone fragments, nerve exposure, duration of anesthesia, and duration of surgery) and the frequencies of hypoesthesia and dysesthesia. Significant associations were found between hypoesthesia and the rs502281 polymorphism (recessive model: combined $\chi^2 = 24.72$, nominal $P = 6.633 \times 10^{-7}$), between hypoesthesia and the rs2063640 polymorphism (recessive model: combined $\chi^2 = 23.07$, nominal $P = 1.563 \times 10^{-6}$), and between dysesthesia and the nonsynonymous rs2677879 polymorphism (trend model: combined $\chi^2 = 16.56$, nominal $P = 4.722 \times 10^{-5}$; dominant model: combined $\chi^2 = 16.31$, nominal $P = 5.369 \times 10^{-5}$). The rs502281 and rs2063640 polymorphisms were located in the flanking region of the *ARID1B* and *ZPLD1* genes on chromosomes 6 and 3, whose official names are “AT rich interactive domain 1B (SWI1-like)” and “zona pellucida-like domain containing 1”, respectively. The rs2677879 polymorphism is located in the *METTL4* gene on chromosome 18, whose official name is “methyltransferase like 4”. **Conclusions**: The GWAS of sensory disturbances after BSSRO revealed associations between genetic polymorphisms located in the flanking region of the *ARID1B* and *ZPLD1* genes and hypoesthesia and between a nonsynonymous genetic polymorphism in the *METTL4* gene and dysesthesia.

1184M

Genes Involved in Brain Development Influence Crying Habits -A Genome Wide Association Study. *C. Tian, C.Y. McLean, E.Y. Durand, N. Eriksson, J.Y. Tung, D.A. Hinds.* Research, 23andme, Mountain View, CA.

Crying, for emotional reasons, is considered unique to humans. Crying habits vary greatly--some crying easily and others rarely. Thus far it is not clear why, though emotional stability has been shown to play a role and excessive emotionality appears to have a familial tendency. In this genome-wide association study, we searched for possible genetic associations with crying easily using a large sample of unrelated customers of 23andMe, Inc., with European ancestry. 60848 cases self reported that they ‘cry easily’ and 94871 controls said that they did not ‘cry easily’. Females are three times more likely to self-identify as ‘crying easily’ than males and individuals who cry easily have a significantly higher rate of psychiatric disorders in our data. We identified genome-wide significant associations with 7 loci, including rs62335062 (P=2.6×10-31, OR=1.111) upstream of IRX2, rs7196282 (P=5.0×10-14, OR=0.928) in an intron of ZNF423, rs2178574 (P=2.7×10-11, OR=1.066) in an intron of LRRTM4, rs2744475 (P=2.1×10-10, OR=1.060) upstream of TFAP2B, rs10838125 (P=2.5×10-10, OR=1.058) between TTC17 and HSD17B12, rs876714 (P=5.7×10-10, OR=1.054) in an intron of BIN3 and close to EGR3, and rs16903275 (P=3.9×10-8, OR=0.94) in microRNA9-2 (MIR9-2). The top two associated genes, IRX and ZNF423, have been shown to be involved in cerebellum development and brain regionalization. The cerebellum is an important brain region that has been linked to crying. LRRTM4 gene product is known to trigger the formation of excitatory synapses and shows highly selective expression in the brain. Mutations in LRRTM family genes have been associated with human handedness and schizophrenia. TFAP2B product, an important factor in the development of ectodermal and neural tissues, is involved in monoaminergic regulation and has been associated with neonatal temperament, alcohol addiction, adolescent depressive symptoms, and attention deficit hyperactivity disorder. The expression of EGR3 is rapidly regulated by neural synaptic activity in the brain cortex, which may be important in defining neuroplastic responses following stimulus. MIR9-2 has been associated with neuron-specific expression and neuronal differentiation during brain development. This study highlights some important genes that potentially impact the neural basis of crying in response to emotional stimulus, which may also shed light on the disease etiology of more serious affective disorders.

1185T

Identification of a novel locus for human-directed fear in dogs. *K. Tiira[1, 2], O. Hakosalo[1, 2], R. Sarviaho[1, 2], M. Sillanpää[3], J. Kere[2,4,5], H. Lohi[1, 2].* 1) Department of Veterinary Biosciences and Research Programs Unit, Molecular Neurology, P.O.Box 63, 00014 University of Helsinki, Helsinki, Finland; 2) The Folkhälsan Research Center, Helsinki, Finland; 3) Department of Biology and Mathematical Sciences, University of Oulu; 4) Department of Biosciences and Nutrition, Karolinska Institutet, and Center for Biotechnology, Sweden; 5) Research Programs Unit, University of Helsinki.

Behavioural, pharmacological, clinical and etiological studies suggest that dogs suffer from human anxiety-like disorders with shared neurobiological etiologies. Fearfulness has obtained high heritabilities in dogs (h^2 0.46) and inbred population structures facilitate gene mapping. We have initiated a large program to dissect the genetic and environmental correlates of different canine anxieties. We aimed here to identify the genetic cause of canine fearfulness in relation to various environmental correlates. We utilized our validated anxiety questionnaire to data collection and to derive several continuous and binomial behavioural variables that describe the dog’s fearfulness. We derived a Human fear-variable, which is a continuous variable emphasizing the avoidance behaviour towards strangers and is highly correlated with generalized fearfulness in the data set ($r_s = 0.92$, P<0.0001). We selected 126 Great Danes (52 cases and 74 controls) with extreme ends of the stranger avoidance behaviour for a genome-wide association study to map the fear locus using canine HD SNP chip arrays (173K). We identified a genome wide significant association in a 4 Mb region at CFA11 using a linear mixed model analysis with puppy socialization as a covariate. Our ongoing analyses aim to replicate the association in larger cohorts available across breeds and to identify the causative gene. This is the first report for a fear locus in dogs and provides insights to the genetic and environmental factors in canine anxiety with a translational potential to human anxiety.

1186S

Genetic determinants of survival in patients with Alzheimer's disease. *X. Wang[1, 2], OS. Lopez[3, 4], RA. Sweet[3, 4, 5], JT. Becker[3, 4], MM. Barmada[1], E. Feingold[1, 2], FY. Demirci[1], IM. Kamboh[1, 4, 5].* 1) HUMAN GENETICS, University of Pittsburgh, PITTSBURGH, PA; 2) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Neurology, University of Pittsburgh, Pittsburgh, PA; 4) Alzheimer's Disease Research Center, University of Pittsburgh, Pittsburgh, PA; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

There is a strong genetic basis for late-onset of Alzheimer's disease (LOAD) and thus far over 20 genes/loci have been identified that affect the risk of LOAD. In addition to disease risk, genetic variation at these loci may also affect components of the natural history of AD, such as survival in AD. However, the role of these known loci in survival of AD patients has not been explored extensively. In the present study, we examined the role of 22 known LOAD genes with the time to death in 983 AD patients recruited from a referral clinic. In a secondary analysis, genome-wide association was examined to identify novel loci that may influence survival in AD. Survival analysis was conducted using Cox proportional hazards regression under an additive genetic model adjusted for the baseline MMSE score, education, gender, psychosis and top four principal components. We found multiple nominally significant associations (P<0.05) either within or adjacent to 10 LOAD genes and 3 of them remained significant in gene-based analyses (*BIN1*, P=4.79E-04; *INPP5D*, P=4.49E-02 and *APOE*, P=3.23E-02). Genome-wide association analysis revealed 8 suggestive novel loci at P<1E-05 (*ALDH4A1*, P=3.24E-06; *IL19*, P=6.62E-07; *NCKAP5*, P=1.37E-06; *CCDC85C*, P= 2.25E-06; *NARS2*, P=3.41E-06; *PKNOX2*, P=8.03E-06; *SDR9C7*, P=2.42E-06; and *SALL4*, P=2.25E-06). These results indicate that in addition to some known LOAD genes, genetic variation in novel loci may also affect survival of AD patients. Additional large follow-up studies in independent samples are required to confirm our potentially novel candidate loci findings.

1187M

Integrative systems approaches to deciphering the genetic landscape of late-onset Alzheimer's disease. *Y. Zhao[1], V. Mäkinen[2], Q. Meng[1], X. Yang[1].* 1) Department of Integrative Biology and Physiology, University of California, Los Angeles, Los Angeles, CA 90095; 2) EMBL Australia, South Australian Health and Medical Research Institute, Adelaide Australia 5000.

Late-onset Alzheimer's disease (LOAD) is a complex neurodegenerative disorder, with the genetic components estimated to account for 60-80% of the disease variability. Recent genome-wide association studies (GWAS) implicated a number of susceptibility loci for LOAD. However, the identified susceptibility loci are substantially inconsistent across GWAS and the underlying genetic mechanisms are still largely unknown. In this study, we utilized an integrative systems approach that leveraged a multitude of genetic and genomic datasets, including 1) LOAD GWAS from the Alzheimer Disease Genetics Consortium (ADGC) from nine cohorts), 2) expression quantitative trait loci (eQTLs) from genetics of gene expression studies of human tissues related to LOAD (such as brain, blood, liver, and adipose tissue), 3) knowledge-driven biological pathways, 4) brain transcriptomic profiles of LOAD, and 5) data-driven gene regulatory networks from multiple human and mouse cohorts. The integration of these diverse data sources enabled tissue-specific investigations on whether the genetic variants associated with LOAD concentrated on gene subnetworks (i.e., specific parts of gene regulatory networks) and whether novel key regulators in the subnetworks could be identified based on data-driven network structures. Our results confirmed the involvement of many well-known LOAD-related processes, such as lipid metabolism, immune and inflammatory response, endocytosis/intracellular trafficking, and cell migration to be significantly enriched for LOAD risk variants across the nine LOAD GWAS datasets. More interestingly, we detected several novel subnetworks related to mitochondrial protein import, viral infection, and pyrimidine metabolism, which show significant expression changes between LOAD patients and nondemented subjects. Finally, by utilizing the gene-gene relationships revealed by the network architecture, we detected key regulator genes, both known (e.g. NCKAP1L and FYB) and novel (e.g. VAV1, and PTPN6), in these LOAD subnetworks. Our results shed lights on the complex mechanisms underlying LOAD and highlight potential novel targets for the highly debilitating disease.

1188T

***TMEM106B* is a genetic modifier of frontotemporal lobar degeneration with *C9ORF72* hexanucleotide repeat expansions.** *M.D. Gallagher[1,2], E. Suh[3], M. Grossman[2], L. Elman[2], L. McCluskey[2], J.Q. Trojanowski[3], V.M. Lee[3], V.M. Van Deerlin[3], A.S. Chen-Plotkin[2], International Collaboration for FTLD.* 1) Cell & Molecular Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, PA; 2) Department of Neurology, Perelman School of Medicine, University of Pennsylvania, PA; 3) Department of Pathology & Laboratory Medicine, Center for Neurodegenerative Research, Perelman School of Medicine, University of Pennsylvania, PA.

Hexanucleotide repeat expansions in chromosome 9 open reading frame 72 (*C9ORF72*) have recently been linked to frontotemporal lobar degeneration (FTLD) and amyotrophic lateral sclerosis (ALS), and may be the most common genetic cause of both neurodegenerative diseases. Genetic variants at *TMEM106B* influence risk for the most common neuropathological subtype of FTLD, characterized by inclusions of TAR DNA binding protein of 43kDa (FTLD-TDP). Previous reports have shown that *TMEM106B* is a genetic modifier of FTLD-TDP caused by mutations in the progranulin gene (*GRN*), with the major (risk) allele of rs1990622 associating with earlier age at onset of disease. Here we report that rs1990622 genotype affects age at death in a single-site discovery cohort of FTLD patients with *C9ORF72* expansions (n=14), with the minor allele correlated with earlier age at death (p=0.024). We replicate this modifier effect in a 30-site international neuropathological cohort of FTLD-TDP patients with *C9ORF72* expansions (n=75), again finding that the minor allele associates with earlier age at death (p=0.016), as well as earlier age at onset (p=0.019). In contrast, *TMEM106B* genotype does not affect age at onset or death in 241 FTLD-TDP cases negative for *GRN* mutations or *C9ORF72* expansions. Thus, *TMEM106B* is a genetic modifier of FTLD with *C9ORF72* expansions. Intriguingly, the genotype that confers decreased risk for developing FTLD-TDP and delayed age of disease onset in *GRN*-associated FTLD (minor, or C, allele of rs1990622) is associated with earlier age at onset and death in *C9ORF72* expansion carriers, providing an example of sign epistasis in human neurodegenerative disease.

1189S

Gene subnetworks in cocaine-induced paranoia: Convergence between populations. *C. Phokaew[1], H. Kranzler[2], L. Farrer[3], H. Zhao[4], J. Gelernter[1,5].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT and VA Connecticut Healthcare, West Haven, CT, USA; 2) Center for Studies of Addiction, Department of Psychiatry, Perelman School of Medicine of the University of Pennsylvania and VISN4 MIRECC, Philadelphia VAMC, Philadelphia, PA, USA; 3) Department of Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA, USA; 4) Department of Biostatistics, Yale School of Public Health, New Haven, CT, USA; 5) Departments of Genetics and Neurobiology, Yale University School of Medicine, New Haven, CT, USA.

Cocaine induce paranoia (CIP) is a common consequence of cocaine use that can cause serious morbidity. We used pathway analysis to identify target genes to aid in our understanding of CIP pathophysiology, based on the principle of identifying reproducible GWAS-derived gene lists from two independent datasets. GWAS data set was generated by using the Illumina Omni1-Quad microarray, as described in our published cocaine dependence (CD) GWAS. The two populations in this study were African American (AA; 1273 cases and 824 controls, 52% male) and European American (EA; 951 cases and 749 controls, 58.9% male). All sample subjects were interviewed using the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA). The CIP phenotype was ascertained via the question : "Have you ever had a paranoid experience when you were using cocaine?" The control group included only subjects who reported lifetime cocaine use. Gene sub-networks were obtained by using the dmGWAS R package on GWAS data and the Reactomes database. P-values from the GWAS (briefly, logistic regression on sex, age, and the first three PCs - Gelernter et al, 2013) was combined with gene-gene interaction data to identify significant gene-gene interaction modules. The AA and EA lists were evaluated for overlapping gene content (which could result from different SNPs In the two populations), and genes the appeared in both group networks was tested by SKAT-O. Gene lists were submitted to the Database for Annotation, Visualization and Integrated Discovery (DAVID) for check for enrichment pathways according to KEGG (Kyoto Encyclopedia of Genes and Genomes) gene interaction database. The pathway analysis considered a total of 22061 genes. From these, four genes out of the 40 identified in AAs and the 88 In EAs were identical between the two populations: GABBR2 (AA p = 0.00056, EA p = 0.0076), ADCY8 (AA p = 0.037, EA p = 0.0099), DLC1 (AA p = 0.0015 , EA p = 0.0065) and ABLIM2 (AA p = 0.0023, EA p = 0.00013). Gene lists from both populations were enriched in several KEGG pathways, including Focal Adhesion (Padj 1.20E-09), ECM-Receptor Interaction (Padj 6.30E-07), etcs Separately, the AA group was most enriched in the Neuroactive Ligand-Receptor Interaction Pathway (Padj 1.40E-03), while the EA group was most enriched in Focal Adhesion Pathway (Padj 2.40E-07). Interaction pathways including GABBR2, ADCY8, DLC1 and ABLIM2 appear the most promising for CIP risk, based on our dataset.

1190M

A genome-wide screen for fear of heights susceptibility loci in a Finnish isolate. *I. Hovatta[1,2], Z. Misiewicz[1], T. Hiekkalinna[3,4], T. Paunio[3,5], T. Varilo[6].* 1) Department of Biosciences, University of Helsinki, Helsinki, Finland; 2) Mental Health and Substance Abuse Services, National Institute for Health and Welfare, Helsinki, Finland; 3) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 4) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 5) Department of Psychiatry, University of Helsinki, Helsinki, Finland; 6) Department of Medical Genetics, Haartman Institute, University of Helsinki, Helsinki, Finland.

Acrophobia (fear of heights) is an anxiety disorder characterized by disproportional or irrational feeling of apprehension cued by the occurrence or anticipation of elevated spaces. It is classified as a specific phobia of naturalistic type under the DSM-V. No specific genetic variants predisposing to acrophobia have been identified. Our goal was to map genes predisposing to acrophobia. We genotyped and analyzed 575 microsatellite markers across the genome in the Finnish schizophrenia cohort, in which acrophobia segregates independently of schizophrenia. The sample constitute mostly of large multigenerational pedigrees from an internal genetic isolate comprising 57 nuclear families including 643 people, 105 of them affected with acrophobia. We first undertook parametric and non-parametric linkage analysis using statistical software packages FASTLINK 4.1P and MERLIN. As a follow-up, we are performing joint linkage and association analyses with PSEUDOMARKER to fine-map the identified loci and to find putative founder alleles predisposing to acrophobia. Finally, we will perform haplotype analysis using MERLIN to identify potential risk haplotype(s) shared among affected family members. Our results from single two-point linkage analysis revealed two suggestive loci with recessive model: 13q34 (Zmax= 2.88) and 5q32-q34 (Zmax=2.15). Variants in D-amino acid oxidase activator (DAOA) gene located at the 13q34 locus were previously associated with schizophrenia. Consistently, we found linkage in individuals affected both with schizophrenia and acrophobia and not those affected only by the latter. However, the 5q32-34 seems specific for acrophobia as omitting individuals with comorbid schizophrenia did not significantly affect the LOD score. The singlepoint non-parametric linkage analysis showed the strongest linkage for region 5q32-q34 [(NPL (all) LOD score 1.51)]. Our study revealed several suggestive loci segregating independently in schizophrenia and acrophobia. The concordance between results from parametric and non-parametric linkage analysis for region 5q32-q34 with individuals only affected with acrophobia indicates this region as potentially harboring acrophobia-associated gene(s). Our results will require follow-up analyses to fine-map the regions of interest. Identification of risk variants would provide novel insight into the genetic basis of the fear of heights phenotype and contribute to the molecular-level understanding of its etiology.

1191T

Ancient human mtDNA variation is associated with Autism spectrum disorder in Europeans. *D. Chalkia[1], O. Derbeneva[1], M. Lvova[1], A. Lakatos[2], J. Leipzig[3], D. Hadley[4], H. Hakonarson[4], D. Wallace[1,5].* 1) Center for Mitochondrial & Epigenomic Medicine, Children's Hospital of Philadelphia Research Institute, Philadelphia, PA; 2) Department of Psychiatry and Human Behavior, University of California at Irvine, Irvine, CA; 3) Center for Biomedical Informatics, Children's Hospital of Philadelphia Research Institute, Philadelphia, PA; 4) Center for Applied Genomics, Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA.

Autism spectrum disorders (ASD) are thought to result from genetic defects in synaptic biogenesis, structure, and maintenance. GWAS and CNV studies in autism have led to the identification of a number of chromosomal loci involved in the structure of the synapse suggesting a synaptic assembly pathway. However, when all of the synaptic loci are added together they still account for only a small proportion of ASD cases. Therefore, additional pathways must be relevant in the genetics of ASD. To explain the complex genetics of ASD, alternative ASD pathways would need to encompass a large number of genes, affect a quantitative trait, and be relevant to the synapse. Mitochondrial bioenergetics fulfills these criteria. Therefore, we are testing the hypothesis that a significant proportion of the risk for developing ASD is the result of inheriting partial defects in genes for mitochondrial bioenergetics. To test our hypothesis, first we determined if ancient human mtDNA variation is associated with ASD risk. To accomplish this, we used two independently generated and genotyped cohorts, the Autism Genetic Resource Exchange (AGRE) and the CHOP Autism Case-Control (ACC). These pre-existing mtDNA single nucleotide polymorphism (SNP) data were generated by Illumina chip analysis. We deduced the mtDNA haplogroups for all the AGRE and ACC samples by first converting the Yoruban mtDNA SNPs included in these arrays to their corresponding positions on the rCRS and then using Mitomaster to assign an mtDNA haplogroup to each sample. To limit the number of variables and thus increase the statistical power of the study, we only utilized cases and controls that harbored European haplogroups. Generalized linear modeling analysis of the AGRE cohort suggests that J mitochondrial lineage and T2 haplogroup are risk factors for ASD (J lineage: OR = 2.22, CI=1.21-4.05, p-value =0.0094; T2 haplogroup: OR= 1.79, CI= 1.26-2.55, p-value=0.0012). Congruently, in the ACC cohort we found that haplogroup T2 is strongly associated with ASD and represents a risk factor (OR=1.45, CI=1.04-2.03, p-value-=0.0284). These data demonstrate that ASD risk is modified by mtDNA haplogroup thus supporting our mitochondrial bioenergetic hypothesis of ASD.

1192S

Genome-wide association study of dementia with Lewy bodies. *J. Bras[1], C.M. Molony[2], A.B. Singleton[3], D.J. Stone[4], International DLB Consortium.* 1) Dept Molecular Neuroscience, University College of London, London, United Kingdom; 2) Merck Research Laboratories, Department of Genetics & Pharmacogenomics (GpGx), Boston, MA; 3) Laboratory of Neurogenetics, National Institutes on Aging, NIH, Bethesda, MD; 4) Merck Research Laboratories, Department of Genetics & Pharmacogenomics (GpGx), Phila, PA.

Dementia with Lewy Bodies (DLB [MIM 127750]) is a complex brain disorder that has been severely underserved and whose etiology remains unclear. A growing body of evidence supports the notion that Alzheimer's disease (AD), DLB, and Parkinson's disease (PD) are members of the same disease continuum. Pure DLB appears to exist in only 20-30% of clinical DLB cases, with the remainder showing some level of AD pathology. Similarly, as many as 20% of AD patients show comorbid DLB pathology. Genetic studies in AD have focused on the "pure" form of the disease when possible, excluding patients showing DLB/ α-synuclein (SNCA) inclusions. Also, drug-development efforts for AD disease modification have almost exclusively focused on the amyloid and tau pathologies. Taken together, these raise a critical concern that the current compounds in clinical trials for AD disease modification, even if successful, may not have full efficacy in up to 20% of patients. Understanding of the genetics of DLB and mixed AD/DLB is therefore critical for identification of both drug targets and pharmacogenetic/compound response predictors. Here we present results from a large genome-wide association study conducted in DLB. We have included only cases that have been neuropathologically diagnosed with DLB, according to the latest criteria greatly reducing the likelihood of contamination of other forms of dementia. Our cohort comprises 1,300 cases and 2500 population controls. We have performed genotyping using Illumina's HumanOmni 2.5M GWAS array plus exome content. Our results confirm that APOE ε4 is a strong genetic risk factor for DLB, and also suggest the involvement of other genes in this disease, opening novel research and therapeutic avenues into this disorder. Future plans for this cohort include whole-exome sequencing of cases.

1193M

The contribution of uncommon coding variants to risk for Alzheimer's disease, frontotemporal dementia, and progressive supranuclear palsy: an exome array study of the multi-ethnic GIFT cohort. *J.A. Chen[1], Q. Wang[1], J. Davis-Turak[1], Y. Li[1], D. Chatzopoulou[1], H. Chui[2], C. Cotman[3], C. DeCarli[4], T. Foroud[5], A. Huang[1], A. Karydas[6], E. Klein[1], W. Kukull[7], J. Lee[1], A. Levey[8], M. Mendez[9], J. Miller[10,11], W. Poon[3], J. Ringman[9], A. Rosen[8], R. Sears[1], J. Shapira[9], A. Varpetian[2], K. Wojta[1], B.L. Miller[6], D.H. Geschwind[1,9], G. Coppola[1,9].* 1) Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, CA; 2) Department of Neurology, University of Southern California, Los Angeles, CA; 3) Institute for Memory Impairments and Neurological Disorders, University of California, Irvine, CA; 4) Department of Neurology, University of California, Davis, CA; 5) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 6) Memory and Aging Center, University of California, San Francisco, CA; 7) National Alzheimer's Coordinating Center, University of Washington, Seattle, WA; 8) Department of Neurology, Emory University, Atlanta, GA; 9) Department of Neurology, University of California, Los Angeles, CA; 10) Department of Nutritional Sciences, Rutgers University, New Brunswick, NJ; 11) Department of Pathology and Laboratory Medicine, University of California, Davis, CA.

Genetic contributions to neurodegenerative diseases such as Alzheimer's disease, frontotemporal dementia, and progressive supranuclear palsy have become increasingly well characterized. However, few studies have examined the effect of low-frequency coding variants on a genome-wide level. Here, we used the Illumina HumanExome BeadChip array to genotype a large number of exonic variants and other polymorphisms in a cohort of patients with dementia (224 with Alzheimer's disease, 168 with frontotemporal dementia, and 48 with progressive supranuclear palsy), and 224 non-demented controls from the Genetic Investigation in FrontoTemporal dementia and Alzheimer's disease (GIFT). An additional multi-ethnic replication cohort of 240 Alzheimer's disease patients and 240 controls was used to validate suggestive findings. Association testing, on both the variant level and the gene level, was performed. No novel loci were detected with genome-wide significance in these tests, likely due to the limited power to detect an effect from rare variants of modest effect size. However, using a gene-wise association test (SKAT), we replicated an association with the known Alzheimer's disease gene ABCA7 in several ethnicities, hinting that exonic variants within this gene modify disease risk. Additionally, two suggestive candidate genes were identified in Alzheimer's disease patients. Corroborating evidence from other exome array studies and gene expression data points toward potential involvement in Alzheimer's disease pathogenesis.

1194T

A variant in *Cadherin 1* (*CDH1*) achieves near genome-wide significance in African Americans using a liability model. *J. Mez[1], J. Chung[2], K.L. Lunetta[3], J. Haines[4], R.P. Mayeux[5,6], M.A. Pericak-Vance[7,8], G.D. Schellenberg[9], L.A. Farrer[1,2,3,10,11], Alzheimer's Disease Genetic Consortium.* 1) BU Alzheimer's Disease Center (Neurology), Boston University School of Medicine, Boston, MA; 2) Biomedical Genetics (Medicine), Boston University School of Medicine, Boston, MA; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 4) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 5) Taub Institute on Alzheimer's Disease and the Aging Brain (Neurology), Department of Neurology, Columbia University, NY; 6) Gertrude H. Sergievsky Center (Neurology), Columbia University, New York, NY; 7) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 8) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 9) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 10) Department of Ophthalmology, Boston University School of Medicine, Boston, MA; 11) Department of Epidemiology, Boston University School of Public Health, Boston, MA.

Late onset Alzheimer's disease (LOAD) risk is influenced by multiple known genetic, clinical and environmental factors. Including these factors as covariates in traditional genetic analyses of subjects ascertained by phenotype (case-control ascertainment) may decrease power to detect an association. However, a liability model can be used to extract risk information from known genetic and non-genetic factors without a reduction in power. A recent genome wide association study (GWAS) by the Alzheimer's Disease Genetic Consortium (ADGC) found that, in addition to the *APOEε4* allele, a variant in the *ABCA7* gene (rs115550680) was significantly associated with LOAD at the genome-wide level in African Americans. In the current study, we conducted a GWAS in African Americans, employing a liability model that included these genetic risk factors as well as age and sex. Subjects included 1,910 well-characterized African American LOAD cases and 3,829 cognitively normal African American controls from 9 datasets from the ADGC. First, we used logistic regression (or logistic generalized estimating equations (GEE) for family-based datasets) to derive a liability score (Pearson residual) for each dataset to serve as a quantitative continuous phenotype for GWAS. The model included *APOEε4* status, rs115550680 (either genotyped or imputed weight), age and sex. Then, we evaluated association of the liability score with a genome-wide set of six million imputed markers using linear regression (or linear GEE for family-based datasets) that included principal components of population substructure. Results were meta-analyzed across datasets. We obtained near genome-wide evidence of association ($p=2.21\times10^{-7}$) between the liability score and a SNP in *CDH1*, a gene which encodes a calcium dependent cell-cell adhesion glycoprotein. In the ADGC's previous African American GWAS of LOAD that used a traditional case-control model, the same *CDH1* SNP reached a p-value of 1.33×10^{-5}, two orders of magnitude larger than using the liability model. The current study suggests a liability model can improve association signals in GWAS. We plan to add more clinical risk factors to our model with the hope of further increasing our power to detect an association.

1195S

A genome wide association study on fine motor speed. *C.L. Satizabal[1,2], J.A. Smith[3], J.C. Bis[4], L. Yu[5], A. Beiser[1,6], W. Zhao[3], J.I. Rotter[7], A.S. Buchman[5,8], R. Au[1,2], S.T. Turner[9], W.T. Longstreth[10], S.L.R. Kardia[3], B.M. Psaty[11], D.A. Bennett[5,8], A.L. Fitzpatrick[11], S. Seshadri[1,2], T.H. Mosley[12], Neuro-CHARGE consortium.* 1) Department of Neurology, Boston University School of Medicine, Boston, MA, USA; 2) Framingham Heart Study, Boston, MA, USA; 3) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI, USA; 4) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, WA, USA; 5) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL, USA; 6) Boston University Schools of Medicine and Public Health, Boston, MA, USA; 7) Institute for Translational Genomics and Population Sciences and Department of Pediatrics, Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, USA; 8) Department of Neurological Sciences, Rush University Medical Center, Chicago, IL, USA; 9) Division of Nephrology and Hypertension, Department of Internal Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA; 10) Departments of Neurology and Epidemiology, University of Washington, Seattle, WA, USA; 11) Department of Epidemiology, School of Public Health, University of Washington, Seattle, WA, USA; 12) Department of Medicine-Geriatrics, University of Mississippi Medical Center, Jackson, MS, USA.

Background: The Finger Tapping Test (FTT) is one of the most extensively used tasks to evaluate fine motor speed, and lower scores are often indicative of brain damage. However, genetic variants associated with fine motor functions have not been investigated in large community samples. The aim of this study is to relate genome-wide genetic variation to fine motor speed in a large sample of middle-aged and elderly individuals using FTT scores. Methods: FTT scores were defined as the average number of taps for the right and left hands over 10 or 15 seconds. We conducted two separate meta-analyses of genome-wide association studies (GWAS) of FTT scores in 7,580 individuals of European and 1,405 of African-American descent from five population-based cohorts of the Neuro-CHARGE consortium. Genotype imputation was based on the 1,000 Genomes reference panel. Results across cohorts were combined with pooled inverse variance-weighted meta-analysis methods using METAL and applying genomic control. We considered p-values of $< 5\times10^{-5}$ as findings of interest. Results: In the European sample, we identified suggestive intronic variants in ASTN1 (rs78553813, $p=1.2\times10^{-6}$); RREB1 (rs9379083, $p=1.3\times10^{-6}$); METTL21C (rs117561181, $p=1.5\times10^{-6}$); UBTD2 (rs116792690, $p=1.9\times10^{-6}$) and ALS2 (rs3731702, $p=2.2\times10^{-6}$). These genes have been associated with glial-guided neuronal migration during brain development, cell differentiation, bone-muscle functions and juvenile lateral sclerosis. Several other suggestive extragenic variants were found on chromosome 6p24.3. As for the African-American sample, we found several suggestive intronic variants encompassing the EFHD1 gene (between $1.6\times10^{-6} < p < 3.6\times10^{-6}$ for the top hits), which expression is augmented during neuronal differentiation; as well as other extragenic variants near LINC00276 (rs1878107, 2.6×10^{-7}) and TIGD2 (rs6853480, $p=2.7\times10^{-7}$). Conclusions: Although our results did not reach genome-wide significance, we found several novel suggestive variants associated with fine motor speed in European and African-American samples. We plan to further explore these findings through increased sample sizes and trans-ethic meta-analyses, which could provide novel insights into the biology of fine motor speed.

1196M

Variants near CCK receptors are associated with electrophysiological responses to pre-pulse startle stimuli in a Mexican American cohort. *T.M. Norden-Krichmar[1], I.R. Gizer[2], K.C. Wilhelmsen[3], N.J. Schork[4], C.L. Ehlers[1].* 1) Department of Molecular and Integrative Neurosciences, The Scripps Research Institute, La Jolla, CA; 2) Department of Psychological Sciences, University of Missouri, Columbia, MO; 3) Department of Genetics and Neurology, University of North Carolina, Chapel Hill, NC; 4) J. Craig Venter Institute, La Jolla, CA.

Neurophysiological measurements of the response to pre-pulse and startle stimuli have been used to study the mechanisms for a wide range of psychiatric disorders. Some Mexican American (MA) populations have a higher risk for the development of alcoholism. We have previously shown that the electrophysiological response to pre-pulse/startle responses is associated with alcohol dependence in a young adult MA population. That is, the participants diagnosed with alcohol dependence demonstrated significantly less inhibition and more facilitation to startle responses following pre-pulse stimuli. In the present study we investigated whether genetic factors associated with this phenomena could be identified. The study included 420 young adult (age 18 - 30 years) MA men (n=170) and women (n=250). Information on alcoholism and other psychiatric disorders were obtained through an interview using the Semi-Structured Assessment for the Genetics of Alcoholism (SSAGA). Acoustic pre-pulse and startle stimuli were presented binaurally through headphones. Electrodes were used to record the event-related potential (ERP) response in frontal cortex to the stimuli. For all subjects, DNA was extracted from blood samples, followed by genotyping using an Affymetrix Axiom Exome1A chip. An exome-wide association analysis of the genotyping data revealed that the *CCKAR* and *CCKBR* (cholecystokinin A and B receptor) genes each had a nearby variant that showed suggestive significance ($p<=E-05$) in association with the pre-pulse response values. The rs2171755 variant (NC_000004.12:g.26502338T>C) is located 12kb upstream from the *CCKAR* gene in a MIRb class SINE repetitive element. The rs58905541 variant (NC_000011.10:g.6296157C>T) is located 24kb downstream from the *CCKBR* gene in a DNaseI hypersensitivity cluster. Significance of these variants was further validated by permutations and inclusion of the covariates age and gender. The neurotransmitter cholecystokinin (*CCK*), along with its two receptors, *CCKAR* and *CCKBR*, have been previously associated with anxiety and panic disorders, schizophrenia, and alcoholism. Additionally, the administration of CCK-related peptides has been found to influence the startle response in rats and humans. These results suggest that variants near *CCKAR* and *CCKBR* may play a role in the pre-pulse/startle response, and possibly in alcohol dependence and other behavioral disorders, in this Mexican American cohort. (Supported by AA06420, DA030976).

1197T

Large-scale genetic predictor of gene expression associated with risk of bipolar disorder. *K.P. Shah, E.R. Gamazon, N.J. Cox, H.K. Im.* Department of Medicine, University of Chicago, Chicago, IL.

Genome-wide association (GWA) studies have successfully identified thousands of loci associated with complex diseases, many of which have also been associated with gene expression phenotypes across a variety of tissues, known as expression quantitative trait loci (eQTLs). The enrichment of eQTLs in GWA studies suggests that altered gene expression plays a role in risk for a number of complex diseases. Recognizing the important role of gene expression in risk for complex diseases, we developed and applied a novel approach, PrediXcan, to predict gene expression traits in GWA studies and test these predicted gene expression traits for association with disease. We developed large-scale predictors of gene expression for all genes using gene expression data from the whole blood of control individuals as part of the GTEx Pilot Project. We then tested each of these predicted gene expression levels for association with bipolar disorder (BPD) using GWA data from the GAIN sample. We found that predicted levels of *RFNG* are associated with risk of BPD ($p\text{-value} = 2.59\times10^{-6}$) even after correcting for multiple testing ($p\text{-value}_{Bonferroni.corrected} = 4.19\times10^{-2}$). Higher predicted *RFNG* expression is associated with lower risk of BPD in this study. Our *RFNG* result replicated in the WTCCC GWA study as well (p-value = 0.00017). *RFNG*, RFNG O-fucosylpeptide 3-beta-N-acetylglucosaminyltransferase, is part of the Notch signaling pathway and involved in neurogenesis. Previous studies have highlighted the importance of Notch signaling in psychiatric disease through GWA studies and linkage studies. Specifically, *NOTCH4* has been associated with risk of schizophrenia and mutations in *NOTCH3* have been seen in patients with CADASIL, a rare autosomal dominant disease characterized by cortical white matter death, stroke, mood disorder, migraines, and dementia. Our results suggest that *RFNG* gene expression may be relevant to the development of BPD further highlighting the importance of the Notch signaling pathway in neuropsychiatric disease risk. This study also shows the potential of our PrediXcan approach for identifying genes relevant to disease phenotypes.

1198S

eQTL analysis of a large-scale RNA-sequencing cohort of schizophrenic and normal brains. *S.K. Sieberts for the Common Mind Consortium, Swedish Schizophrenia Consortium, Schizophrenia Working Group of PGC.* Sage Bionetworks, Seattle, WA.

The most recent schizophrenia GWAS reported >100 independent associated loci, implying the disorder is highly polygenic. To better understand the pathology of neuropsychiatric disease, we formed the CommonMind Consortium (commonmind.org) to generate large-scale data (RNA-seq, ChIP-seq, DNA-seq/genotyping) from human post-mortem brain samples. Here, we focus on eQTL using RNA-seq (Illumina HiSeq2000 - paired end reads) of the dorsolateral prefrontal cortex (BA9/46) in 265 schizophrenia cases and 289 controls. Effects of known clinical (gender, age of death, medications) and technical (brain bank, post-mortem interval, RNA quality, sequencing batch) covariates, as well as hidden confounders, were removed using surrogate variable analysis (SVA). Data were normalized via voom and a linear model was applied to detect eSNPs, adjusting for genetic structure. Genotypes were assayed on the Illumina Infinium HumanOmniExpressExome8 chip and were imputed to 1000 Genomes. Preliminary differential expression analysis using linear models implemented in voom/limma identified 15.6% of all expressed genes as differentially expressed between cases and controls (FDR 5%). These genes were enriched for DNA variants associated with schizophrenia, including rare (allele frequency < 0.1%) nonsynonymous variants in Swedish case-control exome sequencing (p=0.012) and common GWAS variants (p=0.045). Preliminary eQTL analysis of the assayed genotypes (~620,000 with MAF≥0.05) identified 102,461 and 85,015 proximal eSNPs (distance < 1Mb) at an FDR of 5% in controls and patients with schizophrenia, respectively; representing 53.1% and 44.3% of expressed genes. 51,823 eSNPs were common to both groups, and 24.8% of expressed genes have at least one eSNP in common. Preliminary results show that 54 of the 108 GWAS regions from the Psychiatric Genomic Consortium contain eSNPs. Complete analysis using imputed SNPs will examine condition dependent eQTL, incorporating epigenetic information, and identify likely gene candidates in regions indicated by GWAS in hopes of contributing to the understanding of the biological mechanisms contributing to disease. This large dataset will be made public in early 2015, including a catalogue of brain-expressed genes and their isoforms in cases and controls, which will contribute to empowering the research community to make novel discoveries relating neurobiology disease risk and mechanisms in hopes of advancing novel diagnostic tools and therapies.

1199M

A Spatiotemporal Systems Biology Approach to Understanding Autism Spectrum Disorder and Schizophrenia. *A.J. Willsey[1], S.J. Sanders[1], M. Li[2], S. Dong[3], A.T. Tebbenkamp[2], R.A. Muhle[2], S.K. Reilly[2], L. Lin[2], S. Fertuzinhos[2], J.A. Miller[4], C. Bichsel[2], W. Niu[2], J. Cotney[2], X. He[5], E. Hoffman[2], L. Klei[6], J. Lei[5], W. Liu[2], L. Liu[5], C. Lu[5], Y. Zhu[2], E.S. Lein[4], L. Wei[7], J.P. Noonan[2], K. Roeder[5], B. Devlin[6], N. Sestan[2], M.W. State[1].* 1) Psychiatry, University of California, San Francisco, San Francisco, CA; 2) Yale University School of Medicine, New Haven, CT; 3) Peking University, Beijing, China; 4) Allen Institute for Brain Science, Seattle, WA; 5) Carnegie Mellon University, Pittsburgh, PA; 6) University of Pittsburgh, Pittsburgh, PA; 7) National Institute of Biological Sciences, Beijing, China.

Recent advances in genome- and exome-wide methods, including SNP genotyping arrays and high-throughput sequencing, have facilitated identification of genes associated with autism spectrum disorder (ASD) and schizophrenia (SCZ). This ever-expanding list of genes offers an unprecedented opportunity to elucidate the biology of ASD and SCZ. However, the large number of genes involved coupled with the many biological functions of each gene confound interpretation. Working on the hypothesis that the many genes involved in each disorder must disrupt a much smaller number of shared biological processes to result in a common phenotype, we previously identified the midfetal prefrontal cortex and primary motor-somatosensory cortex as a point of convergence in the expression of ASD genes in the human brain. Since this initial analysis, the number of ASD-associated genes has increased more than three-fold, and additional loci continue to be implicated in SCZ. By applying this methodology in a cross disorder analysis of ASD and SCZ we aim to identify novel components of the neuropathology and to determine whether these are shared or distinct between the disorders. Using a rich expression dataset encompassing multiple human brain regions across the timespan of human brain development, we construct co-expression networks around the most current set of 'high-confidence' ASD genes and then interrogate spatial and temporal 'windows' of brain development for enrichment of additional ASD genetic risk. We then identify genes with risk shared across both ASD and SCZ and construct co-expression networks around these genes in order to understand the similarities and differences between the spatial and temporal characteristics of these disorders. Our preliminary findings suggest that we will: 1) strengthen evidence for the spatiotemporal points previously identified as critical nexuses in ASD risk; 2) identify additional nexus points of risk in ASD; and 3) increase our understanding of the similarities and differences between ASD and SCZ, such as the specific brain regions and developmental epochs central to onset of these disorders. The work presented here represents a novel paradigm for progressing from genes to etiology by placing genetic findings in the relevant spatial, temporal, and cellular context. Moreover, identifying key differences between ASD and SCZ is crucial to improving our understanding of these disorders.

1200T

Multiple system atrophy and spinocerebellar degeneration associated with mutations in the COQ2 gene. *H. Sakamoto[1], M. Hirano[1,2], Y. Nakamkura[1], K. Saigoh[2], S. Ueno[1,2], Y. Mitsui[2], S. Kusunoki[2].* 1) Department of Neurology, Sakai Hospital Kinki University Faculty of Medicine, ≤, Osaka, Japan; 2) Department of Neurology,Kinki University Faculty of Medicine, Osakasayama, Osaka, Japan.

Multiple system atrophy (MSA) is a rapidly progressive disorder with severe motor disability within a few years, and is characterized by cerebellar ataxia, parkinsonism, and autonomic disturbances. This disease is clinically classified into two subgroups: MSA with predominant parkinsonism (MSA-P) and MSA with predominant cerebellar ataxia (MSA-C). The cause of MSA is largely unknown, but recently, mutations or sequence variations in the COQ2 gene encoding a protein for coenzyme Q10 synthesis have been identified in patients with MSA. Variations were more frequent in patients with MSA-C. In contrast, no report has described effects of COQ2 variations on clinical phenotypes in other neurodegenerative diseases, including autosomal dominant-spinocerebellar degeneration (SCD), Parkinson's disease (PD), and progressive supranuclear palsy (PSP). In this study, we sequenced the COQ2 gene in 31 Japanese patients with MSA, 20 with known causes of ataxia, 23 with PD, and 11 with PSP. We found the reported variation (p.V343A) in the COQ2 gene in five MSA (MSA-C, 3 and MSA-P, 2). The positive ratio in MSA (5/31, 16%) was larger than in controls (7/200, 3.5%, $p<0.05$), which is consistent with the reported finding. Additionally, we found this reported variation in a patient with SCA8, who had rare symptoms for Japanese patients with SCA8: parkinsonism and sleep apnea syndrome in addition to cerebellar ataxia. No patients with PD and only one patient with PSP had this variation with typical features of the disease. Notably, we found a novel missense mutation in the COQ2 gene in a patient with SCA6. This patient had rare symptoms for SCA6: major urinary incontinence and increased deep tendon reflexes, symptoms common in MSA. Our result suggested that COQ2 variations may affect phenotypes of SCD.

AUTOSOMAL DOMINANT CEREBELLAR ATAXIA AND MENTAL IMPAIRMENT WITH A NOVEL NONSENSE MUTATION OF *PRKCG*. *H. Shimazaki, J. Honda, T. Naoi, M. Namekawa.* Division of Neurology, Dept. of Internal Medicine, Jichi Medical University, Shimotsuke, Tochigi, Japan.

Backgrounds: Autosomal dominant cerebellar ataxias (ADCA) comprise clinically and genetically heterogeneous neurodegenerative disorders characterized by progressive ataxia with other neurological system disturbances. Machado-Joseph disease (MJD) / Spinocerebellar ataxia type 3 (SCA3), SCA6, SCA31, dentatorubral-pallidoluysian atrophy (DRPLA), SCA2 and SCA1 are frequent ADCAs, but other types are rare in Japan. We encountered a family with two patients of cerebellar ataxia with mental impairment. We attempt to identify the causative gene mutation of this family with ADCA. Methods: We investigated the proband with neurological examination, brain MRI, SPECT and gene analyses. Results: The neurological examination revealed cerebellar ataxia and cognitive impairment, but tremor or myoclonus were not observed. Brain MRI demonstrated cerebellar vermian atrophy. Brain SPECT showed cerebellar hypoperfusion. We could not detect CAG repeat expansions of SCA1, 2,3,6,7,8,12,17,DRPLA genes, and sequencing analyses could not reveal pathologic substitutions in the 5' UTR of the puratrophin gene. Whole-exome sequencing (WES) could identify the novel heterozygous nonsense mutation in the PRKCG gene, which is the causative gene for SCA14. This heterozygous mutation was confirmed by Sanger sequencing, and found in another patient, co-segregated within the family members and not found in controls. Conclusion: We could identify PRKCG mutation in this ADCA family. SCA14 usually showed cerebellar ataxia with tremor or myoclonus. Mental impairment is rare in SCA14. To the best of our knowledge, PRKCG gene mutations were only missense mutations in the previous literatures. This family has atypical clinical features with a novel nonsense mutation in the PRKCG gene. We could consider this nonsense mutation of PRKCG gene is associated with atypical clinical symptoms compared with typical ones of SCA14.

1202M

SPG7 mutations in a French-Canadian family affected by a recessive spastic ataxia. *M. Tetreault[1,2], S. Yang[3], K. Choquet[2,3], K. Boycott[4], J. Majewski[1,2], B. Brais[2,3], C4R Consortium.* 1) McGill Univeristy and Genome Quebec Innovation Center, Montreal, QC, Canada; 2) Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) Neurogenetics of motion laboratory, Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada; 4) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ottawa, ON, Canada.

The current implementation of whole exome (WES) and whole genome (WGS) sequencing, in research has greatly accelerated the identification of disease-causing genes in Mendelian disorders, and more importantly in diseases that were poorly diagnosable. The diagnosis of ataxias is difficult due to rarity, clinical and genetic heterogeneity, and still today a large number of patients remain without a molecular diagnostic. We recruited a French-Canadian (FC) family (10 individuals; 4 affected cases) with an adult onset autosomal recessive spastic ataxia with dysarthria. Due to the heterogeneity and the difficulty to identify a disease gene by relying only on clinical features, we decided to send one affected individual for sequencing. WES was performed using Agilent SureSelect capture kit and Illumina HiSeq. A list of rare homozygous and compound heterozygous variants (MAF <3%; in 1000genomes) was produce. Variants that were also homozygous or compound heterozygous in our in-house exome database were excluded. A total of 22 candidate genes remained in our list, among them SPG7, encoding a mitochondrial metalloprotease. Mutations in SPG7 are associated with an autosomal recessive spastic paraplegia (SPG7). Our FC patient is compound heterozygote for two missense variants (p.A510V and p.P750L). The variant p.A510V has already been reported in the literature as a pathogenic variant and seems to be the most frequent mutation in SPG7. This variant was observed at low frequency in 1000genomes and EVS (0.1%; and 0.3%;) but with a frequency of 1%; in our in-house database. The novel variant p.P750L has never been reported in any public or our in-house databases. Both variants are predicted to be pathogenic and are present at a conserved position. Clinical similarities between our patients and reported SPG7 cases, as well as the segregation of the variants with the phenotype confirms SPG7 as the causal gene in this family. The presence of a causing variant in 1%; of the population highlight the existence of "not so rare" variants causing recessive rare diseases and this should be taken into account when searching for genetic causes.

1203T

Discovery, validation and genotyping of CNVs by analysis of genome sequence and microarray. *D. Antaki[1], M. Gujral[1], W. Brandler[1], J. Michaelson[1], D. Malhotra[1], J. Estabillo[1], C. Corsello[4], J. Sebat[1,2,3].* 1) Institute for Genomic Medicine, La Jolla, CA; 2) Department of Psychiatry, UCSD, La Jolla, CA; 3) Department of Cellular and Molecular Medicine, UCSD, La Jolla, CA; 4) Autism Discovery Institute, Rady Children's Hosptial, San Diego, CA.

Advances in Next Generation Sequencing technology have enabled detection of an unprecedented array of structural genetic variants including Copy Number Variants (CNVs). CNVs confer risk for a variety of psychiatric and neurodevelopmental disorders, including Autism Spectrum Disorder (ASD). As we begin to apply whole genome sequencing approaches in our genetic studies of ASD, sensitive and accurate methods for CNV detection are needed. We applied a combination of DNA analysis techniques to the investigation of a cohort of 161 samples (28 ASD trios and 19 discordant sibling pair quad families), including deep 40X whole genome sequencing (325 bp libraries with 100 bp paired end reads), and two independent genotyping array platforms (Affy 6.0 and Illumina 2M). Genotyping was executed via a clustering algorithm, partitioning around medoids, resulting in significant noise reduction commonly found with SNP chip hybridization assays while distinctly segregating CNVs into clusters of heterozygous or homozygous duplications or deletions. Our robust multifaceted clustering method further enabled the detection of de novo CNVs. We demonstrate the advantage of a multidimensional approach in clustering and genotyping CNVs as opposed to the standard unidimensional approach.

1204S

Meta Analysis of Case/Control Autism Exome Sequencing Data. *J.A. Kosmicki[1,2], K. Roeder[3,4], B. Devlin[5], J.D. Buxbaum[6,7,8,9,10,11], M.J. Daly[1,2,12], Autism Sequencing Consortium.* 1) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, 02114; 2) Stanley Center for Psychiatric Research and Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, 7 Cambridge Center, Cambridge, MA, 02142; 3) 3Ray and Stephanie Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA; 4) Department of Statistics, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA; 5) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA; 6) Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 7) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 8) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 9) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 10) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 11) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 12) Harvard Medical School, Boston, Massachusetts, USA.

Autism spectrum disorders (ASDs) currently affect 1 in 66 individuals and are highly heterogeneous in their phenotypic outcome ranging from severely affected individuals with speech impairment, intellectual disability, and behavioral problems to mildly affected individuals. Our understanding of the genetic architecture of ASD has drastically improved thanks in part to large-scale exome sequencing of individuals with autism focusing on rare loss-of-function (LoF) de novo mutations. Here we continue the work, calculating case/control association statistics on all variants, not just the LoF variants, from the exome sequences of 1300 cases and 3318 controls of European descent across three repositories collected by the Autism Sequencing Consortium (ASC). The case/control results were meta-analyzed using a modified version of weighted Z-scores with inverse variance to account for differential allele frequencies in rare variants across the three population samples. Single variant tests were computed using exact tests for the rarest variants (MAF < 4.33×10-3). Rare variant burden tests were used for low frequency (< 0.001%) LoF variants in a given gene to achieve sufficient statistical power to detect association.

Four coding variants falling into four separate genes (*C4BPA*, *BPTF*, *DFNB31*, and *STAG1*) and one gene, *MTMR2*, were identified as exome-wide significant by the single variant and rare variant burden tests respectively. Of the five genes, only *C4BPA* has never been associated with ASD. These and other top results were explored further using the transmission disequilibrium test (TDT) on 1241 trios collected by the ASC which have provided to date the primary discovery analysis through patterns of de novo variation (see abstracts by De Rubeis and He). Of the four exome-wide significant single variants, only *DFNB31* shows over transmission from the TDT. Going forward, combining results from case/control and trio association studies using a unified statistic may increase our power to detect novel genetic associations.

1205M

Interstitial duplication Xp11.4 and triplication of Yq11.22 leading to disruption of TSPAN 7 and NLGN4Y in a child with autism. *W.S. Baek.* Neurology, Parkside Medical Group, Upland, CA.

Introduction TSPAN 7(tetraspanin 7) is a gene of the tetraspanin superfamily located at Xp11.4, which is highly expressed in the prefrontal cortex. TSPAN 7 mutations have been reported to be associated with non-syndromic X-linked mild to moderate mental retardation. NLGN4Y (neuroligin 4, Y-linked) is a protein-coding gene located at Yq11.22, of which missense mutations leading to loss-of-function has been reported in autism. We report an unprecedented case with a combination of both Xp11.4 duplication and Yq11.22 triplication leading to partial duplication of the TSPAN 7 gene presenting as autism. Keywords: tetrspanin 7(TSPAN 7), neuroligin 4, Y-linked (NLGN4Y), copy number variant (CNV), autism Materials and Methods: Case Report A 5 year-old Hispanic boy presented with autism. Birth and family history were unremarkable. He had speech delay and behavioral problems. He was receiving special education and speech therapy. He was not dysmorphic. Results: SNP microarray analysis detected a 1.40MB interstitial duplication of Xp11.4 and a 5.67 MB interstitial triplication of Yq11.22, which was found to be a familial inheritance. Conclusions: The interstitial duplication of Xp11.4 led to disruption of the TSPAN 7 gene. As the duplication disrupts the gene, this may result in a dominant-negative effect. Inheritance of an X chromosome copy number variant (CNV) from a clinically normal mother may yield clinical consequences in male offspring due to differences in gene dosage. The interstitial triplication of the Yq11.22 led to disruption of the NLGN4Y (neuroligin 4) gene. Missense mutations of NLGN4Y leading to loss-of-function have been reported in autism. Although direct inheritance of a Y chromosome CNV from a phenotypically normal father is generally considered not to be clinically significant, we hypothesize that this too might have had an additive effect on the proband.

1206T

TRPM1, the transient receptor potential cation channel M1, harbors rare putatively damaging missense variants disproportionately transmitted to affected sibs in schizophrenia quads. *S. Gulsuner[1], T. Walsh[1], M.-C. King[1], J.M. McClellan[2].* 1) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 2) Department of Psychiatry, University of Washington, Seattle WA.

Schizophrenia can be caused by de novo damaging mutations, either point mutations or CNVs. We extended this model to search for rare inherited damaging mutations in schizophrenia. We screened exome sequence data of the parents of 81 quads, each including a proband with schizophrenia and a healthy sibling. For each gene, all rare putatively damaging variants were identified and aggregated gene by gene. Applying the rare variant transmission disequilibrium test with discordant siblings (RV-TDT-DS), we calculated chi-square values for transmission disequilibrium of these variants for every gene. Genome-wide, the gene TRPM1 was the most extreme outlier for disequilibrium in transmission of rare damaging variants. At TRPM1, 14 parents carried putatively damaging variants, which were transmitted to 11 of 14 affected children and to 2 of 14 unaffected siblings (X2 = 11.63, 1 df; P=0.0006). All rare putatively damaging variants were missense mutations at highly conserved residues. TRPM1 encodes the Transient Receptor Potential Cation Channel M1, which is highly expressed in retina, melanocytes, and brain. In rod bipolar cells, TPRM1 mediates synaptic transmission, specifically by depolarizing bipolar cells in response to glutamate release from photoreceptors. Recessive loss-of-function mutations in TRPM1 lead to congenital stationary night blindness. Recurrent gene-disrupting CNVs at TRPM1 have been previously identified in both schizophrenia and autism patients. TRPM1 lies in the 1.5 MB hotspot for such CNVs on 15q13.3. We suggest screening other cohorts of quads or trios with schizophrenia or autism for transmission disequilibrium at TRPM1, and conversely, evaluating the frequency of mental illness phenotypes in parents of children with congenital stationary night blindness. We also suggest evaluating the possible role of TRPM1 in synaptic transmission in brain structures.

1207S

Screening for Mutations in Non-Syndromic Autosomal Recessive Intellectual Disability Genes in Non-Consanguineous Intellectual Disability and Autism Populations. *X. Liu[1], K. Mittal[2], N. Vasli[2], A. McNaughton[1], A. Mikhailov[2], K. Roetzer[3], M. Hudson[1], C. Windpassinger[3], P. Magee[1], L. Al Ayadhi[4], W. Kaschnitz[3], E. Petek[3], D.J. Stavropoulos[5], M.J. Carter[6], M. Ayub[1], J.B. Vincent[2].* 1) Dept Psychiatry, Queen's Univ, Kingston, ON, Canada; 2) MiND LAB, CAMH, Toronto, ON, Canada; 3) Human Molecular Genetics Institute, Medical University of Graz, Graz, Austria; 4) King Saud University, Ryadh, Saudi Arabia; 5) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 6) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto ON Canada.

Intellectual disability (ID) and autism spectrum disorder (ASD) are believed to occur each with a prevalence of ~1% . In addition, ID is present in upto 70% of individuals with ASD, and in ID populations as many as 28% may meet criteria for ASD. Both ASD and ID are frequently the result of genetic aberrations, however only a fraction of patients currently receive a genetic diagnosis. Genes identified for ID have frequently been implicated in ASD and vice versa. Autosomal recessive (AR) mutations are the main cause of ID in populations where consanguinity rates are high, but even in outbred populations the rate may be 13-24%. Here we use a targeted next generation sequencing approach using Ampliseq primer pools and the Ion Proton platform to assess the involvement of known recessive ID genes in outbred ID and ASD populations, and comparison to some known dominant and X-linked genes. We combined this with a pooling strategy to enable mass screening. Our primer pools targeted 96 known ID and ASD genes, including 67 genes reported as non-syndromic ARID genes, 7 reported as syndromic ARID genes, 3 reported as AR ASD genes, 12 reported as autosomal dominant ASD or ID genes, and 6 reported as X-linked ID or ASD genes. To date, using pools of 20, we have screened ~1,200 ASD and 740 ID individuals from outbred populations. We included as positive controls two samples, with known homozygous base substitution or deletion. Our work flow and pipeline aimed to identify nonsense and damaging missense mutations and indels, homozygous or compound heterozygous for AR, heterozygous for dominant and X-linked recessive and hemizygous for X-dominant. Alignment and analysis was performed using Ion Torrent and Ion Reporter. The control base substitution was present in ~10% of reads for that pool, indicating good coverage and identification, however the 5bp deletion was present in only 8 out of 1300 (0.6%), suggesting the alignment for indels is inefficient. Although analysis and validation is ongoing, we have identified numerous variants of interest in NS-ARID genes such as MAN1B1, but very few in others. We have also identified variants of interest in X-linked genes PTCHD1 and MECP2. A pooling strategy for targeted gene sequencing is an efficient means of screening large numbers of patients for multiple candidate genes, however improved alignment algorithms are needed to identify indels. Some AR genes may be relatively common causes of ID and ASD in outbred populations.

1208M

Association study of *TREM2* exon 2 variants with late-onset Alzheimer's disease in Iranian elderly population. *Z. Mehrjoo[1], A. Najmabadi[2], S.S. Abedini[1], K. Kamali[3], H. Najmabadi[1], H.R. Khorram Khorshid[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Division of Biological Sciences, University of California, San Diego, California, USA; 3) Reproductive Biotechnology Research Center, Avicenna Research Institute, Academic Center for Education Culture and Research (ACECR), Tehran, Iran.

Dementia, a major elderly disability, is increasing all over the world, especially in developing countries. The most common form of dementia is Alzheimer's disease (AD [MIM 104300]), which is defined as a neurodegenerative disorder that affects memory, behavior and thinking ability; it then impairs basic body movement, and eventually leads to death. Recent studies on AD disclosed significant association between the rs-75932628-T variant of the *TREM2* [MIM 605086] gene and AD in European and North American populations, but not in Han Chinese individuals where no rs-75932628-T was identified in AD patients and controls. So far none of these association studies have covered Middle Eastern population. We performed this study to analyze the association between *TREM2* exon 2 variants and late-onset AD in Iran. Until now a total of 131 AD patients and 157 controls have been genotyped using PCR and Sanger sequencing. The rs-75932628-T allele frequency in this cohort of Iranian elderly population was higher than other reported populations (0.86%) but did not show a statistically significant association with AD (odds ratio [OR]: 4.8; 95% confidence interval [CI]: 0.54 to 43.6; P = 0.270). Although we identified more rare variants in AD patients compared to controls, the abundance of TREM2 rare variants do not reach a statistically significant association with AD, which could be a result of low sample size. Therefore, to continue this study and to obtain meaningful results, we are collecting and genotyping more samples.

1209T

Increased Genome-wide Burden of Rare Coding Variants in Schizophrenia. *L.M. Olde Loohuis[1], J.A.S Vorstman[2], A.P. Ori[1], K.A. Staats[1], T. Wang[1], J. DeYoung[1], R.S. Kahn[2], R.M. Cantor[1,3], R.A. Ophoff[1,2,3].* 1) Center for Neurobehavioral Genetics, University California Los Angeles, Los Angeles, CA; 2) Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Department of Human Genetics, University of California Los Angeles, Los Angeles, USA.

Schizophrenia is a highly heritable polygenic disorder with suspected neurodevelopmental and immunological components. While GWAS continue to uncover common single nucleotide variants (SNVs) contributing to this phenotype, to date, these variants explain only a portion of the estimated heritability. In addition to common variants, rare variants have been found to play a role in disease risk, including de novo mutations and genomic copy number variants. However, due to their low minor allele frequencies and modest effect sizes, it is difficult to establish association with rare SNVs using standard association tests. We assessed the burden of rare SNVs in schizophrenia by analyzing the cumulative effects of coding variants occurring in cases or controls only. Our analysis is based on exome SNP array genotyping of 1,002 schizophrenia cases and 931 controls from a homogeneous population from the Netherlands. Using CONDEL, a scoring tool for estimating the functional impact of non-synonymous SNVs, we assigned a burden score to each individual by summing the scores of every variant carried. In cases versus controls, we observe a significantly increased individual genome-wide rare variant burden for deleterious non-synonymous variants (empirical P = 0.024). In addition, an increased number of genes with double hits (empirical P = 0.035), as well as splice site variants (empirical P = 0.003) were seen. The genes implicated by the increased burden of rare coding variants overlap significantly with genes from recent GWAS (empirical P = 0.033), and are enriched for those that are expressed in fetal brain and spleen. We demonstrate that non-synonymous rare variants are important in the etiology of schizophrenia. Previous reports suggest the enrichment primarily of singleton nonsense variants in schizophrenia in a set of pre-selected genes. Our results now extend these and implicate non-synonymous SNVs at a genome-wide level. This signal is enriched for genes implicated through GWAS studies of schizophrenia, implying the contribution of common and rare variants to schizophrenia from the same loci. The genes containing these rare coding variants overlap significantly with genes expressed in the fetal brain and spleen, highlighting the potential involvement of neurodevelopment and immune system in disease etiology.

1210S

Targeted sequencing of candidate genes identified in extended families with Alzheimer disease. *J. Rehker[1], R. Levy[1], R. Nesbitt[1], Q. Yi[2], B. Martin[2], D. Nickerson[2], W. Raskind[2], J. Shendure[2], Z. Brkanac[1].* 1) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

Late onset Alzheimer's disease (AD) is a most common cause of dementia. The genetics of AD is complex with contribution from rare and common variants. In addition to PSEN1, PSEN2 and APP rare variants with large effects were recently identified in TREM2 and PLD3. This indicated that additional genes might play a role in AD. To identify novel genes we have performed exome sequencing in 14 families with 4 or more affected cases that include at least one distant relative (cousin). For each family we have performed frequency filtering to identify private functional variants that most closely co-segregate with the disease. We defined private variants as not present in 1000 Genomes, ESP6500 and dbSNP132. This way we have identified 21 novel candidate genes. To obtain statistical evidence for association we performed a large gene-based case-control study. For 21 candidate genes, whose coding sequence encompass 68,518 bp, and 8 known AD genes we have performed Molecular Inversion Probes (MIP) capture and targeted sequencing of 879 familial AD cases and 478 cognitively normal elderly controls. The cases were obtained from NCRAD and NIMH collections and controls from ACT study. Variant calling and annotation were performed in the same manner as for exome sequencing with modifications due to MIP capture and multiplexing. After quality control, 839 cases and 466 controls were used in analysis. In our analysis we have identified 14 rare functional PSEN1 variants in FAD cases and none in controls (P= 0.0054, Chi-square) thus confirming the validity of our case-control approach. Our case-control analysis excluded 8 genes as candidates as they had more private variants in controls as compared to cases. For three novel genes the association with AD was nominally significant at $p<0.05$ and for 10 genes the analysis was inconclusive due to lack of power or low level of sequencing coverage. The novel gene with the strongest association has 25 rare functional variants in cases and 1 variant identified by the same criteria in controls (p=0.0007). This is highly significant but it does not reach significance level of 10-6 required for genome-wide correction. In order to increase the power of our study we have performed additional sequencing of 13 candidate genes in 384 cases and controls from NCRAD-LOAD study, and 220 cases and 150 controls from Washington University. We will report the results of our combined analysis.

1211M

Identification of Molecular Markers in Parkinson's Disease Using Next Generation Sequencing. *S.M. Sperber[1], Y. Shi[2,3], R. O'Rourke[3], K. Jones[3], E. Berry-Kravis[4], E. Spector[2,3], D. Hall[4].* 1) Genetic Testing Laboratory, Department of Genetics & Genomic Sciences, Icahn School of Medicine at Mt. Sinai, New York, NY; 2) Children's Hospital of Colorado, Aurora, CO; 3) University of Colorado AMC, Aurora, CO; 4) Rush University, Chicago, IL.

Parkinson's disease (PD) is a complex heterogenic neurodegenerative disorder with insidious onset and devastating progressive decline currently affecting over 4.5 million older Americans. Prevalence is projected to double by 2030 causing considerable economic burden. High impact genes that contribute to PD have been identified in individual families and by GWAS studies. How different genetic variants influence the PD phenotype has yet to be fully explored. A targeted test could rapidly identify variants in multiple genes simultaneously that provide risk information and may be informative for potential phenotypic categorization necessary for future therapies. Here we identified genetic variants contributing to PD in a cohort of clinically defined PD patient samples compared to genome population data using a targeted panel of genes associated with PD and next generation sequencing techniques. Ninety-nine patients meeting Gelb criteria for PD were interviewed, examined, and had blood collected for genotyping. The mean age was 68.9±10.3 years, 65% male, and age of onset of disease was 62.1±10 years. Mean UPDRS motor score was 25±11 and mean UPDRS total score was 40±16. A set of high impact genes associated with PD was exon sequenced in a targeted manner, using a PCR-based enriched panel. Sequencing the cohort's genes identified on average, greater than 300 variants per patient. One hundred and nine variants of potential clinical interest were identified. Of the 109 variants, 26 were previously identified as pathogenic, 34 were of uncertain significance, 2 were suggested to be associated with a reduced risk of PD and 47 are likely benign. The patients exhibited variant profiles that highlight the utility of genetic testing to further define the gene pathways and their associated phenotypic characteristics. The targeted nextgen panel is sensitive, cost effective and efficient. The information collected will provide a necessary link between phenotypic and genotypic data pointing to particular pathways for further investigation. Mutation in the chromatin-remodeling factor BAZ1A is associated with intellectual disability. *A. Zaghlool, J. Halvardson, J. Zhao, A. Kalushkova, K. Konska, H. Jernberg-Wiklund, A-C. Thuresson, L. Feuk.* Immunology, Genatics & Patholohy, Science for Life Laboratory, Uppsala University, Sweden.

Exome sequencing of trio samples has led to the identification of several mutations in genes involved in chromatin remodeling in syndromic forms of intellectual disability. However, in most cases functional studies to understand the biological contribution of the mutations to the disease symptoms are still lacking. Here, we used exome sequencing to identify a single non-synonymous de novo mutation in BAZ1A, encoding the ATP-utilizing chromatin assembly and remodeling factor 1 (ACF1), in a patient with severe intellectual disability, autism, profound speech impairment, seizures, hypotonia, hypoplastic finger-nails and distal phalanges. ACF1 has been previously reported to bind to the promoter of vitamin D receptor (VDR) regulated genes and suppress their expression in the absence of vitamin D. Using RNA sequencing, we found that the mutation in BAZ1A affects the expression of many genes, mainly involved vitamin D3 metabolism, synaptic function and extra cellular matrix organization. The differential expression of CYP24A1, involved in vitamin D3 metabolism, and SYNGAP1, involved in axonal formation and synaptic function, correlate with the clinical diagnosis of the patient. By chromatin immunoprecipitation analysis, we show that the differential expression of CYP24A1 is caused by reduced binding affinity of the mutated ACF1. We therefore propose that BAZ1A represents yet another chromatin remodeling gene involved in causing an intellectual disability syndrome.

Whole Exome Sequencing in Females with Autism Implicates Novel and Candidate Genes. *M.G. Butler[1], S.K. Rafi[1], H. Wang[2], D. Stephan[3], A.M. Manzardo[1].* 1) Psychiatry δ Behavioral Sciences and Pediatrics, University of Kansas Medical Center, Kansas City, KS, USA; 2) Silicon Valley Biosystems, Foster City, CA, USA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Classical autism or autistic disorder belongs to a group of genetically heterogeneous conditions known as Autism Spectrum Disorders (ASD) with a predominant male to female (4:1) ratio. The overall occurrence rate is higher than epilepsy or Down syndrome. Although understudied in females, heritability estimates are as high as 90%. A recent review of genetic linkage data, candidate genes and genome-wide association studies along with high resolution DNA microarray and next generation sequencing have led to a compilation of clinically relevant candidate and known genes for ASD for a total of 629 genes (Butler et al., 2014). We chose to undertake whole exome sequencing of 30 well-characterized Caucasian females with autism (average age, 7.7 ± 2.6y; age range, 5 to 16y) selected from the Autism Genetic Research Exchange (AGRE) repository (www.agre.autismspeaks.org) from multiplex families having a high probability of causation due to gene disturbances. Genomic DNA (5μg) samples were used for whole exome sequencing via paired-end next generation sequencing approach using the Illumina HiSeq2000 platform with the Agilent SureSelect Human All Exon v4 - 51Mb. Primary sequence data files were aligned to the reference, variants called and functional significance of each variant was calculated to generate a rank-ordered list. The list of disease causing genes were developed with the primary selection criteria using a machine learning-derived Classification (G2M) score and adding cutoff levels for other predictive parameters (GERP2, PolyPhen2, and SIFT). Putative candidate genes and genomic variants were then subjected to further screening for biological significance. We identified between 100 and 300 genes showing genomic variants of novel or candidate genes for autism per subject using the Classification (G2M) score >0.5, increasing to >0.7 further narrowed the list to 10 to 20 genes. Seventy-eight genes were identified as meeting our selection criteria, range of 1 to 9 genes per female. Five subjects presented with disturbances of X-linked genes (*SYTL4, GPRASP2, PIR, IL1RAPL1, GABRQ*). The cadherin, protocadherin and ankyrin repeat gene families were most commonly disturbed (e.g., *CDH6, FAT2, PCDH8, CTNNA3, ANKRD11*) along with genes related to neurogenesis and neuronal migration (e.g., *SEMA3F, MIDN*) indicating the usefulness of whole exome sequencing in females with ASD from multiplex families to enable identification of known and novel gene mutations.

1214M

Novel compound heterozygous PIGT mutations caused multiple congenital anomalies-hypotonia-seizures syndrome 3. *M. Nakashima[1], H. Kashii[2], Y. Murakami[3], M. Kato[4], Y. Tsurusaki[1], N. Miyake[1], M. Kubota[2], T. Kinoshita[3], H. Saitsu[1], N. Matsumoto[1].* 1) Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Division of Neurology, National Center for Child Health and Development, Tokyo, Japan; 3) Research Institute for Microbial Diseases and World Premier International Immunology Frontier Research Center, Osaka University, Osaka, Japan; 4) Department of Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan.

Recessive mutations in genes of the glycosylphosphatidylinositol (GPI)-anchor synthesis pathway have been demonstrated as causative of GPI deficiency disorders associated with intellectual disability, seizures, and diverse congenital anomalies. In this study, we performed whole exome sequencing in a Japanese patient with progressive encephalopathies and multiple dysmorphism with hypophosphatasia and identified novel compound heterozygous mutations, c.250G>T (p. Glu84*) and c.1342C>T (p. Arg488Trp), in PIGT encoding a subunit of the GPI transamidase complex. The surface expression of GPI-anchored proteins (GPI-APs) on patient granulocytes was lower than that of healthy controls. Transfection of the Arg488Trp mutant PIGT construct, but not the Glu84* mutant, into PIGT-deficient cells partially restored the expression of GPI-APs DAF and CD59. These results indicate that PIGT mutations caused neurological impairment and multiple congenital anomalies in this patient.

1215T

Common, low frequency, and rare coding variants in CHRNA5 contribute to nicotine dependence in European and African Americans. *E. Olfson[1], N.L. Saccone[2], E.O. Johnson[3], N. Breslau[4], D. Hatsukami[5], K. Doheny[6], L. Fox[1], S.M. Gogarten[7], K. Hetrick[6], C.C. Laurie[7], B. Marosy[6], J. Stitzel[8], J. Rice[1], A. Goate[1], L.J. Bierut[1].* 1) Department of Psychiatry, Washington University School of Medicine, St Louis, MO; 2) Department of Genetics, Washington University School of Medicine, St Louis, MO; 3) Behavioral Health Epidemiology Program, RTI International, Research Triangle Park, NC; 4) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI; 5) Department of Psychiatry, University of Minnesota, Minneapolis, MN; 6) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 7) Department of Biostatistics, University of Washington, Seattle, WA; 8) Institute for Behavioral Genetics, University of Colorado, Boulder, CO.

Purpose: The functional nonsynonymous variant rs16969968 in the α5 nicotinic receptor subunit gene (CHRNA5) is the single strongest genetic risk factor for nicotine dependence in European Americans (MAF=0.35), and evidence suggests a similar contribution to risk in African Americans (MAF=0.06). Additional variants in CHRNA5 likely increase liability for nicotine dependence. This study examines targeted sequence data from approximately 3,000 unrelated cases and controls to assess the influence of CHRNA5 coding variation on nicotine dependence. Methods: Community-based recruitment enrolled subjects aged 25-45. Cases had a Fagerstrom Test for Nicotine Dependence score of ≥4 and controls had a score of 0 or 1. Custom next-generation sequencing with mean on-target coverage of 180X was performed on regions associated with smoking behaviors. Logistic regression was used to model case-control status with the variables sex, age, ethnicity, individual common variants (MAF≥5%), individual or collapsed low frequency variants (5%>MAF≥0.5%), and collapsed rare variants (MAF<0.5%). Results: Sequencing identified 24 nonsynonymous variants and 2 frameshift deletions of high quality in CHRNA5. The well-studied rs16969968 was the only common variant among these, and the minor allele was associated with increased risk of nicotine dependence (OR=1.28, p= 0.0007). Three low frequency nonsynonymous variants were identified, and all individually trended in the risk direction. The collapsed low frequency variant term demonstrated that presence of a minor allele was associated with nicotine dependence (OR=1.45, p=0.01). The remaining 22 coding variants were rare (each occurred in 1-4 individuals), and similarly, the collapsed term revealed a risk effect (OR=2.39, p=0.03). Nagelkerke's adjusted R^2 was used to assess the proportion of nicotine dependence variation explained by CHRNA5 variants after adjustment for sex and age. In European Americans, the well-studied rs16969968 variant gave an R^2 of 0.9%, and the addition of all CHRNA5 coding variants increased the R^2 to 2.4%. In African Americans, rs16969968 gave an R^2 of 0.2%, and adding all coding variants increased the R^2 to 0.8%. Conclusions: Our findings suggest that common, low frequency, and rare coding variants in CHRNA5 are associated with increased risk of nicotine dependence. Coding variation in CHRNA5 accounts for over 2% of the nicotine dependence variation in European Americans and close to 1% in African Americans.

Trio-based exome sequencing indicates the ion homeostasis is relevant to bipolar disorder. *N. Matoba[1,2], M. Kataoka[1,3], K. Fujii[4], T. Kato[1].* 1) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN BSI, Wako, Saitama, Japan; 2) Department of Medical Genome Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Kashiwa, Chiba, Japan; 3) Department of Child Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku,Tokyo, Japan; 4) Department of Psychiatry, Dokkyo Medical University School of Medicine, Mibu,Tochigi, Japan.

Background Bipolar disorder (BD) is a mental disorder characterized by recurrent manic and depressive episodes. Heritability of BD is reportedly around 59-87% (Smoller et al., 2003). Though recent genome wide association studies (GWAS) showed associated with several SNPs, each candidate SNP has a weak effect and can collectively explain only 38% of heritability (Lee et al., 2011). Therefore, we hypothesize that multiple rare variants may also contribute to BD.

Methods We recruited participants mainly through E-mail newsletter of Bipolar Disorder Research Network Japan. All probands and their parents were interviewed by a trained psychiatrist using M.I.N.I. In total 59 trios including 35 original trios and independent 24 trios were analyzed. From the exome sequencing data of these trios, we selected only rare variants referring to public databases such as dbSNP137. These variants were classified as “transmitted” or “un-transmitted” based on the inheritance pattern. Then we investigated the characteristics of the set of transmitted variants compared to those in un-transmitted.

Results There was no significant difference of numbers of variants between two groups. Gene ontology analysis showed significant enrichment of 57 GO terms in transmitted variants, of those 6 GOs were confirmed in independent 24 trios. These GOs included calcium ion homeostasis. In addition, this finding was not observed in trios of healthy siblings of probands with autism spectrum disorder (ASD), which showed slightly similar trends in some of those GOs.

Discussion Our finding highlights the role of multiple rare damaging variants related to ion homeostasis in the pathophysiology of BD, which has been supported by genetic association with SNPs of calcium channel genes by GWAS and elevated calcium levels in blood cells among others. The findings need to be replicated in a larger set of families including multiple ethnicities. Since we directly compared "transmitted" and "un-transmitted" variants, the result of gene enrichment analysis are robust to artifacts due to gene length or GC contents and so on. This simple but robust approach could also be utilized to other complex genetic diseases.

1217M

Genome-wide analysis of copy-number variation in Canadian children with developmental coordination disorder implicates neurodevelopmental genes. *F.P. Bernier[1,2,3], S.J. Mosca[2], L.M. Langevin[3,4], A.M. Innes[1,2,3], A.C. Lionel[5,6], C.C. Marshall[5,6], S.W. Scherer[5,6], J.S. Parboosingh[2,3,7], D. Dewey[3,4,8].* 1) Clinical Genetics, Alberta Children’s Hospital, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Calgary, Alberta, Canada; 3) Alberta Children’s Hospital Research Institute, University of Calgary, Alberta, Canada; 4) Department of Pediatrics, University of Calgary, Alberta, Canada; 5) The Centre for Applied Genomics and Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 6) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 7) Genetic Laboratory Services, Alberta Health Services, Calgary, AB, Canada; 8) Department of Community Health Sciences, University of Calgary, Alberta, Canada.

Developmental coordination disorder (DCD) is a common neurodevelopmental disorder characterized by functional motor performance deficits that interfere with daily activities in children and adults. In this pilot study we performed copy number variant (CNV) analysis in 82 well-characterized Canadian children between the ages of 8 and 17 with DCD and 2,988 healthy European controls using identical 2,500,000 SNP microarrays and CNV calling algorithms. We detected a statistically significant increased rate of both rare CNVs (p=0.018) and rare, genic CNVs (p=0.009) between 500 and 1000Kb in cases compared to controls. Within genic CNVs, there was an enrichment of duplications spanning brain-expressed gene (p=0.039) and genes previously implicated in other neurodevelopmental disorders (p= 0.043). Loci previously implicated in other neurodevelopmental disorders were investigated further. Genes and loci of particular interest in this group included: GAP43, RBFOX1, PTPRN2, SHANK3, 16p11.2, and distal 22q11.2. Our findings provide compelling evidence supporting a genetic basis for DCD, and further implicate rare CNVs in the etiology of neurodevelopmental disorders. Our data also suggests that there might be shared susceptibility genes for DCD and other neurodevelopmental disorders.

1218T

Copy Number Variation in Han Chinese Individuals with Autism Spectrum Disorder. *M.J. Gazzellone[1,2], X. Zhou[1,3,4], A.C. Lionel[1,2], M. Uddin[1], B. Thiruvahindrapuram[1], W. Jia[3], S. Caihong[3], L. Shuang[3], K. Tammimies[1,5], S. Walker[1], J. Wei[1], Z. Wang[1], Z. Mingyang[3], L. Wu[3], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 3) Department of Children’s and Adolescent Health, Public Health College of Harbin Medical University, Harbin, Heilongjiang, People’s Republic of China; 4) Heilongjiang Provincial Centre for Disease Control and Prevention, Harbin, Heilongjiang, People’s Republic of China; 5) Center of Neurodevelopmental Disorders, Department of Women’s and Children’s Health, Karolinska Institutet, Stockholm, Sweden.

Background: Autism Spectrum Disorders (ASDs) are a group of neurodevelopmental conditions with a demonstrated genetic etiology. Rare (<1% frequency) copy number variations (CNVs) account for a proportion of the genetic events involved, but the contribution of these events in non-European ASD populations remains relatively unexplored. As clinical microarray testing becomes the adopted standard of care across medical genetics labs worldwide, studies describing the genetic architecture in these other ASD populations will become even more important. Here, we report on rare CNVs detected in a cohort of individuals with ASD of Han Chinese background. **Methods:** DNA samples were obtained from 104 ASD probands and their parents who were recruited from Harbin, China. Probands were diagnosed using the Autism Behavior Checklist (ABC) and Childhood Autism Rating Scale (CARS). The DNA samples were genotyped on the Affymetrix CytoScan HD platform, a high-resolution array comprised of nearly 2.7 million probes. High-confidence CNVs were detected using multiple CNV-calling algorithms. Rare CNVs were identified by comparing data with 873 technology-matched controls from Ontario and 1,235 additional population controls of Han Chinese ethnicity. **Results:** 8.6% of the probands had at least 1 *de novo* CNV (overlapping the *GIGYF2*, *SPRY1*, 16p13.3, 16p11.2, 17p13.3-17p13.2, *DMD*, and *NAP1L6* genes/loci). Rare inherited CNVs affected other plausible neurodevelopmental candidate genes including *GRID2*, *LINGO2*, and *SLC39A12*. An Asian-specific copy number polymorphism (duplication) was also identified at the *YWHAE* locus, which has previously been described as etiologic in ASD and other developmental disorders. **Conclusions:** Our findings help define genomic features relevant to ASD in the Han Chinese and emphasize the importance of using ancestry-matched controls in medical genetic interpretations.

Next Generation Sequencing for the study of ALS and other Motor Neuron Diseases. *C. Gellera[1], B. Castellotti[1], V. Pensato[1], S. Magri[1], D. Di Bella[1], G. Lauria[2], N. Ticozzi[3], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative and Metabolic Diseases, Fondazione IRCCS - Istituto Neurologico Carlo Besta, Milan, Italy; 2) Unit of Neurology,Fondazione IRCCS - Istituto Neurologico Carlo Besta, Milan, Italy; 3) Department of Neurology and Laboratory of Neuroscience, IRCCS Istituto Auxologico Italiano, Milan, Italy.

ALS is an adult-onset, progressive, neurodegenerative disease caused by the selective loss of motor neurons with a large prevalence of sporadic cases (SALS). The pathogenesis is largely unknown, but genetic factors likely play a major role in the disease. Although mutations in several genes have been described, the underlying cause is still unknown in about 50% of familial ALS (FALS) and in the large majority of SALS (80%). Genetic determinants are unlikely to be explained by traditional strategies (linkage analysis or candidate gene approach). In order to better define the genetic contribution in SALS and to fill the genetic gap in FALS, we set up an integrated NGS approach as follow: 1) customized gene panel screening, 2) wide exome sequencing (WES), 3) variant filtering and validation. The panel has been designed by TruSeq Custom Amplicon Studio Design Illumina and includes 31 ALS causative genes. Validation process indicates that these genes are analyzed with a coverage of > 90%. Though still in a limited number of SALS (n=26) (selected to be negative for SOD1, FUS, TARDPB and C9ORF72 gene mutations), data analysis allowed the identification of several variants of possible pathogenic significance. After a first filtering step which excludes intronic variants and known polymorphisms with MAF > 1%, we get a report showing on average 50 variations per sample in exonic or splicing regions. In 10 cases we identified at least one variant of possible pathogenetic significance: 2 cases with a missense variants in GARS gene, 1 case with a missense mutation in VCP gene already described in association with the disease, 1 case with a missense mutation in OPTN gene, 1 case with a missense mutation in SIGMAR1 gene, 1 case with a stop mutation in NEFH gene, 1 case with a missense mutation in DCTN1 gene, 1 case with 2 missense variants in SETX gene, 1 case with a missense variant in SQSTM1 gene, 1 case with a splicing mutation in ASAH1 gene. The genetic panel designed and validated in our laboratory will be used for a high genetic definition process not only for FALS but also for SALS or other overlapping motor neuron phenotypes. WES is currently in progress for 85 FALS of our cohort in an International collaborative study (John Landers, University of Massachusetts; Vincenzo Silani, University of Milano; Cinzia Gellera, Istituto Neurologico Besta, Milano) supported by ARISLA foundation.

Exome sequencing of mesial temporal lobe epilepsy with hippocampal sclerosis in parent-offspring trios. *S.S. Cherny[1], J.K.L. Wong[1], P.C. Sham[1], L. Baum[2], P. Kwan[3].* 1) Department of Psychiatry, University of Hong Kong, Pokfulam, Hong Kong; 2) School of Pharmacy, Chinese University of Hong Kong, Shatin, Hong Kong; 3) Department of Medicine, University of Melbourne, Australia.

Mesial temporal lobe epilepsy related to hippocampal sclerosis (MTLE-HS) is recognized to be the most drug resistant type of epilepsy, and HS is the most common pathological substrate identified in pharmacoresistant temporal lobe epilepsy. The condition is characterized by relatively well-defined clinical, electrographic, radiologic, and pathologic changes. Despite attempts in finding genetic variants associated with epilepsies by genome-wide association studies on European and Chinese subjects by our team and collaborators, limited common variants reached genome-wide significance. Meanwhile, the causes of the pathological changes in MTLE-HS remain unknown, and no preventive intervention has been identified. Discovery of novel genetic markers could allow screening patients with aggressive epilepsy subtypes for early surgical or pharmaceutical intervention, and ultimately lead to genetic therapies. To further explorer the contribution of new, rare variants in MTLE-HS, we plan to sequence exomes of 30 trios of probands with their unaffected parents. So far we have sequenced 9 trios, and 10 *de novo* mutations were identified. Among these, two *de novo* mutations are within genes involved in neurological functions (*NLGN3* and *NBEAL1*) and might be involved in disease development. *NLGN3* was reported to be associated with X-linked autism in a Swedish family and given the high comorbidity of autism spectrum disorders with epilepsy, this *de novo* mutation might contribute to MTLE-HS development.

1221T

Homozygous mutation in Synaptic Vesicle Glycoprotein 2A gene results in intractable epilepsy, microcephaly, intellectual disability and growth retardation. *A. Huq, F. Serajee.* Pediatrics and Neurology, Wayne State University, Detroit, MI.

Synaptic Vesicle Glycoprotein 2A (SV2A) is the binding site of anti-epileptic drug levetiracetam and thus the only known synaptic vesicle target of central nervous system targeted treatment. To date, no pathogenic variant in SV2A gene has been identified in human. We have identified a homozygous mutation in SV2A gene in a patient with intractable epilepsy, microcephaly, intellectual disability and growth retardation. The proband is 4-year-and 6-month old girl of South Asian descent whose parents are multiply consanguineous. She was born healthy but never developed any ability to hold her head up, track or reach for objects. At 2 months of age, she developed seizures and dystonic posturing. The EEG showed multifocal spikes, giant spike and waves correlating with myoclonic seizures and diffuse attenuation superimposed by diffuse fast wave activity correlating with tonic spasms. Her seizures did not respond to antiepileptic medications including clonazepam, topiramate, and levetiracetam and ketogenic diet. The family refused any trial of Vigabatrin or ACTH. The proband also had a brother who died at 7 months of age after a similar disease course. Laboratory studies revealed normal chromosome microarray pattern, mitochondrial studies and metabolic profile. Full exome sequencing, and bioinformatics analysis suggested a homozygous arginine to glutamine mutation in amino acid position 383 (R383Q) in exon 5 of SV2A gene as the candidate mutation. Both the parents were carriers for R383Q variant. Mutations in SV2a gene are not currently known to cause any Mendelian disorder in human. The R383Q change is not observed in known healthy cohorts, exome databases and Database of Single Nucleotide Polymorphisms. Given that heterozygous parents are healthy, it is likely R383Q change acts in a recessive manner. Although SV2A influences exocytosis of neurotransmitter-containing synaptic vesicles, at a cellular level the exact point at which neurotransmitter release is affected in synapse by SV2A remains unknown. The mutation in our patient lies on the cytosolic loop before the 7th transmembrane domain of the protein and alters the second adenine binding domain in SV2A protein suggesting that the mutation may alter SV2A-mediated vesicle priming by adenine nucleotides.

1222S

Personalized medicine in the treatment of epilepsy. *R.G. Lafreniere[1], E. Rossignol[2], F.F. Hamdan[2], S. Mahmutoglu[3], S.L. Girard[1], D. Andrade[3,4], A. Dionne-Laporte[5], C. Boelman[3], M. Blazejczyk[6], O. Diallo[5], A.M. Laberge[2], M. Cadieux-Dion[1], M.P. Dubé[6], G.A. Rouleau[5], H.C. Mefford[7], B. Minassian[3], J.L. Michaud[2], P. Cossette[1], the Canadian Epilepsy Network (CENet).* 1) CHUM Research Centre, Montreal, Canada; 2) Centre Hospitalier Universitaire Sainte-Justine Research Center, Montreal, Canada; 3) The Hospital for Sick Children, Toronto, Canada; 4) Toronto Western Hospital, Toronto, Canada; 5) McGill University, Montreal, Canada; 6) Montreal Heart Institute, Montreal, Canada; 7) Department of Pediatrics, University of Washington, Seattle, WA.

Epilepsy is a common complex neurological disorder characterized by recurrent episodes of paroxysmal abnormal electrical discharges in the brain (seizure). In 65% of epileptic individuals seizures occur without detectable lesion in the brain. Intellectual disability (ID) is observed in ~25% of epileptic individuals. Although treatment is effective in the majority of cases, more than 30% of patients are resistant to anti-epileptic drugs (AEDs). In this project, we hypothesize that pharmaco-resistant epilepsies (PRE) have different etiologies than other epilepsy syndromes associated with the same clinical manifestations, and posit that genetic factors can be used to predict response to AEDs. In 2013, we united Canadian clinicians and investigators to create the Canadian Epilepsy Network (CENet). In order to identify highly penetrant genetic variants that can predict resistance to AEDs, we will conduct whole genome sequencing (WGS) on 1000 epileptic individuals with extremes of response to AED treatment, including 200 multiplex families, as well as 200 epileptic trios (patient + both parents) with severe epilepsy and ID. Based on our previous studies in patients with ID or autism spectrum disorders, we expect a high rate of de novo mutation for epilepsies associated with these co-morbidities. Potentially causative genes/variants will be validated in additional epilepsy samples available through our large collaborative network with similar but complementary projects in the US (Epi4K - 4,000 epilepsy genomes) and Europe (EpiPGX). We will also assess the clinical utility of whole genome sequencing as a diagnostic test for epilepsy in a prospective cohort of 600 epileptic individuals. So far, pre-screening of 36 known genes for epileptic encephalopathy (EE) in 95 patients led us to identify 11 causative mutations in total (11.6%). At the end of the project, we expect to identify 50 novel genes causing severe forms of epilepsy and PRE. Using this catalog of gene variants, we will develop and validate a diagnostic resource (PRE-GENE) to implement WGS as the gold-standard diagnostic test for PRE in clinical practice.

1223M

Identification of rare variants from exome sequencing in a large family with dyslexia. *A. Carrion-Castillo[1], C. Francks[1,2], B. Franke[3], S.E. Fisher[1,2].* 1) Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands; 2) Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, Netherlands; 3) Radboud university medical center, Radboud University, Nijmegen, Netherlands.

Dyslexia is one of the most common human neurodevelopmental disorders (5-10% prevalence), and it has a complex genetic aetiology. So far, the common disease - common variant approach has not identified many risk alleles. Most of the heritability for dyslexia therefore remains unexplained. With the goal of identifying a rare variant with an individually substantial effect on this complex trait, we analyzed a 30 member multigenerational pedigree with dyslexia, in which evidence for a susceptibility locus in Xq27.3 has previously been identified by parametric linkage analysis based on microsatellite genotyping (de Kovel et al. 2004). In the current study, we sequenced the exomes of 10 affected members of the family. After quality-based and frequency-based (MAF ≤0.01) filtering we identified 177 exonic, non-synonymous, rare variants present in at least 7 affected members and not in a set of unrelated people. Microsatellite genotypes and common SNPs called from the exome data were combined to perform nonparametric linkage analysis, which defined three major regions of interest (NPL> 2) on chromosomes 2q, 20q and Xq, and suggestive regions (NPL> 1) on 13 other chromosomes. The 177 variants identified by sequencing were then inferred in the rest of the family members by sampling inheritance vectors from a Markov chain Monte Carlo analysis of the multilocus marker data. We used the imputed allelic dosages for exomic variants to carry out family-based association analysis and to determine which sequence variants reside on the haplotypes that co-segregate with dyslexia in this family. Association and linkage results were used to prioritize a subset candidate variants for validation by Sanger sequencing in all the family members.

1224T

Analysis of major amyotrophic lateral sclerosis genes in Japan. *R. Nakamura[1], J. Sone[1], N. Atsuta[1], H. Watanabe[1], D. Yokoi[1], H. Watanabe[1], M. Ito[1], J. Senda[1], F. Tanaka[2], G. Sobue[1], the Japanese Consortium for Amyotrophic Lateral Sclerosis research (JaCALS).* 1) Department of Neurology, Nagoya University Graduate School of Medicine, Nagoya, Japan; 2) Department of Neurology, Yokohama City University Graduate School of Medicine, Yokohama, Japan.

Background Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disease characterised by progressive upper and lower motor neuron loss. Five to ten percent of ALS patients have a family history of the disease, whereas most patients are sporadic. Mutations in over 20 genes have been identified to cause familial ALS, such as SOD1, TARDBP, FUS, OPTN, ANG and C9orf72. Mutations in these genes have also been identified in some sporadic ALS patients. *Purpose* To investigate the frequency and contribution of mutations in the known ALS genes in sporadic ALS patients in Japan. *Methods* A next-generation sequencing procedure based on the custom AmpliSeq™ panel was designed for sequencing 28 ALS causative or susceptibility genes on the Ion Torrent Personal Genome Machine (PGM™). We analyzed 219 sporadic Japanese ALS patients. *Results* Mutations were identified in 19 of ALS patients. SOD1 mutations were identified in 6 patients, FUS in 3 patients, OPTN in 2 patients, DCTN1 in 2 patients, TARDBP in one patient, SETX in one patient, SPG11 in one patient, ZNF512B in one patient, PRPH in one patient, and FIG4 in one patient. Seven of those mutations were novel non-synonymous variants, and were not present in normal controls. *Conclusions* We identified that 19 sporadic ALS patients have mutations of causative or susceptibility genes of ALS in Japan. This result would help neurologists in clinical practice, especially in genetic counselling.

1225S

De Novo Mutations in Autistic Children from Multiplex Families. *C.L. Simpson[1], Y. Kim[1], C. Wassif[2], N. Hansen[3], J. Mullikin[3], E. Tierney[4], F.D. Porter[2], J.E. Bailey-Wilson[1].* 1) Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, MD; 2) Section on Molecular Dysmorphology, National Institute of Child Health, National Institutes of Health, Bethesda, MD; 3) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Kennedy Krieger Institute, Baltimore, MD.

The presence of excess of de novo single nucleotide variants (SNVs), insertion/deletion (INDEL) and copy number variants (CNVs) has been widely reported in the analysis of whole exome sequencing (WES) in simplex autism families. It is unclear if this is a general excess or if this increased frequency is particularly marked in gene-disrupting mutations. It is also not known if this excessive mutation rate is also observed in multiplex families. We aimed to investigate if affected probands and affected siblings in multiplex families showed excess of de novo mutation compared to unaffected children. We performed WES in 124 individuals from 26 families with 2 or 3 affected children from the Autism Genetic Resource Exchange (AGRE). Poorly performing variants were identified and removed in Golden Helix SVS. Mendelian errors in SNVs were identified using PLINK. Mendelian error rates for the offspring in each pedigree were calculated in R and compared both within and across families using Welch's T test. SNVs were classified into coding and noncoding variation and sub-classified into missense, nonsense and silent mutations. There were 126 affected and 50 unaffected offspring. After quality control, 2.7% of all variants were identified as inconsistent in at least two independent pedigrees and removed as probable sequencing artifacts before analysis leaving 959224 SNVs. Affected individuals did not show higher overall rates of Mendelian inconsistency than unaffected individuals (p=0.4). Comparing only coding SNV mutation rates did not show a significant difference between cases and controls (p=0.8) and there was also no difference when sub-classifying into missense (p=0.6), nonsense (p=0.1) or silent mutations (p=0.6). De novo mutations have been reported as important in simplex autism families and nonsense mutations are the main driver of this excess de novo variation. Overall mutation rates for our multiplex families do not exhibit excessive de novo variation in affected compared to unaffected individuals. Even focusing on only coding variation, no differences appear between cases and controls. Examining the different classes of coding variation, our multiplex families demonstrate a different pattern of de novo variants compared to simplex families. Neither missense, nonsense nor silent mutations show any observed differences between cases and controls. Analyses of additional data and extension of this analysis to INDELs and CNVs are ongoing.

1226M

Differences in Genetic Features May Explain the Discordance of Monozygotic Twins for Schizophrenia. *C. Castellani[1], J. Gui[1], M. Melka[1], R. O'Reilly[2], S. Singh[1,2].* 1) Department of Biology, The University of Western Ontario, London, Ontario, Canada; 2) Department of Psychiatry, The University of Western Ontario, London, Ontario, Canada.

Despite their presumed identity, monozygotic twins often display discordance for a number of traits and disorders including schizophrenia. Attempts to identify causal genes for this common, devastating and often familial disease have remained challenging. Interestingly, the concordance for this disease in monozygotic twins is only 50%, suggesting that traditional genetic elements alone may not account for their origin and manifestation. To this end, we have proposed that the discordance for this disease in monozygotic twins may be due to ontogenetic de novo mutations. Further, the de novo events may include copy number variations, structural variants, indels and single nucleotide variants. In order to test this hypothesis, we have analyzed DNA extracted from blood samples of two pairs of monozygotic twins discordant for Schizophrenia and their parents using Complete Genome Sequencing.

The analysis of the data has revealed that the genomic sequence of monozygotic twins harbor unique variations at the DNA level. The best explanation for some of these differences includes de novo events. Also, a number of these de novo variants present in the affected twins are not shared with their co-twin and may contribute to their disease discordance. We have confirmed a number of such using Real Time PCR technology. These include a CNV loss at 7q11.21, and CNV gains at 15q11.2 and 12q24.21. In addition, a large-scale tandem duplication spanning from 1p36.31 to 1p36.33 which overlaps many genes including the GABRD that has been previously associated with schizophrenia in humans. Further, a number of Single Nucleotide Variants and small insertions and deletions have been identified to be unique between monozygotic twins and not found in parental samples. The results are compatible with the suggestion that the genetic differences between monozygotic twins may arise during ontogeny. More importantly, depending on the gene(s) affected these differences may play a role in the discordance of twins for diseases, including schizophrenia.

1227T

Association analysis of MAPT with cerebrospinal fluid tau using targeted sequencing data in older adults with mild cognitive impairment or Alzheimer's disease. *K. Deters[1], K. Nho[1], S. Kim[1], M.W. Weiner[3], T. Foroud[1], J.Q. Trojanowski[2], L.M. Shaw[2], R.C. Green[5], A.W. Toga[4], A.J. Saykin[1].* 1) Indiana University School of Medicine, Indianapolis, IN; 2) University of Pennsylvania School of Medicine, Philadelphia, PA; 3) University of California, San Francisco, San Francisco, CA; 4) University of Southern California, Los Angeles, CA; 5) Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

The microtubule associated protein tau (*MAPT*) gene encodes the protein tau, one of the main contributors to the pathogenesis of Alzheimer's disease (AD). SNPs of *MAPT* have previously been associated with AD and cerebrospinal fluid (CSF) levels of tau. However, most studies focused on only six haplotype-tagging SNPs of *MAPT*. While SNP genotyping covers only limited portions of the whole genome, whole-genome sequencing (WGS) has been used to obtain the most comprehensive genetic variation of an individual. Thus, we identified complete common variants (minor allele frequency (MAF) > 5%) of the MAPT gene from WGS data to investigate a comprehensive genetic association to CSF tau. WGS of 762 non-Hispanic Caucasian participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI) was used to identify common variants within *MAPT* resulting in 870 SNPs after standard quality control steps. Linear regression models were then used to investigate the association of *MAPT* common variants with CSF tau covarying for age, sex, and *APOE* status. Permutation testing was used to adjust for multiple-testing comparisons. Gene-based analysis of *MAPT* was significantly associated to CSF tau (p=0.03, corrected). *MAPT* SNPs rs117199550 (p=0.018, corrected) and rs63750072 (p=0.039, corrected) were significantly associated with CSF tau and were in linkage disequilibrium (r2=0.616, D'= 0.861). Rs117199550 is intronic and rs63750072 is located in an exon excluded from the major isoforms expressed in the brain but has been implicated in Frontotemporal dementia. Our results suggest that variance within *MAPT* is associated with CSF tau levels. To our knowledge, this is the first study to perform a comprehensive association analysis of *MAPT* variants with CSF tau using WGS. Our findings also suggest that WGS might enable the discovery of new variants associated with AD-related biomarkers.

1228S

Deep whole genome sequencing reveals multiple hits in non-coding sequence of autism risk genes. *F. Hormozdiari[1], M. Duyzend[1], B. Coe[1], J. Huddleston[1], D. Hanna[1], J. Smith[1], P. Sudmant[1], D. Nickerson[1], E. Eichler[1,2].* 1) Genome Sciences, University of Washington, Seattle, WA., Select a Country; 2) Howard Hughes Medical Institute, Seattle, WA.

Exome sequencing of thousands of children with autism spectrum disorder (ASD) has led to the discovery of hundreds of candidate genes based on the excess of disruptive mutations in when compared to unaffected siblings. The combination of de novo coding mutations and known pathogenic copy number variations (CNVs), however, still only accounts for a fraction of simplex ASD cases (~35% of the affected probands). In order to assess the importance of non-coding variation, we performed deep genome sequencing (>50 fold sequence coverage) on 16 autism trios where no de novo truncating mutation had been identified based on exome sequencing. We generated a comprehensive assessment of all types of genetic variation (SNVs, indels, CNVs and mobile element insertions) using a combination of tools (GATK, FreeBayes, Pindel, CommonLaw and GenomeStrip). As expected, we observed a linear correlation between paternal age and number of de novo SNVs per proband (r = 0.49). An average of 45 de novo SNVs and 1760 inherited deletions were identified per trio. In total, we characterized 322 private deletions (>200bp) of which 128 mapped within or near genes. 25% (4/16) of trios showed a pattern of multiple de novo mutations and private deletions in the non-coding region of genes previously implicated in autism and neurodevelopmental disease. One proband, for example, carried four de novo mutations in the intronic regions of *ARID1B*, *ROBO1* (x2) and *STXBP4*. Another proband inherited a 35 kbp and 150 kbp deletion of *MBD5* and *DISC1*, respectively, in addition to a de novo mutation within *ARID1B*. A third patient had a de novo mutation in the noncoding sequence of a metabotropic glutamate receptor, *GRM3*, in addition to three inherited deletions ranging in size from 12 to 120 kbp in autism risk genes *CACNA2D4*, *ARID1B* and *SCN2A*. The convergence of multiple rare non-coding mutations of a potentially deleterious nature in probands provides support for an oligogenic model of autism where the disruption of gene regulation in multiple targets contributes to disease etiology.

1229M

Exome sequencing in extended families with age-related macular degeneration reveals enrichment of genes involved in extracellular matrix pathway. *R. Priya[1], S. Perez[1], M. Mutsuddi[2], K. Branham[3], M. Othman[3], J. Heckenlively[3], A. Swaroop[1].* 1) Neurobiology-Neurodegeneration & Repair Laboratory (N-NRL), National Eye Institute, Bethseda, MD; 2) Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, India; 3) Department of Ophthalmology, University of Michigan, Ann Arbor, MI, USA.

Age-related macular degeneration (AMD) is a major cause of visual impairment in elderly population. Genome- wide association studies have identified 20 common susceptibility loci, which explain up to half of the AMD heritability. More recently targeted sequencing has helped identify penetrant, high-risk low-frequency coding variants at some of the known AMD loci. To further understand the genetic contributions of rare exonic variants, we undertook whole exome sequencing (WES) in 19 AMD families with 2-5 affected members. Exome of 69 samples from 19 families were captured using Agilent SureSelect Human All Exon kit and sequencing data was generated on Illumina GAIIx. Reads were aligned to the human reference genome (NCBI build 37.3) using Burrows-Wheeler Aligner, variants were called using GATK and annotations were done using ANNOVAR. We identified 343 rare segregating variants (MAF ≤ 0.05%) in these families. Subjecting this list to the pathway analysis using the database for annotation, visualization and integrated discovery (DAVID) recognized genes in extracellular matrix (ECM) as top functional clustering. ECM pathway along with complement and lipid metabolisms pathways have been associated with AMD based on GWAS studies. Thus it was interesting to see this association in exome sequencing analysis. Many of these candidates were highly expressed in human fetal (Retina, RPE and Choroid), aged and AMD (Retina) transcriptome data that are relevant in AMD pathophysiology. Taken together, our data shows that exome sequencing in extended AMD families can provide important insights into the disease etiology.

1230T

Large scale whole genome sequencing of Bipolar disorder 1 cases and controls in the BRIDGES study. *L.J. Scott[1], H.M. Kang[1], A.E. Locke[1], M. Flickinger[1], C. Quick[1], J. Carlson[1], D. Absher[2], Z. Chen[1], S. Vrieze[1], J. Li[3], S. Ramos[3], B. Li[3], J.L. Sobell[4], M. Rivera[5,6], L. Legrand[7], M. Burmeister[3,8,9], W.G. Iacono[7], M. McGue[7], M.T. Pato[4], J.A. Knowles[4], G. Abecasis[1], M. McInnis[8,10], S. Zoellner[1,8], G. Breen[5,6], C.N. Pato[4], J.B. Vincent[11], S. Levy[2], R.M. Myers[2], M. Boehnke[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) HusdonAlpha Institute for Biotechnology, Huntsville, AL; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Psychiatry and the Behavioral Sciences, Zilkha Neurogenetics Institute, University of Southern California, Los Angeles, CA; 5) Medical Research Council Social, Genetic and Developmental Psychiatry Center, Institute for Psychiatry, King's College London, London, UK; 6) National Institute for Health Research Biomedical Research Centre for Mental Health at the Maudsley and Institute of Psychiatry, King's College London, London, UK; 7) Department of Psychology, University of Minnesota, Minneapolis, MN; 8) Department of Psychiatry, University of Michigan, Ann Arbor, MI; 9) Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI; 10) University of Michigan Depression Center, Ann Arbor, MI; 11) Center for Addiction and Mental Health. Department of Psychiatry, University of Toronto, ON, Canada.

Bipolar disorder 1 (BP I) is characterized by alternating periods of mania and depression and affects > 1% of individuals worldwide. Bipolar disorder is highly heritable and a substantial fraction of the heritability appears attributable to common variants. Genetic contributions from rare (< .5% minor allele frequency (MAF)) and low (.5 ≤ MAF < 5%) frequency variants are less well defined. Exome sequencing studies are exploring the contributions of coding variation, but in non-coding regions, rare and low frequency variants have been less well queried. Our aim is to ask if there are rare and low frequency non-coding or coding variants with strong effects on BP I risk. We are performing large-scale whole-genome sequencing (coverage ~10-12 x) of blood-based DNA from >3,770 European ancestry BP I cases and unrelated controls with no history of mental illness (BRIDGES study). Our current analysis contains 2,793 individuals: 1,382 BP I cases and 1,411 controls. We identified 43.4M SNPs using the GotCloud pipeline, of which 3.7M are low frequency, 12.2M rare, non-singleton and 21.4M singletons. We have 80% power (additive model) at an alpha of 5×10^{-8} to detect a single variant with 5, 1 or .5% MAF with odds ratios (OR) > 2, 3.6 or 5.3. Likewise, we have 80% power to detect at least one out of 10 variants with MAF of 5, 1 or .5% MAF for variants with OR > 1.7, 2.6, or 3.6, respectively. Using logistic analysis of single variants with adjustment for 10 principle components, we did not observe genome-wide significance association for any variant. We also did not observe multiple testing corrected significant gene-level associations of low-frequency (MAF < 1%) protein truncating and/or protein altering variation using SKAT-O or the CMC test, or from burden testing of deleterious coding singleton variants. Our current analyses suggest that, similar to other many other common, complex diseases, there are no or few moderately rare or low-frequency variants of large effects on risk for BP1. Larger sample sizes and sequencing-based studies will be necessary more fully query the contributions of BP1 risk variants from across the allelic spectrum.

1231S

Trio-Based Whole Genome Sequence Analysis of a Cousin Pair with Refractory Anorexia Nervosa. *P. Shih[1], A. Van Zeeland[2], A. Bergen[3], T. Carland[4,5], V. Bansal[1], P. Magistretti[6], W. Berrettini[7], W. Kaye[1], N. Schork[1,5].* 1) Dep of Psychiatry, Univ California, San Diego, La Jolla, CA; 2) Cypher Genomics, La Jolla, CA; 3) SRI, Palo Alto, CA; 4) The Scripps Research Institute, La Jolla, CA; 5) J. Craig Venter Institute, La Jolla, CA; 6) Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 7) University of Pennsylvania, Philadelphia, PA.

Anorexia Nervosa (AN) has an onset during adolescence and is characterized by emaciation, fear of gaining weight despite being underweight, and has the highest mortality rate of all psychiatric illnesses. Despite the serious health and psychosocial consequences of this illness, very few treatments are effective at reversing the core symptoms of AN. AN is highly heritable and show a homogeneous clinical presentation of persistent food refusal and high anxiety traits. However, AN etiology is believed to be heterogeneous as no major susceptibility gene has been consistently replicated in multiple populations. AN symptoms and personality traits tend to be present in unaffected family members of the patients, suggesting that certain shared genetic factors within each family may contribute to unique phenotype risk of the affected. To gain insights into the role "private variants" may play in AN and to maximize genetic information from family members of AN, here we leveraged a family-based study design combined with whole genome sequencing to search for genetic variants that may influence AN risk in an affected cousin pair together with their parents. By capitalizing on the homogeneity of the disease presentation among the two cousins, who both have a diagnosis of refractory AN, we report methods by which we interrogated shared chromosomal segments transmitted to them from their common grandparents that carried likely AN-related functional variants in this family.

Exome Association Study and 2nd SNP-GWAS of Japanese Parkinson's disease. *W. Satake[1], D. Shigemizu[2], Y. Suzuki[3], K. Yamamoto[4], H. Tomiyama[5], M. Yamamoto[6], M. Murata[7], N. Hattori[5], T. Tsunoda[2], M. Kubo[8], S. Tsuji[9], Y. Nakamura[10], S. Sugano[3], T. Toda[1].* 1) Div of Neurol/Mol Brain Sci, Kobe Univ, Japan; 2) Med Informatics, Cen for Genome Med, RIKEN, Japan; 3) Dept of Med Genome Sci, the Univ of Tokyo, Japan; 4) Kurume Univ, Japan; 5) Dept of Neurol, Juntendo Univ, Japan; 6) Takamatsu Neurol Clinic, Japan; 7) Dept of Neurol, Natl Cen Hsp of Neurol and Psy, Japan; 8) Genotyping Development, Cen for Genome Med, RIKEN, Japan; 9) Dept of Neurol, The Univ of Tokyo, Japan; 10) The Univ of Chicago, USA. The Univ of Tokyo, Japan.

Parkinson's disease (PD) is a complex disorder caused by multiple genetic variants, and one of the most common neurodegenerative disorders worldwide. We previously reported a Japanese SNP-GWAS which detected 4 PD-risk loci; *PARK16*, *BST1*, *α-synuclein*, and *LRRK2* (Satake *et al*, *Nature Genet* 2009). In order to search for further PD-risks in exonic areas, we performed whole exon (exome) sequencing of 755 PD patients using Sureselect and HiSeq2500. Average depth of our data is x 126, and 94.4 % of whole exon sequence was covered by 10 x or more reads. At first, using exome sequencing data of 625 PD cases and 259 controls, we tested association between PD and exonic SNVs within the 4 PD-loci (*PARK16*, *BST1*, *α-synuclein*, and *LRRK2*) reported by our previous SNP-GWAS. Genetic variants with strong PD-risk do not exist within these 4 PD-loci, indicating that these 4 PD-loci will contribute to this disease as common variants. We will subsequently test association between whole exonic SNVs and PD to identify novel PD-genes haboring rare-variant risks. Moreover, in parallel, to identify further common variant PD-risks, we performed Japanese 2nd SNP-GWAS which expanded our previous one. Using 1,948 cases and 28,990 controls, we identified a novel susceptibility locus with $P < 5 \times 10^{-8}$. Expression level of a gene within the locus is reduced when the risk SNP exists. In a fly model, knockout of the gene worsen moter function. Our genomic and *in-vivo* model data show that this gene is a novel PD-risk.

1233T

Identifying Genetic Variants Associated with Anorexia Nervosa via Exome Sequencing. *Q. Wei[1], E. Pruett[1], R. Adan[2], R. Cone[1], B. Li[1].* 1) Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Department of Neuroscience and Pharmacology, Rudolf Magnus Institute of Neuroscience, University Medical Centre, Utrecht, The Netherlands.

Anorexia Nervosa (AN) is a psychiatric illness characterized by inability to maintain a minimal normal weight and persistent fear of gaining weight. It has the highest rate of mortality among psychiatric disorders and is estimated to affect 0.5%-1% of the population. Family and twin studies indicated that AN is highly heritable, and the estimated genetic contribution ranges 56-75%. However, the genetic etiology of AN is largely unknown. Previous genome-wide association studies assaying common variants failed to reveal genome-level significance. In this study, we carried out exome sequencing to identify rare variants associated with AN. We sequenced 24 AN patients and 47 of their relatives from pedigrees with high load of AN as well as 65 unrelated cases, and obtained 178 controls from National Database for Autism Research. In our analysis we focused on genes that are expressed in the prefrontal cortex of brain and functional variants (nonsynonymous, stop and splicing) that are deleterious predicted by Polyphen-2 and SIFT, LRT, MutationTaster, or CADD. Four genes (XIRP2, EXOG, MUSK, GRM6) harboring rare deleterious variants are enriched in AN patients with $p<0.0001$ in the single variant test. Furthermore, we carried out gene-based burden tests by collapsing multiple rare variants in a gene, and identified KIAA0317 with $p < 0.001$. We are exploring different grouping and weighting schemes for gene-based burden tests as well as pathway and network-based analyses to potentially increase power.

1234S

A Population-based Approach for Detecting Rare Recessive Variation Implicates the Cholesterol Biosynthesis Gene *DHCR24* in Autism Spectrum Disorder and Intellectual Disability. *E.T. Lim[1,2], Y. Chan[1,2], S. Goetze[1], D. Spatt[2], L. Kratz[3], M.B. Johnson[1,2], M. Chahrour[1,2], J.N. Hirschhorn[1,2], S. Raychaudhuri[2,4], J.M. Silverman[5], A. Kolevzon[5], J. Buxbaum[5], F. Winston[2], R.I. Kelley[3], M.J. Daly[2,6], C.A. Walsh[1,2], T.W. Yu[1].* 1) Boston Children's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Kennedy Krieger Institute, Baltimore, MD; 4) Brigham and Women's Hospital, Boston, MA; 5) Mount Sinai School of Medicine, New York, NY; 6) Massachusetts General Hospital, Boston, MA.

We developed and applied a statistical method (RAFT for Recessive Allele Frequency-based Test) for detecting rare recessive variants to a whole-exome genotyping dataset for ~1,000 families and discovered a rare missense variant (allele frequency = 0.5%) in *DHCR24*, a cholesterol synthesis gene, that is inherited recessively in 3 children from a single European American family affected by autism spectrum disorder (ASD). Subsequently, we discovered another 2 families of Middle Eastern ancestry with 6 children affected by ASD and intellectual disability with 2 other rare recessive missense variants in *DHCR24* (RAFT $P = 7.64 \times 10^{-10}$).

Recessive deleterious mutations in *DHCR24* have been associated with the cholesterol biosynthesis disorder desmosterolosis. But other than neurodevelopmental impairment, two of the three families did not exhibit additional distinctive features to suggest that diagnosis. Cholesterol is known to be important for the formation of myelin sheaths and membrane lipid rafts, and is a signaling molecule involved in critical developmental pathways that regulates skeletal and limb development. Recessive mutations in several genes that affect the precursors for cholesterol synthesis have been implicated in various neuro-developmental diseases, such as Smith-Lemli-Opitz syndrome, desmosterolosis and lathosterolosis. *DHCR24* is also named *Seladin-1* (Selective Alzheimer's Disease Indicator-1) based on initial discoveries that the mRNA expression of the gene was found to be down-regulated in individuals with Alzheimer's Disease.

To evaluate the cholesterol synthesis functionality of the missense variants identified in ASD patients, we adapted a protocol to express human *DHCR24* mutant proteins under the control of a GAL1 promoter in S. cerevisiae (Gilk et al., 2010) and optimized a biochemical assay for measuring desmosterol to cholesterol conversion (Waterham et al., 2001) to evaluate the pathogenicity of the missense variants detected in these families with autism and intellectual disability. Having validated the approach, we are now applying it to the mutations we have observed to test if the missense variants result in reduced cholesterol synthesis.

1235M

Mutational and transcriptional analysis in Autism Spectrum Disorders support their oligogenic model disturbing common functional pathways. *M. Codina-Solà [1, 2, 3], B. Rodriguez-Santiago[3, 4], J. Background: Autism spectrum disorders (ASD) are a group of neurodevelopmental disorders with high heritability. There is high genetic heterogeneity and recent genetic findings support a double or multiple-hit model. **Methods**: We have performed Whole Exome Sequencing (WES) in 36 ASD patients to identify ASD causative mutations and rearrangements along with RNAseq to study the transcriptomic consequences. Pathway enrichment studies were performed by ConsensusPathDB. **Results**: We have detected likely causative mutations with monogenic models in 6 cases: 3 de novo loss-of-function mutations (genes *SCN2A*, *MED13L* and *KCNV1*), one de novo missense (*CUL3*) and two X-linked inherited mutations (genes *MAOA*, *CDKL5*). Inherited missense mutations in candidate genes, rarely mutated in controls, including *SCN2A* and *MED13L* were also found in the ASD cohort, suggesting the presence of ASD risk variants, contributing in an additive manner to the phenotype. Transcriptomic studies validated 90% of WES variants, identified deregulation (overexpression of *SEM6AB*, *MECP2*), Allele Specific Expression (*FUS*, *EP300*) and nonsense mediated decay (*RIT1*, *ALG9*) as a consequence of rare mutations. Pathway enrichment studies of inherited rare variants reveal the presence of recurrent alterations, including the previously implicated pathways PI3K-Akt signaling and Axon Guidance. **Conclusions**: WES has proven to be a highly efficient technology to identify the molecular defect in a proportion of probably monogenic ASD forms in our cohort (16.6%), as well as to detect potential risk variants contributing to the disorder in an additive oligogenic manner. Concomitant whole blood transcriptomic data allowed us to evaluate in part the functional consequences of genetic variants. Deregulation of common functional pathways by rare inherited variants such as PI3-Akt signaling pathway and Axon guidance could guide the identification of pharmacological treatments.

Whole-exome sequencing of multiplex families identifies several rare coding variants in known and novel Late-Onset Alzheimer genes. *B.W. Kunkle[1], M.A. Kohli[1], K.L. Hamilton[1], W.R. Perry[1], R.M. Carney[1], P.L. Whitehead[1], J.R. Gilbert[1], E.R. Martin[1], G.W. Beecham[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) Hussman Institute for Human Genetics, University of Miami, Miami, FL; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH.

We performed whole-exome sequencing (WES) on 28 multi-generational, late-onset Alzheimer disease (LOAD) families to identify rare LOAD risk variants. The pedigrees chosen for WES display a dominant inheritance pattern, have an average of eight Alzheimer-affected subjects, are free of known Alzheimer disease (AD) mutations, and do not cluster for the APOEe4 allele. 1-4 affected subjects per pedigree were sequenced in 22 families. Results for these families were combined with six previously reported pedigrees (4-9 affected subjects sequenced). Variants were filtered for segregating, nonsynonymous or splice-site rare variants (MAF<0.005) assuming autosomal or X-linked dominant models. Filtered variants were examined for implication as LOAD candidate genes by comparing results across families, and by comparison to GWAS-confirmed LOAD susceptibility genes and biologically relevant KEGG AD pathway genes. Six new rare missense variants in the genes PLEKHG5, ADAMTSL4, OR2L13, ZBTB11, CCDC39, and SEMA4B segregated with disease status in two or more different families. An additional family segregated a separate rare missense variant in PLEKHG5, and another family segregated a different rare missense mutation in ADAMTSL4. Three candidate genes (ABCG2, CD163L1, DMD) from our previously reported WES received additional support, and a new variant in the previously reported TTC3 gene segregated in two different pedigrees. Several of these genes have been functionally implicated in dementia-related processes and diseases (i.e. SEMA4B regulates axonal extension and synapse development; ABCG2 is involved in amyloid-β clearance across the blood brain-barrier; TTC3 is a Down syndrome critical region protein crucial for neuron survival), supporting their potential role in LOAD pathogenesis. In addition to these candidates, filtered variants also segregated with disease in the two LOAD GWAS genes (SORL1 and EPHA7), and several KEGG AD pathway genes (LPL, CACNA1D, RYR3, GRIN2A and NCSTN), making them important candidates for causal variants. In conclusion, WES of LOAD pedigrees identified several rare missense variants co-segregating with disease in multiple families and supported the involvement of rare variants in previously reported genes (TTC3, SORL1 and EPHA7) as being involved in AD risk.

1237S

Targeted resequencing of non coding functional DNA elements in autism. *D. Malhotra[1 6], A. Watts[1], T. Chapman[1], N. Plongthongkum[2], A. Gore[2], A. Fung[2], K. Zhang[2], J. Sebat[1 3 4 5].* 1) Department of Psychiatry, University of California San Diego, La Jolla, CA, USA; 2) Department of Bioengineering, University of California San Diego, La Jolla, CA; 3) Institute of Genomic Medicine, University of California San Diego, La Jolla, CA; 4) Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA; 5) Beyster Center for Genomics of Neuropsychiatric Diseases, University of California San Diego, La Jolla, CA; 6) Neuroscience Discovery and Translational Area, Pharma Research & Early Development (pRED), F. Hoffmann-La Roche Ltd, Basel, Switzerland.

While the role of rare de novo loss of function single nucleotide variants (SNVs) and copy number variants (CNVs) in autism is now firmly established, the genetic contribution of non-coding functional DNA elements to autism risk is unknown. We developed an inexpensive and high-throughput padlock probe based assay to resequence 5 megabase (Mb) of non-coding functional genome in 500 autism quad families from Simons Simplex Collection (SSC). We designed 77,277 padlock probes to capture the target region which mainly includes a) conserved mutation hotspots (CMH) in the human genome and, 2) putative enhancer and promoter elements of 95 high-risk autism genes. We performed a series of optimization experiments to develop an assay that a) captured 99.7% of target bases, b) had high sensitivity and specificity to detect SNVs confirmed empirically by testing the assay in two hapmap trios that were whole-genome sequenced at deep coverage by the 1000 genomes project and, c) had greater than 40X coverage per base per sample in a 384 sample multiplexed Illumina HiSeq sequencing run. Our experimental approach and study design will provide insights into the role of rare variation in the non-coding functional genome in risk for autism.

1238M

Identification of Rare Variants for Bipolar Disorder by Exome Sequencing in Multiplex Families. *S. Ramdas[1], J. Li[2], AB. Ozel[2].* 1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Bipolar Disorder is a heritable psychiatric disease characterized by alternating manic and depressive episodes. The phenotypic and genetic complexity in this disorder has made the identification of causal genes or biological pathways a considerable challenge. In this study, we focus on 34 multigeneration multiplex BPD families from the NIMH repository. Owing to the high occurrence of BPD in these families, we hypothesize that these families represent a nearly Mendelian subset of bipolar cases and transmit one or a few high-impact coding variants that result in the disorder. We genotyped and performed exome sequencing for 90 affected individuals in 34 families representing first cousin pairs or more distant relatives, aiming to detect functionally damaging rare variants in regions shared by affected relatives. Variant filtering were applied to identify those that are bi-allelic, have a minor allele frequency of less than 1% in European samples from the Exome Sequencing Project and 1000 Genomes, and are damaging missense, nonsense, or splicing site variants, resulting in a median of 508 variants per family. As exome chip genotype data allow inference of genomic segments shared among family members identically by descent (IBD), we used Beagle to identify IBD regions shared by BPD cases within each family. This led to a further reduction in the number of candidate variants, with a median of 147 variants. We found that HLA genes HLA-DRB1 and HLA-DRB5 showed damaging mutations in 8 and 7 families respectively. These genes have been previously reported to be associated with schizophrenia. Also found in our final list of genes are glutamate receptors GRIK3 and GRIN3B, and calcium channel receptor CACNA1C, all of which are known risk loci. Validation and segregation analyses using 254 additional members of the same families are underway to further prioritize the candidate genes and pathways (This study is supported by the IMHRO - Johnson & Johnson Rising Star Translational Research Award.).

1239T

A Cohort for Researching Autism Genetics in New Zealand. *B. Swan[1], J.C. Jacobsen[1], R. Hill[2], B. Tsang[3], M. Taylor[1], D. Love[4], J. Taylor[5], R.G. Snell[1], K. Lehnert[1].* 1) Centre for Brain Research and School of Biological Sciences, The University of Auckland, Auckland, New Zealand; 2) Department of Neurology, Auckland City Hospital, Auckland, New Zealand; 3) Paediatrics & Newborn Services, Waitemata District Health Board, Auckland, New Zealand; 4) Diagnostic Genetics, LabPLUS, Auckland City Hospital, Auckland, New Zealand; 5) Genetic Health Service New Zealand, Auckland City Hospital, Auckland, New Zealand.

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that presents with impaired social capabilities and restricted behavioural traits. It has a strong genetic aetiology and is observed in communities throughout the world. We have recently established a study investigating the genetic contributions to ASD in New Zealand, and to this end have developed a unique research cohort consisting of diverse populations living in New Zealand.

Recruitment of subjects was performed through collaboration with clinicians and an online project registry (www.mindsforminds.org.nz). Since August 2013, 899 participants have either registered themselves or been registered by their care-giver (232 self-registered, 667 registered by carer). Upon registration, participants can elect to enter information detailing age, sex, ethnicity, diagnosis, clinical specialists, prior DNA testing, and other relevant diagnoses for the participant or their family. Within this database we currently have an ASD research cohort that includes 684 diagnosed with ASD or Asperger's (Asp) (492 and 192, respectively). The male to female ratio of participants diagnosed with ASD is 5:1 (2.3:1 for Asp). Self-attributed ethnic background reflects New Zealand's population: 757 European (84.2%), 122 Maori (13.6%), 25 Polynesian (2.8%), and 35 Asian (3.9%) (individuals can register as more than one ethnicity). The 2006 census national population frequencies of these ethnicities in New Zealand is European 76.8%, Maori 14.9%, Polynesian 7.2%, and Asian 9.7%. The ASD/Asp cohort includes 119 multiplex families, 320 individuals with co-occurring neurological disorders [ASD:196; Asp:124], and 78 individuals with co-occurring gastrointestinal disorders [ASD:52; Asp:26]. This database is subsequently being used to identify participants for exome and genome sequencing. We are currently consenting individuals and undertaking exome sequencing on our first group of subjects with the goal of eventually sequencing the entire cohort.

Mutations in adaptor protein AP-5 subunits lead to peripheral neuropathy, spastic paraplegia and parkinsonism with aberrant endolysosomes. *M. Madeo[1], J. Edgar[2], F. Darios[3], T.N. Jepperson[1], J. Li[4], C. Blackstone[5], M.S. Robinson[2], J. Hirst[2], M.C. Kruer[1].* 1) Sanford Children's; 2) Cambridge University; 3) INSERM; 4) Vanderbilt; 5) NIH NINDS.

AP-5 is one of five adaptor protein complexes that play important roles in intracellular trafficking. We identified 7 patients with mutations in AP-5 subunits whose clinical phenotype ranged from isolated peripheral neuropathy to spastic paraplegia with parkinsonism. Primary cultured fibroblasts from affected patients showed accumulation of enlarged endolysosomes. Patient cells also displayed autofluorescence and accumulation of lysosomal storage material by electron microscopy. These findings indicate that AP-5 mutations lead to diverse neurological phenotypes and further support links between endosomal-lysosomal dysfunction and hereditary spastic paraplegia and parkinsonism.

1241M

Targeted sequencing of African American autism spectrum disorder patients reveals loss of function variants in novel autism genes. *P. Whitehead[1], A.J. Griswold[1], D. Van Booven[1], N. Dueker[1], J.A. Rantus[1], J.M. Jaworski[1], S.H. Slifer[1], M.A. Schmidt[1,2], W. Hulme[1], I. Konidari[1], M.L. Cuccaro[1,2], E.R. Martin[1,2], J.L. Haines[3], J.R. Gilbert[1,2], J.P. Hussman[4], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Hussman Institute for Autism, Baltimore, MD, USA.

Whole exome sequencing studies in autism spectrum disorder (ASD) have identified no single factor accounting for the genetic risk, though several candidate genes and molecular pathways have been implicated. These studies have been performed primarily in individuals of white European ancestry. However, the incidence of ASD is similar across ethnicities (1 in 68 children in whites, 1 in 81 in blacks) begging the question whether the risk genes identified are generalizable across races and ethnicities. We are currently investigating rare ASD risk variants by integrating GWAS with targeted massively parallel sequencing of candidate regions from GWAS Noise Reduction analyses of European ASD datasets (Hussman et. al., 2011). We targeted 689 GWAS-NR associated genes and evolutionarily conserved intronic and intergenic regions. We sequenced 140 ASD cases and 180 controls of African ancestry determined by principal component analysis using Eigenstrat. We identified 10,859 coding single nucleotide variants (SNVs) in exons of targeted genes. Among these exonic mutations are 5,544 nonsynonymous variants and 93 LOF alterations (46 stop gains, 6 stop losses, and 41 splice sites). LOF variation has been previously implicated as ASD risk factors in whites so we examined the genes affected by such alterations in our black cohort. There was no overall enrichment for LOF mutations in black ASD cases ($p = 0.553$) and only a single previously identified ASD candidate gene was affected by a LOF (MYO16). A total of 29 other genes had at least one LOF in a black ASD case and not in a control. These include novel candidate genes within pathways previously implicated in ASD. A stop mutation was found in a single case in KCNIP1 (voltage-gated potassium channel interacting protein 1) which modulates GABAergic signaling in mouse models. A stop in SRGAP3 (SLIT-ROBO Rho GTPase activating protein 3) was identified in another case and the Rho-GTP signaling gene has been implicated by copy number screens in intellectual disability. Finally, two mutations in the cytoskeletal structural gene IFLTD1 (intermediate filament tail domain containing 1) were identified in two separate cases. Overall, targeted sequencing of European ASD associated genes reveals loss of function variants in novel genes in black ASD cases, but in implicated ASD pathways. This suggests that novel genes in similar underlying pathways might contribute to the genetic risk of ASD in other ethnicities.

1242T

Exome sequencing of 43 sporadic cases with an autism spectrum disorder in a local cohort of families identifies severe *de novo* variants and implicates additional genes in ASD pathogenesis. *W. Banks[1], D. Cunningham[1], E. Hansen[1], K. Ratliff-Schaub[3], E. Butter[3], D. Schulteis[4], C. Boreman[4], B. Kelly[2], P. White[2], G. Herman[1,3].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) Department of Pediatrics, Nationwide Children's Hospital, Columbus, OH; 4) Department of Pediatrics, Wright-Patterson Air Force Base, OH.

Autism spectrum disorders (ASD) are a common group of complex neurodevelopmental disorders, with over 500 CNVs and genes implicated in ASD pathogenesis to date. To identify additional loci involved in ASD, we undertook whole exome sequencing (WES) of 43 simplex trios from the Central Ohio Registry for Autism (CORA), a local cohort of over 200 families. Psychological testing records including ADOS and IQ, a detailed medical history, clinical genetic testing at a minimum including microarray and Fragile X DNA, and a 3-generation pedigree are gathered on all affected individuals. Families were chosen for WES based on a review of psychological and medical testing records, as well as the absence of ASD or related psychological disorders in the extended pedigrees. Exome captured libraries were prepared using Agilent Human All Exon V4/V5 kits and sequenced on an Illumina HiSeq2500. A locally developed analysis pipeline (Churchill) was used to identify statistically supported variants from the raw sequence data. The presence of putative *de novo* variants in the proband, and their absence in both parents, was validated via Sanger sequencing.

To evaluate the possible significance of coding variants identified, we analyzed 1) the predicted effect on protein structure by SIFT and PolyPhen2; 2) the expression profile of the affected gene in the developing CNS (BrainSpan.org); 3) phenotypes identified in mouse models; and 4) previous associations of the gene with human neurodevelopmental phenotypes, including intellectual disability (ID) and ASD. Severe *de novo* variants were confirmed in three genes (*LRP1*, *KDM5B*, and *IQSEC2*) previously found to harbor *de novo* variants in cases of ASD or ID. In addition, developmental expression patterns and/or mouse models displaying abnormal neurologic or behavioral phenotypes have been described for several other genes identified, supporting their potential involvement. Further studies in larger ASD cohorts, as well as functional studies in *in vitro* and/or *in vivo* models may further help clarify the role of these candidate loci in disease pathogenesis.

1243S

De novo and rare inherited mutations implicate the transcriptional coregulator TCF20/SPBP in autism spectrum disorder. *A.O.M. Wilkie[1,3], C. Babbs[1], D. Lloyd[1], A.T. Pagnamenta[2], S.R.F. Twigg[1], J. Green[1], S. McGowan[1], G. Mirza[2], R. Naples[1], V.P. Sharma[1,3], E.V. Volpi[2], V. Buckle[1], S.A. Wall[3], S.J.L. Knight[1], J.R. Parr[4].* 1) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Craniofacial Unit, Oxford Radcliffe Hospitals NHS Trust, John Radcliffe Hospital, Oxford, United Kingdom; 4) Institute of Neuroscience, Newcastle University, Newcastle Upon Tyne, United Kingdom.

Background: Autism spectrum disorders (ASDs) are common and have a strong genetic basis, yet the cause of ~70-80% ASDs remains unknown. By clinical cytogenetic testing we identified a family in which two brothers had ASD, mild intellectual disability and a chromosome 22 pericentric inversion, not detected in either parent, indicating *de novo* mutation with parental germinal mosaicism. We hypothesised that the rearrangement was causative of their ASD and localised the chromosome 22 breakpoints. **Methods:** The rearrangement was characterised using fluorescence in situ hybridisation, Southern blotting, inverse PCR and dideoxy-sequencing. Open reading frames and intron/exon boundaries of the two physically disrupted genes identified, *TCF20* and *TNRC6B*, were sequenced in 342 families (260 multiplex and 82 simplex) ascertained by the International Molecular Genetic Study of Autism Consortium (IMGSAC). **Results:** IMGSAC family screening identified a *de novo* missense mutation of *TCF20* in a single case and significant association of a different missense mutation of *TCF20* with ASD in 3 further families. Through exome sequencing in another project we independently identified a *de novo* frameshifting mutation of *TCF20* in a woman with ASD and moderate intellectual disability. We did not identify a significant association of *TNRC6B* mutations with ASD. **Conclusions:** *TCF20* encodes a transcriptional coregulator (also termed SPBP) that is structurally and functionally related to a single paralogous gene, *RAI1*. Notably, *RAI1* encodes the critical dosage-sensitive protein implicated in the behavioural phenotypes of the Smith-Magenis and Potocki-Lupski 17p11.2 deletion/duplication syndromes, in which ASD is frequently diagnosed. Our study provides the first evidence that mutations in *TCF20* are also associated with ASD and should encourage further investigation of the normal functions of TCF20/SPBP in neurodevelopment and the role of mutations in ASD.

1244M

***MEF2C* haploinsufficiency is a recurrent finding in patients with autism spectrum disorders.** *A. Ziegler[1,2], R. Delorme[2,3,4], P. Bonneau[1,6], A. Guilmatre[2,3], T. Bourgeron[2,3,5], D. Bonneau[1,6].* 1) Department of Biochemistry and Genetics, CHU Angers, Angers, France; 2) Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France; 3) CNRS URA 2182 "Genes, synapses and cognition," Institut Pasteur, Paris, France; 4) Assistance Publique-Hôpitaux de Paris, Robert Debré Hospital, Department of Child and Adolescent Psychiatry, Paris, France; 5) University Denis Diderot Paris 7, Paris, France; 6) UMR CNRS 6214 INSERM 1083, Angers, France.

Since the first description of *MEF2C* haploinsufficiency syndrome in 2009, 42 patients have been reported either with deletion or point mutation of this gene. Intellectual disability (ID) is the core disorder of this syndrome but autistic features such as stereotypic movements and lack of social communications are commonly reported. To further assess the role of *MEF2C* in autism spectrum disorder (ASD), we looked for *MEF2C* point mutations by Sanger sequencing and for MEF2C copy number variations by SNP-array in a cohort of 195 patients with ASD and a mild to severe ID. We identified a de novo frameshift mutation leading to a premature stop codon in 2 siblings with ASD and severe intellectual disability. A maternal germinal mosaicism was confirmed based on the haplotype. A de novo *MEF2C* deletion was also found in a patient with ASD and a mild intellectual disability. In this study, we observed *MEF2C* haploinsufficiency in 1,5% (95% confidence interval: 0- 3.2%) of patients with ASD. This is the first study to look specifically at *MEF2C* in ASD. Of note, a mutation in MEF2C was also found once by whole-exome sequencing in another cohort of 175 trios with ASD. According to this notable *MEF2C* haploinsufficiency frequency in ASD, we strongly recommend to pay specific attention to this gene when performing non-targeted genetic screening in ASD with a comorbid ID even for patients without severe ID.

1245T

Assessing the role of methylation in autism brains. *S.E. Ellis[1], S. Gupta[1], A. Moes[1], A.B. West[2], D.E. Arking[1].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Department of Neurology, University of Alabama School of Medicine, Birmingham, AL.

The high prevalence of autism spectrum disorder (ASD) and very limited understanding of relevant risk factors have sparked an intense focus on elucidating the genetic basis of ASD. GWAS, exome-sequencing, and RNA-Seq have all helped the field move forward, but the vast majority of the risk remains unexplained. Given that prenatal brain development is both critical to the progression of ASD and a period in which development is sensitive to alterations in epigenetic pathways, many groups have turned to investigating the role of methylation in ASD. To date, microarray studies have looked for methylation differences between ASD brains and controls; however, these have been limited by the digital nature of methylation arrays and small sample sizes. We report results from the largest study to date, relying on next-generation methylation sequencing (reduced representation bisulfite sequencing) in 63 cortical brain samples (BA19), comprising 34 controls and 29 individuals with autism, a subset of ASD, all of whom were diagnosed using ADOS and ADI-R (among other exclusions). After extensive quality control, we performed a single site analysis across 739,980 CpGs looking for methylation differences between cases and controls. This analysis identified 28 differentially methylated CpGs ($q<0.05$), eight of which demonstrate a mean methylation difference greater than 10 percent (5 hyper- and 3 hypo-methylated in ASD). While none of these 28 sites fall in regions demonstrating differential gene expression (as measured by RNA-Seq), six are exonic, nine fall within promoters, 16 are within CpG Islands (CGI), and five are within CGI shores, suggesting a potential functional role for these individual sites. In particular, one exonic CpG site in SHANK3 demonstrates a 6.4% decrease in methylation in ASD cases. While the need to validate this finding by an independent method remains, this finding is of particular interest for future investigation as SHANK3 has frequently been reported to have a role in ASD. Finally, ongoing studies will leverage these data, along with RNA-seq carried out on these same individuals, to gain a more complete understanding of the relationship between methylation and gene expression in the prefrontal cortex with risk for ASD.

1246S

Methylation pathway and chromatin modification in autism. *M. Smith, P. Flodman, J. Bevilacqua, J-J. Gargus.* Dept Pediatrics, Univ California, Irvine, Irvine, CA.

We analyzed data from exome sequencing in 9 probands with autism. In each of the autistic probands our analyses revealed the presence of rare and low frequency potentially functionally damaging variants in genes that encode enzymes involved in synthesis of methyl residues and/ or genes that encode enzymes involved in the transfer of methyl residues to or from chromatin, (histones and DNA). A rare allele in lysine specific methyltransferase KMT2C variant rs10454320 occurred in 3 of the 9 autistic probands; a rare allele at KMT2C variant rs78352960 occurred in 2 autistic probands. A rare allele KMT2C variant at rs200804156 occurred in 1 autistic proband. It is interesting to note that one proband had 3 rare variants in KMT2C and one rare variant in KMT2D lysine specific methyltransferase rs201114196. Low frequency potentially damaging variants in the MTRR gene 5 methyltetrahydrofolate homocysteine methyltransferase reductase rs2287780 occurred in 2 autistic probands. An autistic twin pair had a rare potentially damaging variant in MTHFS 5-10 methenyltetrahydrofolate synthetase. The variants described were potentially damaging and were inherited from one or other of the parents where testing of family was possible (5 out of 7 families) and were present in heterozygous state in the probands. We identified rare potentially damaging variants in genes that encode proteins involved in chromatin modification. Rare potentially damaging variants, each identified in 1 proband occurred in KDM5A lysine specific demethylase at rs200804533, in KAT2B lysine acetyl transferase at rs148960024, in CHD8 chromatin helicase at rs2000465274 in CHD6 chromatin helicase at rs61752057. Studies by Melnyk, James and coworkers have implicated methylation dysregulation in autism PMID: 21519954. There is increasing evidence that abnormalities of chromatin modification are frequent cause of cognitive disorders in children, (Ronan and Crabtree PMID: 23568486). It is important to consider the possibility that rare or unusual variants and perhaps even common variants in a specific pathway may play roles in the etiology of autism and that de novo and inherited variants may have impact.

1247M

Mutation Screening in Saudi Parkinson's Disease Patients. *B.R. Al-Mubarak[1], A. Magrashi[1], M. AlTurki[1], S. Boholega[2], T. Alkhairallah[2], B. AlTawil[1], H. Abou Al-Shaar[1], L. Al-Jomaa[1], N. Al Tassan[1].* 1) Genetics, King Faisal Specialist Hospital, Riyadh, Saudi Arabia; 2) Neurosciences, King Faisal Specialist Hospital, Riyadh, Saudi Arabia.

Parkinson's disease (PD) is classified as the second most prevalent aging-related neurodegenerative disease after Alzheimer's, and is predicted to affect approximately 8-9 million individuals by 2030. The disease is characterized by the occurrence of four cardinal symptoms: bradykinesia, resting tremor, rigidity and postural imbalance. In most cases the disease occurs sporadically with complex etiopathology involving a combination of genetic propensity and environmental factors. However, familial cases also exist accounting for 15-20% of the patients. Mutations in *PARKIN*, *SNCA*, *DJ-1*, *PINK1*, and *LARRK2* genes have been reported in patients with different modes of inherence of PD. In this study we sought to determine the genetic basis underlying PD in 97 Saudi individuals affected with either sporadic or familial form of the disease through screening the entire ORF region in addition to exon-intron junctions of known PD-causing genes for possible disease-related variants. Direct sequencing of *PARKIN*, *SNCA*, *DJ-1*, *PINK1* and *LARRK2* genes in these samples failed to reveal pathogenic mutations with the exception of one familial case homozygous for c.938 C>T (p.Thr313Met) mutation in *PINK1*. Moreover, the mutation analysis was extended to include more recently identified PD susceptibility genes particularly, *FBXO7* , *GIGYF2* , *VPS35* , and *UCHL1* . Out of the 121 detected SNVs, only few were potential disease-causing mutations, while the majority was either present in ethnically matched normal controls or did not segregate with the mode of inheritance. The absence of pathogenic mutations in the screened genes in our cohort doesn't rule out the possibility of their involvement in the development of the disease, as gene expression maybe perturbed. However, it also suggests that other genetic factors may be implicated in these patients. These findings are in keeping with the long-held notion of the complexity and genetic heterogeneity of PD.

1248T

Genetics of dementias in a Turkish cohort. *R. Guerreiro[1,2], G. Guven[3], J. Bras[1], L. Darwent[1], J.R. Gibbs[1,2], N. Unaltuna[3], H. Gurvit[4], B. Bilgic[4], H. Hanagasi[4], M. Emre[4], A. Singleton[2], J. Hardy[1], E. Lohmann[4,5].* 1) Department of Molecular Neuroscience, UCL Institute of Neurology, University College London, Queen Square, London, UK; 2) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, Maryland, USA; 3) Department of Genetics, Institute for Experimental Medicine, Istanbul University, Istanbul, TR; 4) Behavioral Neurology and Movement Disorders Unit, Department of Neurology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, TR; 5) Department Of Neurodegenerative Diseases, Hertie Institute for Clinical Brain Research, University of Tübingen, and DZNE, German Center for Neurodegenerative Diseases, Tübingen, GER.

Turkey has a population of over 77 million, with a growth rate of 1.5% per year and an average life expectancy of 73.2 years. Large family units, high birth rates, and high rates of consanguineous marriages can often be found in this population, making genetic diseases a common health problem. In parallel, the improvement of living standards and health services will increase survival rates and, consequently, the incidence of Alzheimer's disease (AD [MIM 104300]) and other dementias. The current study is the first large molecular study of dementias in Turkey. Our main goals were: 1) to establish the frequency of mutations in the most common genes known to cause dementias (APP, PSEN1, PSEN2, MAPT, GRN and C9orf72); 2) to characterize the mutation spectrum in these genes by describing genotype-phenotype correlations; 3) to study recessive forms of dementia; 4) to identify novel genes/variants involved in different forms of dementia. We have established a cohort of 150 families presenting with different forms of dementias that we have been studying by using genome-wide genotyping techniques and next generation sequencing combined with Sanger sequencing. We established a frequency of 11.2% of mutations and variants in APP, PSEN1 and PSEN2, and of 5.2% of pathogenic mutations in MAPT, GRN and C9orf72, suggesting that mutations in these genes are not uncommon in Turkey. The application of exome sequencing to the cases without mutations in the known dementia genes revealed some unexpected results with the identification of a previously reported NOTCH3 mutation in an AD family and three homozygous TREM2 mutations in Frontotemporal dementia-like (FTD [MIM 600274]) families. NOTCH3 mutations have been previously associated with Cerebral arteriopathy, autosomal dominant, with subcortical infarcts and leukoencephalopathy (CADASIL [MIM 125310]) while TREM2 mutations are known to cause Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOSL [MIM 221770]). Exome sequencing is a valid, rapid and cost-effective tool to identify genetic mutations in complex diseases like dementias, and is particularly useful in the study of autosomal recessive forms of disease when coupled with loss-of-heterozygosity analyses. The application of exome sequencing to neurological syndromes has revealed several unexpected phenotypes for mutations in known disease genes, that otherwise would have never been screened for, given the atypical presentation.

1249S

Mutation screening in exon 2 of synaptic gene SHANK3 in Brazilian individuals with Autism Spectrum Disorder. *D.BA. Rosan[1], P.P NASCIMENTO[1], A.L BOSSOLANI-MARTINS[2], L.A BRITO[3], M.R PASSOS-BUENO[3], A.C FETT-CONTE[4].* 1) Universidade Estadual Paulista Junior de Mesquita Filho; 2265 Rua Cristóvão Colombo, Jardim Nazareth, 15054-000, São José do Rio Preto, SP, Brazil; 2) Universidade Federal do Mato Grosso do Sul Campus Paranaiba, 800 Rua Maria Antonia - 79500-000, Paranaíba, MS, Brazil; 3) Universidade de São Paulo, instituto de Biociencias, 14 Rua do Matão, - Butantã, 05508-090, São Paulo - SP, Brazil; 4) Faculdade de Medicina de São José do Rio Preto, 5416 Av. Brigadeiro Faria Lima, Vila São Pedro, 15090-000 - São José do Rio Preto - SP - Brazil.

Austism Spectrum Disorder (ASD) is a complex behavioral disorder characterized by manifestations usually noted before the age of three and that affect the field of social communication and behavioral domain, atypical behaviors, restricted and repetitive interests, compromising the entire life of the individual. With a complex etiology, numerous genetics, epigenetics and environmental factors can explain this changes that affect 1-110 individuals with males being affected four times more than females. Large numbers of genes have been proposed and investigated in the predisposition to ASD. Many of them are expressed in the development of the adult brain, such as those responsible for encoding proteins involved in the formation and function of synapses. Among the major genes are SHANK family, which act particularly in post-synaptic region and are composed by three genes, SHANK1, SHANK2 and SHANK3 that are expressed in different regions of the brain encoding scaffolding proteins of the postsynaptic synapses. All these genes have been described as candidates for autism by the significant association of mutations with the behavioral phenotype and intellectual deficits. The SHANK3 gene, the most studied SHANK of the family, is located on 22q13.3 region and is predominantly expressed in the cerebral cortex and cerebellum. The exon 2 of SHANK3 gene has never been studied in a brazilian individuals with idiopathic ASD and this study aimed to evaluete the presence of mutations in this exon to investigate a possible association with the behavioral phenotype. We sequenced 190 Brazilian individuals and found a heterozygous alteration of A/G at the position 22: 50675139 resulting in a substitution of the amino acid threonine by an alanine at codon 42. The change was found in a 21 years old male patient with diagnosis of autism without phenotypic changes. Karyotypic investigation and molecular testing to Fragile-X syndrome were normal. We searched for this mutation in the "1000 Genomes- Deep Catalog of Human Genetic Variation" and in "NHLBI Exome Sequencing Project (ESP) Exome Variant Server" and nothing was found. Genetic studies have demonstrated the strong association of mutations in SHANK3 with susceptibility to psychiatric disorders, particularly autism, however, little is known about the neural consequences of these mutations and further investigations should be carried out to clarify the causes of this disease.

1250M

Variations in hotspot region of β-amyloid precursor protein (APP) gene in various neurological disorders from Hyderabad, a cosmopolitan city of South India. *W. Thomas[1], S. Divyakolu[1], VR. Sreekanth[2], VR. Om Sai[3], V. Nagaratna[3], Q. Hasan[1, 4], YR. Ahuja[1].* 1) Department of Genetics and Molecular Medicine, Vasavi Medical and Research Centre, Hyderabad, Andhra Pradesh, India; 2) Department of Neurology, Apollo Hospital, Jubilee Hills, Hyderabad, Andhra Pradesh, India; 3) Department of Medical Sciences, National Institute of Mentally Handicapped, Bowenpally, Secunderabad, Andhra Pradesh, India; 4) Department of Genetics and Molecular Medicine, Kamineni Hospital, LB Nagar, Hyderabad, Andhra Pradesh, India.

Background: Non-synonymous mutations/ polymorphism in amyloid precursor protein (APP) gene causes overproduction of Aβ proteins or affects its split into Aβ40 and Aβ42 peptides. Aβ42 has been considered to be a toxic peptide playing a major role in the pathogenesis of Alzheimers (AD). Similar APP plaques were observed in the brains of Down syndrome (DS) patients and high level of plasma APP was observed in patients with severe Autism spectrum Disorder (ASD). The aim of this study was to evaluate exon 16 and 17, the hotspot regions of APP gene in patients with neurobehavioral disorders like AD, DS and ASD.

Methods: A total of 75 cases were recruited in the study which included AD (n=25), DS (n=25), and ASD (n=25). Polymerase chain reaction (PCR) analysis and sequencing was carried out using exon-intron encompassing primers for the selected APP gene regions. In-silico analysis was also carried out to identify the impact of sequence variants on the protein structure.

Results: Three exonic variants, two in exon 16: V683V, H684Y and one in exon 17, H733Q were identified in sporadic AD cases. Apart from these, two intronic variants were also observed. In-silico analysis showed that H733Q mutation may affect the structure and function of APP, whereas H684Y mutation is neutral. In an ASD case, our analysis showed an intronic variation ie., an A insertion at c.1964-13_1964-12insA. In-silico analysis predicted that this variation affects the elongation feature of the transcript. None of the DS cases had any variation in this hotspot region.

Conclusion: Our data indicate that variations in the selected hotspot region of APP may play an important role in the aetiology of neurobehavioural disorders.

1251T

DYT16 revisited: exome sequencing identifies PRKRA mutations in a European dystonia family. *M. Zech[1, 2], F. Castrop[1], B. Schormair[1, 2], A. Jochim[1], T. Wieland[2], N. Gross[1], P. Lichtner[2], A. Peters[2], C. Gieger[2], T. Meitinger[1, 2], T. Strom[1, 2], K. Oexle[1], B. Haslinger[1], J. Winkelmann[1, 2, 3].* 1) Technical University of Munich, Munich, Germany, Munich, Germany; 2) Helmholtz Zentrum München, Munich, Germany; 3) Stanford University School of Medicine, Palo Alto, CA, USA.

Objective: Recessive DYT16 dystonia associated with mutations in PRKRA has until now been reported only in seven Brazilian patients. The aim of this study was to elucidate the genetic cause underlying disease in a Polish family with autosomal-recessive, early-onset generalized dystonia and slight parkinsonism, and to explore further the role of PRKRA in a dystonia series of European ancestry. Methods: We employed whole-exome sequencing in two affected siblings of the Polish family and filtered for rare homozygous and compound heterozygous variants shared by both exomes. Validation of the identified variants as well as homozygosity screening and copy number variation analysis was carried out in the two affected individuals and their healthy siblings. PRKRA was analyzed in 339 German patients with various forms of dystonia and 376 population-based controls by direct sequencing or high-resolution melting. Results: The previously described homozygous p.Pro222Leu mutation in PRKRA was found to segregate with the disease in the studied family, contained in a 1.2 Mb homozygous region identical by state with all Brazilian patients in chromosome 2q31.2. The clinical presentation with young-onset, progressive generalized dystonia and mild parkinsonism resembled the phenotype of the original DYT16 cases. PRKRA mutational screening in additional dystonia samples revealed three novel heterozygous changes (p.Thr34Ser, p.Asn102Ser, c.-14A>G), each in a single subject with focal/segmental dystonia. Conclusions: Our study provides the first independent replication of the DYT16 locus at 2q31.2 and strongly confirms the causal contribution of the PRKRA gene to DYT16. Our data suggest worldwide involvement of PRKRA in dystonia.

1252S

Rapid multiplex sequencing of genes associated with progressive neurodegenerative disorders. *M.O. Dorschner[1,2,3], M.A. Weaver[1,2,3], G.L. Carvill[5], H.C. Mefford[5], I.F. Mata[3,4], C.P. Zabetian[3,4], M. Rumbaugh[3,4], T.D. Bird[3,4], D.W. Tsuang[2,3].* 1) Department of Pathology, University of Washington, Seattle, WA; 2) Department of Psychiatry & Behavioral Sciences, University of Washington, Seattle, WA; 3) Geriatric Research, Education, and Clinical Center, VA Puget Sound Health Care System, Seattle; 4) Department of Neurology, University of Washington, Seattle, WA; 5) Department of Pediatrics, University of Washington, Seattle, WA.

Alzheimer's disease (AD) is an insidious neurodegenerative disorder that accounts for significant morbidity and mortality. While there are multiple causes of dementia, including dementia with Lewy bodies (DLB), frontotemporal dementia (FTD) and Parkinson's disease dementia (PDD), greater than half of cases are due to Alzheimer's disease. Dementia manifests clinically with subtle and poorly recognized cognitive deficits and slowly becomes more severe and eventually incapacitating. An accurate diagnosis early in the disease process would greatly improve the ability of physicians to predict disease progression and manifestation of specific symptoms. We developed a multigene sequencing panel for several purposes: 1) to establish an assay for clinical diagnostic testing; 2) to select research subjects for discovery-based efforts prior to exome or genome sequencing, and 3) to identify rare disease-causing variants and study the type and distribution of variants with respect to phenotypic characteristics. The coding regions of these genes were captured with gap-fill molecular inversion probes (MIPs) and sequenced using Illumina technology. Sequence data were aligned with BWA and variants called with GATK. Several genes proved difficult to capture due to GC content and sequence context. To improve the capture of these genes, we made several modifications to the protocol and separated the poorly performing MIPs from those that were working efficiently. Two captures were performed for each sample and combined after amplification. With 928 MIPs we were able to obtain adequate coverage for > 95% of the target when sequenced in pools of 192 subjects. To test the ability of our panel to detect disease-causing variants we assayed a set of positive controls with 11 known mutations. 9 of the 11 known mutations were detected. The two failures were located in the *PRNP* gene, in a difficult to capture segment. The assay was tested with 53 individuals clinically diagnosed with a variety of neurodegenerative disorders for which the genetic etiology was unknown. Six individuals carried predicted pathogenic, likely pathogenic, or risk variants. The combination of molecular inversion probe enrichment and next generation sequencing provides a rapid, low cost procedure for screening large numbers of individuals for neurodegenerative disorders. We are currently expanding and deploying this assay to screen additional populations with dementia and Parkinson's disease.

Genome sequencing in X-Linked Ataxia Dementia. *J.L. Farlow[1], K. Hetrick[2], H. Ling[2], B. Craig[2], M. Farlow[1], E. Pugh[2], K. Doheny[2], T. Foroud[1].* 1) Medical and Molecular Genetics, Indiana University School of Medicine, 410 West 10th Street, HS 4000, Indianapolis, IN 46202; 2) Center for Inherited Disease Research, Johns Hopkins University, 333 Cassell Drive, Suite 2000, Baltimore, MD 21224.

X-Linked Ataxia Dementia (XLAD), also known as X-linked spinocerebellar ataxia type 4, is a neurodegenerative disorder characterized by ataxia in childhood, variable onset upper motor neuron disease, and adult-onset dementia. In the one kindred described with this syndrome, moderate phenotypic variability is observed in affected males, and carrier females show a milder phenotype that includes cognitive and motor abnormalities. Previous linkage studies demonstrated a LOD score of 5.29 in the region Xq21.33-q23. Further genotyping on two distantly related affected males and two unaffected males on an Illumina Omni1-Quad array narrowed this region to 19Mb and ruled out a large copy number variant. Whole genome sequencing (30X) was performed on an obligate carrier female and her affected son to identify the causative mutation in this region. The Agilent SureSelectXT2 Library Prep Kit and Illumina HiSeq2000 were used to generate 100bp paired end sequencing data. Paired end alignment was performed to the GRCh37 reference genome with Burrows-Wheeler Aligner, and duplicates were marked using Picard. The Genome Analysis Toolkit was used for insertion/deletion (indel) realignment, base call quality score recalibration, multi-sample variant calling (Unified Genotyper), and Variant Quality Score Recalibration. Variants were annotated by ANNOVAR and the recently developed Combined Annotation-Dependent Depletion program. Variants of interest were visually inspected using the Integrated Genomics Viewer. The average transition/transversion ratio for exonic variants and all variants was 3.10 and 2.12 respectively, and the percentage of variants found in dbSNP137 was 98.98%. There were 7,901 variants identified in the region of interest. Of these, 5,798 were heterozygous in the mother and hemizygous in the son, and 505 of these were not observed in 1000 Genomes, the Exome Sequencing Project, and dbSNP137. Variants were retained if they were in an exonic, splicing, UTR, or regulatory region. Using these criteria, 22 variants (3 single nucleotide variants and 19 indels) were retained, all of which were in UTR or regulatory regions. Genome sequencing has not identified a clearly causative exonic variant for this region. Further work remains to look for structural variants such as larger insertions or deletions and inversions. For all variants identified, challenges remain to predict the resulting functional impact and to prioritize variants for molecular characterization.

1254T

Prion disease with chronic diarrhea associated with PRNP mutation Q160X has reduced penetrance. *J.C. Fong[1], J. Bang[1], A. Legati[2], K.J. Rankin[1], N. Block[1], R. Ketelle[1], A.M. Karydas[1], G. Coppola[2], M.D. Geschwind[1].* 1) Dept of Neurology, UCSF Memory and Aging Center, San Francisco, CA; 2) Depts of Psychiatry and Neurology, UCLA, Los Angeles, CA.

Background: Prion diseases are neurodegenerative disorders occurring in genetic, sporadic, or acquired forms. Genetic prion disease is caused by mutations in the prion protein gene (PRNP)—missense, nonsense, insertions, deletions—each associated with varying symptoms, including mutations characterized by diarrhea and dysautonomia. To date, nonsense PRNP mutations have not been associated with reduced penetrance. We report a rare nonsense PRNP mutation in an index case, diagnosed initially with an unspecified dementia, and his unaffected father. Methods: The proband was evaluated clinically. Whole exome sequencing or WES (Illumina) was done on the proband and both parents. Reads were mapped to GRCh37 using BWA. Variants were called with GATK, then annotated and filtered using the Ingenuity platform (Qiagen). Results: The proband presented at age 30 with a 5-yr history of chronic diarrhea, followed by behavior, language, memory problems, and recent movement, gait, and swallowing difficulty. Symptoms began at age 25 with alternating diarrhea/constipation. At Yr1, he had trouble managing finances, academic problems, and agitation. By Yr2, he dropped out of college and was fired from his job for forgetting to complete tasks. He was fired from a 2nd job for making violent threats against coworkers. Between Yrs4-4.5, speech and language declined. By Yr5, he required help with activities of daily living. Exam at Yr5 showed severe grammar deficits with intact semantic knowledge, mild motor deficits, and gait ataxia. MRI showed profound, diffuse bilateral cortical and white matter atrophy without restricted diffusion. Paternal FHx was significant for an autosomal dominant pattern of dementia (clinically Alzheimer's or AD) preceded by diarrhea in 5 relatives, including a great-aunt (died at age 51) whose autopsy showed plaques and tangles. WES identified a PRNP Q160X mutation with methionine homozygosity at PRNP codon 129. The asymptomatic 56yo father had the same mutation with methionine-valine heterozygosity at codon 129. Conclusions: The proband's gastrointestinal symptoms at onset and slow course are distinct from most other prion diseases. Codon 129 heterozygosity could explain lack of symptoms in the father. AD pathology in the aunt does not preclude the presence of a PRNP mutation, as mutations have been associated with dual AD and prion pathology. PRNP testing should be considered in cases of unexplained diarrhea and dementia with or without positive FHx.

Rare disease allele penetrance and loss-of-function tolerance in a dominant disease gene: analysis of variation in >60,000 exomes. *E.V. Minikel[1,2,3], S.M. Vallabh[1,2], M. Lek[1,3], D.G. MacArthur[1,3], Exome Aggregation Consortium (ExAC).* 1) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Prion Alliance, Boston, MA; 3) Broad Institute, Cambridge, MA.

Sequencing of control individuals at an ever-larger scale has long promised to shed light on disease biology, but sample sizes are only now approaching the numbers required to afford insights into ultra-rare diseases and into genes with short coding sequences, where fewer variants are expected a priori. Here we demonstrate the power of massive exome data sets to address two critical questions about the biology of a dominant disease gene: the penetrance of previously reported disease mutations, and the discovery of loss-of-function (LoF) variants that demonstrate the tolerance of this gene to heterozygous inactivation. As part of the Exome Aggregation Consortium (ExAC) we aggregated exome sequence data from >60,000 individuals from >60 studies and performed joint variant calling of SNPs and indels across all samples. To demonstrate this dataset's power to illuminate rare disease biology, we analyzed rare (<0.1%) variation in the prion protein gene (PRNP). Prion diseases affect 1 person per 1 million population per year, and the PRNP coding sequence is short (253 codons). As no samples were ascertained on neurodegenerative disease phenotypes, they should offer an unbiased view of rare PRNP variation. We therefore used this dataset to answer two longstanding questions in prion disease biology: (1) are pathogenic point mutations in PRNP fully penetrant, and (2) is prion protein LoF tolerated in humans? We find that reported disease-associated missense mutations in PRNP are found in our dataset at >20 times the frequency expected based on genetic prion disease incidence, suggesting that a subset of mutations are either benign or incompletely penetrant. The pathogenic variants most common in our controls are those least frequently reported in prion disease patients, and vice versa, suggesting that these variants occupy a spectrum from mild risk factor to fully penetrant Mendelian mutation. Prion protein (PrP) knockout confers total resistance to prion disease and is associated with relatively mild phenotypes in mice, cows and goats. Reducing PrP expression is therefore considered to be a therapeutic strategy in prion disease, yet no LoF allele has ever been observed in humans. We find three heterozygous LoF alleles in our dataset, consistent with expectation, and phenotypic follow-up suggests that these individuals are healthy. This supports reduction of PrP expression as a viable therapeutic strategy in this class of diseases.

A novel insertion mutation of *MAPT* causes FTDP-17 with distinct pathology. *H. Morino[1], Y. Matsuda[1], R. Ohsawa[1], K. Hiraki[1], T. Kurashige[2], Y. Izumi[3], Y. Yamazaki[2], T. Takahashi[2], A. Takashima[4], Y. Soeda[4], T. Miyasaka[5], M. Higuchi[6], N. Sahara[6], T. Suhara[6], H. Shimada[6], H. Maruyama[2], H. Ito[7], H. Kawakami[1].* 1) Department of Epidemiology, Research Institute for Radiation Biology and Medicine, Hiroshima University, Hiroshima, Japan; 2) Department of Clinical Neuroscience & Therapeutics, Institute of Biomedical & Health Sciences, Hiroshima University, Hiroshima, Japan; 3) Department of Clinical Neuroscience, Graduate School of Medicine, University of Tokushima Graduate School, Tokushima, Japan; 4) Department of Aging Neurobiology, National Center for Geriatrics and Gerontology, Ohbu, Japan; 5) Neuropathology Department of Medical Life Systems, Faculty of Life and Medical Sciences, Doshisha University, Kyoto, Japan; 6) Molecular Neuroimaging Program, National Institute of Radiological Sciences, Chiba, Japan; 7) Department of Neurology, Graduate School of Medicine, Wakayama Medical University, Wakayama, Japan.

PURPOSE: *MAPT*, *LRRK2*, *GRN*, and *C9orf72* are known as responsible genes for several neurological disorders, including progressive supranuclear palsy (PSP), Parkinson's disease (PD), and frontotemporal dementia (FTD). We conducted genetic analysis of a family with PSP, PD, and FTD over two generations in order to identify a causative gene for these neurological disorders.

METHODS: We performed high-density SNP typing on three affected and two unaffected persons, followed by exome sequencing on the three affected persons. Candidate regions were selected by linkage analysis and Homozygosity Haplotyping based on the results of the high-density SNP analysis. The variants were obtained using BWA, Samtools, Picard, and GATK from the exome sequencing data. We reduced the candidates by referring to the public variant databases, and confirmed the remaining mutations by Sanger sequencing. In addition, we screened for the mutations in other patients with similar symptoms.

RESULTS: Relatively long segments of high LOD score exist on chromosome 6, 9, 14, 17, and 20. Homozygosity Haplotyping indicated common haplotype regions of chromosome 13 and 17 in the patients, but not in the unaffected. From the result of exome sequencing two novel variants remained finally. One was located in the *microtubule-associated protein tau* (*MAPT*) gene that is known as the causative gene of frontotemporal dementia with parkinsonism on chromosome 17 (FTDP-17). The same variant was detected in two PD patients of another family, and the haplotype around the variant was identical to that of the index family. Biochemical experiment indicated that the MAPT mutation reduced the ability of microtubule polymerization, and accelerated tau aggregation. Pathological findings from autopsy of the FTD patient demonstrated notable observations.

CONCLUSION: The novel *MAPT* variant we identified presumably causes FTDP-17. The variant is located in the region in which several mutations were reported previously, but it is more unique that the variant is non-frameshift single amino acid residue insertion. In the further investigation, we will aim at revealing the pathogenic mechanism by evaluating biochemical changes by the mutation.

Strategy to discover new ALS causative genetic variant in Japanese ALS patients. *J. Sone[1], R. Nakamura[1], M. Nakatochi[2], H. Watanabe[1], N. Atsuta[1], F. Tanaka[3], G. Sobue[1]*. 1) Department of Neurology, Nagoya University Graduate School of Medicine, Nagoya, Aichi, Japan; 2) Center of advanced medicine and clinical research, Nagoya University Hospital, Nagoya, Aichi, Japan; 3) Department of Neurology and Stroke Medicine , Yokohama City University Graduate School of Medicine, Yokohama, Kanagawa, Japan.

Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease characterized by progressive muscle atrophy, paralysis, and death within a few years of diagnosis. A number of hypotheses for the pathogenesis of ALS have been proposed, however, the pathogenic mechanism has not been clarified, and no effective therapy has been developed. Approximately 90% of ALS cases are sporadic (SALS) and 10% are familial ALS (FALS). Recently, many FALS causative genes have been identified with next-generation sequencing methods and reported. To clarify the pathogenesis of ALS, we are now doing a study on the genomic basis of FALS and SALS with a next generation sequencer and about 1,000 cases of DNA samples from the Japanese Consortium of Amyotrophic Lateral Sclerosis (JaCALS). At first, we established a genetic screening system of already discovered ALS causative genes with an Ion Torrent sequencer. We selected 28 ALS genes as follows, *SOD1, ALS2, SETX, SPG11, FUS, VAPB, ANG, TARDBP, FIG4, OPTN, VCP, UBQLN2, SIGMAR1, DAO, NEFH, DCTN1, TAF15, EWSR1, PRPH, GRN, CHMP2B, ZNF512B, PFN1, ATXN2, TFG, C9orf72, RNF19A* and *SQSTM1*. We designed a primer set for multiplex PCR by Ion Ampliseq Designer. The total coverage of the designed primer set was 97.7 % of all exon of the 28 ALS genes. We made a fragment library of ALS patients with the Ion Ampliseq kit, the designed primer set and analyzed sequences with Ion torrent systems. We screened the discovered ALS causative variant in 28 ALS genes, then we divided the ALS patients into two groups, the causative variant positive ALS group and the causative variant negative ALS group. Next, we engaged in exome sequencing of the causative variant negative ALS group. We are now collecting exon data and analyzing it with the dbSNP database, the 1000 genome database and the HGVD database (Human Genetic Variation Database in Japan). We will present the progress of this study.

1258S

Mutation detection in Amyotropic Lateral Sclerosis from RNAseq data. *K.A. Staats[1], A. Furterer[1], S. de Jong[1], A. Ori[1], L. Olde Loohuis[1], T. Wu[1], E.R. Dennis[1], C. Lomen-Hoerth[2], M. Wiedau-Pazos[3], R.A. Ophoff[1]*. 1) Center for Neurobehavioral Genetics, UCLA, Los Angeles, USA; 2) Department of Neurology, UCSF, San Francisco, USA; 3) Department of Neurology, David Geffen School of Medicine at UCLA, Los Angeles, USA.

Amyotrophic Lateral Sclerosis (ALS) is a devastating progressive neurodegenerative disease, resulting in selective motor neuron degeneration and paralysis. Patients die approximately 3-5 years after diagnosis, as, at current, there is no medical cure available. Disease pathophysiology is multifactorial, including disease mechanisms such as excitotoxicity, RNA metabolism and aggregation, but is not yet fully understood. Approximately 10% of all ALS patients suffer from the disease with a familial history for which a genetic cause is assumed. Genetic analysis has proven fruitful in the past to further understand genes modulating the disease and increase knowledge of disease mechanisms, including the discovery of ALS genes such as *SOD1*, *TARDBP*, *FUS-TLS* and *C9orf72* (among others). Here, we performed RNA sequencing on whole blood from ALS patients not carrying the *C9orf72* repeat expansion. Besides obtaining gene expression data, we have analyzed the RNAseq data for disease causing variants in coding sequence. This was conducted with an adapted protocol of SNPiR with GATK variant calling. Variants detected were tested for validation by Sanger sequencing, including the validated pathogenic mutation I383V in *TARDBP*. This method allows for the secondary use of RNAseq data for (pathogenic) coding variant detection, though it is not suitable for all ALS mutations, as some mutations are not in transcripts expressed in whole blood. We used this method to examine known ALS genes but are now expanding the effort for detection of novel mutations.

1259M

***PRKAR1B* mutation associated with a new neurodegenerative disorder with unique pathology.** *T.H. Wong[1], W.Z. Chiu[1], G.J. Breedveld[2], K.W. Li[3], J.M.H. Verkerk[4], D. Hondius[3,5], R.K. Hukema[2], H. Seelaar[1], P. Frick[6], L.A. Severijnen[2], G.J. Lammers[7], J.H.G. Lebbink[8], S.G. van Duinen[9], W. Kamphorst[5], J.M. Rozemuller[5], E.B. Bakker[10], M. Neumann[6,11], R. Willemsen[2], V. Bonifati[2], A.B. Smit[3], J.C. van Swieten[1,12,13], Netherlands Brain Bank, The International Parkinsonism Genetic Networks.* 1) Neurology, Erasmus Medical Center, Rotterdam, Netherlands; 2) Clinical Genetics, Erasmus Medical Center, The Netherlands; 3) Molecular and Cellular Neurobiology, Centre for Neurogenomics and Cognitive Research, Neuroscience Campus Amsterdam, VU University, Amsterdam, The Netherlands; 4) Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands; 5) Pathology, VU University Medical Centre, Amsterdam, The Netherlands; 6) DZNE, German Centre for Neurodegenerative Disease, Tübingen, Germany; 7) Neurology, Leiden University Medical Centre, Leiden, The Netherlands; 8) Cell Biology and Genetics and Radiation Oncology, Erasmus Medical Center, Rotterdam, The Netherlands; 9) Pathology, Leiden University Medical Centre, Leiden, The Netherlands; 10) Clinical Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 11) Neuropathology, University of Tübingen, Tübingen, Germany; 12) Alzheimer Centre, Neuroscience Campus Amsterdam, Amsterdam, The Netherlands; 13) Neurology, Neuroscience Campus Amsterdam, Amsterdam, The Netherlands.

Pathological accumulation of intermediate filaments can be observed in neurodegenerative disorders, such as Alzheimer's disease [MIM 104300], frontotemporal dementia [MIM 600274] and Parkinson's disease [MIM 168600], and is also characteristic of neuronal intermediate filament inclusion disease. Intermediate filaments type IV include three neurofilament proteins (light, medium and heavy molecular weight neurofilament subunits) and a-internexin. The phosphorylation of intermediate filament proteins contributes to axonal growth, and is regulated by protein kinase A. Here we describe a family with a novel late-onset neurodegenerative disorder presenting with dementia and/or parkinsonism in 12 affected individuals. The disorder is characterized by a unique neuropathological phenotype displaying abundant neuronal inclusions by haematoxylin and eosin staining throughout the brain with immunoreactivity for intermediate filaments. Combining linkage analysis, exome sequencing and proteomics analysis, we identified a heterozygous c.149T>G (p.Leu50Arg) missense mutation in the gene encoding the protein kinase A type I-beta regulatory subunit (*PRKAR1B* [OMIM 176911]). The pathogenicity of the mutation is supported by segregation in the family, absence in variant databases, and the specific accumulation of PRKAR1B in the inclusions in our cases associated with a specific biochemical pattern of PRKAR1B. Screening of *PRKAR1B* in 138 patients with Parkinson's disease and 56 patients with frontotemporal dementia did not identify additional novel pathogenic mutations. Our findings link a pathogenic *PRKAR1B* mutation to a novel hereditary neurodegenerative disorder and suggest an altered protein kinase A function through a reduced binding of the regulatory subunit to the A-kinase anchoring protein and the catalytic subunit of protein kinase A, which might result in subcellular dislocalization of the catalytic subunit and hyperphosphorylation of intermediate filaments.

1260T

Transcriptome sequencing in bipolar disorder identifies a global downregulation in the anterior cingulate and dysregulation of G protein-coupled receptors. *C. Cruceanu[1,2,4], P. Pavlidis[3], S. Rojic[3], P.P. Tan[3], J.P. Lopez[1,2], S.G. Torres-Platas[2,4], G.A. Rouleau[1,4], G. Turecki[1,2].* 1) Human Genetics, McGill Univ - Douglas Hosp Res Inst, Montreal, QC., Quebec, Canada; 2) McGill Group for Suicide Studies & Douglas Research Institute, Montreal, QC, Canada; 3) Centre for High-Throughput Biology and Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada; 4) Department of Neurology and Neurosurgery, McGill University, Montreal, QC, Canada.

Objective: Bipolar disorder (BD) is a complex mental illness characterized by episodes of mania and depression. Gene expression changes and alterations in regulatory mechanisms have been associated with BD, mainly through candidate gene and a limited number of global microarray expression studies in postmortem brain, but questions remain about isoform-specific dysregulation of known genes as well as the plethora of non-coding transcripts whose importance has been demonstrated recently in the brain but not characterized for bipolar disorder. Method: RNA sequencing (RNA-seq) is a powerful technique that captures the complexity of gene expression, and greatly improves upon previous approaches in both accuracy and level of information. We used RNAseq in tissue from the anterior cingulate gyrus from 13 BD cases and 13 matched controls. We sequenced an average of 180M paired-end reads per subject, and obtained information from ~22,000 transcribed coding and non-coding RNA species. Results: We computed differential expression between cases and controls using the HTSeq pipeline and detected 10 differentially expressed transcripts at a false discovery rate of <5%, replicated these findings using Cufflinks, and validated them by quantitative real-time PCR. Among the most significant results, we observed genes coding for Class A G protein-coupled receptors (GPCRs), SSTR2 (somatostatin receptor 2), CHRM2 (cholinergic receptor, muscarinic 2) and RXFP1 (relaxin/insulin-like family peptide receptor 1). Interestingly, a gene ontology analysis of the entire set of differentially expressed genes pointed to an overrepresentation of genes involved in GPCR regulation. We further followed-up the top genes by querying the effect of treatment with mood stabilizers commonly prescribed in BD through an in vitro study, and found evidence that these drugs affect expression of some of these genes. Conclusion: By using total transcriptome analysis with RNASeq in the post-mortem BD brain, we identified a global downregulation in the ACC, and interesting profile of GPCR dysregulation, and pointed to several new BD genes. Furthermore, we characterized the non-coding transcriptome in BD and possibly identified the first long intergenic non-coding RNAs in BD. Our findings have important implications in regards to fine-tuning our understanding of the dysregulated BD brain as well as for identifying potential new drug target genes or pathways.

1261S

Targeted-resequencing gene panels for the genetic diagnosis of spinocerebellar ataxia and spastic paraplegia in Italian patients. *D. Di Bella[1], S. Magri[1], E. Sarto[1], S.M. Caldarazzo[1], M. Plumari[1], S. Baratta[1], L. Nanetti[1], C. Mariotti[1], C. Gellera[1], P. Bauer[2], F. Taroni[1].* 1) Unit of Genetics of Neurodeg and Metabolic disease, IRCCS Istituto Neurologico C Besta, Milan, Italy; 2) Institute of Medical Genetics, University of Tübingen, Tübingen, Germany.

Spinocerebellar ataxias and hereditary spastic paraplegias (HSP) are genetically highly heterogeneous group of neurological disorders involving both central and peripheral nervous system. More than 50 genes have already been identified for each disease group, but >50% of the patients remain undiagnosed. With the advent of next-gen sequencing, virtually all known disease genes can be tested at once, hugely increasing the expected diagnostic yield. We defined a comprehensive disease gene list and developed 2 different TruSeqCustomAmplicon (TSCA, Illumina) exon enrichment assays for 54 HSP genes and 76 genes for both dominant (SCA) and recessive (SCAR) spinocerebellar ataxias. Aim of the study was to analyze all the patients referred to our laboratory and negative for the common genes. Our data indicate that we could sequence 90% of the coding regions of these genes at more than 20X coverage. Mean coverage was 400-600 reads. A standard bioinformatic pipeline for mapping and annotation yielded a total of 200-400 variants in our disease genes per subject, which can be reduced to 5-10 with a filtration strategy. We included in the study 60 patients (9 AD, 15 AR, 36 S) with ataxia and 37 patients with sporadic spastic paraplegia. Overall, pathogenic mutations were identified in ~20% of patients negative for the common disease genes. In particular, in patients with ataxia, we identified mutations in 2 challenging genes (SYNE1 and SACS), which are extremely difficult to be studied by conventional sequencing because of their length. Moreover, we identified mutations in extremely rare SCA genes (SCA5 and SCA14) in 2 large families. As regards HSP, we could identify mutations in the large SPG11 gene and in rarer AR genes (GBA2, SPG39). Different missense variants of uncertain pathogenicity were identified in genes responsible for dominant ataxia and several heterozygous mutations were identified in recessive genes. All high-quality variants were confirmed by Sanger sequencing indicating reliability of this approach. Further analyses are required for the validation of uncertain variants and the assessment of the presence of large in/del mutations in recessive genes in which heterozygous mutations have been identified. In conclusion, our data confirm the need for multiplexed gene panel approach for the detection of the molecular causes of neurodegenerative diseases with high genetic heterogeneity. (E-Rare grant to PB and FT; Italian Ministry of Health grant to FT).

1262M

Deconstructing obsessive-compulsive disorder (OCD) by whole exome sequencing and integration of clinical endpoints and cognitive domains. *L. Domenech[1], K. Rabionet[1], G. Escaramis[1], D. Trujillano[1], S. Ossowski[1], A. Carracedo[2], P. Alonso[3], X. Estivill[1].* 1) Bioinformatics and Genomics Program, Centre for Genomic Regulation, Barcelona, Spain; 2) Santiago de Compostela University, Spain; 3) Hospital Universitary Bellvitge, IDIBELL, L'Hospitalet de Llobregat, Barcelona, Spain.

Obsessive-compulsive disorder (OCD) is a neuropsychiatric condition that affects 1-3% of the population worldwide. Genome-wide association studies for elucidating the genetic basis of OCD have given extremely limited results. We are taking a genome-centric approach to exhaustively explore the genome of selected OCD cases and to evaluate new aspects of the disease biology. As a first step in an integrative approach to dissect the biology of OCD we have performed whole-exome sequencing (WES) of 200 cases of OCD that underwent exhaustive clinical, neuro-psychological, and neuro-imaging assessment, and received standardized treatment. Control samples for WES have been the 1000 genome project European subset of WES data, the European-American data of the exome variant server (EVS), and the in-house data from over 500 WES of Spanish non-psychiatric subjects. We have implemented a Unified Mixed-Effect Models for Rare Variant Association to perform the analysis of this set of WES data. This approach can evaluate the association to disease of both rare and common variants detected by WES, implementing a combination of a Burden Test and a Sequence Kernel Association Test (SKAT), weighted by the variants' effects and frequencies. We are also developing a pathway-based approach, which will work on protein-protein interaction sub-networks (PPI-SNs), build by integrating knowledge from PPIs and identified recurrently mutated genes. In comparison to rare exome variant association studies on pathways we expect this new approach to more specifically identify protein interactions, regulatory mechanisms or protein complexes involved in OCD development. After pathway analysis and protein-protein interaction (PPI) approaches we have found an accumulation of mutations in epigenetic and neurodegenerative-related genes. Strong evidence of association of several genes in these pathways will be obtained throughout replication in well-characterized cohorts of OCD in the framework of the International OCD consortium and functional analysis of the identified variants. Supported by the Spanish Ministry of Economy and Competitiveness. LD is supported by a Severo Ochoa fellowship.

1263T

Targeted sequencing of a visual migraine aura locus on chromosome 9q22. *M.E. Hiekkala[1], M.A. Kaunisto[1,2], V. Artto[3], S. Paavonen[3], E. Hämäläinen[2], M. Färkkilä[3], A. Palotie[2,4], M. Kallela[3], M. Wessman[1,2].* 1) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland; 2) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 3) Dept. of Neurology, Helsinki University Central Hospital, Helsinki, Finland; 4) The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Migraine is a common and disabling neurological disorder characterized by recurrent multiphase attacks. The two main phases of a migraine attack are the aura phase and the following headache. In most cases aura is visual but it can also be sensory, motor or speech disturbance. We have identified a migraine visual aura locus in Finnish families on 9q21-q22 (Tikka-Kleemola et al. 2010). The same region has also shown linkage to occipitotemporal lobe epilepsy and migraine with aura in a Belgian family (Deprez et al. 2007). Further evidence for a migraine locus on 9q22 was reported in the genetic isolate of Norfolk Island (Cox et al. 2012).

In order to identify susceptibility variants on 9q22 we decided to sequence a 10 Mb large region showing a significant evidence of linkage to migraine visual aura in our previous microsatellite and SNP genotyping analyses. DNA samples of 85 individuals belonging to 13 families - having multiple migraine visual aura patients - were sequenced using NGS targeted sequencing techniques (SeqCap EZ Choise XL Nimblegen, HiSeq Illumina). The mean bait coverage of the targeted area of all sequenced samples was 109. Thus far data from three families, altogether 19 individuals has been analyzed. These analyses highlighted 93 potentially functional, low frequency or rare (MAF <5%) exonic variants that occurred in at least two affected offspring. These variants were located in 51 genes, many of which are involved in functions of membrane transport, neural development or epigenetic regulation. One of the functionally interesting candidate genes, *HIATL1*, harbors a previously unknown missense variant predicted to be deleterious. The variant was identified in one of the families segregating perfectly. It exists in the Finnish exome dataset Sequencing Initiative Suomi (SISu; http://www.sisuproject.fi/) with a frequency of 0.0011 but not in any other public dataset. HIATL1 belongs to the superfamily of solute carriers but its specific biological function is not well studied. It is highly expressed in the skeletal muscle but also in the central nervous system and especially in hippocampus. After analyzing data from all the families the most interesting variants will be genotyped in other visual migraine aura sample sets.

Exome sequencing of familial agenesis of corpus callosum cases. *L. Jouan[1], B. Oulad Amar Ben Cheikh[1], H. Daoud[1], A. Dionne-Laporte[1], S. Dobrzeniecka[1], D. Spiegelman[1], D. Rochefort[1], P. Hince[1], A. Szuto[1], P.A. Dion[1,2], E. Sherr[5], H. Théoret[3,4], G.A. Rouleau[1].* 1) Montreal Neurological Institute and Hospital, Department of Neurology and Neurosurgery, McGill University, Montréal, QC H3A 1A1, Canada; 2) Department of Pathology and Cell Biology, Faculty of Medicine, Université de Montréal; 3) Department of Psychology, Université de Montréal, QC H3C 3J7, Canada; 4) CHU Sainte-Justine Research Center, Montreal, QC H3T1C5, Canada; 5) Department of Neurology, University of California, San Francisco, California, United States of America.

Agenesis of the corpus callosum (ACC), the largest connective structure in the brain which assures transfer of information between the two cerebral hemispheres, is a common brain malformation which can be observed either as an isolated condition or as a manifestation of numerous congenital syndromes. Its estimated prevalence is 3 to 7 per 1000 births but it has also been shown that 3-5% of individuals with neurodevelopmental disorders have ACC. The exact prevalence of asymptomatic ACC is unknown but it has been estimated to be around 0.5/10000. While accumulating evidence suggests an important contribution of genetics to the etiology of ACC, causative genes remain largely unknown. To identify novel ACC genes, we performed exome sequencing in a family with three children with ACC and no other malformation. Since our pedigree clearly suggested a recessive mode of inheritance, we prioritized genes with either homozygous or compound heterozygous (CH) mutations shared by the three affected patients. We identified rare CH mutations in the *CDK5RAP2* gene (Cyclin dependent kinase 5 regulatory subunit-associated protein 2), c.G280C (p.G94R) and c.A3695G (p.N1232S) inherited from the unaffected mother and father, respectively. Interestingly, *CDK5RAP2* is also known as *MCPH3*, a causative gene for autosomal recessive primary microcephaly in which the reduced brain size is believed to result from asymmetric division of neuronal progenitor cells causing a reduced number of neurons. To validate the role of the *CDK5RAP2* gene in ACC, we used the Access Array System (Fluidigm) combined with next generation sequencing to screen 288 additional patients with ACC as well as 288 unaffected controls. We identified one additional patient with 2 rare potential compound heterozygous mutations in *CDK5RAP2*, therefore reinforcing the role of this gene in isolated ACC. This is the first description of *CDK5RAP2* recessive mutations in patients with isolated ACC. Altogether, our findings unravel an unprecedented role of *CDK5RAP2* in cerebral cortex development and offer novel insights into the physiopathology of ACC.

Rare Alleles Altering Schizophrenia Risk Occur in Exons and Noncoding Functional Sequences. *E.K. Loken[1, 2, 3], S.-A. Bacanu[1, 2], D. Walsh[4], F.A. O'Neill[5], K.S. Kendler[1, 2], B.P. Riley[1, 2].* 1) Virginia Institute for Psychiatric Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept. of Psychiatry, Virginia Commonwealth University, Richmond, VA; 3) Clinical and Translational Research Center, Virginia Commonwealth University, Richmond, VA; 4) Health Research Board, Dublin, Ireland; 5) Queens University Belfast, Belfast, Northern Ireland.

Background: Schizophrenia demonstrates high heritability, in part accounted for by common simple nucleotide variants (cSNV), rare copy number variants (CNV) and most recently rare exome variants (rSNV). Although heritability explained by rSNV and CNV is small compared to that explained by cSNV, rSNV in functional sequences may identify specific disease mechanisms. However, current exome methods do not capture a large proportion of potentially functional bases where rare variation may impact disease risk: as much as two-thirds of conserved sequences lie outside the exome in noncoding regions of cross-species evolutionary constraint. Methods: We reasoned that the candidate loci from the Psychiatric Genomics Consortium Phase 1 (PGC1) schizophrenia study represent good target loci to test for the impact of rare SNVs in non-coding constrained regions. We developed custom reagents to capture mammalian constrained non-coding regions, exons and 5'- and 3'-untranslated regions (UTRs) in the 12 PGC1 loci for pooled sequencing in 912 cases and 936 controls. Results: Our design contains substantially more highly conserved bases (46,412 vs. 31,609) and variants (390 vs. 193) in noncoding as compared to coding targets. Using C-alpha to detect excess variance due to aggregate risk increasing or decreasing rSNV effects, we identified signals attributable to alleles with MAF < 0.1% in both coding sequences and in functional noncoding sequences, including variants within ENCODE transcription factor binding sites, DNase hypersensitive regions, and histone modification sites in neuronal cell lines. We also observed significant excess risk-altering variation in the CUB domain of CSMD1, a gene expressed in the developing central nervous system. Discussion: These results support the hypothesis that common and rare variants in the same loci contribute to schizophrenia risk, but highlight the need to expand capture strategies in order to detect trait-relevant sequence variation in a broader set of functional sequences.

1266T

A targeted-resequencing approach for the genetic diagnosis of inherited peripheral neuropathies in Italian patients. *S. Magri[1], D. Di Bella[1], M. Milani[1], S.M. Caldarazzo[1], P. Saveri[2], I. Moroni[3], D. Pareyson[2], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative and Metabolic Disease, IRCCS Istituto Neurologico Carlo Besta, Milan, MI, Italy; 2) Neurology Unit 8, IRCCS Istituto Neurologico Carlo Besta, Milan, MI, Italy; 3) Child Neurology Unit IRCCS Istituto Neurologico Carlo Besta, Milan, MI, Italy.

Inherited peripheral neuropathies are a complex group of genetically heterogeneous disorders caused by mutations in more than 70 genes that lead to the distal degeneration of peripheral nerves. They are divided into 3 groups according to the phenotype and the neuropathological changes: 1) Charcot-Marie-Tooth (CMT) disease characterized by motor and sensory neuropathy, subdivided into demyelinating (CMT1-4) and axonal (CMT2) forms; 2) distal hereditary motor neuropathies (dHMN), which have only motor involvement; 3) hereditary sensory neuropathies (HSN), which involve sensory nerves. These disorders not only represent a phenotypic continuum, but also show a genetic overlap and inheritance pattern variability. For these reasons, efficient genetic diagnosis would require a comprehensive and systematic approach such as that provided by NGS technology. We developed and validated two customized gene panels using TruSeqCustomAmplicon (Illumina) technique: one included 53 genes for CMT2 and dHMN, while the second one included 54 genes for CMT1-4 and HSN. We analyzed 78 patients previously screened for the CMT1A deletion/duplication and for ~4-5 genes selected according to the phenotype. We identified ~300 variants per patient, which are reduced to 2-8 by filtering. All variants were subsequently imported into a local database created specifically for the purpose of: 1) filtering identified variants according to quality criteria, functional consequence, and frequency in variant databases; 2) annotating the frequency of polymorphic variants in the Italian population; 3) collecting data to allow an easy and quick query also by other laboratories. Coverage analysis revealed that more than 90% of the target region has coverage greater than 20X and a mean coverage of about 400X. The molecular cause of the disease was identified in 24/78 patients (30.8%). Moreover, likely pathogenic/uncertain variants were identified in 18% of patients and one heterozygous mutation in recessive genes was identified in 22% of patients. In these cases, further analyses are required to validate variants and to assess the possible presence of large in/dels. In conclusion, this approach allowed us to increased by 10-fold the number of genes analyzed, significantly expanding the diagnostic yield. Our data confirm the usefulness and time/cost effectiveness of NGS-based gene panels for the genetic diagnosis of hereditary neuropathies. (Supported by Italian Ministry of Health grant to FT).

Molecular Studies of mTOR and Tau pathways in Focal Cortical Dysplasia. *M.G. Mazutti[1], F.R. Torres[1], P.A.O. Ribeiro[1], S.H. Avansini[1], R. Secolin[1], B. Carvalho[1], M.G. Borges[1], F. Rogério[2], L.S. Queiroz[2], A.C. Coan[3], H. Tedeschi[3], E.P.L. Oliveira[3], F. Cendes[3], I. Lopes-Cendes[1], The Brazilian Institute of Neuroscience and Neurotechnology (BRAINN).* 1) Department of Medical Genetics; School of Medical Sciences, University of Campinas UNICAMP , Campinas, Brazil; 2) Department of Anatomical Pathology; School of Medical Sciences, University of Campinas UNICAMP , Campinas, Brazil; 3) Department of Neurology; School of Medical Sciences, University of Campinas UNICAMP , Campinas, Brazil.

Focal cortical dysplasia (FCD) is a sub-type of malformation of the cerebral cortex which is a frequent cause of intractable focal seizures, requiring surgical treatment. FCD presents cortical architecture abnormalities also observed in tuberous sclerosis (TS) and hemimegalencephaly (HME). In addition, FCD, TS and HME show aberrant expression of genes belonging to the mTOR signaling pathway. Potential involvement of Tau pathway was also reported in FCD. Therefore, the similarity in histological features as well as abnormal gene expression pattern suggests that pathogenic mechanisms could be common to these three disorders. Recently, somatic mosaic mutations have been indentified in patients with TS and HME. Therefore, the objective of this work is to investigate whether somatic mosaic mutations in genes belonging to the mTOR and Tau pathways are present in the central nervous system of patients with FCD. NGS was performed in genomic DNA extracted from brain tissue resected by surgery (BTRS) and peripheral blood of patients with FCD. We performed exome capture with Nextera® Expanded Kit (Illumina®) and NGS on a Hiseq 2500 bench top sequencing machine. A bioinformatics pipeline was applied, using filters to variants present only in brain tissue. To date, BTRS and blood samples of four patients with FCD were sequenced and a total of 749 and 91 variants were identified in genes belonging to the mTOR and Tau pathways, respectively. Among these variants we found 107 and 12 mutations in a mosaic state (present only in the BTRS samples), respectively; including 77 variants not described in databases of human mutations. Genes disrupted by mutations code for proteins involved in regulation of cell growth and cellular processes such as proliferation, differentiation and development, as well as genes already implicated in other cerebral cortical malformations. Our preliminary results confirm the presence of mosaic mutations in mTOR and Tau pathways in FCD. However, it is still not clear whether these mosaic mutations are a causative factor in FCD or a consequence of mutations in another gene whose disruption causes a cumulative mutational burden by dysregulation of mitotic checkpoints. Additional experiments, including high-deep NGS, will be carried out in order to answer these questions. Supported by CEPID-FAPESP.

Evidence for association of CDH26 with Autism Spectrum Disorders. *F. Mentch[1], R. Golhar[1], K. Wang[1,2], J. Bradfield[1], S. Murray[3], H. Hakonarson[1,4].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Zilkha Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Department of Pathology, University of California San Diego, La Jolla, CA; 4) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

Background: Autism spectrum disorders (ASDs) have been associated with genetic variation near neuronal cell-adhesion molecules (NCAMs). Apart from association through common GWAS variants, this category of molecules has been shown to be disrupted due to rare copy number variation (CNVs) in a subset of ASD cases. Here, we investigated if rare single nucleotide variants (SNVs) in neuronal cell adhesion genes are associated with ASD. Methods: We performed exome capture and targeted sequencing of 99 cell adhesion genes, including neurexins, neuroligins, semaphorins, cadherins, protocadherins and other ASD candidate genes. A total of 225 ASD cases were sequenced on Illumina HiSeq. Variants were annotated using ANNOVAR then filtered for potential pathogenic impact. Candidate variants were subsequently tested for association in 3,100 ASD cases and unrelated 2,992 controls (966 cases, 776 controls on Veracode; 2,134 cases, 2,216 controls on Goldengate) previously registered in the de-identified biorepository at the Center for Applied Genomics (CAG) at The Children's Hospital of Philadelphia (CHOP). EIGENSTRAT and R::KNN1 were used to control for population stratification and PLINK for Chi-Squared test for association. Results: Of 292 annotated SNPs from the targeted sequencing studies and typed in 3,100 ASD cases and 2,992 controls, three missense mutations in CDH26, not reported previously, were found to be associated with ASD ($0.0001 <= P <= 0.007$), with the top SNP surviving Bonferroni corrections for multiple testing. Of those, (1) rs11086690 (MAF 0.007, OR 2.06, SIFT 0.18) is located at the end of the Ca2+ binding site, which mediates cell-cell contact, with (2) rs28409250 (MAF 0.007, OR 1.94, SIFT 0.72) residing close to a Ca2+ binding site, whereas (3) rs41310817 (MAF 0.009, OR 1.83, SIFT 0.3) is not part of any protein domain. rs11086690 is in strong linkage disequilibrium (LD) with rs28409250 ($r2=0.99$), while rs41310817 ($r2=0.57$), and rs28409250 and rs41310817 ($r2=0.56$) is similar. Conclusions: These associations demonstrate that both common and rare variants in CDH26 associate with ASDs, suggesting they may play a role in the pathogenesis of the disease.

1269T

Searching for a common founder - exome sequencing of sporadic early-onset Parkinson's disease in Norway. *A.H. Rengmark[1], L. Pihlstrøm[1], Z. Iqbal[1], M.D. Vigeland[2], M. Toft[1].* 1) Department of Neurology, Oslo University Hospital, Oslo, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway.

Age is a major risk factor for developing Parkinson's disease (PD), and <1 % of patients develop disease before the age of 40. Mutations in known autosomal recessive genes are normally found in up to 10 % of patients with early-onset PD (EOPD). The Norwegian population is relatively homogeneous and of limited size. Common founder mutations have therefore been identified in a number of Mendelian disorders in the past. We hypothesized that a subset of sporadic EOPD in Norway might be caused by one or several founder mutations inherited as a recessive trait. 53 unrelated Norwegian EOPD patients were included in the study (mean age 37.1 ± 4.1 SD, range = 26-47 years). Library preparation and exome sequencing was performed by commercial providers, using Illumina and Solid sequencing platforms. Bioinformatics analyses were based on BWA (alignment) and GATK (processing and variant calling). To identify single nucleotide variants (SNVs) shared by ≥2 patients we used FILTUS, a new bioinformatic tool developed at our institution. Non-synonymous coding homozygous SNVs with minor allele frequency ≤0.02 in 1000genomes and EPS5400 databases were further filtered by removing: (1) populations-specific variants found in our in-house database, (2) sequencing platform specific variants and (3) SNVs located in highly polymorphic genetic regions. All remaining SNVs were verified by Sanger-sequencing. We also performed genotyping with the Infinium HumanExomeCore bead chip (Illumina) to identify runs of homozygosity (ROH). Our analyses have identified 12 genes containing homozygous SNVs shared by 2-5 patients. This includes variants in the MYO7B (myosin VIIB) and MYADML2 (myeloid-associated differentiation marker-like 2) genes. 23 homozygous SNVs were identified within ROH, including a mutation in the PRR12 gene that was found in 2 different patients. The function of this gene is not well characterised, but has been reported to be expressed in the brain. All identified homozygous SNVs are currently being genotyped in larger patient series and candidate genes will be sequenced in additional EOPD patients. In addition, analyses of compound heterozygous variants and indels are on-going. Our study will indicate if exome sequencing of sporadic patients with an extreme phenotype (early disease onset) can be used to identify new autosomal recessive genes contributing to complex disorders.

1270S

Whole exome sequencing identifies MEOX2 as a candidate genetic factor in posterior cortical atrophy. *E.C. Schulte[1, 7], R. Perneczky[2], A. Kurz[2], J. Diehl-Schmid[2], D. Rujescu[3], M. Hüll[4], A. Peters[5], C. Gieger[6], T. Meitinger[7, 8], H. Klünemann[9], J. Winkelmann[1, 7, 8, 10]*. 1) Neurologische Klinik und Poliklinik, Technische Universität München, Munich, Germany; 2) Klinik für Psychiatrie, Technische Universität München, Munich, Germany; 3) Klinik für Psychiatrie, Friedrich Schiller Universität Jena, Jena, Germany; 4) Universitätsklinik für Psychiatrie und Psychotherapie, Albert Ludwigs Universität Freiburg, Freiburg, Germany; 5) Institute for Epidemiology II, Helmholtz Zentrum München, Munich, Germany; 6) Institute for Genetic Epidemiology, Helmholtz Zentrum München, Munich, Germany; 7) Institut für Humangenetik, Helmholtz Zentrum München, Munich, Germany; 8) Institut für Humangenetik, Technische Universität München, Munich, Germany; 9) Psychiatrische Klinik, Universität Regensburg, Regensburg, Germany; 10) Department of Neurology and Neurosciences, Stanford University, Palo Alto, CA, USA.

Background: Posterior cortical atrophy (PCA) is a rare neurodegnerative condition presenting with an impairment in visual processing skills which shares clinical characteristics with Alzheimer's disease (AD). The causes of PCA are not fully understood. Here, we performed whole exome sequencing in nine individuals with PCA in search for rare genetic variants that contribute to this phenotype. Methods: Whole exomes of 8 individuals with PCA and one trio were sequenced. Identified variants were filtered under autosomal dominant (auto dom), autosomal recessive (auto rec) and de novo models. Burden tests (CAST) were performed for all candidate genes using data from 3891 in-house exomes and 4300 NHLBI ESP exomes as controls. Subsequently, the coding regions of the most plausible biological candidate, *MEOX2*, were screened for variants by high-resolution melting curve analysis in 1271 individuals with AD and 3426 general population controls. Results: We identified de novo missense variants in *KIRREL3*, *MEOX2* and *CACNA1S*. Joint analysis of all 9 PCA cases yielded 44 and 37 genes harboring rare variants (MAF $\leq$ 0.1% for dom and $\leq$ 2.5% for rec alleles) in at least 30% of cases under an auto dom and rec model, respectivley. None of these overlapped with any of 13 genes in which the affected son of the trio held homozygous or compound heterozygous variants. None of the variants occurred in more than a single case. Burden testing identified 7 auto dom—*ANKR6/LYRM2, KEL, NAA16, NYX, PPP1R3E, SIGIRR*—and 3 auto rec —*AFAP1L2, ALPK2, IFNA10*—candidate genes in which rare variants were associated with the PCA phenotype at exome-wide significance. As *MEOX2* has been linked to AD, we screened the coding regions of this gene for additional rare variants in a large AD sample. Rare nonsynonymous variants in MEOX2 showed a trend towards being more common in individuals with AD compared to controls (38 of 1271 AD vs. 72 of 3426 controls; p=0.07, χ^2 test). The de novo variant was not found again. Conclusions: We were unable to causally link rare coding variants in any gene to the PCA phenotype but created the first bias-free short-list for potential candiate genes for PCA. A de novo variant in the homeobox gene *MEOX2* seemed especially interesting because individuals with extreme AD phenotypes have been shown to harbor copy number variants overlapping *MEOX2* and *Meox2*$^{-/-}$ mice develop an AD-like phenotype.

1271M

Exome sequencing identifies a novel missense mutation in MFN2 in familial dysautonomia. *Z. Wei[1], D. Li[2], E. McCormick[3,4], RM. Chiavacci[2], L. Tian[2], MJ. Falk[3,4], H. Hakonarson[2,3,5]*. 1) Department of Computer Science, New Jersey Institute of Technology, Newark, New Jersey, USA; 2) The Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, 19104, USA; 3) Division of Human Genetics Department of Pediatrics, The Children's Hospital of Philadelphia and The Perelman School of Medicine, Philadelphia, Pennsylvania, 19104, USA; 4) Division of Child Development and Metabolic Disease, Department of Pediatrics, The Children's Hospital of Philadelphia and The Perelman School of Medicine, Philadelphia, Pennsylvania, 19104, USA; 5) Division of Pulmonary Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

Whole exome sequencing (WES) analysis identified a novel heterozygous c.1699A>G (p.M567V) missense mutation in MFN2 that segregated with familial dysautonomia in which the teenage daughter has history of headaches, poor coordination and unawareness of her body position, extreme fatigue and weakness, and the mother has a similar history of muscle fatigue/pain/heaviness, frequent headaches, intermittent confusion episodes and non-refreshing sleep. Extensive clinical diagnostic genetic testing and whole mitochondrial genome sequencing were unrevealing before the research-based WES analysis. We examined missense, nonsense, splice-altering, and coding indels matching the dominant inheritance model. Results were filtered to exclude synonymous variants, variants with minor allele frequency (MAF) greater than 0.5%, and variants previously identified in controls by our in-house exome variant database. Relevant candidates were taken forward for manual curation. MFN2, encodes a mitochondrial membrane protein that participates in mitochondrial fusion and contributes to the maintenance and operation of the mitochondrial network, was identified as the most likely candidate. Mutations in this gene cause hereditary motor and sensory neuropathy and Charcot-Marie-Tooth disease type 2A, which are both disorders of the peripheral nervous system. We are currently conducting follow-up functional studies to elucidate the mechanisms in mitochondrial fusion defect that will be presented together.

1272T

Inherited and de novo Transposable Elements in schizophrenia. *F. Macciardi[1,7,8,9], G. Guffanti[2], P. DeCrescenzo[2], C. Pato[3], H. Mangalam[4], A. Rodriguez[5], R. Madduri[5], S. Gaudi[6].* 1) Dept of Psychiatry & Human Behavior, University of California, Irvine, Irvine, CA; 2) Department of Psychiatry Division of Epidemiology & Division of Child and Adolescent Psychiatry Columbia University/NYSPI New York, NY; 3) Department of Psychiatry and the Behavioral Sciences Keck School of Medicine, USC, Los Angeles, CA; 4) OIT, University of California, Irvine, Irvine, CA; 5) MCS, Argonne National Laboratory Computation Institute, University of Chicago; 6) Istituto Superiore di Sanita', Rome, Italy; 7) Center for Autism Research and Treatment (CART), University of California, Irvine, California; 8) Center for Epigenetics and Metabolism, University of California, Irvine, California; 9) Department of Pharmacological and Biomolecular Sciences, University of Milan, Milan, Italy.

Transposable Elements (TEs) accumulated over evolutionary time making up between 1/2 and 2/3 of the human genome. LINE1s are particularly active in creating new retro transposition events, several of which can be highly polymorphic and not easy to detect. The extent of transposon-mediated mutagenesis has been mostly investigated using sophisticated sequencing library design to specifically capture TE insertions. Recently, two computational methods, Retroseq and Tangram, have been developed to allow detecting TE insertions using traditional next-generation sequencing. We developed a workflow to detect TE insertions using either one of the two algorithms, compare the calls made by each single algorithm and retain a list of TE insertions identified by both algorithms, perform local de novo alignment (Velvet) of the regions harboring the new insertion sites (computational validation) and assign TE family and type to the de novo assembled sequence using RepeatMasker. We analyzed the whole genome sequences from six members of a family in which schizophrenia (SZ) segregates. This family is part of the Genomic Psychiatric Cohort (GPC) sample (Pato et al, 2013). Our goals are (1) to identify de novo TE insertions that may represent potential risk factors to develop SZ and (2) to estimate the sensitivity of the method to detect and computationally validate new TE insertions. We identified 29 new L1 insertions and we replicated 2 previously described L1HS originally identified in a re-analysis of the 1,000 Genomes Project trios (Rouchka et al, 2010), but not yet reported in Repbase to our best knowledge. RepeatMasker classifies all the 29 insertions as either L1HS and/or L1P1 with the only exception of 1 L1PA2, confirming that these are mostly evolutionary young insertions. More than half (55%) of these insertions are located within known GENCODE v7 annotated genes or lincRNAs, supporting the impact of young insertions on gene function and regulatory elements. None of the insertions is de novo, but the pattern of inheritance from parents to offspring suggests that all insertions are germline. At least 3 of them, all mapping to known genes, are transmitted uniquely from the SZ affected mother to two SZ affected children. This is the second study that evaluates the pattern of inheritance of new TE insertions other than the 1000 genomes Project and the first one that looks at transmission disequilibrium of germline TEs in a SZ affected family.

1273S

Evidence for differential X chromosome gene expression in children with sex chromosome aneuploidies. *D. Hong[1,3], X. Zhang[1,2], X. Zhu[1,2], A. Reiss[1,3], A. Urban[1,2].* 1) Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA; 2) Genetics, Stanford University, Stanford, CA; 3) Center for Interdisciplinary Brain Sciences Research, Stanford University, Stanford, CA.

Introduction: Sex differences in neurodevelopment have been well-documented. Prior research in this area has primarily focused on the influence of sex hormones, though there is increasing evidence that differential gene expression from the sex chromosomes plays an equally important role. Sex chromosome aneuploidies, such as Turner syndrome (45X) and Klinefelter syndrome (47XXY), provide a unique model in which to investigate these effects. Analysis of gene expression patterns may help elucidate evidence for sex-chromosome associated dosage effects. Methods: Using peripheral whole blood, we undertook deep RNA-Seq to characterize expression profiles from a cohort of four individuals - a twin pair of a 9-year old female with TS and her 9-year old typically developing sister, as well as a 10-year old male with KS and an 8-year old male control. Sequencing was completed using Illumina HiSeq with ~50M 2×100nt paired-end reads per proband. Overall transcript levels from the X chromosome were quantified and compared to overall transcripts from all autosomes. Results: Despite the small sample size, the ratio of X chromosome activity relative to autosomes suggests that global transcription activity of the X chromosome is dose-dependent, as both the typically developing female twin (46XX) and the male with Klinefelter syndrome (47XXY) had greater than 10-fold higher X:autosome ratios compared to the female twin with Turner syndrome (45X) and the typically developing male control (46XY). Conclusion: Previous studies characterizing sex chromosome function suggest that dosage compensation mechanisms compensate for dose imbalance between males and females, as well as between the sex chromosomes and autosomes. This includes the existence of homologous pseudoautosomal regions on the sex chromosomes and upregulation of the active X chromosome in females and the single X chromosome in males to match the expression output of autosomes genome-wide. However, these mechanisms are insufficient to explain the notable phenotypic variance associated with sex chromosome aneuploidies. Here we provide novel evidence for dosage-related transcriptome sequencing patterns that directly correlate with the number of X chromosomes in a cohort of children with sex chromosome aneuploidies.

1274M

Subcortical band heterotopia (double cortex syndrome) not associated with DCX or LIS1 gene mutations. *E. Andermann[1, 5, 6, 8, 10], D. Amrom[1, 5, 6, 10], F. Dubeau[2, 4, 5, 6, 10], D. Melançon[3, 5, 7, 10], D. Tampieri[3, 5, 7, 10], F. Andermann[4, 5, 6, 9, 10], B. Dobyns[11].* 1) Neurogenetics Unit; 2) Seizure Service; 3) Department of Neuroradiology; 4) Seizure Clinic; 5) Montreal Neurological Hospital and Institute; 6) Department of Neurology & Neurosurgery; 7) Department of Radiology; 8) Department of Human Genetics; 9) Department of Pediatrics; 10) McGill University, Montreal, Quebec, Canada; 11) Departments of Pediatrics and Neurology, University of Washington; and Center for Integrative Brain Research, Seattle Children's Research Institute, Seattle, WA.

Subcortical band heterotopia (SBH), also called double cortex syndrome, is a malformation of brain cortical development due to deficient neuronal migration. It is classically due to either DCX or LIS1 gene mutations, resulting in a predominantly anterior or posterior distribution of the SBH respectively. However, a number of patients do not harbor point mutations or deletions/duplications of either of these genes, suggesting even greater genetic heterogeneity. We reviewed our database of adult epilepsy patients with SBH in whom no DCX or LIS1 mutation was found. Fifteen patients presenting with epilepsy, with or without associated cognitive delay, had SBH detected on brain MRI for which no DCX or LIS1 mutation was found. They had no associated pachygyria. All patients were sporadic. They were evaluated with a karyotype and DCX and/or LIS1 mutation analysis, depending on the pattern of distribution of their SBH. A few patients had both DCX/LIS1 sequencing and deletion/duplication analysis when their SBH was diffuse. In one woman, the karyotype showed a rearrangement of chromosome 9 suggesting a paracentric inversion of the q13->q22.3 region. Karyotype in both parents was normal, indicating a de novo chromosomal rearrangement in the proband. This patient had a history of infantile spasms, morning myoclonic seizures and pervasive developmental delay. She presented a thick and diffuse SBH. DCX/LIS1 sequencing and deletion/duplication analysis were negative. A CGH microarray with 135000 oligonucleotides was added and did not reveal any deletion or duplication. A higher resolution CGH microarray performed in order to detect a possible microdeletion or duplication was inconclusive for gene identification. Genetic evaluation of SBH deserves DCX and/or LIS1 sequencing and deletion/duplication analysis, but does not always reveal the genetic cause of this brain malformation. Karyotype analysis and/or CGH array may be of interest in these unsolved cases. Whole exome sequencing should be carried out to elucidate the genetic cause and provide genetic counseling for these families.

1275T

The astrocytic transporter Slc7a10 (Asc-1) is required for glycinergic inhibitory function. *J.T. Ehmsen[1], Y. Liu[2], Y. Wang[2], J.D. Rothstein[1], S.H. Snyder[1], M.P. Mattson[2], A. Hoke[1].* 1) Department of Neurology, Johns Hopkins, Baltimore, MD; 2) Laboratory of Neurosciences, National Institute of Aging Intramural Research Program, Baltimore, MD.

Slc7a10 (Asc-1) is a sodium-independent neutral amino acid transporter known to be the primary mediator of D-serine transport in the brain. Slc7a10 transports a number of additional amino acids including glycine, L-alanine, L-serine, and L-cysteine, as well as their D-enantiomers. We find that Slc7a10 is enriched in cerebellar Bergmann glia and within a subset of astrocytes of the caudal brain and spinal cord, in a distribution corresponding to high densities of glycinergic inhibitory synapses. Accordingly, we find that spinal cord glycine levels are significantly reduced in Slc7a10-null mice and that spontaneous glycinergic postsynaptic currents in motor neurons of mice lacking Slc7a10 show substantially diminished amplitude, identifying the likely etiology of sustained myoclonus and early postnatal lethality previously described for these animals. These observations establish a critical role for astrocytic Slc7a10 in glycinergic inhibitory function in the central nervous system, and implicate SLC7A10 as a candidate gene in human hyperekplexia and stiff person syndrome.

Temporal mRNA expression profile of cyclooxiganase-2a and cyclooxiganase-2b genes in adult and larvae zebrafish brain after pentylenetetrazole-induced seizure. *H.M. Gomide, P.G Barbalho, D.M Nakata, I.L Cendes, C.V Maurer-Morelli.* Medical Genetics, State University of Campinas, Capinas, Sao Paulo, Brazil.

Introduction: Although zebrafish have become a model for seizure studies, there are no studies about neuroinflammatory response after seizure in this model; therefore, we investigated the temporal mRNA expression profile of ciclooxigenase-2 genes after pentylenetetrazole (PTZ)-induced seizure in adult and immature zebrafish brain. Methods: All experiments were approved by Animal Ethical Committee/UNICAMP (#3098-1). Seven days post-fertilization (dpf) larvae and adult zebrafish were separated in Seizure (SG) and Control (CG) groups (n=5 each group. Larvae sample was composed by pooling 20 heads, and adult sample by pooling two brain). Animals from SG were exposed to PTZ 15mM, and animals from CG were handled in PTZ-free water. At 0.05h, 1h and 6h after seizure, animals were anesthetized and their heads/brains collected for RT-qPCR that was carried out in triplicates with ef1α as endogenous controls using TaqMan System. The relative quantification was calculated by the equation RQ=2-$\Delta\Delta$CT. Statistical analyses were performed by Mann-Whitney test, using the GraphPad Prism with $p < 0.05$. Results: for seven dpf larvae, only the cox-2b mRNA was increased at 0.05h and 1h after PTZ-induced seizure when compared to CG. The mean ± SEM data were: (i) cox2a: CG0.05h 1.2±0.06 vs SG0.05h 1.3±0.12 (p = 0.42); CG1h 1.32±0.5 vs SG1h 2.33±0.52 (p=0.055); CG6h 1.08±0.11 vs SG6h 1.04±0.06 (p=0.34); (ii) cox-2b: CG0.05h 0.93±0.02 vs SG0.05h 1.73±0.18 (p= 0.004); CG1h 1.43±0.4 vs SG1h 2.58±0.23 (p =0.047); CG6h 1.08 ±0.11 VS SG6h 1.05±0.13 (p=2.7). For adult zebrafish, the cox-2b mRNA levels were increased only at 6h after PTZ-induced seizure compared to CG. The mean ± SEM data were: (v) cox-2a: CG0.05h 0.74±0.08 vs SG0.05h ± (p = 0.42); CG1h 0.66±0.12 vs SG1h 0.62±0.06 (p =0.34); CG6h 1.08±0.2 vs SG6h 0.87±0.22 (p=0.07); (vi) cox-2b: CG0.05h 1.04±0.09 vs SG0.05h 1.3±0.2 (p=0.2); CG1h 1.03±0.06 vs SG1h 1.21±0.13 (p=0.2); CG6h 0.98±0.03 vs SG6h 1.21±0.08 (p=0.04). Conclusion: This is the first study investigating the temporal mRNA expression profile of cox2a and cox2b genes in adult and larvae zebrafish brain after seizures. Our results showed that both genes have different mRNA expression response after PTZ-induced seizure, suggesting that zebrafish cox-2b is more similar than is cox-2a from mammalian Cox-2. This study provides evidence that this little fish is a valuable model for further studies of inflammation and seizures. Support: FAPESP and CNPq.

Profiling gene expression in CFW mouse brains to refine our understanding of the genetic architecture of behavioral traits. *S. Gopalakrishnan[1], P. Carbonetto[1], N.M. Gonzales[1], E.H. Leung[1], J. Park[1], E. Aryee[1], J. Davis[3], C.C. Parker[2], A.A. Palmer[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Dept. of Psychology and Program in Neuroscience, Middlebury College, Middlebury, VT; 3) Stanford School of Medicine, Department of Genetics, Stanford, California.

Translating results from genome wide association studies to elucidate the underlying biology of complex human diseases and traits remains a massive challenge. It is now widely appreciated that variation in gene expression plays an important role in the genetic architecture of most complex traits. However, it is not always feasible to access the relevant tissues in human subjects to measure gene expression. Here we demonstrate the use of an outbred (CFW) mouse population to model neuropsychiatric traits for methamphetamine response sensitivity, conditioned fear behavior and prepulse inhibition. We complement this with RNA-Seq assays to quantify gene expression in three brain regions that are relevant to these traits, the hippocampus (n = 80), striatum (n = 55) and pre-frontal cortex (n = 54). The CFW mouse stock offers several important advantages over other mouse populations for mapping, especially the resolution of QTL regions. We mapped QTLs and eQTLs in these animals using genotypes obtained from a modified Genotyping-by-Sequencing protocol and a linear mixed model. Each QTL region contains many fewer genes as compared with traditional mouse populations; however, in many cases the QTLs still implicate dozens of genes. In these cases, gene expression data can be useful to prioritize candidate genes within QTL regions. In each tissue, we identified expression QTLs (eQTL) using two approaches: a linear mixed model approach to assess support for associations, and a two-sample paired t-test to identify allele-specific expression. Using eqtlbma (Flutre et al.) to model shared eQTLs across tissues, we find that a high proportion of eQTLs (approximately 70%) are common to the three brain tissues, with a small set of tissue specific eQTLs. Within each behavioral QTL, we prioritize genes for which there is an eQTL under this QTL peak, i.e. genes with expression affected by a variant associated with behavior are ranked higher than genes without such an eQTL. Preliminary results suggest that gene expression is an important mediator of behavior, with more than half of the QTL regions containing at least one variant that is also an eQTL.

1278T

Contiguous deletion of CADPS2 and GRM8 associates with severe autism spectrum disorder. *C. Hatano[1], T. Yokoi[1], K. Wakui[2], K. Enomoto[1], Y. Kuroda[1], I. Ohashi[1], R. Kosaki[3], K. Kurosawa[1].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Division of Medical Genetics, National Center for Child Health and Development, Tokyo, Japan.

Autism spectrum disorders (ASDs) are complex neurobehavioral conditions and known to have multi-hit etiology models. Some copy number variations (CNVs) in human genes, in both cases of rare inherited and de novo, contribute to genetic weakness in ASD patients. The identification of those genes seems to support proving the clinical states. We report on a female patient with severe autism, associated with contiguous deletion of CADPS2 and GRM8 at 7q31. She was born to nonconsanguineous parents at 41 weeks of normal pregnancy. The parents were healthy and their family history was unremarkable. Her birth weight was 3328 g (+0.82 SD), length 49.4 cm (+0.47 SD), and the head circumference 34.5 cm (+1.14 SD). She was first evaluated in neonate because of feeding difficulty and developmental delay (DD). She needed gavage feeding for the first three months. The standard karyotyping revealed an apparently balanced translocation, 46,XX,t(7;10)(q31.3;q23.2). Her height was 95 cm (-3.3 SD), weight 13.6kg (-1.8 SD) at 5 7/12 years of age. She crawled at 3 years old and was able to walk with help at 5 years of age. She threatened self-injury. Together with severe intellectual disability (ID) and behavioral abnormalities as ASD, we performed cytogenetic microarray analysis, which revealed a de novo 4.3Mb deletion at 7q31, extending from position 122,292,088-126,610,540 (hg19). The deleted interval included CADPS2 (calcium-dependent activator of secretion) and GRM8 (glutamate receptor, metabotropic 8). Haploinsufficiency of CADPS2 is known to cause mild intellectual delay. While GRM8 is one of the CGH-specific CNVs that can drive attention deficit hyperactivity disorder (ADHD) etiology. However, more severe intellectual disability and autism phenotype observed in our patient is inconsistent with a dosage effects of the two genes. This combinatorial suppression of the 2 genes attribute to the etiology. These results suggest that synergy of haploinsufficiency of contiguous genes contributing neuronal development and functional network of neural activity has a crucial role in the severe phenotype of ASD and DD/ID.

Genome-wide gene expression analysis of identical twins discordant for autism spectrum disorder. *A. Saffari[1], C.C.Y. Wong[2], M. Arno[3], A. Ronald[1,2], L.C. Schalkwyk[2], J. Mill[2,4], R. Plomin[2], F. Dudbridge[5], E.L. Meaburn[1,2].* 1) Department of Psychological Sciences ,Birkbeck, University of London, London, UK; 2) King's College London, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, De Crespigny Park, London, UK; 3) Genomics Centre, School of Biomedical and Health Sciences, King's College London, London, UK; 4) University of Exeter Medical School, Exeter University, St Luke's Campus, Exeter, UK; 5) Faculty of Epidemiology and Population Health,London School of Hygiene and Tropical Medicine, University of London, London, UK.

Autism spectrum disorder (ASD) defines a collection of complex neurodevelopmental disorders, typified by impairments in social interaction and language. Multiple lines of evidence suggest a strong genetic basis to ASD. However, identical twins do not show complete concordance indicating that epigenetic and environmental (i.e. non-genetic) factors may also contribute to ASD risk.

This study aims to investigate the biological basis of non-genetic contributions to ASD risk by characterizing gene expression differences in ASD-discordant identical twins. Our sample consists of 53 sets of identical twins concordant (N = 6) and discordant (N = 36) for ASD and ASD traits, and concordant controls (N = 11) that were derived from the longitudinal, population-based Twins Early Development Study (Haworth, Davis, & Plomin, 2012). Genome-wide expression profiling of whole blood samples was initially performed using the Affymetrix Human Gene array, which was subsequently followed up with RNA-Sequencing (RNA-Seq) using the Illumina TruSeq kit, performed in order to gain a more detailed, higher-resolution profile of transcription. Whilst the array-based analysis failed to identify differentially expressed genes associated with the disorder that reached genome-wide significance, pathway-based analysis identified several pathways previously associated with ASD, these included nerve growth factor (NGF) signaling and glutathione-mediated detoxification pathways. Our current efforts are focused on analysis of the RNA-Seq dataset, investigating both differential expression and differential splicing.

To our knowledge, this study represents the largest of its kind to systematically investigate non-genetically mediated gene expression differences in ASD-discordant twins, the identification of which will help to shed light on the biological pathways dysregulated in ASD. DNA methylation (Illumina 27k Human Methylation array) and DNA variation (Illumina Human OmniExpressExome) data are also available for the same sample, and future work will be focused on the integration of these diverse and multi-dimensional datasets to help tease apart the relationship between genotype, epigenotype and phenotype.

A mouse model of 2q23.1 deletion syndrome implicates MBD5 in neuronal development. *J. Young[1], V. Camarena[1], L. Cao[1], C. Abad[1], Y. Toledo[1], M. Araki[2], K. Araki[2], K. Walz[1].* 1) Hussman Inst Human Genomics, Univ Miami, Miami, FL; 2) Kumamoto University, Kumamoto, Japan.

Individuals with 2q23.1 deletion syndrome have a range of well-defined behavioral abnormalities that include intellectual disability, motor delay, behavioral abnormalities and a distinctive craniofacial phenotype. Common to these patients is a partial or total deletion of a single gene, methyl-CpG binding domain protein 5 (*MBD5*), suggesting that haploinsufficiency of this gene is responsible for the phenotype. To confirm this hypothesis and to examine the role of MBD5 in vivo we have generated and characterized an *Mbd5* gene trap mouse model. Our analysis of heterozygous mutant mice revealed a striking similarity in the behavioral manifestations of mice compared with human 2q23.1 microdeletion carriers including abnormal behavior, cognitive impairment and motor and craniofacial abnormalities. In addition, cortical neuronal cultures allowed the detection of a deficiency in neurite outgrowth. Our study indicates that the $Mbd5^{+/GT}$ mouse model recapitulates most of the hallmark phenotypes observed in 2q23.1 deletion carriers. These findings support the causal role of MBD5 in 2q23.1 microdeletion syndrome and suggest a role for MBD5 in neuronal processes. The $Mbd5^{+/GT}$ mouse model will advance our understanding of the abnormal brain development underlying the emergence of 2q23.1 deletion-associated behavioral and cognitive symptoms.

Caldecott[3].* 1) Department of Human Genetics, Radboud University Medical Centre, Nijmegen, Gelderland, Netherlands; 2) Department of Cognitive Neurosciences, Donders Institute for Brain Cognition and Behaviour, Radboud University Medical Centre, Nijmegen, The Netherlands; 3) Genome Damage and Stability Centre, School of Biological Sciences, University of Sussex, Sussex, UK; 4) Molecular and Cellular Therapeutics, The Royal College of Surgeons in Ireland, Dublin, Ireland; 5) National Centre for Medical Genetics, Our Lady's Children's Hospital, Crumlin, Dublin, Ireland; 6) Centro Andaluz de Biología Molecular y Medicina Regenerativa (CABIMER), Departamento de Genética, CSIC (Centro Superior de Investigaciones Científicas)-Universidad de Sevilla, Sevilla, Spain; 7) Department of Neurology, University Hospital Galway, Galway, Ireland; 8) Division of Neurology, Beaumont Hospital, Dublin, Ireland; 9) School of Medicine and Medical Science, University College Dublin, Dublin, Ireland; 10) Kreb's Institute, Department of Molecular Biology and Biotechnology, University of Sheffield, Sheffield, UK; 11) Center of Genomics, Helmy Institute, Zewail City of Science and Technology, Giza, Egypt; 12) These authors contributed equally to this work.

Patients with heritable DNA repair deficiency syndromes often have increased susceptibility to cancer and pronounced neurological dysfunction. By using exome sequencing, we identified a homozygous truncating mutation, c.425+1GT>A, in the DNA repair gene *TDP2* in three brothers from a consanguineous family, as well as a second homozygous truncating mutation, c.413_414delinsAA, in an additional unrelated individual. The affected individuals were characterized by early appearance of seizures and were all intellectually disabled. They also developed progressive ataxia that eventually resulted in confinement to a wheelchair. This clinical picture indicates an important neurodevelopmental role for Tyrosyl DNA phosphodiesterase-2 (TDP2) and suggests that this enzyme is continuously required for neural maintenance.

TDP2 is an enzyme that repairs 'abortive' Topoisomerase II (TOP2)-induced DSBs. TOP2 removes torsional stress from DNA and facilitates gene transcription by introducing transient DNA double-strand breaks (DSBs). Such DSBs are normally rejoined by TOP2 but on occasion can become abortive and remain unsealed. Lymphoblastoid cells from affected individuals that lack TDP2 activity are indeed hypersensitive to TOP2-induced DSBs. Furthermore, loss of TDP2 inhibits TOP2-dependent gene transcription in cultured human cells and in mouse post-mitotic neurons. We also show that TDP2 is required for normal levels of many gene transcripts in developing mouse brain, including numerous gene transcripts associated with neurological function and/or disease, and for normal interneuron density in mouse cerebellum.

In summary, we have identified inactivating mutations in TDP2 in individuals with intellectual disability, seizures and progressive ataxia. Moreover, we show that TDP2 protects gene transcription from endogenous abortive TOP2 activity, including the transcription of many genes involved in neurological development or function. Collectively, these data identify TDP2-dependent DNA break repair as a critical guardian of gene expression and highlight abortive TOP2 activity as a threat to normal neuronal development and maintenance.

Diagnostic assessment using next generation sequencing in extremely heterogeneous neurodegenerative disorders, hereditary ataxia and spastic paraplegia. *Z. Iqbal[1], L. Pihlstrøm[1], A. H. Rengmark[1], S. Pilar Henriksen[1], S. L. K. Rydning[1,2], I. M. Wedding[1], J. A. Koht[3], C. Tallaksen[1,2], M. Toft[1].* 1) Department of Neurology, Oslo University Hospital, Oslo, Norway; 2) Faculty of Medicine, University of Oslo, Oslo, Norway; 3) Department of Neurology, Vestre Viken Hospital Trust, Drammen, Norway.

Hereditary ataxias (HA) and hereditary spastic paraplegias (HSP) are very heterogeneous and rare neurodegenerative disorders. Because of the extreme clinical and genetic heterogeneity of these conditions, the establishment of molecular diagnosis has been challenging, both regarding the cost and labor-intensive experimental designs. Recently, after the advent of next generation sequencing techniques, there are several opportunities to develop a single inexpensive test and easy workflows in different diagnostic settings. Here, we have ascertained 119 clinically well-characterized patients from all-over Norway, with HA (n=61), HSP (n=44), and a mixed phenotype of HA/HSP (n=14) patients. Polyglutamine expansions had been excluded in the affected probands with ataxia phenotypes. We have followed a cost-effective, fast, and robust procedure by using a Haloplex target enrichment kit (Agilent technologies, Santa Clara, CA), in order to screen coding sequences of 91 genes implicated in these conditions, of which 89 well known and two candidate genes were included in the design. DNA from ten individuals was pooled and a single barcode was assigned, and subsequently all 12 pools were sequenced by using a single lane of Illumina HiSeq, which resulted in high quality data with an average 98.95% bases covered >80x in the targeted intervals. Our bioinformatics pipeline and criteria to assign plausible pathogenicity selected about 50 candidate variants for further validation and confirmation. We identified known pathogenic mutations and novel potential variants in several genes, including *ANO10*, *BEAN1*, *BSCL2*, *CYP2U1*, *GRID2*, *KCND3*, *KIF1A*, *KIF5A*, *PRKCG*, *REEP1*, *SPG7*, *SPG11*, and *SYNE1*. After the ongoing validation analysis, we will be able to establish the diagnosis in a certain subset of patients, in both HA and HSP. With this approach, it will be possible to estimate mutation frequencies in the involved genes. Moreover, in a heterogeneous group of disorders, such diagnostic testing will reduce the total duration of eventual correct diagnosis after the first appearance of the patient to the clinic. In conclusion, our data will have extended implications in the field of clinical genetics and development of diagnostic procedures.

1283M

Identifying biomarkers in chronic neuropathic pain. *P.C McHugh[1], D.P Finn[2], R. Airley[1], D.A Buckley[1].* 1) Pharmacy, University of Huddersfield, Huddersfield, WE., United Kingdom; 2) Pharmacology & Therapeutics, National University of Ireland, Galway, Ireland.

Chronic pain, including neuropathic pain, is poorly understood. It is estimated that almost 1 in 5 adults experience moderate-severe pain and often receive inadequate treatment. With a growing ageing population, this is fast becoming a significant healthcare issue that requires urgent attention. Blood biomarkers can provide us with a tool for early diagnosis and in turn facilitate improved treatment strategies. We wish to identify pain-related molecules, systems or pathways (biomarkers) in human plasma with the aim of improving our understanding, diagnosis and treatment of neuropathic pain. To identify novel biomarkers that can discern neuropathic pain patients from healthy controls we are using a neuropathic pain-control pilot sample (n= 20. For this we are employing a combination of quantitative PCR, PCR arrays and Affymetrix array systems to analyse gene expression (RNA), and HPLC/Mass Spectrometry for plasma analyses. Our preliminary data identifies several molecules that can differentiate between neuropathic pain and healthy controls. To validate our findings we are currently developing two independent neuropathic pain cohorts (case-control); one at NUI Galway and the other through the Leeds Pallium Research Group. These molecules could be developed into a diagnostic test that can differentiate neuropathic pain subtypes, allowing clinicians to better treat this condition.

Genetic diagnosis of neurological diseases using NGS - Report of 48 cases. *D. Garcia, A. Romera-Lopez, D. Valero-Hervas, V. Felipe, G. Hernandez, C. Collado, R. Rodriguez-De Pablo, A. Arilla-Codoner, J.C. Trivino, S. Zuniga-Trejos, G. Marco, D. Cantalapiedra, L. Perez-Carbonero, C. Buades, C. Camprubi, R. Minambres, S. Santillan.* Sistemas Genomicos, Paterna, Valencia, Spain.

The diagnosis of neurological diseases is often not straightforward, mainly due to the presence of nonspecific overlapping clinical symptoms and of genetic heterogeneity. A global approach using high throughput technologies such as NGS could be of great assistance to improve their diagnosis. We present our experience in the analysis of neurological diseases using a 200-gene NGS targeted resequencing panel. Samples from 48 patients were submitted to our laboratory for genetic testing. Clinical indications included Spastic Paraplegia (17), Motor/Sensitive Hereditary Neuropathy (12), Ataxia (6), Parkinson (4), Miastenia (3), Joubert Syndrome (2), Frontotemporal Dementia (2), Hyperkalemic Periodic Paralysis (1) and SMA (1). Coding exons and splice-site regions of the genes associated with each pathology were analysed. Enrichment and sequencing were carried out using SureSelect Enrichment System (Agilent) and SOLiD 5500/MiSeq (Life Technologies/ Illumina). Mean depth was established at 200x. In 7 out of 48 samples (14%), a genetic cause that confirmed the clinical diagnosis was found. Taking into account all the samples, 63 variants (confirmed by Sanger sequencing) were identified and classified into pathogenic (7), probably pathogenic (2), unknown (53) and probably benign (1). According to their effect, missense (29), synonymous (21), splice-site (8), frameshift (3) and nonsense (2) mutations were found. In 21 out of 48 samples, no variants (pathogenic/unknown) were identified. Despite being moderate, 14% of genetically diagnosed patients suggests that NGS is effective for the diagnosis of neurological diseases. A better understanding of unknown significance variants, that would allow classifying them into SNPs or pathogenic mutations, could significantly increase the diagnosis rate.

1285S

Transcriptome analysis of distinct mouse strains reveals kinesin light chain-1 splicing as an amyloid beta pathology modifier in Alzheimer's disease: A mouse-to-human translational approach to complex diseases. *T. Morihara[1], M. Sato[1], M. Silverman[3], H. Akatsu[2], N. Hayashi[1], M. Yokokoji[1], K. Yanagida[1], R. Hashimoto[1], H. Yamamori[1], T. Tsunoda[4], Y. Yamaguchi[5], K. Kamino[1], M. Takeda[1].* 1) Psychiatry, Osaka University, Suita, Osaka, Japan; 2) Choju Medical Institute, Fukushimura Hospital, Toyohashi-shi, Aichi, Japan; 3) Department of Biological Sciences, Simon Fraser University, Burnaby, Canada; 4) Center for Genomic Medicine, RIKEN, Yokohama, Japan; 5) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Sendai, Japan.

[Background] Amyloid beta (Aβ) is the central pathology of Alzheimer's disease (AD). The genes controlling Aβ accumulation in the brain of sporadic AD are largely unknown. Human genetic studies require huge research resources and do not reveal the role of the identified genes. To overcome the difficulties of human genetic study, we combined distinct mouse strains with transcriptomics to directly identify Aβ modifier genes.

[Methods and Results] We have observed that APP Tg mice with DBA/2 genetic backgrounds have significantly lower levels (-74.7 to 57.7%, p<0.0001-0.0002) of Aβ compared with SJL and C57BL/6 mice (Morihara PNAS 2014). These data suggested that some gene(s) in DBA/2 drastically suppress Aβ accumulation. To avoid detecting secondary affected genes by Abeta, we used non-Tg mice in the absence of Aβ accumulation and performed the first transcriptome analysis to select candidate genes differentially expressed in DBA/2 mice. The 2nd transcriptome analysis using APP-Tg mice with mixed genetic backgrounds from these three strains revealed kinesin light chain-1 (Klc1) as an Aβ modifier. The following QPCR measurement confirmed the array data and suggested that Klc1 splice variant E (Klc1E) control the accumulation levels of Aβ in mouse brain. The expression levels of Klc1E were significantly correlated with the levels of Aβ (R2= 0.21 to 0.39, p<0.0001-0.0002) in these mice. We expanded mouse strain analysis by adding two mouse strains. Three strains with higher Aβ accumulation shared common Klc1 allele and had higher expression levels of Klc1E. In contrast two strains with lower Aβ shared another common Klc1 allele and had lower levels of Klc1E. In human, KLC1E levels in brain (AD: n=10. Cont: n=14) and lymphocyte (AD: n=47, Cont: n=17) were significantly higher in AD patients compared to controls. Functional analysis using neuroblastoma cells showed that knockdown of KLC1E decrease the production of Aβ (-39.3 to -44.7%, p<0.0001). Taken together, mouse transcript, mouse genetic, human transcript and functional analysis strongly suggested that KLC1E control Aβ pathology in AD.

[Conclusion] The expression levels of KLC1E control Aβ pathology. The unique combination of distinct mouse strains and model mice with transcriptomics is useful for the study of genetic mechanisms of complex diseases.

1286M

Circadian Network and Autism: Role of the JARID1 Genes. *Z. Talebizadeh[1], A. Shah[1], D. Kalinowska[2], L. DiTacchio[2].* 1) Pediatrics, Children's Mercy Hospital, and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Kansas Medical Center, Kansas City, KS.

The circadian clock coordinates diverse cellular processes and functional outcomes, including behavior and cognition. Abnormalities in the clock genes may have a role in autism, but the underlying mechanism remains unknown. Members of the JARID1 gene family (JARID1a-d), histone demethylases, have been shown to be involved in the circadian molecular machinery in a recent work of our collaborator. JARID1a activates CLOCK-BMAL1, whereas JARID1b and JARID1c act as repressors. These opposing roles suggest that the optimal ratio among JARID1 isoforms is vital in maintaining the proper function of the circadian system. Imbalance in these isoform ratios may contribute to the etiology of diseases. Furthermore, miR132 orchestrates translational control of the circadian clock by targeting chromatin remodeling genes, including MECP2 and JARID1a. The splicing profiles of JARID1, and factors that regulate the expression of such isoforms, are not fully known. Our hypothesis is that JARID1 mis-splicing may present in at least a subset of subjects with autism. Recent findings have shown cross links between DNA methylation and gene regulatory processes, including alternative splicing and miRNA. Therefore, we used data from a DNA methylation marker for subject stratifications. We evaluated the expression level of multiple JARID1 alternative splicing transcripts in autistic subjects stratified based on the absence or presence of a given DNA methylation-related marker (DM) in lymphoblastoid cell line-derived RNAs, using Exon array profiling, TaqMan assays, followed by DNA sequencing. A distinct pattern was detected in the expression level of alternatively spliced JARID1 isoforms for autistic subjects with DM compared to those without DM and controls. Additional experiments, including miRNA mimics, are underway to further characterize the role of miR132 in regulating JARID1a by finding which isoforms(s) show miR132-dependent expression. This is the first study to evaluate a clock gene in autism, at the alternative splicing level in conjunction with DM markers. Our study indicates that (1) JARID1 undergoes complex splicing resulting in multiple splice variants, and (2) subject stratification using DM may assist with finding a more homogeneous subset to better understand the underlying mechanisms involved in autism. Funding: This study was supported by Patton Trust-KCALSI grant.

RNA-sequencing and gene co-expression analysis identifies novel genes and pathways in bipolar disorder. *N. Akula[1], J.R Wendland[1], K.H Choi[2], B.K Lipska[3], J.E Kleinman[4], F.J McMahon[1].* 1) Human Genetics Branch, National Institute of Mental Health (NIMH), National Institutes of Health (NIH), Bethesda, MD 20892; 2) Dept of Psychiatry and Program in Neuroscience, Uniformed Services University of the Health Sciences, Center for the Study of Traumatic Stress, Bethesda, MD 20814; 3) Human Brain Collection Core, NIMH/NIH, Bethesda, MD 20892; 4) Lieber Institute for Brain Development, Baltimore, MD 21205.

Bipolar disorder (BP) is a highly heritable psychiatric illness affecting ~2% of the population. Genome-wide association studies (GWAS) have consistently identified several common variants associated with BP. Less consistent results have emerged from gene expression studies, partly due to limited sample sizes. Weighted gene co-expression network analysis (WGCNA) may be a more powerful approach, since it exploits patterns of co-expression among genes, but the approach has not yet been applied to RNA-seq data, where gene expression can be measured precisely over a wide dynamic range. We generated deep RNA-seq data from post-mortem dorsolateral prefrontal cortex obtained from a total of 11 BP cases and 11 age and sex-matched controls, sequenced in two batches (Akula et al, 2014). WGCNA identified 40 coexpression modules, of which 9 were preserved between the batches (Zsummary > 10). Six of the preserved modules were significantly associated with BP (meta-p value < 0.05). Functional analysis in DAVID of genes within these 6 preserved modules revealed significant enrichment for several GO terms, including synapse, neuron projection, postsynaptic density, ion transport, and ATP binding, among others. Five of these modules were also significantly enriched for differentially expressed genes identified in Akula et al, 2014 (hypergeometric pvalue < 0.05), and 3 modules were significantly enriched (hypergeometric p-value < 0.05) for genes associated with BP in a previous GWAS (Chen et al 2013). Thus two modules were preserved between batches, associated with BP, enriched for genes known to be differentially expressed in BP, and enriched for prior BP GWAS hits. Some of the co-expressing hub genes in these modules include DCC, CAMK2D, KCNQ3 and NPAS3, which have been previously implicated in BP and related disorders. These results demonstrate that WGCNA can be applied to RNA-seq data with good results. Applied to BP, WGCNA produced results that were broadly consistent with prior findings and implicated additional genes and pathways that may contribute to risk for BP. This approach may help unify GWAS and gene expression results to suggest biological hypotheses deserving of additional study.

GluD1 is over-expressed in iPSC-derived FOXG1 neurons: a potential common therapeutic target for Rett syndrome. *S. Amabile[1], T. Patriarchi[1,2], A. Bartolini[1], M.G. Lolli[1], D. Yasui[3], C. Lo Rizzo[1], F. Ariani[1,4], F. Mari[1,4], M.A. Mencarelli[1,4], J.W. Hell[2], I. Meloni[1], A. Renieri[1,4].* 1) Medical Genetics, Univerity of Siena, Siena, IT., Si, Italy; 2) Department of Pharmacology, School of Medicine, University of California Davis, Davis, CA, United States; 3) Department of Medical Microbiology and Immunology, University of California Davis, Davis, CA, United States; 4) Genetica Medica, Azienda Ospedaliera Universitaria Senese, Siena, Italy.

Rett syndrome is due to de novo mutations in MECP2, CDKL5 or FOXG1 genes. In spite of their involvement in the same disease, a functional interaction between the three genes has not been proven and disease mechanisms remain elusive. MeCP2 and FoxG1 are transcriptional regulators; CDKL5 encodes for a kinase protein involved in multiple cellular processes including gene expression. We hypothesized that mutations in the three different genes may lead to similar phenotypes by deregulating expression of common genes. To verify this hypothesis, we have used a human model based on induced pluripotent stem (iPS) cells-derived neurons from MECP2, CDKL5 and FOXG1 patients. We previously demonstrated by quantitative RT-PCR and protein analysis an over-expression of GRID1 in both iPSC-derived MECP2 and CDKL5 neuronal precursors and neurons (Livide Eur J Hum Genet 2014). We demonstrate here that GRID1 is overexpressed also in iPSC-derived FOXG1 neuronal precursors and neurons. GRID1 encodes GluD1, a member of the delta family of ionotropic glutamate receptors that is located on the post-synaptic site and induces inhibitory or excitatory presynaptic differentiation depending on the specific brain region. GluD1 overexpression may thus favor either glutamatergic or GABAergic maturation in different brain areas and neuronal subtypes. We therefore explored the expression of excitatory/inhibitory markers. We indeed found the expected imbalance but in opposite directions. Quantitative RT-PCR on iPSCs-derived neurons mutated in CDKL5 demonstrated that the glutammatergic markers VGLUT1 and VGLUT2 are over-expressed while the GABAergic markers GAD1 and GAD2 are down-regulated. On the contrary, iPSCs-derived FOXG1 neurons demonstrated a down-regulations of the excitatory markers and an up-regulation inhibitory markers. The different imbalance found is consistent with the specific endophenotype of the patients from whom the iPSCs are derived: the FOXG1 patient does not manifest epilepsy while the CDKL5 patient has a severe epilepsy not controlled by therapy. In conclusion, at present GluD1 overexpression is the only common proved altered marker during neuronal differentiation of iPSC derived from patients mutated in MECP2, CDKL5 and FOXG1. Modulation of the basic defect by inhibition of GLUD1 could be thus explored as a therapeutic tool in both typical Rett and its variants.

1289M

Phenotypic, molecular, functional and structural analysis of new DCX and LIS1 mutations causing the subcortical band heterotopia/lissencephaly spectrum. *D.R. Amrom[1, 3, 4, 8], G. Brouhard[6, 8], S. Bechstedt[6, 8], K. Topropova[9], D. Melancon[2, 3, 7, 8], D. Tampieri[2, 3, 7, 8], S. Reck-Peterson[9], E. Andermann[1, 3, 4, 5, 8].* 1) Neurogenetics Unit; 2) Department of Neuroradiology; 3) Montreal Neurological Hospital and Institute; 4) Department of Neurology & Neurosurgery; 5) Department of Human Genetics; 6) Department of Biology; 7) Department of Radiology; 8) McGill University, Montreal, QC, Canada; 9) Department of Cell Biology, Harvard Medical School, Boston, MA, US.

Subcortical band heterotopia (SBH), also called double cortex syndrome, and lissencephaly (LIS) are part of a spectrum of malformations of cortical development due to deficient neuronal migration, referred to as the SBH/LIS spectrum. Most patients have either DCX or LIS1 gene mutations, associated with predominant anterior or posterior distribution of SBH, respectively. We report the phenotypic, molecular, functional, and structural analysis of new DCX and LIS1 mutations causing SBH/LIS. Patient 1 is a 46-year-old woman of French-Canadian ancestry who had onset of epilepsy at 3 months of age. She had multiple types of seizures and a diagnosis of Lennox-Gastaut syndrome refractory to antiepileptic medication. Brain MRI showed double cortex predominating in the frontal regions. DCX sequencing showed a c.578delA variant. The parents were not available for genetic testing. Using in vitro assays, we measured the ability of recombinant variant DCX protein to interact with microtubules. The c.578delA variant was found to be defective in promoting microtubule nucleation and polymerization, and showed impaired cooperative binding to microtubules. Patient 2 is a 28-year-old man of British ancestry. At 6 months of age he presented mild developmental delay and his first seizures. He had multiple types of seizures, most of them generalized, that were refractory to antiepileptic medication. He has pseudobulbar signs and severe developmental delay. Brain MRI showed a predominantly posterior lissencephaly associated with partial callosal agenesis and a cavum septum pellucidum, as well as diffuse cerebellar atrophy. LIS1 sequencing revealed duplication of five nucleotides in exon 8 (c.728_732dupATCAA). The parents declined genetic testing. Bioinformatic analysis of the mutant sequence and mapping onto the LIS1 structure showed that the change introduces a five residue stretch of altered sequence followed by a premature stop codon at residue 250, early in the 4th WD repeat of the Lis1 beta propeller. We report two new pathogenic variants causing severe phenotypes of the SBH/LIS spectrum. Our functional analyses show that the DCX variant disrupts microtubule binding as well as the cooperative interaction between DCX molecules. Based on our structural interpretation of the LIS1 variant, it is very likely that the LIS1 protein does not fold properly, is unable to bind dynein, and is likely targeted for degradation in cells.

1290T

***De novo TBR1* mutations in sporadic autism disrupt protein functions.** *P. Deriziotis[1], B.J. O'Roak[2,3], S.A. Graham[1], S. Busquets-Estruch[1], D. Dimitropoulou[1], R.A. Bernier[4], J. Gerdts[4], J. Shendure[2], E.E. Eichler[2,5], S.E. Fisher[1,6].* 1) Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands; 2) Department of Genome Sciences, University of Washington School of Medicine, Seattle, Washington, USA; 3) Department of Molecular and Medical Genetics, Oregon Health & Science University, Portland, Oregon, USA; 4) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, Washington, USA; 5) Howard Hughes Medical Institute, Seattle, Washington, USA; 6) Donders Institute for Brain, Cognition and Behaviour, Nijmegen, Netherlands.

Next-generation sequencing recently revealed that recurrent disruptive mutations in six genes - *CHD8*, *DYRK1A*, *GRIN2B*, *PTEN*, *TBR1*, and *TBL1XR1* - may account for 1% of sporadic autism cases. *TBR1* is of particular interest because it encodes a neuron-specific transcription factor of the T-box family, with established roles in patterning of the central nervous system, including regulation of neuronal identities during cortical development. The recurrence of *de novo TBR1* mutations in sporadic autism spectrum disorders suggests that the identified mutations are likely to be pathogenic. Nonetheless, functional experiments in model systems are essential to determine the precise effect of mutations on protein function and provide insight into the molecular mechanisms of the disorder. Here we report the first functional analyses of *TBR1* variants identified in sporadic autism. *De novo* truncating (p.A136PfsX80 and p.S351X) and missense (p.K228E and p.N374H) mutations disrupt multiple aspects of TBR1 function, including subcellular localization, interactions with co-regulators and transcriptional repression. Missense mutations (p.Q178E, p.V356M, p.Q418R and p.P542R) inherited from unaffected parents did not disturb function in our assays. Our findings support the hypothesis that *de novo* mutations in sporadic autism have severe functional consequences and highlight the power of coupling novel genetic data to empirical assays of protein function in order to illuminate crucial molecular networks involved in complex neurodevelopmental disorders such as autism.

1291S

Analysis of actin cytoskeleton dynamics in stem cells from autistic patients. *K. Griesi-Oliveira[1,2], M. Suzuki[1], D.Y. Sunaga[1], A.L. Sertie[2], M.R. Passos-Bueno[1].* 1) Biosciences Institute - University of Sao Paulo, Sao Paulo, SP, Brazil; 2) Instituto Israelita de Ensino e Pesquisa - Hospital Israelita Albert Einstein.

Autism spectrum disorders (ASD) are are genetically heterogeneous diseases, which has been made difficult the understanding of their etiology. However, several genes implicated in the etiology of ASD are part of common molecular pathways, indicating these different genetic alterations may cause similar effects during neurogenesis. One of such common mechanisms may be the cytoskeleton dinamics regulation, which is essential for organization of dendritic spines and axonal growth and guidance. However, the relationship between these mechanisms and the etiology of ASD has been poorly explored in the literature, specially in their functional aspects. Previous results from our group have suggested a disturbance in cytoskeleton dynamics in cells from autistic patients. Thus, here we aimed to investigate the actin cytoskeleton dinamics regulation in stem cells from human exfoliated deciduous teeth (SHED) from ASD idiopathic patients. First, we incubate the cells of 13 patients and 8 controls for 24h using Rho kinase inhibitor (ROCKi) in order to depolymerize the microfilaments. To induce actin reconstruction, ROCKi was washed out and cells were treated with drugs that activate specifically Rac2, Cdc42 or RhoA. The percentage of cells presenting actin filaments were counted at 15, 30, 45 and 60 minutes after drugs application. Our results showed that 5 out of the 13 patients presented a significant lower percentage of cells with recovered actin filaments at all time points compared to controls when treated with Rac2 or cdc42 activator, and among these, 2 patients respond abnormally to RhoA activation (unpaired t-test $p<0.05$). We also treated the cells with a drug that directly activates the three RhoGTPases, making them constitutively activated. Upon this treatment, 4 patients responded abnormally compared to controls. Interestingly, these are the same patients that had responded abnormally to the specific activactors. We tested all the five patients that presented abnormal actin reconstitution for expression of Rac2, cdc42 and RhoA and we found that one of them has lower expression of these three RhoGTPases. These results suggest that, at least for a group of ASD patients, the dynamics of actin polymerization is slower compared to control individuals and that for one of them this could be due to lower expression of RhoGTPases. We believe that this study can contribute for the understanding of the common molecular mechanisms involved in ASD etiology.

1292M

Transcription and methylation reveals microglia related and non-coding RNA networks specifically altered in Dementia with Lewy Bodies. *C. Humphries[1,2], M.A. Kohli[1], P. Whitehead[1], G. Beecham[1], D.C. Mash[3], M.A. Pericak-Vance[1], J. Gilbert[1].* 1) Hussman Inst Human Genomics, Univ Miami, Miami, FL; 2) John T. MacDonald Department of Human Genetics, Univ Miami, Miami, FL; 3) Department of Neurology, Univ Miami, Miami, FL.

Dementia with Lewy Bodies (DLB) is the second most common dementia. To understand the molecular processes in DLB, we investigated transcription and DNA methylation in human post-mortem brain tissue. Transcription was examined using total RNA-seq permitting the identification and quantitation of known genes and non-coding RNAs. DNA methylation was examined using Illumina's Infinium HumanMethylation450 BeadChip. Neuropathological specimens were from the temporal poles (BA 38) of ten age, sex and race-matched cases each of DLB, late-onset Alzheimer's disease (LOAD) and normal controls. RNA was extracted using Qiagen's miRNeasy kit and libraries prepared with Epicentre's Script-Seq protocol. Samples were run on Illumina's HiSeq2000, generating 40-65 million reads per library. The program DESeq2 was used to examine transcriptional differences between Gencode genes. Transcriptional analysis between DLB and Controls revealed 4,770 genes out of a total of 30,929 genes (Gencode) to have expression differences ($p<0.05$). Of these, 469 were significant after controlling for multiple testing using False Discovery Rate (FDR<0.05). Subsequent comparison of these 469 DLB genes to LOAD revealed seven non-coding RNAs specifically altered. To find cellular processes disrupted in DLB, we performed network analysis using weighted gene co-expression network analysis (WGCNA). We found the 4,770 genes with expression differences between DLB and CON formed 13 networks. Eight networks were highly correlated to both DLB and LOAD. The other five networks were specific to DLB. Interestingly, the networks that correlated to both DLB and LOAD were primarily made up of protein coding genes. Non-coding RNAs primarily made up the networks specific to DLB. Using DAVID, we found the gene networks correlated to both DLB and LOAD are involved in acetylation. Genes in networks specific to DLB are mainly involved in mesoderm development ($p=2.2E-2$). Genes involved in mesoderm development give rise to the hematopoietic stem cells that generate the immune cells, microglia, that are enriched in DLB brains compared to LOAD and control brains. Assessment of DNA methylation within these networks revealed that DLB samples have significant hypermethylation. The study of this network of genes with altered expression and methylation specific to LOAD may offer a fruitful approach to advancing our understanding the role that non-coding RNAs and genes play in the etiology of Dementia with Lewy Bodies.

1293T

Loss-of-function mutations of progranulin (PGRN) in siblings with familial FTLD. *E. Vitale[1], S. Napoletano[1], S. PappatÃ [3], A. Postiglione[4], M.T. Gentile[5], L. Colucci-D'Amato[5], P. Sorrentino[2], G. Milan[2].* 1) Institute of Protein Biochemistry (IBP), CNR-National Research Council, Pozzuoli (NA), Napoli, Italy; 2) Geriatric Center "Frullone" ASL Napoli 1 - Naples-Italy; 3) Institute of Bioimaging and Biostructures , CNR, Naples-Italy; 4) University of Naples "Federico II", Naples-Italy; 5) Experimental Neuropatology, SUN Caserta-Italy.

Mutations in the progranulin (PGRN) gene, located on chromosome 17q21.32, have been linked to familial Fronto-Temporal Lobar Degeneration (FTLD) dementia. Loss-of-function mutations of PGRN represent a frequent cause of middle-age cognitive impairment characterized by selective neurodegeneration of the prefrontal and anterotemporal cortices and in a few select cases, have been identified as the cause of primary progressive aphasia (PPA) in women. Although it is well known that PGRN mutations induce haploinsufficiency of this protein, the pathogenic mechanisms by which PGRN deficiency leads to brain dysfunction and damage remain unclear. We analyzed the PGRN genes in two siblings ascertained as having FTLD, III-2H72, a male and III-3H73, a female. The two affected siblings exhibited FTLD according to the Lund-Manchester criteria. To carry out the analysis, we designed primers to amplify all exons and intron-exon boundaries of the PGRN gene and sequenced the amplified fragments using the Sanger method. We found a g.101349_101355delCTGCTGT deletion in exon 6 CDS. The mutation we identified results in a premature stop codon with a frameshift error and mRNA non-sense mediated decay. To exclude the possibility that this was a common mutation, we design an ARMS-PCR test for this mutation and check it in about 250 healthy controls matched by age, sex and geographic regions. We found no deletions carried by any of these individuals, providing specificity to the association we identified between the disease and the deletion. A subsequent CGH assay performed on the DNA from the two patients demonstrated no additional evident genomic alterations. Differential gene expression measurements revealed a significant downregulation of PGRN in the two individuals carrying the deletion when compared to controls. In addition, the correlation between PGRN mRNA expression levels and cognitive impairment was statistically significant in FTLD patients. Furthermore, PGRN protein analyses demonstrated a PGRN protein deficiency, corroborating the defective PGRN gene expression. These results strongly suggest that PGRN could be the causative disease gene in this familial FTLD.

1294S

Significant Enrichment of Disease-specific Polymorphisms surrounding microRNAs suggests further involvement in Schizophrenia and Bipolar Disorder. *V. Williamson, M. Mamdani, G. McMichael, S. Bacanu, V. Vladimirov.* Psychiatry, Virginia InstPsychiatric & Behavioral Genetics, Richmond, VA.

Schizophrenia (SZ) and bipolar disorder (BD) are debilitating neuropsychiatric disorders with substantial impact on the quality of human life. Since 2006, numerous genome-wide association studies (GWAS) have been performed to identify loci associated with SZ and BD disease risk. In one of the largest GWAS to date, performed by the Psychiatric Genetic Consortium (PGC), the most significant association signal originated from a microRNA locus (hsa-miR-137) which has been previously implicated in adult neurogenesis and neuronal maturation. Moreover, bioinformatically predicted and experimentally validated gene targets of hsa-miR-137 were also associated with SZ and BD (at genome-wide significance), suggesting a novel, miRNA-mediated mechanism of disease etiology. These results, coupled with the increasingly recognized neurodevelopmental role of miRNAs, have prompted us to investigate the genetic enrichment of disease-associated polymorphisms affecting miRNA genes. Using complementary statistical approaches (Simes and the Sum of Squares (SST) tests), we have detected robust, significant disease enrichment of 1367 LD-independent (r2 >0.8) SZ and BD related polymorphisms surrounding (+/- 1MB) miRNAs in the most recent follow-up PGC GWAS findings. In order to identify the putative regulatory relationships between these enriched variants and their cognate miRNAs' functions, we performed expression quantitative trait locus (eQTL) analysis in postmortem brains (prefrontal cortex, Brodman Area 46) from the Stanley Medical Research Institute (N=27 SZ, 29 BD, 22 Controls). We detected 23 significant cis and 9 trans eQTLs associated with our miRNAs (False Discovery Rate <0.05). In our study, the most significant eQTL, rs3733047 (A/G, Chr3: 52871929), was associated with hsa-miR-135a expression, which demonstrated a clear temporal expression during normal brain development in a recent study. Rs3733047 exerted allelic effects on hsa-miR-135a expression by creating an additional putative binding site for the transcription factor, GATA2. GATA2 regulates postmitotic neuronal differentiation and its expression is significantly downregulated (mRNA and protein) in postmortem prefrontal cortex of SZ subjects. Taken together, the significant disease enrichment of variants surrounding miRNAs and the subsequent identification of miRNA eQTLs suggest a larger role for miRNA dysregulation in the etiology of Schizophrenia and Bipolar Disorder.

1295M

The transcriptome of 16p11.2 syndrome patients uncovers a link between autism and ciliopathies. *A. Reymond[1], E. Migliavacca[1,2], C. Golzio[3], K. MÃnnik[1], I. Blumenthal[4], E.C. Oh[3], L. Harewood[1], J. Kosmicki[5,6], M.N. Loviglio[1], L. Hippolyte[7], A.M. Maillard[7], M.M. van Haelst[8], J. Andrieux[9], J.F. Gusella[4,10], M.J. Daly[5,6], J.S. Beckmann[2,7,11], S. Jacquemont[7], M.E. Talkowski[4,10], N. Katsanis[3], The 16p11.2 European Consortium.* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics (SIB), Lausanne, Switzerland; 3) Center for Human Disease Modeling and Department of Cell biology, Duke University, Durham, North Carolina 27710, USA; 4) Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts 02114, USA; 5) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, 02114; 6) Program in Medical and Population Genetics and Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, 7 Cambridge Center, Cambridge, MA; 7) Service of Medical Genetics, Lausanne University Hospital (CHUV), Lausanne, Switzerland; 8) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 9) Institut de Génétique Médicale, CHRU de Lille - Hôpital Jeanne de Flandre, Lille, France; 10) Departments of Genetics and Neurology, Harvard Medical School; 11) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland.

Hemizygosity of the 16p11.2 ~600 kb BP4-BP5 region (29.5 to 30.1Mb) is one of the most frequent known genetic etiology of autism spectrum disorder (ASD). It is also associated with a highly penetrant form of obesity and a significant increase in head circumference. Mirror phenotypes are observed in carriers of the reciprocal duplication, who present a high risk of being underweight, microcephalic and/or developing schizophrenia. We profiled the transcriptome of individuals carrying reciprocal CNVs in 16p11.2 and analyzed the data using a gene dosage model. The genome-wide transcript perturbations correlated with clinical endophenotypes of this CNV and were enriched for genes associated with ASD. We also uncovered a significant correlation between 16p11.2 copy number changes and expression levels of genes mutated in ciliopathies. This result was replicated in orthologous mouse models, raising the possibility that ciliary dysfunction might contribute to 16p11.2 pathologies. In support of this correlation, we found structural ciliary defects specifically in the CA1 hippocampal region of a mouse model duplicated for the 16p11.2 orthologous region. Moreover, using an established zebrafish model we show strong genetic interaction between KCTD13, a key driver of the mirrored neuroanatomical phenotypes of the 16p11.2 CNV and ciliopathy-causing genes. Strikingly, overexpression of BBS7 rescues the head size and neurogenesis defect of kctd13 morphants, while suppression or overexpression of CEP290 and KCTD13 rescues reciprocally KCTD13-induced phenotypes. Our findings are likely relevant in humans as a patient carrying a de novo 16p11.2 deletion and a heterozygous null CEP290 allele was negative for the majority of 16p11.2-associated pathologies. Taken together, our data suggest that dysregulation of ciliopathy genes, and hence ciliary dysfunction, likely contributes to the clinical phenotypes of this CNV, and possibly to ASD, and that transcripts overexpressed by 16p11.2 deletions or duplications might represent therapeutic targets.

1296T

Transcriptome Profiling and Behavioral Analysis of a VIPR2-CNV Mouse Model of Schizophrenia. *T. Chapman[1], A. Noor[1], A. Halberstadt[1], D. Malhotra[1], M. Geyer[1], J. Sebat[1,2,3].* 1) Department of Psychiatry; 2) Department of Cellular and Molecular Medicine; 3) Institute of Genomic Medicine, University of California San Diego, La Jolla, CA.

Rare copy number variants (CNVs) are risk factors for schizophrenia and have the potential to reveal new biological mechanisms and pharmacological targets. We previously demonstrated the genetic association of schizophrenia with a novel microduplication on chromosome 7q36.3, centered on the gene VIPR2. This gene encodes a class II GPCR (VPAC2) that is coupled to cAMP signaling and is expressed throughout the brain. To elucidate possible effects of increased VIPR2 dosage on brain and behavior, we utilized a transgenic mouse model that contains multiple copies of a YAC-inserted human VIPR2 and its surrounding genomic region. We determined by qPCR that human and endogenous mouse VIPR2 share a similar pattern of gene expression in brain, with low to moderate expression in frontal cortex and hippocampus and higher expression in thalamus. Because increased VIPR2-cAMP signaling could alter CREB transcription, we analyzed the effect of VIPR2 overexpression on transcriptome profiles from four brain regions using RNA sequencing. In parallel, VIPR2 transgenic mice were characterized on a number of behavioral tasks with translational relevance to schizophrenia, including T-maze, fear conditioning and extinction, prepulse inhibition, and locomotor assays.

1297S

Gene expression and neuronal morphology in differentiating human induced Pluripotent Stem Cells (iPSCs) from individuals with chromosome 15q11.2 deletions. *D.K. DAS[1,2], K. Chowdari[1], C. Celik[3], L. D'Aiuto[1], W. Joel[1], A. Ghosh-Bhattacharjee[1], V.L. Nimgaonkar[1].* 1) Department of Psychiatry, WPIC, University of Pittsburgh, Pittsburgh, PA. United States; 2) Genetic Research Centre, National Institute for Research in Reproductive Health, JM Street, Mumbai, India; 3) GATA School of Medicine, 06018 Ankara, Turkey.

Background: Copy number variants at 15q11.2 are associated with intellectual disability, autism and schizophrenia (SZ). This region, spanning BP1-BP2 encodes *CYFIP*, *NIPA1*, *NIPA2* and *TUBGCP5*. From animal models, all four genes are important for brain morphogenesis. As these genes have not been investigated in human neurodevelopment, we have analyzed gene expression and neuronal morphology in differentiating iPSCs from individuals with 15q11.2 deletion. **Methods**: The proband and his mother, both bearing a deletion at chr 15q11.2 were compared with an unrelated control without deletion. The proband was also diagnosed with SZ, but not his mother. The deletions were identified using qPCR and array-CGH. Fibroblasts derived from skin biopsies were reprogrammed with Sendai viral vector expressing transcription factors Sox2, c-Myc, Klf4 and Oct4. Following quality control, the iPSCs were differentiated into neural rosettes and neuronal progenitor cells (NPCs) and then to glutamatergic neurons. Gene expression was analyzed using qPCR and normalized against beta actin. To evaluate dendritic spine morphology, iPSCs derived neurons were transfected with pEGFP vector and immunostained with human anti-CYFIP antibody **Results**: In fibroblasts, reduced expression of all 4 genes was noted (FC: 0.2-0.3). The expression levels were generally higher in iPSCs, however, fold changes are still reduced for these genes: *CYFIP* (0.78), *NIPA2* (0.67), *TUBGC5* (0.59). Expression increased further in NPCs, but the expression of *NIPA1* was remarkably variable. Since, CYFIP interacts with FMRP, expression of *FMRP* gene was analyzed. *NIPA1* and *CYFIP* expressions are correlated with the expression of *FMRP* across all three cell types (Pearson's correlations: 0.95 and 0.81; p = 0.004 and 0.051, respectively). Further, immunostaining indicates that CYFIP is localized to dendritic spines, concordant with animal model data. Dendritic spine density is being quantified using confocal images of pEGFP transfected and immunostained neurons **Conclusions**: Reduced expression of *CYFIP*, *NIPA2* and *TUBGC5* (but not *NIPA1*) was observed in all cell types examined. Thus, there may be compensatory expression changes in *NIPA1*. The expression of *NIPA1* and *CYFIP* is correlated with *FMRP*, suggesting regulatory mechanisms. Consistent with animal models, CYFIP may be related to dendritic spine complexity. We are currently relating the function of these four genes in relation to neuronal differentiation and morphology.

1298M

Spatio-temporal 16p11.2 Protein Network Implicates Cortical Late Mid-fetal Brain Development and RhoA Pathway in Psychiatric Diseases. *L.M. Iakoucheva[1], G.N. Lin[1], R. Corominas[1], I. Lemmens[2], X. Yang[3], J. Tavernier[2], D.E. Hill[3], M. Vidal[3], J. Sebat[4,1].* 1) Department of Psychiatry, University of California San Diego, La Jolla, CA, USA; 2) Department of Medical Protein Research, VIB, and Department of Biochemistry, Faculty of Medicine and Health Sciences, Ghent University, Belgium; 3) Center for Cancer Systems Biology (CCSB) and Department of Cancer Biology, Dana-Farber Cancer Institute, and Department of Genetics, Harvard Medical School, Boston, MA, USA; 4) Beyster Center for Genomics of Psychiatric Diseases, University of California San Diego, La Jolla, CA, USA.

Psychiatric disorders autism and schizophrenia have a strong genetic component, and copy number variants (CNVs) are firmly implicated. Recurrent deletions and duplications of chromosome 16p11.2 confer high risk for both diseases, but the pathways disrupted by this CNV are poorly defined. Here we investigate the dynamics of 16p11.2 network by integrating high-confident physical interactions of 16p11.2 proteins with spatio-temporal gene expression from developing human brain. We observe profound changes in protein interaction networks throughout different stages of brain development and/or in different brain regions. We identify late mid-fetal period of cortical brain development as most critical for establishing connectivity of 16p11.2 proteins with their partners. Furthermore, our results implicate the regulation of CUL3/KCTD13/RhoA pathway in layer four of inner cortical plate as crucial for controlling brain size and connectivity, and its dysregulation as potential determinant of the 16p11.2 CNV phenotypes.

1299T

Transcriptome signature of schizophrenia-associated rare copy number variants (CNVs) in lymphoblastoid cell lines (LCLs). *W. Moy[1], J. Duan[1,2], E.I. Drigalenko[3], J. Freda[1], . MGS[4], H.H. Goring[3], A.R. Sanders[1,2], P.V. Gejman[1,2].* 1) Department of Psychiatry and Behavioral Sciences, NorthShore University HealthSystem, Evanston, IL; 2) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) Molecular Genetics of Schizophrenia (MGS) Collaboration.

Schizophrenia (SZ) has been shown to be significantly associated with multiple rare CNVs that often encompass more >1 gene, making uncertain which CNV-genes and downstream pathways are relevant to pathogenesis. We carried out RNAseq (>9M depth, 1×50bp) transcriptome analyses to identify expression signature profiles associated with each SZ-associated CNV in LCLs from 27 subjects of European ancestry carrying SZ-associated CNVs (with at least 5 subjects for each CNV), namely 22q11.21_del (n= 13), 16p11.2_dup (n=9), and 15q13.3_del (n=5), and 657 subjects (265 SZ cases and 392 controls) without these CNVs. A total of 10,813 genes had detectable expression with a mean log2RPKM>1. We controlled analyses for sequencing batch, sex, age, affection status, Epstein-Barr viral load, growth rate, energy status and genotypic ancestral PCs. Within each CNV region, we found >90% genes showing expression associated (FDR<5%) with CNV status, consistent with expected gene dosages. Outside the CNV regions, we found variable numbers of genes with expression associated (FDR<5%) with CNVs (N): 22qdel (516), 16pdup(1), 15qdel (12), representing the downstream genes affected by the CNV. Gene set enrichment analysis (GSEA) of the 516 genes with expression associated with 22qdel showed an enrichment (FDR<5%) of gene ontology (GO) terms related to chromatin modification, translation elongation, and histone modification. Given the small number of genes associated with other CNVs, we further explored the GSEA for a larger set of genes associated with CNV status at nominal p<0.05, but with a fold difference of expression >1.2 or <0.8 (~2SD). We observed enrichment (P<0.05) of pathways and GO terms relevant to brain disorders, such as cognition, neuron development and differentiation, and regulation of neurotransmitter levels for genes with expression associated with 22qdel and 16dup. To identify the primary CNV gene/s possibly causing the downstream effects on brain-related gene set/pathway, we further examined the connectivity between CNV genes and the downstream genes of each CNV-induced brain-related gene sets by DAPPLE, and identified sialophorin (SPN) and mediator complex cubunit 15 (MED15) as possible "driver" genes at 16pdup and 22qdel, respectively. Our transcritpome analysis in LCLs of SZ-CNV carriers thus suggested plausible gene pathways relevant to SZ for each CNV region.

Functional analysis of *GRIN2A* mutations in childhood epileptic encephalopathies. *L. Addis[1, 2], L.R. Vidler[2], D. Ursu[2], D.A. Collier[2], D.K. Pal[1].* 1) Department of Clinical Neuroscience, Institute of Psychiatry, King's College London, London, U.K; 2) Neuroscience Discovery, Eli Lilly Research Centre, Windlesham, Surrey, U.K.

Epileptic encephalopathies are severe brain disorders characterized by seizures and abundant epileptiform activity which contribute to cognitive and behavioural impairments. Landau-Kleffner syndrome (LKS) and continuous spikes and waves during slow-wave sleep (CSWS) are closely related encephalopathies with regression in language and global cognitive skills respectively. They show electroclinical overlap with Rolandic epilepsy (RE), the most frequent childhood focal epilepsy, forming a clinical spectrum of epileptic, cognitive, language and behavioural disorders. Recently it was discovered that around 20% of cases in this spectrum are caused by mutations in the NMDA glutamate receptor *GRIN2A*. Here we set out to determine the disease mechanism of five missense *GRIN2A* mutations recently described in these patients. Mutations spread across the gene were chosen: P79R, C231Y, C436R, E714K and N976S, and were inserted into *GRIN2A* cDNA. HEK cells were transiently transfected with the mutant *GRIN2A*, and standard *GRIN1* constructs allowing formation of heteromers. 1) Western blotting of total protein lysates revealed that all mutations caused a decrease in GRIN2A protein levels, with levels reduced to around 65% for P79R, 40% of non-mutant levels for C231Y, E714K and N976S and to 10% for C436R. The loss of the disulphide-bond of the cysteine residue in C436R is hypothesized to drastically destabilise the protein and cause its degradation. The amino acid changes of C231Y, E714K and N976S are also predicted to be destabilising. 2) Single-cell calcium imaging was used to assay glutamate binding and NMDAR function. Mutations P79R and C231Y decreased the glutamate potency compared to non-mutated construct by increasing the half maximally effective concentration of agonist (EC50) by 3 and 5 times respectively, meaning the mutant receptors can only be activated by higher concentrations of the agonist. There was no deleterious effect from E714K, predicted to be near the glutamate binding pocket, or from the intracellular N976S mutation. C436R showed no glutamate response, which is most likely due to the very low levels of expressed protein. 3) Cell surface expression of the mutant proteins using fluorescent imaging in transfected HEK also revealed alterations. Taken together, these data suggest that mutations across *GRIN2A* affect the expression and function of the receptor in different ways, with the end result of altered NMDA receptor currents and neuronal excitability.

Transcriptional regulation at the *TREM* gene cluster in AD brains. *M.M. Carrasquillo[1], A. Allen[1], J. Burgess[1], M.L. Kachadoorian[1], S. Aryal[1], F. Zou[1], H.S. Chai[2], C.S. Younkin[1], J.E. Crook[3], V.S. Pankratz[2], A.A. Nair[2], S. Middha[2], S. Maharjan[2], T. Nguyen[1], L. Ma[1], S.J. Lincoln[1], K.G. Malphrus[1], G.D. Bisceglio[1], R.C. Petersen[4], N.R. Graff-Radford[5], D.W. Dickson[1], S.G. Younkin[1], N. Ertekin-Taner[1,5].* 1) Department of Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Department of Biostatistics, Mayo Clinic, Rochester, MN; 3) Department of Biostatistics, Mayo Clinic, Jacksonville, FL; 4) Department of Neurology, Mayo Clinic, Rochester, MN.; 5) Department of Neurology, Mayo Clinic, Jacksonville, FL.

Association of missense variants in *TREM2* and *TREML2* with susceptibility of late-onset Alzheimer's disease (LOAD) has been replicated in several large case-control series including our own Mayo series (N=10,000). More recently, higher blood *TREM2* mRNA and TREM2 protein levels were reported by others to correlate strongly with AD status. In this study, we evaluate the association of brain specific transcripts encoded by the *TREM* gene cluster on chromosome 6 (*TREM1*, *TREML1*, *TREM2*, *TREML2*, *TREML4*) with variants at this locus and their effect on risk of LOAD. Utilizing Illumina DASL array data from our published brain expression genome-wide association study (eGWAS), expression levels in ADs (197 cerebellum, 202 temporal cortex) were compared to levels in non-AD (177 cerebellum, 197 temporal cortex) via multivariable linear regression, adjusting for age-at-death, sex, *APOE*-ε4, RIN, and transcript levels of 5 CNS cell-type specific genes. RNAseq data from 96 LOAD brains has been obtained and will be employed for characterization of the mechanism of transcriptional changes of *TREM* genes. For validation, *TREM* transcripts detected via RNAseq will be measured individually using isoform-specific TaqMan® gene expression assays in additional samples. The associations of gene isoforms with cisSNPs will be tested using multivariable linear regression analyses controlling for appropriate covariates. *TREML1* and *TREML4* were significantly higher in the ADs compared to the non-ADs (beta=0.085, p=0.048 and beta=0.048, p=0.048, respectively) in our eGWAS of temporal cortex tissue. Furthermore, in preliminary blood DASL array data from 7 ADs and 26 clinically, non-demented controls from the Mayo Clinic Study of Aging, *TREML1* also has higher expression in the ADs compared to controls (beta= 0.38, p=0.014). eQTL analysis from our eGWAS revealed significant association of *TREML1* temporal cortex expression levels with a putatively regulatory variant located between the *TREM2* and *TREML2* genes. This variant, which has a Regulome score = 2, is also significantly associated with AD status. Thus, *TREM* family genes appear to have differential expression in brain and blood. Completion of RNAseq and isoform specific expression analysis is expected to fine tune our understanding of these gene expression changes in this gene family. eQTL study of these transcript levels may uncover novel AD risk variants at the *TREM* gene cluster that have an effect on transcriptional regulation.

Polymorphism in the miRNA-433 binding site of FGF20 is a strong risk factor for Parkinson's disease in Iranian population. *S. Abtahi, H. Darvish, A. Movaffagh, R. Dastmalchi, B. Emamalizadeh.* Medical genetics, Shahid beheshti university of medical sciences, Tehran, Iran.

DNA variations at the fibroblast growth factor 20 gene have been reported to associate with Parkinson's disease (PD). The rs12720208, a functional SNP located in the 3' UTR region of the gene, was first reported as a risk factor for the PD. Some other studies tried to replicate the result in different populations through case-control studies. However, to our knowledge, no significant association between the rs12720208 and PD was reported. In this study, we genotyped the rs2720208 SNP in 520 PD patients and 520 healthy controls from Iran. Significant differences was found in allele and genotype frequencies between patients and controls (Fisher exact $p<1\times10-6$). The results suggest that the rs12720208 (C/T) polymorphism is a strong risk factor for PD in Iranian population.

Integration of miRNA-mRNA networks to elucidate the complexity of psychiatric disorders. *C. Chen[1], L. Cheng[2], C. Zhang[3], J.A. Badner[4], E.S. Gershon[4], C. Liu[1,5].* 1) State Key Laboratory of Medical Genetics, Central South University, Changsha, Hunan, China; 2) Northwestern University, Chicago, IL, USA; 3) The University of Chicago, Chicago, IL, USA; 4) Department of Psychiatry and Behavioral Neuroscience, The University of Chicago, Chicago, IL, USA; 5) Psychiatry department, University of Illinois at Chicago, Chicago, IL, USA.

MicroRNAs (miRNAs) are small, non-coding, endogenous RNAs involved in regulating gene expression and protein translation. One single miRNA can target multiple mRNAs and a single mRNA can also be targeted by multiple miRNAs. We consider that miRNA-mRNA clusters with statistically significant associations can explore potentially regulatory mechanism and, therefore, of biological interest. In this study, we collected 89 parietal cortex samples from Stanley Medical Research Institute(SMRI), and after quality control, each sample has 420 miRNA, 19,984 mRNA and more than 1,000,000 SNPs screened. We first constructed scale-free networks including both miRNA and mRNA, and found one module exhibited differential expression between controls and psychotic patients. In this module, mir-320e acted as one of hub nodes. Quantitative Trait Locus(QTL) result indicated mir-320e was regulated by genetic variants. Another hub gene, PDLIM5, was validated by five miRNA binding prediction software. To further investigate the causal relationship between PDLIM5 and mir-320e, we applied Network Edge Orienting (NEO) and found mir-320e regulates PDLIM5. In summary, we detected one classic regulation pathway: Genotype ->mir.320e -> PDLIM5 -> gene module -> psychotics, which can be partially explain the etiology of psychiatric disease.

1304M

Disruptions to the miRNA regulatory pathway may cause an increased rate of schizophrenia in individuals with 22q11.2DS. *W. Manley, S. Ryan, S. Siecinski, L.M. Brzustowicz.* Genetics, Rutgers University, Piscataway, NJ.

Schizophrenia is a complex and poorly understood disease caused by the interplay of many environmental and genetic factors. The 22q11.2 deletion syndrome (DS) is a disorder that is caused by the microdeletion of part of chromosome 22 leading to a 25-fold greater chance of developing schizophrenia in affected individuals versus the general population. The missing 22q11.2 region contains DGCR8, which is required for the initial step of miRNA biogenesis. However, the 22q11.2 deletion itself is not directly the cause of schizophrenia, since 75% of individuals with this deletion do not develop the disease. We hypothesize that the 22q11.2 deletion increases the risk of schizophrenia through alterations in miRNA regulatory networks via depletion of several miRNAs. This may serve as a protective buffer against the accumulation of deleterious mutations at other schizophrenia risk loci. We have derived human neural stem cells (NSCs) from individuals with the 22q11.2 deletion. The NSCs were generated from iPSCs using Neural Induction Media (Life Technologies). In order to ensure the presence of the 22q11.2 deletion, a FISH probe for 22q11.2 (TUPLE) was used (Cell Line Genetics). Also, the levels of DGCR8 gene expression were quantified using the 7900HT Fast Real-Time PCR System (Applied Biosystems) along with Taqman Gene Expression Assays to ensure DGCR8 reduction in 22q11.2 DS NSCs relative to otherwise healthy control NSCs. We have begun to characterize disruptions to the miRNA regulatory network in the NSC lines using Taqman Array Human Microarray Cards Version 3.0. Here we will present the miRNAs that we have identified to be differentially expressed in otherwise healthy control NSCs versus 22q11.2 DS NSCs. Our preliminary data shows that of the 377 tested miRNAs, there are nearly 30% that have altered expression levels greater than 2 fold or less than .5 fold. We predict that these miRNAs could be involved in the elevated risk of developing schizophrenia in individuals with 22q11.2 deletion syndrome versus the general population. Future studies will focus on determining the biological targets of these miRNAs using miRNA target prediction software.

RNA-seq analysis reveals potential link between mammalian mitochondrial fatty acid synthesis (mtFAS II), RNA processing, and neurodegeneration. *S.L. Mitchell[1], A. Parl[1], S.D. Turner[2], D.C. Crawford[1], D.G. Murdock[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Public Health Sciences, University of Virginia School of Medicine, Charlottesville, VA, USA.

Mutations in ACSF3, the gene encoding the first enzyme of the mitochondrial fatty acid synthesis (mtFAS II) pathway, cause combined malonic and methylmalonic aciduria (CMAMMA). Patients diagnosed with CMAMMA in adulthood display psychiatric and neurological symptoms similar to those observed in Alzheimer disease. The mechanism by which defects in mtFAS II result in these phenotypes is not understood. We recently demonstrated a link between mtFAS II function and PPAR-activated gene transcription. To further investigate the potential role of mtFAS II in transcriptional regulation we knocked down the pathway in HeLa cells and performed RNA-seq. HeLa cells were transfected with either a control siRNA (n=3) or siRNA to NDUFAB1 (n=3) to knockdown expression of acyl-carrier protein (ACP1), which is necessary for mtFAS II function. Single-end read 50 base pair sequencing was completed on the Illumina Hi-Seq 2000. After sequence alignment and assembly, differential gene expression analysis was performed. A total of 3,197 transcripts were significantly differentially expressed after false discovery rate (FDR) correction for multiple testing. Of these, 364 transcripts exhibited an increase or decrease in expression greater than or equal to 1.5-fold, including 303 protein-coding transcripts, 35 non-coding RNA (ncRNA) transcripts, and 31 pseudogenes. Many of the ncRNAs were among the transcripts with the highest fold changes. Remarkably, most exhibited decreased expression and are involved in RNA processing, including RPPH1 and RMRP whose expression was reduced by approximately 90% and five members of the C/D box family of small nucleolar RNAs whose reductions in expression ranged from 83% to 90%. Significant decreases in key ncRNAs responsible for RNA processing are consistent with observations that deficiencies in mtFAS II result in mitochondrial tRNA processing defects in yeast. We describe the first evidence from mammalian cells linking the mtFAS II and RNA processing pathways. These data suggest nuclear RNA processing may also be affected by a loss of mtFAS II function. Defects in RNA processing have been identified as a possible mechanism underlying neurodegeneration in diseases including ALS, Huntington, and Prion diseases. These three diseases were also identified in pathway analysis of our gene expression data. Results from this study point to a possible link between mtFAS II dysfunction, RNA processing, and neurodegeneration.

1306S

The Genetic Factors and Molecular Mechanisms Underlying Lewy Body Pathology in Alzheimer's Disease. *O. Chiba-Falek, C. Linnertz, M.W. Lutz, J. Byrne, J.F. Ervin, C. He, J. Allen, N.R. Miller, K.A. Welsh-Bohmer, A.D. Roses.* Duke University School of Medicine, Department of Neurology, Durham, NC, USA.

The genetic basis and molecular mechanisms that lead to Lewy Body (LB) pathology in 15-20% of Alzheimer disease cases (LBV/AD) are largely unknown. Parkinson's disease (PD), the prototype of LB spectrum disorders has been studied most extensively. Genetic studies including large GWAS implicated Alpha-synuclein (SNCA) and Leucine-rich repeat kinase2 (LRRK2) in the pathogenesis of PD. Furthermore, aggregates of insoluble alpha-synuclein protein are the major component of LBs and strong evidence demonstrated the importance of SNCA over expression in PD etiology. Mitochondrial dysfunction has been implicated in PD and Bender et al have recently showed that the translocase of the outer mitochondrial membrane (Tom40) encoded by TOMM40 gene mediates mitochondrial dysfunction induced by accumulation of alpha-synuclein protein in PD. The broader role of SNCA, LRRK2 and TOMM40 genes in other LB disorders is yet to be studied, as well as the molecular genetic interplay among these genes that predispose LB pathology. Using 107 LBV/AD cases and over 400 AD control subjects we tested the associations of variants in these three loci with LB pathology in AD and identified variants, SNPs and short sequence repeat (SSR), within SNCA and TOMM40 that were significantly associated with increased risk for LB pathology. When the analyses were stratified by LRRK2 genotype, the associations with SNCA variants became stronger. Next, we investigated the expression regulation of SNCA, LRRK2 and TOMM40 in relation to LB pathology. We detected significant differences in transcript levels of each of these genes in the brain cortical tissues from autopsy-confirmed LBV/AD cases compared with AD controls; expression levels of SNCA, LRRK2 and TOMM40- mRNA were increased as a function of LB pathology. Furthermore, we tested the cis-associations of the LB-risk variants with their nearby genes and identified cis-variants that modulate expression level of these genes in human brain. Our findings demonstrated that SNCA, LRRK2 and TOMM40 contribute to LB pathology in AD patients and suggested that expression regulation of these genes may be a molecular basis underlying the observed LB associations.

1307M

REPS1 is a novel gene of Neurodegeneration with Brain Iron Accumulation. *A.B. Drecourt, N. Boddaert, I. Desguerre, D. Chretien, A. Muunich, A. Rotig.* Inserm U1163 Imagine Institute, Paris, Paris, France.

Neurodegeneration with brain iron accumulation (NBIA) encompasses a group of rare neurogenerative disorders with different clinical, brain MRI and molecular features, underlined by progressive extrapyramidal dysfunction and iron accumulation in the brain. To date, mutations in PANK2, PLA2G6, FA2H, ATP13A2, C2orf37, CP, FTL and WDR45 have been associated with NBIA. Nevertheless a large number of individuals have "idiopathic NBIA", with unknown etiology. Exome sequencing of two sisters with NBIA identified two heterozygous mutations in the REPS1 gene. REPS1 is involved in endocytosis and the two mutations (p.Ala113Glu and p.Val78Leu) affect its EH1 domain that interacts with RAB11FIP2. Western Blot analysis detected a low level of REPS1 in patient's fibroblasts. The function of REPS1 in iron metabolism is unknown, but it was shown that RABB11-FIP2 functions in transferrin recycling. We investigated the iron metabolism and oxidative stress in patient's fibroblasts. Patient fibroblasts exhibited a dramatic iron overload, measured by a colorimetric ferrozine-based assay. Consistently steady-state levels of ferritin, iron responsive protein (IRP1) and SOD2 were increased whereas aconitase activity was decreased. This indicates that REPS1 mutations induce deregulation of iron metabolism. Over-expression of the wild-type REPS1 cDNA in patient's cells reduces the iron overload of these cells that display almost normal iron content. Our experiments demonstrate that REPS1 is a new gene of NBIA. Improvement in our understanding of the biochemistry and pathophysiology of this form of NBIA will help develop novel therapeutics for this neurological condition.

1308T

Impaired Function is a Common Feature of Neuropathy- Associated GARS Mutations. *L.B. Griffin[1,2], R. Sakaguchi[3], D. McGuigan[3], M.A. Gonzalez[4], C. Searby[5], S. Züchner[4], Y.M. Hou[3], A. Antonellis[1,6,7].* 1) Cellular and Molecular Biology Program, University of Michigan Medical School, Ann Arbor, MI; 2) Medical Scientist Training Program, University of Michigan Medical School, Ann Arbor, MI; 3) Department of Biochemistry and Molecular Biochemistry, Thomas Jefferson University, Philadelphia, PA; 4) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 5) Department of Pediatrics, Division of Medical Genetics, University of Iowa, Iowa City, IA; 6) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI; 7) Department of Neurology, University of Michigan Medical School, Ann Arbor, MI.

Charcot-Marie-Tooth (CMT) disease is the most common inherited peripheral neuropathy, affecting one in 2,500 individuals worldwide. Six aminoacyl-tRNA synthetase (ARS) genes have been implicated in CMT disease with an axonal pathology. ARS genes encode essential enzymes responsible for charging tRNA with cognate amino acids. Thirteen mutations in the glycyl-tRNA synthetase (GARS) gene have been identified in patients with autosomal dominant CMT type 2D (CMT2D) characterized by impaired motor and sensory function in the upper extremities. While studies have revealed loss-of-function characteristics of GARS mutations, only a small subset of the mutations has been rigorously tested. We evaluated nine CMT-associated GARS mutations to assess if impaired function is a common feature. Our results demonstrate a strong correlation between impaired GARS function and CMT disease. Additionally, one mutation previously associated with CMT disease (S581L) did not demonstrate impaired function in our assays, failed to segregate with disease in two families with CMT, and was identified in the general population, indicating that S581L is not a disease-associated mutation and supporting the notion that impaired GARS function correlates with disease pathogenesis. Wild-type endogenous GARS forms puncta in neurons in vitro and in vivo. Seven GARS mutations impair granule formation in cultured neurons, suggesting that impaired localization may result in CMT2D disease pathogenesis. It is critical to identify proteins interacting with GARS in these structures to understand granule function and how disruption of these structures may lead to CMT disease. Impaired granule formation observed for mutant GARS proteins may be due to reduced binding to protein partners required for granule formation. Preliminary mass spectrometry data reveal that GARS associates with ribosomal complex proteins, including initiation factors and RPLP0. Previous studies demonstrated that archaeal ARS enzymes associate with ribosomes via RPLP0. This interaction may be critical in neurons for tRNA recycling for translation efficiency in the soma and axons. Current studies to identify differential protein partners of wild-type and mutant GARS will provide insight into the function of GARS-associated granules and may help explain the dominant toxicity seen in ARS-mediated CMT disease.

1309S

Novel Cytoplasmic Roles for the RNA-binding Protein, TDP-43. *R. Smith, N. Alami, J.P. Taylor.* Cell & Molecular Biology, St. Jude Children's Research Hospital, Memphis, TN.

Tar DNA Binding Protein of 43 kDa (TDP-43) is a DNA/ RNA binding protein that is found in ubiquitinated cytoplasmic inclusions in a collection of neurodegenerative diseases. While these inclusions contain ubiquitin and TDP-43, they are tau and alpha-synuclein negative, characterizing a unique "TDP-43 pathology." Furthermore, mutations in TDP-43 have been found to play a causative role in Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Lobar Degeneration (FTLD). The normal function of TDP-43 is unclear and how mutations in TDP-43 cause disease is still undetermined. TDP-43 contains two RNA recognition motifs and the protein is shuttled between the nucleus and cytoplasm. Although TDP-43 has been described to be predominately localized to the nucleus, cytoplasmic localization is seen in normal conditions within wild type tissue. This localization could highlight a critical but yet undefined role for TDP-43 in the cytoplasm. To address this hypothesis we utilized the Drosophila model to investigate several potential roles for TDP-43 in RNA processing. By over-expressing either human TDP-43 or the Drosophila ortholog, TBPH in various larval tissues, we have elucidated potential cytoplasmic functions, such as long-range transport of RNA for local translation at the synaptic terminal. This axonal transport and formation of cytoplasmic granules is dependent on the RNA-binding domain of TDP-43. Additionally, we found that ALS mutant TDP-43 granules display disrupted anterograde movement and abnormal TDP-43 distribution in the neuromuscular junction and cell body. Additionally, in muscle cells we observed cytoplasmic TDP-43 aggregates and cell toxicity that is reversed by inhibition of RNA binding. Our data identifies a novel cytoplasmic role for TDP-43 in RNA processing and transport that is disrupted by the introduction of disease-causing mutations, leading to cell death. Our results have furthered our understanding of the normal functions of TDP-43 and will advance future studies of TDP-43 associated disease.

Allelic expression analysis in the brain suggests a role for heterogeneous insults affecting epigenetic processes in autism spectrum disorders. *E. Ben-David, S. Shohat, S. Shifman.* Dept. of Genetics, The Hebrew University of Jerusalem, Jerusalem, Israel.

Monoallelic expression, including genomic imprinting, X-chromosome inactivation and random monoallelic expression of autosomal genes are epigenetic phenomena. Genes that are expressed in a monoallelic way may be more vulnerable to genetic or epigenetic mutations. Thus, comprehensive exploration of monoallelic expression in human brains may shed light on complex brain disorders. Autism-related disorders are known to be associated with imprinted genes on chromosome 15. However, it is not clear whether other imprinted regions or other types of monoallelic expression are associated with autism spectrum disorder (ASD). Here, we performed a genome-wide survey of allele expression imbalance (AEI) in the human brain using single-nucleotide polymorphisms (SNPs) arrays, in 18 individuals with ASD and 15 controls. We identified an individual with a large (~100) number of monoallelic expressed SNPs. This widespread monoallelic expression was limited to the prefrontal cortex, and was not found in the cerebellum of the same individual. Another individual was found to have a highly skewed pattern of X chromosome inactivation. This skewed inactivation was stronger in the neural cell types (neurons, oligodendrocytes and astrocytes) than in microglia. Using our data, we were also able to define the allelic expression status of known imprinted genes in the human brain. We found that many of the known imprinting genes are biallelic expressed, and other genes showed isoform-specific imprinting patterns. We were also able to discover an abnormal imprinting event in an individual with ASD, in the imprinting locus on chromosome 15q11-13. Lastly, we developed an analysis of individual-level expression, focusing on the difference of each individual from the mean. We found that individuals with ASD had more genes that were up- or down-regulated in an individual-specific manner. We also identified pathways perturbed in specific individuals. These results underline the heterogeneity in gene regulation in ASD, at the level of both allelic and total expression.

1311T

GRIP2-mediated AMPA Signaling Defects Contribute to Autism Social Behavioral Deficits. *T. Niranjan[1,2], A. Adamczyk[1], M. Han[1], R. Mejias[1], R. Rose[1], H.C. Bravo[3,4], M. Taub[4], C. Schwartz[5], D. Valle[6], R. Huganir[7], T. Wang[1,6].* 1) The Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins University, Baltimore, MD; 3) Center for Bioinformatics and Computational Biology, University of Maryland, College Park, MD; 4) Department of Biostatistics, Johns Hopkins University School of Public Health, Baltimore, MD; 5) Greenwood Genetics Center, Greenwood, SC; 6) Department of Pediatrics, Johns Hopkins University, Baltimore, MD; 7) Department of Neuroscience, Johns Hopkins University, Baltimore, MD.

Autism spectrum disorders are clinically and genetically heterogeneous, and likely involve several hundred risk genes. Identification of disrupted brain signaling pathways that underlie Autism endophenotype is crucial for discovery of novel drug targets. Glutamate mediates the majority of excitatory neurotransmission in the CNS via its family of receptors including AMPA-, NMDA-, and mGluR-type receptors. Glutamate Receptor Interacting Proteins 1 and 2 (GRIP1/2) are neuron-enriched scaffolding proteins with seven PDZ domains. PDZ4-6 bind directly to the c-termini of AMPA receptor 2/3 (GluA2/3), Liprin-α, and EphrinB1/2 to form a postsynaptic protein complex, which plays a crucial role in AMPA receptor trafficking and synaptic function. mGluR and NMDA signaling defects are implicated in Autism-associated conditions, such as Fragile X Syndrome, Rett Syndrome, and Shank2/3 deficiencies. However AMPA signaling defects in Autism are poorly understood. We recently identified functional GRIP1 mutations that alter GluA2 synaptic trafficking and contribute to Autism social deficits. To determine if GRIP2 may mediate AMPA signaling defects in Autism, we sequenced exons of GRIP2 in a cohort of Autism patients (n=480) and ethnically matched controls (n=480), and identified a significantly increased mutation load at PDZ4-6 (p=0.022) in Autism patients. In proband families, affected sibs who carry GRIP2-PDZ4-6 mutations show more severe deficits in reciprocal social interactions defined by ADIR's social scores as compared to affected sibs who do not carry the mutations. These mutations have functional effect; two result in significantly reduced binding with GluA2/3, while four others significantly alter interactions with EphrinB1/2 and Liprin-α. *Grip2*-knockout mice exhibit reduced preference for social novelty (p<0.001) in a modified three-chamber test, and exhibit reduced social interaction (p<0.05) in a male dyadic social interaction test. Furthermore, enhancing AMPA signaling using a receptor desensitization inhibitor improves sociability in BTBR mice (p<0.001), an established Autism model. These study results support GRIP2-mediated AMPA signaling defects as a novel mechanism for social behavioral deficits in Autism. Characterization of GRIP2 deficiency in Autism shall provide valuable insights into the pathogenesis and identify novel drug targets for correction of social behavioral deficits in Autism.

1312S

A polymorphic di-nucleotide repeat (DNR) variant in the 5'UTR of *DPYSL2* gene affects its regulation via mTOR signaling. *X. Pham, Y. Liu, R. Wang, A. Pulver, D. Valle, D. Avramopoulos.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Schizophrenia (SZ) is a common, disabling neuropsychiatric disorder with a complex etiology. It is estimated that as much as 80% can be attributed to genetic factors. Previous linkage and association studies have implicated *DPYSL2* on chr8p21 as a candidate gene for SZ. *DPYSL2* encodes CRMP2 which is important in axonal growth, and its dysfunction may result in neurodevelopmental abnormalities. We previously identified a polymorphic dinucleotide repeat (DNR) located in the 5'-untranslated region of *DPYSL2*, with a characteristic 5'-terminal oligopyrimidine (5'-TOP) tract, a target for mTOR mediated regulation pathway. The 13 CT repeat allele (risk) of the DNR was found to be associated with SZ compared to the 11 CT repeat common allele (WT). We performed dual luciferase assays in HEK293 cells and mouse primary cortical neurons and the risk allele showed ~3-fold decrease in luciferase activity as compared to the WT allele in both cell types. Further, polysome profiling of the constructs showed the fraction of luciferase mRNA in polysomes associated with the risk allele was reduced by ~3-fold compared to the WT allele. Here we show that increasing concentrations of Rapamycin, an allosteric mTOR inhibitor, reduced luciferase expression in constructs from both alleles, the risk allele remaining lower at 0-30 nM. At concentrations higher than 30 nM, both alleles reached a plateau at the same levels. The same trend was recapitulated in both HEK293 cells and mouse primary cortical neurons. Our results suggest that the difference we observe between the two DNR alleles is mediated by mTOR signaling. Using arrays of > 4,000 human transcription factors and proteins, we screened for those that bind differentially to the two alleles within the 5'-TOP of *DPYSL2* and might produce the decreased gene expression observed in the risk DNR allele. We identified a number of such proteins, one of which is a ribosomal binding protein (RBP) *HuD/ELAVL4* that is also involved in mTOR signaling. Further *HuD/ELAVL4* has been shown to play a crucial role in neuronal differentiation. How this RBP interacts with *DPYSL2* in the WT and risk form to mediate gene expression in neurons is the subject of our current studies. In conclusion, we show that *DPYSL2* is regulated by the mTOR signaling pathway and a SZ associated DNR variant in the 5'-UTR of *DPYSL2* affects this regulation.

Functional analysis in *C. elegans* of candidate genes for schizophrenia. *S.B. Pierce[1], S. Gulsuner[1], T. Walsh[1], J.M. McClellan[2], M.C. King[1,3].* 1) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 2) Department of Psychiatry, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA.

Schizophrenia (MIM 181500) is genetically highly heterogeneous, with both *de novo* and inherited mutations playing an important role in the illness. Large numbers of rare or private mutations have been identified in individuals with schizophrenia and only a few genes have been found to harbor mutations in more than one unrelated person. Not all identified mutations will be causal and methods must be developed for assessing the biological relevance of affected genes and individual mutations. The nematode *C. elegans* provides an efficient platform for studying the neurobiological impact of putative disease genes and mutations. Advantages include: (1) a simple nervous system in which the cells are invariant in number, position, and connectivity; (2) genetic manipulability; and (3) transparency allowing for *in vivo* visualization of neurons with fluorescent reporter genes. Many genes of interest for neuropsychiatric disorders are conserved in *C. elegans* and disrupting these genes can lead to changes in neuronal morphology or alterations in animal behavior. We previously showed that persons with schizophrenia are enriched for damaging *de novo* point mutations in genes expressed in fetal prefrontal cortex. Of 54 genes identified in our study as harboring damaging *de novo* mutations, 29 (54%) are predicted to have unique *C. elegans* orthologs. We are screening this set of candidate genes by RNAi for neurological phenotypes, including defects in axon guidance, dendritic branching, or neurotransmitter-specific neuron function. To screen for axon guidance phenotypes we are using an RNAi-sensitized strain of *C. elegans* expressing a fluorescent reporter in a large number of interneurons and motor neurons, including all GABAergic neurons. We showed that knockdown by RNAi of *lpd-3*, the ortholog of our candidate gene *KIAA1109* (MIM 611565), causes axon guidance defects, including abnormal branching of commissural axons and decreased numbers of commissures reaching the dorsal cord. RNAi data is available for *C. elegans* orthologs of many, but not all, human genes; in particular not for all genes that are candidates for human neurological phenotypes. This approach will enable functional characterization of a large number of genes and suggest the best neurological phenotypes to use for further study of promising candidates. The functional consequences of select human mutations will be examined by replacing the function of the orthologous *C. elegans* gene in transgenic animals.

1314T

New mutations of *CYP2U1* in patients with spastic paraplegia and exploration of mitochondria dysfunctions. *C. Tesson[1,2], KH. El Hachimi[1,2], F. Fellman[3], G. Banneau[4], L. Raymond[1,2,4], M. Mairey[1], S. Morais[1], E. Obre[5], C. Durand[5], M. Zaki[6], J. Lavie[5], D. Lacombe[5], C. Goizet[5], A. Brice[1,4], A. Durr[1,4], F. Darios[1], G. Stevanin[1,2].* 1) Institut du Cerveau et de la Moelle épiniÃre (ICM, INSERM U1127, UPMC UMR_S1127 Sorbonne Universités, CNRS 7225, NEB), Pitié-SalpÃªtriÃre Hospital, Paris, France; 2) Ecole Pratique des Hautes Etudes, Hésam Université, Laboratoire de Neurogénétique, Paris, France; 3) Dpt de Génétique Médicale, CHUV, Lausanne, Suisse; 4) APHP, Dpt de Génétique, Paris, France; 5) Université de Bordeaux, France; 6) National Research Institute, Cairo, Egypt.

Hereditary spastic paraplegia (HSP) is considered one of the most heterogeneous group of neurological disorders, both clinically and genetically. It comprises pure and complex forms that clinically include slowly progressive lower-limb spasticity resulting from degeneration of the corticospinal tracts. At least 73 loci accounting for these diseases have been mapped to date, and mutations have been identified in 53 genes, most of which playing a role in intracellular trafficking. We recently reported that loss-of-function mutations in *CYP2U1* are responsible for an autosomal recessive form of early onset HSP. This gene codes for an enzyme involved in fatty-acid metabolism. We performed the screening of *CYP2U1* in a new cohort of 259 index patients with HSP or sporadic spastic paraplegia. We have now identified 2 new causative mutations in this gene: i) c.1469G>A/ p.C490Y, at the homozygous state in a North African sporadic case with early onset and thinning of the corpus callosum, ii) c.1A>C/ p.M1L at the homozygous state in 2 siblings with early onset HSP in a consanguineous family originating from Switzerland. Interestingly, this last mutation is also present in an asymptomatic sister aged 50 years suggesting an incomplete penetrance or a metabolic compensation in this individual. Exome sequencing on the 3 siblings identified some candidate variants involved in lipid metabolism or in the mitochondria that potentially explain this phenomenon.

In addition, previous experiments we demonstrated in human cells (fibroblasts and lymphoblast) of 2 patients with the p.D316V mutation that the pathophysiology of this clinic-genetic entity includes alteration of mitochondrial architecture and bioenergetics with increased oxidative stress. We are extending these observations to 3 additional cases using 3D electronic microscopy and preliminary results also show an enlargement of the endoplasmic reticulum (ER) in fibroblasts. Moreover, overexpression experiments in COS7 cells suggest that part of the physiopathology is explained by a partial loss of colocalisation of mutated forms with the mitochondria compared to controls. Our combined results focus attention on lipid metabolism as a critical HSP pathway with a deleterious impact on ER and mitochondrial functions.

1315S

Behavioral phenotyping of mice deficient in CHRNA7. *J. Yin[1,2], C.P. Schaaf[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX.

15q13.3 microdeletion syndrome is a rare genetic disorder caused by a deletion of a segment of chromosome 15. The deletion is commonly 1.5Mb in length and encompasses 6 genes, but patients with small deletions, which only encompass the CHRNA7 gene, have also been reported. The clinical phenotypes associated with this syndrome are variable, but commonly include developmental delay/intellectual disability and impaired social interaction. Other clinically important features include epilepsy, impulsive behavior, aggression, and schizophrenia. A mouse model deficient of CHRNA7 was generated and reported to be grossly normal in growth, anxiety-like behaviors, learning and memory, as well as sensorimotor gating. However, deficits in social interaction and repetitive behavior have not been assessed in this mouse model. We tested heterozygous and homozygous CHRNA7 mutant mice and their wildtype littermates for repetitive behaviors in self-grooming, holeboard exploration, and marble burying test, and for social interaction behaviors in the three-chamber paradigm, partition test, and social interaction video scoring. A detailed assessment of the aforementioned behaviors will be presented and be discussed in the context of human 15q13.3 microdeletion phenotypes.

1316M

Regulatory function of CACNA1C schizophrenia-associated variants. *N. Eckart[1], R. Wang[1], M. Zeledòn[1], M. Szymanski-Pierce[1], D. Valle[1], D. Avramopoulos[1,2].* 1) Johns Hopkins University, Institute of Genetic Medicine, Baltimore, MD; 2) Johns Hopkins University, Department of Psychiatry, Baltimore, MD.

Schizophrenia (SZ) and bipolar disorder (BP) are complex psychiatric disorders, together affecting over 3.5% of the US population. They have overlapping clinical presentations, and onset in the second or third decade of life. Association and family studies indicate a shared genetic risk. One variant that has been independently and repeatedly associated with both disorders is rs1006737, a single nucleotide polymorphism (SNP) in the third intron of the CACNA1C gene. Variants identified by association studies are often in non-coding regions of the genome and enriched in expression quantitative trait loci (eQTLs). We previously reported that the risk allele of rs1006737 is correlated with decreased expression of CACNA1C (p=0.001) in a study of 195 post-mortem tissue samples from the superior temporal gyrus (STG). In 100 post-mortem tissue samples from the dorsolateral prefrontal cortex (DLPFC) we found that the risk allele trends toward increased expression of CACNA1C, .in agreement with published data from Bigos et al. in the DLPFC (p=0.002). The variant rs1006737 tags a haplotype with several other SNPs, all located in the third intron. We are testing these for allele-specific regulatory potential using dual luciferase reporter assays. Following up on previous results, now using 4 biological replicates for each construct, we report that for two constructs, one containing rs2159100 and a second containing both rs1077306 and rs10744560, the risk alleles show statistically significant increases in luciferase expression compared to the common alleles when transiently transfected in HEK293 cells (p=4.8*10-4 and p=2.1*10-3, respectively). In addition to differences in regulatory potential, we also explore allele-specific protein binding, using electrophoretic mobility shift assays (EMSAs). We show that 4 of 7 the SNPs tested have allelic differences in protein binding profiles in HEK293 and SK-N-SH cells. In a protein microarray, we find that the risk allele for rs11062170 binds 7 proteins that do not show strong binding with the common allele. These proteins include calcium dependent proteins (ANXA11), transcription factors (MAPK8, MAX, MLX), and splicing factors (ROD1). Our data indicate that the haplotype tagged by rs1006737 plays a role in regulating transcription of CACNA1C. It appears there may be multiple functional variants, as we see allelic differences in enhancer activity as well as protein binding profiles for multiple SNPs.

1317T

Dysregulated Sonic Hedgehog signaling in MED12-related XLID disorders. *S. Srivastava[1], T. Niranjan[1], M. May[2], C. Skinner[2], R. Stevenson[2], C. Schwartz[2], T. Wang[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Greenwood Genetic Center, Greenwood, SC.

Mediator of RNA polymerase II transcription subunit 12 homolog (MED12) is a core subunit of the Mediator Complex that plays a key role in transcriptional regulation. Recurrent mutations in MED12 were found in patients with X-linked intellectual disability (XLID) syndromes including FG syndrome (R961W) and Lujan syndromes (N1007S), and sporadic mutations in patients with Ohdo syndrome. MED12-related XLID disorders exhibit a wide phenotypic spectrum including variable degrees of cognitive impairment, behavioral defects, and multiple congenital anomalies. Molecular mechanisms underlying these distinct neurodevelopmental phenotypes remain poorly understood. MED12 functions as a direct suppressor of Gli3-dependent Sonic hedgehog (SHH) signaling pathway and involves in REST (RE1silencing transcription factor)-imposed epigenetic restriction of neuronal gene expression. By screening a large cohort of patients with XLID of unknown etiology, we identified five new mutations that segregate with the disease phenotype in the probands families and are absent in more than 500 normal males. All five are missense mutations involving highly conserved amino acid residues. Four (N854S, N898D, R1214C, and R1295H) are located in the Leu-Ser (LS) rich-domain where the recurrent mutations for FG and Lujan syndromes were found and one (R206Q) in the Leu (L)-rich domain. To understand the molecular mechanisms of these mutations in XLID phenotype, we performed real-time RT-PCR quantification studies on the transcript levels of three genes, *CREB5*, *BMP4*, and *NGN2*, in the SHH signaling pathway in lymphoblasts from probands patients. Transcript levels for all three genes show significant increase in lymphoblasts carrying the four MED12 mutations within the LS domain but minimal or no change for the mutation in L domain. These results are consistent with previous findings that MED12-LS domain plays an important role in the negative regulation of the Gli3-dependent SHH signaling. Genotype-phenotype correlation and REST-dependent neuronal gene expression are currently being investigated. Results of these studies expand the clinical spectrum and support that dysregulated Gli3-dependent SHH signaling contributes to the phenotypic features of MED12-related XLID disorders.

1318S

Transcriptome analysis of Lphn3 null mutant mouse brain and implications for ADHD and Addiction. *D. Wallis[1], S. Galaviz[1], B. Baker[1], M. Tucker[1], T. Ioerger[2].* 1) Department of Biochemistry and Biophysics, Texas A&M University, College Station, TX; 2) Department of Computer Science and Engineering, Texas A&M University College Station, TX 77843-3474.

Latrophilin 3 (LPHN3), a GPCR, has been identified by linkage and association studies performed by separate research groups in separate cohorts as a prime candidate gene for ADHD and Addiction. Lack of readily identifiable functional polymorphisms suggests that non-coding variations determining the quantity and/or quality of LPHN3 isoforms are likely contributors to these behaviors, but the mechanisms by which LPHN3 might influence susceptibility and gene expression profiles in neurons are essentially unknown. We generated the Lphn3 null mutant mouse in order to evaluate gene function. We have already reported behavioral characterization of these mice indicating that they are both hyperactive and display increased reward seeking behavior. Here we describe the results after comparative transcriptome analysis of 3 brain regions over time between male wild type and null mutant Lphn3 littermates. Brains were harvested and dissected at 3 time points to reflect different stages of brain development (4 days, 4 weeks, and 6 months). Three brain regions known to play roles in ADHD: the hippocampus (important for learning and memory), the prefrontal cortex (the brain area essential for most executive functions), and the striatum (the location of dopaminergic reward-processing circuitry key in ADHD) were also independently sampled. We performed 100 bp single end reads on a HiSeq2500 and got over 13 million reads per sample. Preliminary analysis has focused on changes in transcription between time points and regions based on genotype. Some of the more surprising results indicate that Serpina3n is one of the most downregulated genes in all 3 brain regions in null mice at 6 and 1 month, but is relatively unchanged at 4 days. While we fully anticipate differential gene expression over time, we are startled by the lack of correlation of genes identified as showing changes between nulls and mutants at Day 4 in comparison to the other time points. This suggests that analysis of even earlier time points might be beneficial and supports the concept that ADHD is a developmental disorder. Further data analysis will emphasize neurotransmitters and their receptors, transporters, and metabolism genes as well as neurodevelopmental and survival genes. Enrichments for GO pathways will be determined.

1319M

Dual-marker lineage specific sorting in heterogeneous Parkinson's disease patient-specific iPSC-derived dopaminergic neuronal cultures. *K. Belle[1, 2, 3], B.A. DeRosa[1, 2, 3], J.M. Van Baaren[1,3], J.M. Vance[1,3], D.M. Dykxhoorn[1,3].* 1) John P. Hussman Institute for Human Genomics, Miami, FL 33136, United States; 2) Dr. John T. MacDonald Foundation Department of Human Genetics, Miami, FL 33136, United States; 3) University of Miami Miller School of Medicine, Miami, FL 33136, United States.

Parkinson's disease (PD) is a neurodegenerative disease characterized by the loss of dopaminergic neurons (DAns). Model systems and cell lines have helped improve our understanding of PD neuropathologies. In addition to failing to faithfully recapitulate the full spectrum of PD phenotypes, animal models lack the genetic architecture of human disease. PD studies in human patient fibroblast and immortalized cell lines are hampered by the fact that they are not the relevant tissue type affected in PD. To better understand PD genetics, we have used reprogramming and derivation techniques to derive stem cell lines genetically identical to patients diagnosed with PD, which, in turn, have been differentiated to relevant neuronal cell types, midbrain dopaminergic neurons. Advancements in the field of iPSC research make it a powerful tool for modeling genetic diseases by functional and transcriptomic studies. This is especially important for the study of progressive neurological diseases such as PD. While studies of autopsy brains provide endpoint data, longitudinal in vitro studies to measure disease-related dysfunction and gene expression changes can be performed with iPSC derived cultures. One challenge associated with gene expression studies from iPSC culture is the heterogeneity inherent to the differentiation to specific cell types. This is due to heterogeneity in both the cellular composition and developmental maturity of the differentiating cultures. To overcome this limitation, we have designed and tested lentiviral-based fluorescent reporter constructs that allow for the identification and isolation of specific cell types and developmental stages. Utilizing promoter reporter constructs for the tyrosine hydroxylase (TH) and dopamine beta hydroxylase genes, both markers for DAns, we were able to enrich for DAns mature enough to produce dopamine. We have created a dual-marker system by incorporating a previously designed promoter reporter for Synapsin1 (SYN1) to further enrich our sample for mature SYN+/TH+ DAns. These enriched cultures show increase expression of mature DAn markers and related genes. This dual-marker system will be further utilized in gene expression studies of PD patient derived neuronal cultures to measure subtle gene expression differences between the DAns of patients and controls.

1320T

Investigating the role of RBFOX1 in human stem cell-derived glutamatergic neurons. *H.N. Cukier[1], B.A. DeRosa[1,2], K.C. Belle[1,2], Y.S. Park[1,2], A.J. Griswold[1], J.M. Lee[1], M.L. Cuccaro[1,2], J.R. Gilbert[1,2], D.M. Dykxhoorn[1,2], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Autism spectrum disorders (ASDs) are a group of devastating neurodevelopmental conditions that currently afflict about 1 in every 68 children. Since most genetic causes are quite rare, investigations of ASD loci using genome wide association studies (GWAS) have identified relatively few consistent signals of interest. Our group performed a joint analysis of three independent, family-based GWAS datasets for a total of 2,963 families. The top hit with a near genome-wide significance (rs3095508, joint $p=6.04 \times 10^{-8}$) was in the *RNA binding protein, fox-1 homolog 1* (*RBFOX1*) gene. *RBFOX1* had a total of 9 SNPs with $p<1\times10^{-5}$. *RBFOX1* is a neural splicing cofactor that regulates alternative splicing. Both our group and others have identified copy number variants and point mutations in *RBFOX1* in ASD individuals. In addition to ASD, *RBFOX1* has been connected to bipolar disorder, epilepsy, and schizophrenia. To better understand the impact of *RBFOX1* on neuronal functionality, we are evaluating how *RBFOX1* expression modulates neuronal function in iPSC-derived glutamatergic neuronal cells. The viability and functionality of the glutamatergic neurons in which *RBFOX1* has either been overexpressed or silenced by RNA interference are assessed at multiple time points during in vitro neurogenesis. Overexpression experiments are performed with lentiviral transduction and genomic integration the wild type form of *RBFOX1* variant 4 driven under a CMV promoter, as well as an ASD-specific nonsense mutation at R173X that we identified in a sporadic ASD family. Each condition is compared at a gross morphological level to determine if modulating *RBFOX1* produces recognizable qualitative or quantitative phenotypes. Since *RBFOX1* plays a key role in splicing and transcription, RNA-seq analysis of the iPSC-derived neurons under three conditions (*RBFOX1* knockdown, overexpression and no treatment) will be used to complement the functional analysis to identify key networks regulated by *RBFOX1*. Collectively, it appears that *RBFOX1* may play a broader role in ASD pathogenesis and other neurological disorders than has been previously suspected.

1321S

Mutant dystrophin Dp71$\Delta_{78\text{-}79}$ stimulates cellular proliferation in the inducible system PC12 Tet-On. *A. Herrera-Salazar[1], J. Aragón[1], J. Romo-Yáñez[1], A. Sánchez-Trujillo[1], V. Ceja[1], R. García-Villegas[2], C. Montañez[1].* 1) Genética y Biología Molecular, CINVESTAV-IPN, México, Distrito Federal, Mexico; 2) Fisiología, Biofísica y Neurociencias, CINVESTAV-IPN, México, Distrito Federal, México.

Duchenne muscular dystrophy (DMD), a X-linked disease, is a degenerative muscle disorder caused by mutations in the DMD gene resulting in the absence of cytoskeletal dystrophin or the presence of truncated protein. DMD gene has a complex transcriptional regulation that give rise to several tissue-specific proteins named according their molecular weight (Dp427, Dp260, Dp116, Dp71, Dp40). Dp71 is the major DMD gene product expressed during embryonic development and in adult brain. In addition, patients with severe mental retardation have mutations that affect Dp71 expression. The differential cellular distribution of Dp71 isoforms, spliced out at exons 71, 71-74 and 79, suggest different functions for these proteins. Reports using PC12 cells, a neuronal model, have shown alterations in the nerve grow factor (NGF)-induced neuronal differentiation and cell cycle when Dp71 expression is depleted. Nevertheless, the mechanism of Dp71 dystrophin function has not been describe yet. As an attempt to define the functional role of Dp71 domains, our team have been studied a novel mutant protein, Dp71$\Delta_{78\text{-}79}$, which lacks exons 78 and 79. This deletion does not affect the interaction sites with β-dystroglycan, syntrophin and dystrobrevin. In this work we generated an inducible system by stable transfection of PC12 Tet-On cells with pTRE2pur-Myc/Dp71$\Delta_{78\text{-}79}$ construct. Doxycycline was used to switch on the transcription of mutant dystrophin and the effects were analyzed by Western blot and optical and confocal microscopy. Results shown that PC12 cells transfected with Dp71$\Delta_{78\text{-}79}$ have an increase in the cell growth rate when NGF is added in the medium rather than stimulate differentiation, when compared to control cells. Western blotting analysis show an increase in the expression of β-dystroglycan (dystrophin-associated protein related with cell adhesion, signal transduction and regulation of actin cytoskeleton) and a decline in Dp71a (endogenous dystrophin) and Grb2 (mediator of Ras-related signaling pathway) when comparing cells expressing Dp71$\Delta_{78\text{-}79}$ to control cell. Confocal microscopy exhibits β-dystroglycan variation in subcellular localization in Dp71Δ78-79 clone. Proliferating cell nuclear antigen (PCNA) and focal adhesion kinase (FAK) expression is also increased in this construct. Our results suggest that the mutant dystrophin isoform Dp71$\Delta_{78\text{-}79}$ has a role in cell cycle in this system.

1322M

Prenatal malnutrition reprogrammed postnatal gene expression in mammals' brain. *JW. Xu[1,2,3], XY. Zhou[1,2], YQ. Xiang[1,2], T. Wang[1,2], L. He[1,2], XZH. Zhao[1,2].* 1) Reproductive Medicine Centre,The First Affiliated Hospital of Zhengzhou Universtiy, Zhengzhou, China; 2) Children's Hospital and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) Bio-X Institutes, Key Laboratory for the Genetics of Developmental and Neuropsychiatric Disorders (Ministry of Education), Shanghai Jiao Tong University, Shanghai, China.

Background: Converging evidence suggests that schizophrenia is a neurodevelopmental disease with environmental influences during early brain development. Prenatal nutritional deficiencies have long been implicated in the etiology of schizophrenia. The birth cohorts affected by the Dutch Hunger Winter of 1944-1945 and 1959-1961 Chinese famine who suffered a nutrition deficiency showed a two fold increase in the incidence of schizophrenia in adulthood. **Material and Methods:** We established a prenatal "famine" rat model, names RLP50 that induced by maternal exposure to a diet restricted to a 50% low (6%) protein diet to explore increased schizophrenia risk in those born during the Chinese famine. NimbleGen gene expression microarray was used to investigate the differential expression genes, MBD-seq was used to detect whole genome DNA methylation, MASSARRAY EpiTYPER was used to validate the MBD-seq data. **Results:** We show prenatal malnutrition reprograms adult prefrontal cortex gene expression in the offspring of RLP50, 415 genes showing modest significant expression differences ($P<0.05$), of which 48 genes showed highly significance ($P<0.01$), related to neurotransmitters and olfactory function. In the hippocampus, we identified 2987 genes with significant ($p<0.05$) expression differences, and 841 genes with highly significant ($p<0.01$) expression differences, the differentially expressed genes were related to synaptic function and transcription regulation. DNA methylome profiling of the hippocampus revealed a systematic epigenetic changes of which majority showed hypermethylation (86.9%). Remarkably, plasma membrane was significantly enriched in both profiling screens ($P = 2.37\times10^{-9}$ and 5.36×10^{-9}, respectively). Furthermore, Slc2al associated with cognitive impairment, showed significant down-regulation and hypermethylation in the hippocampus of the RLP50 offspring. The gene expression and DNA methylation differential affected the same GO function term-plasma membrane ($P=3.93\times10^{-9}$) and cell projection ($P=9.78\times10^{-7}$).**Conclusion:** We show that the gene expression reprogramming was less significant in the PFC of RLP50 offspring compared with that of the hippocampus, as well as the genome-wide DNA methylation. Our results suggest that prenatal exposure to famine will reprogram postnatal brain gene expression, disturbed synaptic and neurodevelopment, impairing learning and memory, and therefore contribute to predisposition to schizophrenia.

1323T

Gene expression profiling of human astrocytes treated with bexarotene and related compounds shows an increase in the neuroprotective cytokine GMCSF. *R.F. Richholt[1,2,3], I.S. Piras[4], A.M. Persico[4], M.J. Huentelman[1,2,3].* 1) Translational Genomics Research Institute, Phoenix, AZ; 2) Arizona Alzheimer's Consortium, Phoenix, AZ; 3) Evelyn F McKnight Brain Institute at the University of Arizona; 4) Lab. of Mol. Psychiatry and Neurogenetics, Univ. Campus Bio-Medico, Rome, Italy.

Characteristic neuropathology of Alzheimer's disease (AD) includes the accumulation of extracellular amyloid plaques in the brain. These plaques are thought to be formed by an imbalance between beta-amyloid (Aβ) production and clearance. Recent studies in multiple AD mouse models show that treatment with the RXR agonist bexarotene (BEX) restores cognitive functions and in some models results in reduced soluble and oligomeric Aβ. These observations position BEX as a potential agent for AD prevention therapy. RXR and LXR activation has been shown to increase expression of the cholesterol transporters ABCA1 and ABCG1, as well as APOE. These increases were attributed to the benefits of the BEX treatment on Aβ, but they also caused concern regarding its potential use in patients carrying the epsilon 4 allele variant of APOE. How these molecules facilitate AB clearance is not fully understood; therefore we utilized gene expression profiling to investigate BEX and related RXR/LXR agonists in human cells. Human primary astrocytes (Lonza) were treated for 48 hours with 100nM concentrations of the following RXR/LXR agonists - BEX, honokiol, and 9-cis retinoic acid (RA). Gene expression analysis was conducted with Illumina HumanHT12 v4 BeadChips and differential expression analysis was performed with the R package Limma. Hierarchical clustering and gene ontology analysis was also conducted. BEX and RA significantly upregulated ABCA1 and ABCG1 ($p<0.01$, validated by qRT-PCR), but APOE was unaffected by any of the three drug treatments. Cluster analysis identified a group of immune response genes that were upregulated at three hours by all drugs. Among these genes, BEX increased granulocyte-macrophage colony stimulating factor (GMCSF) (Log2 fold change 1.64, $p<0.01$), a cytokine that is known to be neuroprotective. Additionally, treatment of cultured human microglia with BEX demonstrated a significant increase in GMCSF across a similar time course. This study is the first to examine the molecular effects of BEX in human cells. Our results suggest that BEX treatment does not upregulate APOE expression and therefore should remain a strong candidate for anti-amyloid therapy in humans. Additionally, our results demonstrate that BEX may act at least in part via upregulation of GMCSF. Several studies show that upregulation of GMCSF can reverse both cognitive impairment and amyloidosis. BEX likely represents a novel approach to upregulate GMCSF in the central nervous system.

1324S

Persistent neurocognitive decline is associated with vascular and epithelial damage to the choroid plexus and β-amyloid plaques in an outbred rat model. *A.J. Wyrobek[1], S. Bhatnagar[1], B. Rabin[2].* 1) Lawrence Berkeley National Laboratory, Berkeley, CA; 2) University of Maryland, Baltimore Campus, Baltimore, MD.

CNS damage in youth may accelerate neurocognitive decline later in life and hasten the onset of neurological diseases. Understanding the molecular mechanisms of CNS damage after radiation exposures is of special importance for patients receiving cranial radiotherapy, astronauts returning from extended space missions, and has relevance to those experiencing traumatic head injuries. We employed an outbred rat model (Sprague Dawley) to investigate the time-course of molecular and cellular CNS damage after HZE irradiation with 56Fe (1 Gev/n; 10 or 100 cGy), using age-matched shams and young animals as reference. Irradiated rats showed persistent neurocognitive deficits on novel object recognition and bar-press assays. CNS transcriptomic findings pointed to persistent molecular changes in the choroid plexus (CP), the structure that produces cerebral spinal fluid (CSF). Groups of rats were exposed at 2 or 6 months (m) of age and CNS tissue was sampled at 4, 9 or 21 m later. Beginning at 4 m after exposure, there was increased CP endothelial fibrosis especially in the small fenestrated capillary vessels, and the CP epithelium produced less transthyretin (Ttr) protein, a major component of CSF. Ttr is a β-amyloid-binding protein that facilitates β-amyloid clearance. There was also a progressive increase in β-amyloid plaques beginning at 9 m after exposure. Unirradiated animals did not show age-related changes in CP fibrosis or Ttr expression, but showed a small increase in plaque frequency with age. Our findings are consistent with the hypothesis that CNS neurotoxic exposures or trauma early in life may cause persistent CP dysfunctions that lead to persistent neurocognitive decline associated with the diminished production of molecular factors required for β-amyloid clearance and prevention of β-amyloid plaque build-up in advanced aging. No association between telomere length and exposure to life course stress or adversity in two longitudinal New Zealand cohorts. *S. Jodczyk[1], J.F Pearson[2], D.M Fergusson[3], L.J Horwood[3], J.K Spittlehouse[3], P.R Joyce[2], M.B Hampton[1], M.A Kennedy[1].* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of the Dean, University of Otago, Christchurch, New Zealand; 3) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand.

Telomeres are specialised structures that maintain the integrity of the genome. They shorten with each cell division, eventually reducing the telomere to a critical length and triggering cell senescence and apoptosis. Previous research suggests that various life stressors increase the rate of telomere shortening with potential impact on disease states and mortality later in life. The objectives of this study were to establish and validate a qPCR method for telomere length measurement and apply this assay to two longitudinal cohorts. The first was the Christchurch Health and Development Study (CHDS) (n=677), a birth cohort that has followed participants for over 30 years and the second was the Christchurch Health, Aging and Lifestyle Cohort (CHALICE) (n=351), a population sample of 50 year olds. We hypothesised that telomere length would be proportional to an individual's cumulative exposure to life course stress and adversity. We experienced difficulty establishing a reliable multiplexed method (MMQPCR) for telomere length measurement on the Lightcycler 480 platform. This was due to complexities in extraction and analysis of data and differential heating across the Peltier block. In addition, we discovered that choice of hot-start DNA polymerase was critical for the success of the assay. Six of the 12 hot-start enzymes tested yielded primer dimers with the telomere-specific primers, presumably due to activity of the enzyme below the specified activation temperature. Reliable data could only be obtained by implementing a modified form of the original single amplicon qPCR method, which was validated with Southern blotting. No associations were found between telomere length and life course stress or adversity in either cohort. The stressors examined in the CHDS cohort spanned the antenatal through to young adulthood periods and included childhood physical or sexual abuse, substance use and mental health problems. Correlations were very small ranging from -0.06 to 0.06, and none were statistically significant. The stressors assessed in the CHALICE cohort included BMI, cholesterol levels and smoking status. We conclude that up to the age of 50, life course stressors have negligible effects on telomere length. Although telomere length does not appear to provide a sensitive measure of the effects of environmental stress, it may be that telomere erosion measures obtained by comparing telomere length before and after exposure to stress would be more effective.

1326T

Polymorphisms in the TCF4 gene interact with body mass index to influence lithium response among patients with bipolar disorder. *E. Ryu[1], A. Cuellar-Barboza[2], M. Prieto[2], J. Geske[1], C. Colby[1], J. Biernacka[1,2], M. Frye[2].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Psychiatry and Psychology, Mayo Clinic Rochester, Rochester, MN, USA.

Background: Although lithium is considered as the first line of treatment for bipolar disorder (BD), half of BD patients do not respond to it. Recent studies have indirectly suggested a potential connection between lithium's protective cellular effects and TCF4 on chromosome 18. TCF4 codes for transcription factor 4, shown to affect multiple signaling pathways involving cell survival and neuronal differentiation, together with neuropsychiatric phenotypes including schizophrenia. Therefore, we assessed the association between genetic variants in TCF4 with lithium response to treatment of BD, allowing the genetic effect to be modified by body mass index (BMI), which has also been associated with lithium response.

Methods: Data from 341 BD patients previously treated with lithium was used to assess the association between lithium response (no response, intermediate response, or response) and 20 TCF4 SNPs previously reported to be associated with schizophrenia. Adjusting for age and sex, cumulative logit models including BMI-SNP interactions were applied to jointly test the main effect of each SNP and its interaction with BMI.

Results: Among 341 patients, 52% responded to lithium treatment, 32% showed intermediate response, and 16% had no response. The joint test showed nominally significant evidence of association between two intronic SNPs in TCF4 (rs17512836 and rs17597926) with lithium response (P= 0.009). These two SNPs were in almost complete in linkage disequilibrium (r2=0.99) and showed an interaction effect with BMI (P=0.003), indicating that the effect of these SNPs on lithium response depends on BMI.

Conclusion: TCF4 is a member of the basic helix-loop-helix (bHLH) family of transcription factors that have an important role in a number of developmental processes. Our results suggest that the SNPs in this gene may interact with BMI for lithium response. Future work is needed to replicate this finding and to investigate the biological mechanism behind this association.

Multiple functional linear models and three dimensional functional principal component analysis for image-genetic data analysis in clouds. *J. Jiang[1], N. Lin[1], L. Luo[3], J. Yu[1], V. Calhoun[2,3], C. Gupta[2], M. Xiong[1].* 1) School of Public Health, UTHSC, Houston, TX; 2) The Mind Research Network, Albuquerque, NM; 3) University of New Mexico.

Large-scale integrated genetic and imaging data analysis is a new approach used to uncover the individual variability and mechanism of disease development. This approach, which has not been well developed, has the potential to open a new avenue for dissecting genetic structure of complex disease and personal medicine. Joint analysis of imaging and genetic data will identify genes significantly associated with disease and provide useful information on target therapy. The widely used statistical methods for image-genetic analysis often employ some simple summarizing statistics to represent image signals. As a consequence, these methods often formalize image-genetic studies as a traditional genetic study of a single quantitative trait in which we test association of a single SNP with a single summarizing statistic of the image signals. However, summarizing statistics completely ignore distribution of signals of the image in two or three dimensions. In addition, single SNP analysis methods are difficult to deal with next-generation (NGS) data. To overcome these limitations, we extend one dimensional principle component analysis to three dimensional principle component analyses (3DFPCA) and use 3DFPCA scores to represent image data. These 3DPCA score are then taken as multiple quantitative traits. To deal with NGS data, we use one gene or one genomic region as an unit of genetic analysis. In other words, we develop multiple functional linear models for image-genetic analysis. The methods for parameter estimation and statistics for testing association of gene or genomic region are also developed. Since both imaging- and genetic-domain observations include a huge number of variables, joint image and genetic analysis on such Big Data represents a computational challenge that cannot be addressed with conventional computational techniques. To address this challenge, we develop sophisticated algorithms for joint analysis of imaging and genetic data running on Amazon cloud computer. The proposed method was applied to the mind clinical imaging consortium's schizophrenia image-genetic study with 9,766 genes (746,575 SNPs) typed in 94 schizophrenia patients and 75 healthy controls. The excellent QQ plot of our results showed that we did not inflate the false positive rates. We identified 44 significant ly associated genes, 20 of which can be confirmed to be associated with Schizophrenia from the literature.

1328M

Whole genome analysis of high-dimensional phenotypic data: Multiple testing in the context of genome-wide analysis. *S.E Medland[1], B.M Neale[2,3,4], N. Jahanshad[5,6], D.P Hibar[5,6], A. Arias Vasquez[7,8], J.L Stein[9], N.G Martin[10], B. Franke[7,8], M.J Wright[11], P.M Thompson[5,6,12], the ENIGMA consortium.* 1) Quantitative Genetics, QIMR Berghofer, Brisbane, QLD, Australia; 2) Program in Medical and Population Genetics, The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) Psychiatric and Neurodevelopmental Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 5) Imaging Genetics Center, Institute for Neuroimaging & Informatics, Keck School of Medicine of University of Southern California, Los Angeles, California, USA; 6) Department of Neurology, University of Southern California, Los Angeles, California, USA; 7) Donders Institute for Brain, Cognition and Behaviour, Nijmegen, The Netherlands; 8) Departments of Psychiatry, Human Genetics & Cognitive Neuroscience, Radboud University Medical Center, Nijmegen, The Netherlands; 9) Neurogenetics Program, Department of Neurology, UCLA School of Medicine, Los Angeles, USA; 10) Genetic Epidemiology, QIMR Berghofer, Brisbane, QLD, Australia; 11) NeuroImaging Genetics, QIMR Berghofer, Brisbane, QLD, Australia; 12) Departments of Neurology, Psychiatry, Engineering, Radiology, Pediatrics and Ophthalmology, University of Southern California, Los Angeles, California, USA.

Genome-wide association (GWAS) has been a highly successful technique for the identification of replicable loci influencing a wide variety of traits. Arguably, much of the consistency and robustness of effects identified using GWAS methods derives from the development and application of genome-wide approaches to correct for multiple testing which have reduced the number of false positives within the literature. As GWAS are almost exclusively univariate in nature, extension of the multiple testing corrections to account for running GWAS on multiple traits has focused on Bonferroni corrections for the number of independent traits being analysed. However, with the increasing focus on BIG data problems, where genome-wide analyses are repeatedly applied to dense sets of correlated phenotypes, a more structured approach would be useful. One such big data problem commonly encountered in imaging genetics is the analysis of voxel-level brain imaging data, where over 2 million data points with complex correlational structures are typically extracted. Here we present a series of analyses to determine the genome-wide significance threshold required to maintain a family-wise error rate of < 5% for voxel-level image analysis. Following Dudbridge and Gusnanto, we estimated the dimensionality of the voxel-level volumetric analysis in three independent cohorts (ADNI, BIG and QTIM), for whom structural MRI and genome-wide data were available. To examine the robustness of these results we examined the impact of field strength (from 1.5 to 4 tesla magnets), voxel size and image processing. Across data sets with over 2 million data points each we estimated the dimensionality of the voxel-level analysis to be approximately 10,000. Adopting a Bonferroni correction for testing 10,000 independent traits, the genome-wide, voxel-wide tensor based morphology significance threshold would then be $p< (5 \times 10^{-8})/10{,}000 = 5 \times 10^{-12}$. Importantly, the threshold remained stable in down-sampled data sets (an approach that is often advocated as a method of reducing the multiple testing burden). Encouragingly, the largest imaging genetics studies of brain volume to date, performed as part of the ENIGMA consortium, show effects on the order of $P = 10^{-23}$, indicating that this threshold is within the reach of available sample sizes. These findings also have implications for other high-dimensional phenotype sets such as gene expression data.

1329T

MicroRNAs associated with declarative memory phenotypes. *J. Neary[1], H. Kulkarni[1], J. Peralta[1], D. Cruz[2], D. Reese McKay[3], E. Knowles[3], P. Fox[4], J. Curran[1], H. Göring[1], L. Almasy[1], R. Olvera[5], P. Kochunov[6], R. Duggirala[1], J. Blangero[1], D. Glahn[3], M. Carless[1].* 1) Dept Genetics, Texas Biomedical Research Inst, San Antonio, TX; 2) Dept. Psychiatry, University of Texas Health Sciences Center San Antonio, San Antonio, TX; 3) School of Medicine, Yale University, Hartford, CT; 4) Research Imaging Institute, University of Texas Health Sciences Center San Antonio, San Antonio, TX; 5) School of Medicine, University of Texas Health Sciences Center San Antonio, San Antonio, TX; 6) School of Medicine, University of Maryland, Baltimore, MD.

Declarative memory refers to long-term memory that can be consciously recalled, such as factual information and events. Declarative memory impairment, a well-established endophenotype for several psychiatric illnesses, can be indexed either behaviorally, or through in vivo measures of brain structure. To understand genetic contributions to declarative memory, we sequenced microRNAs (miRNAs) from peripheral blood cells of 1,152 Mexican Americans within ~50 large pedigrees who have undergone magnetic resonance imaging (MRI) and cognitive assessment; we then assessed gray matter thickness, surface area, and volume for nine neuroanatomical structures relevant to declarative memory and five memory-related neurocognitive traits. 1,583 mature miRNAs (1,539 known, 42 SNP-altered in whole genome sequence data, 2 novel) were tested for association with 14 declarative memory-related phenotypes. In total, 2,390 significant ($p<0.05$) associations were detected, as well as 3 significant associations ($p<3.16\times10^{-5}$) after correction for multiple testing. Some miRNAs previously implicated in memory-related disorders (miR-107, miR-148a-3p, miR-25-3p, miR-35c-5p) were associated with multiple phenotypes, as were several other miRNAs, including miR-1972 (6 phenotypes, $p=2.74\times10^{-2}$-5.34×10^{-6}), miR-5586-5p (11 phenotypes, $p=4.21\times10^{-2}$-2.56×10^{-5}), miR-7706 (5 phenotypes, $p=2.61\times10^{-2}$-$<1.00\times10^{-7}$), and miR-922 (3 phenotypes, $p=1.93\times10^{-2}$-3.51×10^{-5}). We also identified significant associations between miRNA sequences altered by SNPs and several phenotypes. Additionally, both novel miRNAs identified by sequencing were also associated ($p<0.05$) with several phenotypes, and one was highly expressed in ~15% of our cohort, which may suggest that this miRNA is cohort-specific. Our data suggests that miRNAs may act as peripheral biomarkers for declarative memory, and further investigation of the correlation between blood and brain miRNAs may help to implicate these in neurodevelopment, neurodegeneration and synaptic plasticity. Our early analysis in baboon tissue suggests that only ~21% of miRNAs show significantly different expression levels between blood and brain tissue. The identification of SNP-altered miRNAs and novel miRNAs, which appear to be at least nominally associated with declarative memory phenotypes, further suggests that (cohort-specific) genetic variation may be important in regulatory function for miRNA biogenesis.

1330S

Expanding the phenotypic spectrum of AFG3L2-associated ataxia. *A. Knight Johnson, S. Halbach, K. Silver, D. Waggoner.* University of Chicago, Chicago, IL.

Pathogenic variants in AFG3L2 have been associated with spinocerebellar ataxia, type 28 (SCA28), which is an autosomal dominant disorder associated with slowly progressive gait and limb ataxia, lower limb hyperreflexia, dysarthria, nystagmus, ptosis and ophthalmoparesis. The mean age of onset of symptoms is 27 years, with a reported range of 3-60 years. The majority of AFG3L2 pathogenic variants described to date have been missense changes in exons 15 and 16 within the M41-protease domain of the gene. We present a case with a de novo pathogenic variant in AFG3L2 in a 7 year old male with a history of upper body tremors starting at 6 months of ages, significant rapidly progressive ataxia, and cerebellar atrophy. Between 6-8 months the patient was noted to have episodic upper body tremors that occurred multiple times per day, truncal hypotonia and delayed motor and speech development. At age 12 months bilateral esotropia was noted. A brain MRI obtained at 12 months was normal, a repeat MRI at age 2 years showed cerebellar atrophy. By age 6 years the patient had significant balance issues requiring support to walk or stand, and dysarthria. The family history was not significant for ataxia, and the patient had no siblings. Whole exome sequencing was performed, and a de novo variant in the AFG3L2 gene, c.1994G>T, was identified. This variant results in a missense change, p.Gly665Val, in a highly conserved amino acid residue in exon 16. Three different pathogenic missense changes involving the adjacent amino acid residue, p.Met666, have previously been described in patients with SCA28. This patient exhibited an earlier age of onset than any previously described case of SCA28, and has more rapidly progressive disease than is typical for the disorder. The clinical variability that has previously been described includes rare cases of individuals who present at age 6-8 and only two cases of presentation at age 3 in identical twin siblings. The twins had slower progression than our current case. Our patient expands the known phenotypic spectrum of SCA28 suggesting a possible modifier gene affect. A previous case of homozygous mutations in AFG3L2 in siblings has been described where the mutations affected the binding of AFG3L2 to paraplegin and resulting in a severe phenotype that included features of spasticity and neuropathy. This raises the possibility of other minor changes in the SPG7 gene (codes for paraplegin) to modify the phenotype of SCA28.

1331M

Expanding the phenotypic spectrum of *TUBB4A*-associated hypomyelinating leukoencephalopathies. *S. Miyatake[1], H. Osaka[2,3], M. Shiina[4], M. Sasaki[5], J. Takanashi[6], K. Haginoya[7], T. Wada[8], M. Morimoto[9], N. Ando[10], Y. Ikuta[11], M. Nakashima[1], Y. Tsurusaki[1], N. Miyake[1], N. Matsumoto[1], H. Saitsu[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Division of Neurology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, Jichi Medical School, Tochigi, Japan; 4) Department of Biochemistry, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 5) Department of Child Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan; 6) Department of Pediatrics, Kameda Medical Center, Chiba, Japan; 7) Department of Pediatric Neurology, Takuto Rehabilitation Center for Children, Sendai, Japan; 8) Genetic Counselling and Clinical Research Unit, Kyoto University School of Public Health, Kyoto, Japan; 9) Department of Pediatrics, Graduate School of Medical Science, Kyoto Prefectural University of Medicine, Kyoto, Japan; 10) Department of Pediatrics, Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 11) Department of Neurology, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

Leukoencephalopathies are a heterogeneous group of disorders affecting the white matter of the brain. Hypomyelination with atrophy of the basal ganglia and cerebellum (H-ABC) is one of those characterized by early-onset motor regression and/or delay followed by extrapyramidal symptoms. A recurrent *de novo TUBB4A* mutation was recently reported in 11 patients with H-ABC. Interestingly *TUBB4A* mutations also cause DYT4 dystonia, suggesting that *TUBB4A* mutations may have a broader phenotypic spectrum. Here we performed whole-exome sequencing analysis of patients with genetically unsolved hypomyelinating leukoencephalopathies, identifying eight patients with *TUBB4A* mutations, and allowing the phenotypic spectrum of *TUBB4A* mutations to be investigated. Fourteen patients with hypomyelinating leukoencephalopathies, 7 clinically diagnosed with H-ABC, and 7 with unclassified hypomyelinating leukoencephalopathy, were included. Six heterozygous missense mutations in *TUBB4A*, 5 of which are novel, were identified in 8 patients [6/7 H-ABC patients (the remaining patient is an atypical case), and 2/7 unclassified hypomyelinating leukoencephalopathy patients]. In 4 cases with parental samples available, the mutations occurred *de novo*. The effect of the mutations on microtubule assembly was examined by mapping altered amino acids onto 3D models of the αβ tubulin heterodimer. The p.Glu410Lys mutation, identified in patients with unclassified hypomyelinating leukoencephalopathy, directly impairs motor protein and/or microtubule-associated protein interactions with microtubules, while the other mutations affect longitudinal interactions for maintaining αβ tubulin structure, suggesting different mechanisms in tubulin function impairment. In patients with the p.Glu410Lys mutation, the clinical course appeared generally milder compared to the typical H-ABC patients. Their basal ganglia atrophy was unobserved or minimal although extrapyramidal features were detected, suggesting its functional impairment. We conclude that *TUBB4A* mutations cause typical H-ABC. Furthermore *TUBB4A* mutations associate cases of unclassified hypomyelinating leukoencephalopathies with morphologically retained but functionally impaired basal ganglia, suggesting *TUBB4A*-related hypomyelinating leukoencephalopathies encompass a broader clinical spectrum than previously expected. Extrapyramidal findings may be a key for consideration of *TUBB4A* mutations in hypomyelinating leukoencephalopathies.

1332T

Genetic enrichment of multiple sclerosis risk loci in multiple sclerosis patients with co-morbid diseases. *M.F. Davis[1], J.L. Haines[2], J.C. Denny[3].* 1) Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Patients with MS are at a higher risk of developing a number of other diseases, specifically other autoimmune diseases. There are many shared genetic risk factors between autoimmune diseases, including multiple sclerosis (MS), and patients with MS are at higher risk of the development of other diseases. Studies of specific co-morbidities of MS have been published, but there are few studies that have the clinical data necessary to conduct a broad study of the clinical landscape of MS. Electronic medical records (EMR) have extensive clinical data for patients and provide an opportunity to collect data on all diseases a patient experiences, rather than a narrow interview conducted for a disease-specific research study. We previously created and validated algorithms to identify patients with MS and detailed clinical traits of MS disease course from EMRs. Using a de-identified EMR dataset of 5,789 MS patients, we are now creating algorithms based on ICD-9 billing codes, text key words, and medications to identify and characterize diseases that occur co-morbidly with MS. We are comparing the distributions of co-morbid diseases identified to those in published literature. 1,000 of these patients are genotyped on the ImmunoChip. We will perform analysis to determine if patients with particular co-morbidities are enriched for specific MS risk loci.

1333S

Microbiome profiling in whole blood using RNA-seq reveals disease-specific patterns. *S. Mangul[1], A.P. Ori[2], K.A. Staats[2], L.M. Olde Loohuis[2], G. Jospin[3], J.A. Eisen[3], E. Eskin[1], R.A. Ophoff[2].* 1) Department of Computer Science, University of California, Los Angeles, Los Angeles, California, 90095; 2) Center for Neurobehavioral Genetics, University of California, Los Angeles, Los Angeles, California, 90095; 3) Department of Evolution and Ecology, College of Biological Sciences, University of California, Davis, 95616.

Microbial communities in and on the human body represent a complex mixture of bacteria, viruses, archaea and microbial eukaryotes containing in total more than ten times the number of genes found in the human genome. Advances in high-throughput sequencing offer a powerful culture-independent approach to study the underlying diversity of microbial communities of human tissues in health and disease. Availability of comprehensive compendiums of reference microbial genomes and rRNA genes provides ample possibilities to use sequencing data to profile microbial communities present across different human tissues. Reads mapped to microbial reference databases can be used to assign taxonomy to microbial species and identify genes expressed across different samples and subjects. Here, we analyzed RNA-seq datasets from 192 humans from four disease groups (i.e. schizophrenia, bipolar disorder, amyotrophic lateral sclerosis and unaffected controls). Non-mapped RNA-seq reads (failed to map to the human genome) are mapped to a compendium of reference marker genes and microbial genomes and subsequently used to study underlying diversity of microbes in blood. We perform analysis of microbial communities using Phylosift, a phylogeny-driven method that uses Bayesian methods to asign taxonomic IDs and to compare community diversity between samples. More specifically, Phylosift uses phylogenetic comparison of reads to reference databases of rRNA and protein coding "marker" genes to profile individual microbial communities and then carries out edge principal components analysis to compare communities. Additionally we validate individual microbial communities using genomic sequence data of the same individual. Using identical procedures we are able to use non-mapped reads to profile diversity of microbial communities. We are able to confirm the microbial genomes at different abundance levels. Using sequencing data from 192 individuals we were able to study microbiome diversity in blood in subjects with and without brain disorders. In particular, we observe distinctive patterns of microbiota composition in schizophrenia patients. Further analysis is needed to decipher the origin and meaning of these differences. The widespread detection of microbial species in whole blood and the observed differences in disease groups underscores the involvement of the microbiome in human health and disease.

1334M

COFS syndrome due to ERCC1 mutation without Nucleotide Excision Repair defect. *Y. CAPRI[1], N. CALMELS[2], M. GERARD[3], V. BELAVOINE[4], I. DORBOZ[5], D. RODRIGUEZ[5,6,7], V. LAUGEL[2,8], O. BOESPFLUG-TANGUY[4,5], L. BURGLEN[5,7,9].* 1) Medical Genetics, Robert Debré University Hospital, Paris 19eme, Paris, France; 2) Department of Molecular Genetics, University Hospital Strasbourg, 67091 Strasbourg; 3) Department of Genetics, University Hospital Caen, 14000 Caen; 4) Department of Pediatric Neurology and metabolic diseases, APHP- Robert Debré University Hospital, 75019 Paris; 5) INSERM U1141, Paris; 6) Department of Pediatric neurology, APHP -Trousseau University Hospital, 75019 Paris, France; 7) Centre de référence des malformations et maladies congénitales du cervelet, APHP-Trousseau University Hospital, 75012 Paris; 8) Department of Pediatric, University Hospital Strasbourg, 67098 Strasbourg; 9) Department of Genetics, APHP- Trousseau University Hospital, 75012 Paris.

Cerebro-oculo-facio-skeletal syndrome (COFS syndrome) is a heterogeneous disease characterized by the association of microcephaly, congenital cataract or microphtalmia, arthrogryposis, severe psychomotor delay, growth retardation and facial dysmorphism. COFS syndrome is due to Nucleotide Excision Repair (NER) defect. ERCC6, ERCC5, ERCC2 and ERCC1 mutations have been involved in COFS syndrome. ERCC1 mutations have been reported in 1 patient with COFS syndrome and in 2 other patients; one patient developed a type II Cockayne syndrome and the other had a severe form of Xeroderma pigmentosum with neurodegeneration symptoms (both syndromes belong to the same spectrum of DNA repair disease as COFS). The patient is the 1st girl of consanguineous Algerian parents. Pregnancy was uneventful but at birth, she displayed distal arthrogryposis and rapidly developed microcephaly, seizures and severe encephalopathy. Brain MRI showed brainstem and cerebellar hypoplasia, and myelinisation delay. She could not walk, sit nor speak. She died at 5 years from chest infection. The 2nd pregnancy of the couple was interrupted because of the recurrence of the disease with arthrogryposis observed at 28 weeks of gestation (WG) and cerebellar hypoplasia at 32WG, confirmed by foetal brain MRI. The pregnancy was terminated at 34WG. We report the 4th familial case of ERCC1 mutations. In this family, homozygous p.Phe231Leu mutation was associated with COFS syndrome but no NER defect was observed. This family confirmed ERCC1 involvement in COFS syndrome but NER defect seemed inconsistent compared to what can be observed when ERCC6 and ERCC5 is mutated. The p.Phe231Leu mutation was already reported in 2 out of the 3 published patients with ERCC1 mutations (one at the homozygous state, and the other in combination with a nonsense mutation). The pathogenicity had already been confirmed by complementation assay and this mutation was not found in 6,000 control exomes. The absence or low consequence of ERCC1 mutations on NER function in homozygous individuals could suggest a predominance of transcriptional anomalies in COFS/Cockayne syndrome. For clinical relevant patients, functional study is probably not sufficient to decide if ERCC1 is involved. But among the 3 reported patients with the p.Phe213Leu ERCC1 mutation, clinical findings are highly variable and more patients are needed to precise the phenotype and eventually the genotype-phenotype correlation of ERCC1 mutations.

1335T

MindCrowd: web-based testing of 19,202 individuals suggests family history of Alzheimer's disease is associated with decreased episodic memory performance in young adults. *M.J. Huentelman[1,2], J.J. Corneveaux[1,2], I. Schrauwen[1,2], A.L. Siniard[1,2], J. Peden[1], E. Reiman[4,2], R. Caselli[5,2], E. Glisky[2,3], L. Ryan[2,3].* 1) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 2) Arizona Alzheimer's Consortium, Phoenix, AZ; 3) University of Arizona, Tucson, AZ; 4) Banner Alzheimer's Institute, Phoenix, AZ; 5) Mayo Clinic, Scottsdale, AZ.

Episodic memory is influenced by both heritable and non-heritable components; however, most studies are largely underpowered to detect all but those that exert large effects on the cognitive task of interest. To address these sampling and cohort diversity concerns, we created a web-based (at mindcrowd.org) paired associate episodic memory task (PAL) in an attempt to interrogate a large cohort of individuals that span a morezersus 12 years or less of education for 14/16/20 years of education respectively), marital status (p=0.0002, r=1.3% higher performance in single individuals), handedness (p=0.0006, r=1.7% higher scores in right handed subjects), and the presence of a first-degree relative diagnosed with Alzheimer's disease (AD, p=0.002, r=1.3% higher performance in individuals without a first degree relative with AD). This AD first-degree relative effect is enhanced when individuals under the age of 42 are analyzed separately from those over 42 (p=4.3e-05). Prior work, on smaller cohorts, has demonstrated the influence of the AD risk-associated APOE locus has a minimal effect on cognitive performance in unaffected relatives suggesting that these findings are most likely explained by an as of yet undefined heritable factor(s). After removing the three easiest word pairs in the PAL task, we also noted a significant association above age 70 in individuals with first degree relatives with AD. These findings suggest that heritable factors associated with first degree AD risk exert an effect on cognitive performance even in healthy individuals at young adult ages. Our results demonstrate the effectiveness of web-based recruitment for the study of cognition across a diverse cohort and further highlight the potential utility in identifying genes associated with cognition and their role in AD.

1336S

Phenotypic spectrum associated with PTCHD1 deletions and truncating mutations. *J.B Vincent[1], A. Chaudhry[2], A. Noor[3], B. Degagne[1], K. Baker[4], K.F. Boerkoel[5], L.A. Bok[6], A.F. Studies of submicroscopic genomic copy number variants (CNVs) have identified candidate genes associated with autism spectrum disorders (ASD) such as PTCHD1, NRXN1, SHANK2 and SHANK3. Four families have been reported in literature with exonic deletions of PTCHD1 in individuals with ASD and/or intellectual disability (ID), with minimal description of phenotypic features. Here, we describe the first and largest cohort of individuals with PTCHD1 deletions or truncating mutations. We report phenotype information for 21 males and one female from 15 unrelated families. Eighteen of these individuals have deletions involving PTCHD1 gene while four patients have truncating mutations within the PTCHD1 coding region. Our data suggests that individuals with disruption of PTCHD1may have subtle dysmorphic features including a long hypotonic face, prominent forehead, puffy eyelids and thin upper lip. They do not have a recognizable pattern of associated congenital anomalies or growth abnormalities. They have mild to moderate global developmental delays, and many have prominent behavioural issues. 45.5% of subjects (10/22) have a diagnosis of ASD or have ASD-like behaviours. The only consistent neurological finding in our cohort is orofacial hypotonia and mild motor incoordination. While detailed neuropsychological studies of individuals with PTCHD1 disruptions are needed to better define the cognitive and behavioural phenotype, our findings suggest that hemizygous PTCHD1 loss of function causes an X-linked neurodevelopmental disorder with a strong propensity to autistic behaviours. Because there is limited information so far on the functionality of PTCHD1, we have not included missense mutations in the current analysis, however it would be of interest to see whether patients with missense changes predicted to be damaging and not present in controls individuals also share some of the subtle features reported here. Likewise, patients with deletions of the region upstream of PTCHD1 were not included, as it is currently not known whether these CNVs exert an effect through PTCHD1 or through another mechanism. Again, it will be interesting to evaluate the clinical features in these patients and to compare to the PTCHD1 deletion and truncation patients reported here.

1337M

Report of a Colombian family with new clinical features for autosomal dominant sleepwalking and night terrorsautosomal dominant. *M. Lattig, L. Hernandez.* Biological Sci, Univ de los Andes, Bogota, Colombia.

Sleepwalking and night terrors are sleep disorders classified as excitement Parasomnias. These disorders generate a considerable decree in the individual's quality of life. There is only one study that previously reported an autosomal dominant inheritance pattern in an American family demonstrating linkage with a region between the SNP type markers rs728331 and rs286819 (Licis, et al. 2011). We report second case in a three-generation Colombian family with 18 affected individuals, with a dominant inheritance pattern and reduced penetrance. However, there are some mayor differences between the reported family and ours. Onset prevalence and sex-affected ratio are the mayor phenotypic distinctions. We propose that we may have a new condition that is caused by different genes.

1338T

The transcriptional regulator ADNP links the nBAF (mSWI/SNF) complexes with autism. *F. Kooy[1], G. Vandeweyer[1], C. Helsmoortel[1], A. Van Dijck[1], A.T. Vulto-van Silfhout[2], B.P. Coe[3,4], R. Associazione Oasi Maria Santissima, Troina, Italy; 12) Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, The Netherlands.

Mutations in ADNP were recently identified as a frequent cause of syndromic autism, characterized by deficits in social communication and interaction and restricted, repetitive behavioral patterns. Based on its functional domains, ADNP is presumed transcription factor. The gene interacts closely with the SWI/SNF complex by direct and experimentally verified binding of its C terminus to three of its core components. A detailed and systematic clinical comparison of the symptoms observed in our patients allows a detailed comparison with the symptoms observed in other SWI/SNF disorders. While the mutational mechanism of the first 10 patients identified suggested a gain of function mechanism, an 11th patient reported here is predicted haploinsufficient. The latter observation may raise hope for therapy, as addition of NAP, a neuroprotective octapeptide, has been reported by others to ameliorate some of the cognitive abnormalities observed in a knockout mouse model. It is concluded that detailed clinical and molecular studies on larger cohorts of patients are necessary to establish a better insight in the genotype phenotype correlation and in the mutational mechanism.

1339S

Prenatal and perinatal risk factors for autism spectrum disorders. *A. Anhalt[1], L.R. Simard[1], X-Q. Liu[1, 2].* 1) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 2) Department of Obstetrics, Gynaecology, and Reproductive Sciences, University of Manitoba, Winnipeg, Manitoba, Canada.

Background: Autism spectrum disorders (ASD) are complex neurodevelopmental disorders. Twin studies have shown that ASD is affected by genetic factors; though, discordancy (e.g. only one twin is ASD-affected) was observed in at least 20% of identical twins. Environmental and epigenetic factors may contribute to the discordance in identical twins. Of these, various pre-/perinatal factors (e.g. abnormal/breech presentation) have been associated with ASD. However, previous studies usually do not account for age at first diagnosis or covariate effects, such as birth year or maternal age at birth. **Objectives:** The objectives of this study are to investigate the relationships between: 1) ASD and twinning, 2) pre-/perinatal conditions and twinning, and 3) pre-/perinatal conditions and ASD, while incorporating age at first diagnosis and covariates. **Methods:** We identified families with twins and/or ASD-affected individuals using administrative data from the Population Health Research Data Repository in the province of Manitoba (HIPC#2013/2014-41). We estimated the prevalence of ASD in 5 to 9 year old twins during 5-year periods. We compared the presence of pre-/perinatal complications between twins and singletons. Using survival analysis models, we examined the role of prenatal factors in ASD. **Results:** After applying quality control measures, we identified ~4000 families with at least one twin pair and ~4000 families with at least one ASD-affected individual; >100 of these families included twins and ASD-affected individuals. We estimated the prevalence of ASD in twins to be 0.56% in 1996-2001 and 1.15% in 2001-2006; our prevalence estimates in twins are higher than published estimates for all 5 to 9 year old children during these periods in the province. In our preliminary analyses, twins were more likely than singletons to experience prenatal (OR=1.62; 95% CI=1.32-1.99) or perinatal complications (OR=2.32; 95% CI=2.12-2.54). The overall presence of prenatal conditions was not associated with ASD. Further analyses will examine specific pre-/perinatal conditions and incorporate covariate effects. **Significance:** Identifying potential risk factors for ASD may aid in developing effective methods for the prevention, diagnosis, and treatment of these disorders. Future directions include comparing DNA methylation and gene expression profiles between discordant identical twins and incorporating any significant pre-/perinatal factors in the epigenetic analyses.

Evidence of a Genetic Basis for Developmental Topographical Disorientation. *S.F. Barclay[1], F. Burles[2], K. Rancourt[1], N.T. Bech-Hansen[1], G. Iaria[2].* 1) Department of Medical Genetics and Alberta Children's Hospital Research Institute, University of Calgary, Calgary, Alberta, Canada; 2) Department of Psychology, Hotchkiss Brain Institute & Alberta Children's Hospital Research Institute, University of Calgary, Calgary, Alberta, Canada.

BACKGROUND: The ability to find our way around familiar and foreign environments, known as topographical orientation, is a complex cognitive task involving many brain regions. A variety of brain lesions can result in an inability to navigate, known as acquired topographical disorientation. Distinct from these cases is Developmental Topographical Disorientation (DTD), in which topographical disorientation is present in a subject with no apparent brain structural abnormalities and apparently intact general cognitive skills (Neuropsychologia 47: 30-40, 2009). The defining characteristics of DTD are that individuals (a) have not suffered any brain injury, (b) are not affected by neurological conditions, and (c) have apparently well-preserved cognitive functions; and yet they (d) get lost daily in very familiar surroundings and have done so since childhood. In a study of 120 individuals with DTD (Exp Brain Res. 206: 189-96, 2010), one third of the subjects reported one or more family members with similar orientation difficulties, suggesting that DTD may be a genetic disorder. OBJECTIVE: To collect phenotypic data from families to determine whether there may be a genetic basis for DTD. METHODS: We have developed an online test that includes a diagnostic questionnaire (the Santa Barbara Sense of Direction Scale) and a virtual reality cognitive map test, and have used this online protocol to test and diagnose relatives of participants who report a family history of DTD. RESULTS: We have recruited five families to our study in which at least two members have a DTD phenotype confirmed by our online testing protocol. In total, among these five families, we have tested 30 individuals and confirmed DTD in 13. Each of these families supports an autosomal dominant mode of inheritance, in that every affected individual has an affected parent, and men and women appear to be affected in approximately equal proportions. CONCLUSION: Our evidence suggests that some cases of DTD are genetic, suggesting that there is a heritable basis to the complex cognitive function of navigation.

Genetic Basis of Dynamic Auditory Processing with Application to Reading Ability. *J.F. Flax[1], M.J. Bruni[2], S.L. Wolock[2], C.W. Bartlett[2], L.M. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Childrens, OH.

Acoustic characteristics of human language follow distinct patterns of amplitude and frequency changes. Insensitivity to amplitude modulation (AM) and frequency modulation (FM) of sounds in terms of discrimination of sound and speed of processing has been associated with dyslexia. Given that developmental dyslexia occurs in higher prevalence among children with specific language impairment (SLI) and many children on the autism spectrum also have language impairments with concomitant dyslexia, we proposed that this phenotype may be useful for finding susceptibility loci to these disorders. In this study, the genetic and environmental correlations between AM and FM tasks and reading tasks was examined in SLI and ASD families prior to quantitative trait linkage analysis. Three extended pedigrees ascertained for specific language impairment (SLI) with 117 subjects and 52 families ascertained for both SLI and autism spectrum disorder with 248 subjects were analyzed. The AM and FM perceptual thresholds were determined for 2 Hz, 20 Hz and 240 Hz. Reading was assessed by single word and single non-word reading (Woodcock Battery). Heritabilities and genetic correlations were modeled with SOLAR. Linkage analysis was conducted with the PPL framework. Univariate heritabilities for both AM and FM were found to be significant ($p<.05$). AM and two reading measures showed an environmental correlation ($p=1\times10^{-6}$), but did not have a significant genetic correlation. The opposite was true for FM which showed a genetic, but not environment correlation with the reading measures ($p=0.02$ and $p=0.013$). Linkage analysis established linkage to chromosomes 20 (FM 2Hz PPL=65%). Chromosome 10 showed linkage to both AM 2Hz and FM 2Hz (PPLs of 66% and 33%, respectively) suggesting it is not specific to either AM or FM but may relate to processing slow changes in auditory input. A strong environmental correlation of AM and reading ability indicates that the similarity between these two measures is driven mostly by a common set of environmental experiences, not shared genetics. FM and reading ability appear to have genetic drivers that could be elucidated by future molecular genetics studies examining association of genes in the linked regions. FM perceptual thresholds and the acoustic and perceptual phenotypes they may represent could be useful for identifying additional reading genetic loci.

1342S

Linkage analysis of IQ discrepancy in autism: an attempt to replicate. *A.Q. Nato[1], N.H. Chapman[1], H.K. Sohi[1], R.A. Bernier[2], J.M. Viskochil[3], H. Coon[3], E.M. Wijsman[1,4,5].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 2) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, USA; 3) Department of Psychiatry, University of Utah, Salt Lake City, UT, USA; 4) Department of Biostatistics, University of Washington, Seattle, WA, USA; 5) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

In individuals with autism spectrum disorders, performance IQ (PIQ) is often greater than verbal IQ (VIQ). Linkage analysis of IQ discrepancy (PIQ-VIQ) in University of Washington (UW) nuclear families identified several genomic regions with evidence of linkage, including the strongest evidence on chromosomes (chr) 10p12 and 17 [Hum Genet 2011:129,59-70]. These signals were not apparent when analyses were rerun without IQ data on parents, and attempts to replicate these signals in datasets without parental IQ data (AGRE and AGP) were unsuccessful. Here, we attempt to replicate these two linkage signals in large multi-generational families from Utah (UT), where IQ data are available on multiple generations.

A total of 1,532 individuals were available in 67 UT families, ranging from 4 to 177 people. 631 subjects are typed for 6,044 SNPs, and 509 of these subjects have IQ data. In the UW dataset, Wechsler PIQ was measured by block design and object assembly subscales, while VIQ was measured by vocabulary and comprehension subscales. A diversity of IQ measures were present in the UT families, so we chose single subtests to represent PIQ and VIQ, with an effort to stay as close as possible to original UW measures. For PIQ, we used block design from Wechsler tests and pattern construction from DAS tests (BD). For VIQ, we used vocabulary from Wechsler tests and naming vocabulary or word definition from DAS tests (VOC). Analysis of this revised definition of IQ discrepancy (BD-VOC) in the UW families showed the regions of interest on chr 10 and 17.

We estimated multipoint IBD sharing in the UT families with Markov chain Monte Carlo (MCMC) methods due to the large size of the pedigrees. We used PBAP to select a subpanel of markers to maximize information while using informative markers in linkage equilibrium that were spaced sufficiently for the MCMC methods. We performed variance components linkage analyses in SOLAR, using models allowing for additive effects with and without dominance in both the major gene and polygenic components. Using SNPs selected from the 6k panel, we found a moderate lod score (~0.75) on chr 10p12, in addition to a larger lod score 20 cM away. The chr 17 signal did not replicate. Analyses with more genotyped individuals, using SNPs from a 750k chip, are underway.

1343M

Identifying endophenotypes associated with Age-related Macular Degeneration in the Amish. *M. Pericak-Vance[1], R.J. Sardell[1], J.N. Cooke Bailey[2], W. Cade[1], L.D. Adams[1], R. Laux[2], D. Fuzzell[2], L. Reinhart-Mercer[1], L. Caywood[1], D. Dana[3], A.S. Bowman[3], M.G. Nittala[4], S. Sadda[4], J.L. Haines[2], D. Stambolian[3].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Departments of Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA; 4) Doheny Eye Institute, Los Angeles, CA.

Age-related macular degeneration (AMD), a leading cause of blindness in older adults, is a complex disease with several known genetic and environmental risk factors. However, a substantial portion of heritability in disease risk remains unexplained. In addition to reflecting unidentified rare genetic variants, this missing heritability may also be an artifact of challenges in defining the complex phenotype. Ocular Coherence Tomography (OCT) imaging quantifies fine-scale features of AMD, potentially allowing the identification of endophenotypes associated with the disease. We ascertained both genetic samples and detailed phenotype data via OCT from both affected and unaffected related individuals from Amish populations across Pennsylvania, Ohio and Indiana. The Amish provide an excellent opportunity to analyze the heritability of complex traits given their large nuclear families, while their relatively uniform genetic and environmental background increases power to detect rare genetic variants. We sampled 51 individuals (22 males, 29 females) from 19 Amish families with mean age of 73 (range 49-99). Approximately 8% of individuals had no AMD, 51% had early AMD, 25% intermediate AMD, 9% geographic atrophy and 6% advanced neovascular AMD. In preliminary analyses, we assessed the extent to which the AMD phenotype may be independent of genotype by measuring the correlation of features between left and right eyes. We defined the phenotype using both traditional presence/absence of drusen and quantitative OCT parameters (drusen area and volume). Across all 51 individuals, presence of drusen was strongly correlated between left and right eyes; 94% of individuals were concordant between eyes for presence of small drusen, 86% for medium drusen, and 90% for large drusen. Drusen area in both a 3mm circle (Spearman's r_s=0.48) and a 5mm circle (r_s=0.72), and drusen volume in a 3mm (r_s=0.34) and a 5mm circle (r_s=0.72) were also correlated between eyes. These results suggested individual repeatability of quantitative phenotypic traits. OCT parameters were also correlated with the traditional Age-Related Eye Disease Study (AREDS) scale AMD grade (r_s=0.42-0.57); correlation coefficients did however suggested additional variation in the relationship, confirming that OCT parameters may help to define the disease process. Further analyses on the heritability of quantitative AMD traits may therefore enable the identification of endophenotypes associated with this disease.

1344T

***P54NRB/NONO* mutations link intellectual disability to impaired gene expression and altered circadian rhythm.** *M. LANGOUET[1], M. RIO[1,2], S. MOUTTON[1], K. SIQUIER-PERNET[1], C. BOLE-FEYSOT[3], N. CAGNARD[4], P. NITSCHKE[4], A. MUNNICH[1,2], D. MIRCSOF[5], P. SEEBECK[6], L. GASPAR[5], S. BROWN[5], J. AMIEL[1,2], L. COLLEAUX[1].* 1) Imagine Institute, Necker-enfants malades hospital, Paris, France; 2) Genetic Service, Necker-enfants malades hospital, AP-HP, Paris, France; 3) Genomic platform, Imagine Institute, Necker-enfants malades hospital, Paris, France; 4) Bioinformatic platform, Imagine Instiute, Necker-enfants malades hospital, Paris, France; 5) Chronobiology and sleep research group, Institute of pharmacology and toxicology, University of Zurich; 6) Center of integrative rodent physiology, University of Zurich.

We report on two unrelated patients presenting a novel syndromic XLID featuring slender build-macrocephaly, scoliosis, severe elocution disability with mandibulofacial dysostosis and, a thick corpus callosum at brain MRI. High-throughput sequencing identified two distinct null mutations in the *P54NRB/NONO* X-linked gene: c.1131G>A; p.Ala377Ala and c.1394dup; p.Asn466Lysfs*13. P54NRB/NONO belongs to the DBHS (Drosophila Behaviour Human Splicing) protein family with three members in mammals i.e. P54NRB/NONO, PSPC1, and PSF/SFPQ. DBHS proteins are nuclear proteins implicated in multiple aspects of RNA production and processing, as well as RNA surveillance via binding and retaining hyper-edited RNA in subnuclear bodies named paraspeckles. In addition, they serve as chromatin-regulating transcriptional cofactors within the mammalian circadian clock. Finally, PSF and P54NRB have been implicated in dendritic RNA transport. We demonstrated that both mutations lead to complete absence of the P54NRB/NONO protein and over-expression of the two other DBHS proteins in patients' cells. Whole transcriptome comparison of patients' fibroblasts vs controls reported global deregulation of gene expression. Moreover, clock gene expression analysis using reporter assays revealed reduced circadian clock amplitude in these cells. Finally, CT scans of P54nrb/Nono-deficient mice described a dramatic flattened nose phenotype that may mimic the severe malar hypoplasia observed in patients. Collectively, our data identify *P54NRB/NONO* as a new neurodevelopmental disease gene and support the role of DBHS proteins in brain development and function through a clinically recognizable *NONO*-deficiency syndrome. Finally, they further argue that altered circadian clock function may contribute to the pathogenesis of intellectual disability.

1345S

Gene expression analysis of methamphetamine addicted and schizophrenic patients in correlation with their psychiatric symptoms. *A. Haghigatfard[1], M. Amini faskhodi[2].* 1) Department of biology, Science and Research Branch, Islamic Azad University, Tehran, Iran; 2) Department of biology, Tehran medical Branch, Islamic Azad University, Tehran, Iran.

Methamphetamine is a neurotoxin and potent psycho-stimulant of the phenethylamine and amphetamine classes that is used to treat attention deficit hyperactivity disorder (ADHD) and obesity. Schizophrenia is a chronic multifactorial and multigenic , disabling psychiatric disorder that affects about 1% of the population worldwide. Symptoms of schizophrenia including positive, negative and cognitive deficits. majority of methamphetamine addicted have the same psychiatric symptoms like hallucination and bizarre behavior. Researches suggesting that some parts of brain in schizophrenic patients and methamphetamine addicts are neurodegenrated but the mechanisms of this degeneration is not clear. gene expression analysis could help to understand the molecular mechanisms of this neurodegeneration and explain the cause of same psychiatric symptoms in these two groups .this researches also can help to understand the pathogenesis of schizophrenia and methamphetamine effect on brain. We have studied Methamphetamine affects on gene expression in individuals who are addicted (several time in one year). also 50 schizophrenic patients with same age. blood samples collected from 50 addicted ,50 schizophrenic patients and 50 normal person in the same range of age(23-30years old). RNA of whole blood extracted by column method kit . cDNA synthesized and expression of 3000 gene investigated with DNA microarray technique. expression of 12 gene had been affected in patients and addicts . over expression of NDUFS1 and NDUFS2 , and decreasing of expression in 5HT2a,DRD2,DRD3,BDNF,DISC,NRG1,MAOA,bcl2,NDUFV1 and NDUFV2 . Over expressions were significant in schizophrenics & addicts in compare with normal but Over expressions were significant in addicts in compare with schizophrenic patients. Microarray results for two gene NDUFS1 and NDUFS2 confirmed by Real Time PCR syber green method and results analyzed by SPSS and Bonferroni statistical software. In our samples a significant affects of Metamphetamin and schizophrenia on expression of several genes especially in mitochondria complex 1 subunits genes have been detected.It seems that the mechanism of neurodegeneration in both group is the same but rate of degeneration is higher in methamphetamine addicts . May be that's why in PANSS psychiatric test the negative symptoms were in same scores for both group but positive symptoms including hallucination and exaggerated behaviors got higher scores in addicts.

1346M

Early-onset Behr syndrome due to compound heterozygous mutations in OPA1. *P. Amati-Bonneau[1], E. Colin[1], F. Oca[1], M. Ferré[1], A. Chevrollier[1], N. Gueguen[1], V. Desquiret-Dumas[1], S. N'Guyen[2], M. Barth[1], X. Zanlonghi[3], M. Rio[4], I. Desguerre[5], C. Barnerias[5], M. Momtchilova[6], D. Rodriguez[7], A. Slama[8], G. Lenaers[9], V. Procaccio[1], P. Reynier[1], D. Bonneau[1].* 1) Unité Mixte de Recherche CNRS 6214 - INSERM 1083, Département de Biochimie et Génétique, Centre Hospitalier Universitaire, Angers, France; 2) Département de Neuropédiatrie, Centre Hospitalier Universitaire, Angers, France; 3) Clinique Sourdille, Nantes, France; 4) AP-HP, Service de Génétique Médicale, Hôpital Necker, Paris, France; 5) AP-HP, Service de Neuropédiatrie, Hôpital Necker, Descartes University Paris O5, Paris, France; 6) AP-HP, Service d'Ophtalmologie, Hôpital Armand Trousseau, HUEP, Paris France; 7) AP-HP, Service de Neuropédiatrie & Centre de Référence de Neurogénétique, Hôpital Armand Trousseau, HUEP; UMPC Univ Paris 06; Inserm U1141; Paris, France; 8) Laboratoire de Biochimie, AP-HP Hôpital Kremlin-Bicêtre, Paris, France; 9) Institut des Neurosciences de Montpellier, INSERM U1051. Hôpital Saint Eloi, Montpellier, France.

The Behr syndrome (MIM#210000) is characterized by the association of early-onset optic atrophy with spinocerebellar degeneration resulting in ataxia, pyramidal signs, peripheral neuropathy and developmental delay. Although the disorder is believed to be inherited in an autosomal recessive manner, it may be clinically heterogeneous, encompassing several genetic aetiologies and patterns of inheritance. Recently, an adult-onset Behr-like syndrome, including optic atrophy and ataxia, was reported in two brothers carrying a heterozygous mutation in the optic atrophy type 1 (OPA1) gene. Heterozygous mutations in OPA1, a gene encoding for a dynamin-related GTPase involved in mitochondrial dynamics and mtDNA maintenance, are the main causes of autosomal dominant optic atrophy (DOA). In DOA, the optic neuropathy occurs insidiously in the first decade of life leading to various levels of visual impairment. As many as 20% of patients with DOA exhibit extra-ocular neuromuscular signs including deafness, chronic progressive external ophthalmoplegia, ataxia, peripheral neuropathy and mitochondrial myopathy with multiple mtDNA deletions, also called the "DOA plus" phenotype. Apart from these autosomal dominant forms, only a few syndromic cases have so far been reported with compound heterozygous OPA1 mutations suggestive of either recessive or semi-dominant patterns of inheritance. However, the clinical spectrum of these emerging double-mutant OPA1-related disorders remains to be characterized. We here report four cases of children affected by the Behr syndrome associated with compound heterozygous OPA1 mutations. The four unrelated children are affected with a strikingly similar early-onset neurological syndrome associating severe visual impairment due to optic atrophy (4/4), cerebellar ataxia with cerebellar atrophy evidenced by brain MRI (4/4), peripheral neuropathy (4/4), digestive involvement (2/4) and deafness (1/4).These results confirm the importance of searching a compound heterozygosity for OPA1 in severe paediatric cases of complicated optic neuropathy.

1347T

Association of common variants in *CCM* genes with disease severity in familial Cerebral Cavernous Malformations Type 1. *H. Choquet[1], L. Pawlikowska[1,2], J. Nelson[1], C.E. McCulloch[3], A. Akers[4], B. Baca[5], Y. Khan[5], B. Hart[6], L. Morrison[5,7], H. Kim[1,2,3], Brain Vascular Malformation Consortium (BVMC).* 1) Department of Anesthesia and Perioperative Care, University of California San Francisco (UCSF), San Francisco, CA., USA; 2) Institute for Human Genetics, UCSF, San Francisco, CA, USA; 3) Department of Epidemiology and Biostatistics, UCSF, CA, USA; 4) Angioma Alliance, Durham, NC, USA; 5) Department of Neurology, University of New Mexico (UNM) , Albuquerque, NM, USA; 6) Department of Radiology, UNM, Albuquerque, NM, USA; 7) Department of Pediatrics, UNM, Albuquerque, NM, USA.

Objective: Familial cerebral cavernous malformation (CCM) is an autosomal dominant disease caused by mutations in *CCM1*, *CCM2* or *CCM3* genes, and characterized by multiple brain lesions that often result in intracerebral hemorrhage (ICH), seizures, and neurological deficits. Carriers of the same genetic mutation can present with variable symptoms and severity of disease, suggesting the influence of modifier factors. As the three CCM proteins interact and can form a CCM1-CCM2-CCM3 protein complex in vitro, the purpose of this study was to investigate whether common variants in *CCM* genes modify disease severity, as manifested by ICH and greater total or large lesion counts, in a genetically homogenous group of CCM1 patients. Methods: Hispanic CCM1 subjects (n=188) harboring the common Hispanic mutation (CHM, Q455X) in *CCM1* were analyzed. Clinical assessment and cerebral MRI were performed at enrollment to determine ICH and lesion counts. Samples were genotyped on the Affymetrix Axiom Genome-Wide LAT1 Human Array. We analyzed 25 common variants (MAF≥1%) in the 3 *CCM* gene loci for association with ICH as well as with total and large (≥5 mm in diameter) lesion counts. Gene loci were defined as ± 10 kb upstream and downstream of the sequence. Results: At baseline, 30.3% of CCM1-CHM subjects had ICH, with a mean ± SD of 60.1 ± 115.0 (range 0 to 713) for total lesions and 4.9 ± 8.7 (range 0 to 104) for large lesions. The minor allele of rs7777835 at the *CCM2* locus was modestly associated with fewer number of total lesions (22% fewer, P= 0.037) at baseline, independent of age and gender and adjusted for family structure. Common variants in *CCM1* and *CCM3* were not associated with ICH nor with total or large lesion counts. Conclusions: Common variants in the 3 *CCM* genes do not seem to contribute strongly to the variability of CCM1 disease severity; however, larger studies are needed to confirm these findings.

Change of neuronal gene expression by administration of various anti-depressant in primary neocortical neurons. *N.A. Nguyen, K. Miyake, T. Kubota.* Epigenetic Medicine, University of Yamanashi, Chuo, Yamanashi, Japan.

Anti-depressants are widely used for treatment of depression. Among many anti-depressants, imipramine, a representative anti-depressant, is recently known to have an effect to restore the expression of Brain-derived neurotrophic factor (*BDNF*) gene, which is decreased in the patients with depression, by increasing histone acetylation. However, it is largely unknown whether other anti-depressants have similar epigenetic effect to change gene expression. To address this question, we examined the effect of five anti-depressants (imipramine, citalopram, fluoxetine, duloxetine, amitriptyline) to genes associated with depressive status. As a result, quantitative RT-PCR assay showed that all five anti-depressants increased *BDNF* expression by 48-hour treatment in primary neocortical neurons in mice, but did not increase glucocorticoid receptor (*GR*) gene expression, which is known to be decreased by mental stress during infancy in hippocampus region in mice. These results indicate that one of major mechanism among anti-depressants may be restoration of *BDNF* expression in the brain. We are currently performing comprehensive gene expression and histone modification analyses to know the differences of effect between the anti-depressant. Our study will shed a new insight in understanding of the molecular and epigenetic mechanism of anti-depressants.

Premorbid psychiatric diagnosis in young persons with 22q11.2 deletion syndrome who later developed schizophrenia. *E. Chow[1,2,3], A.S. Bassett[2,3,4].* 1) Clinical Gen Service, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 2) Clinical Gen Res Prog, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 3) Dept of Psychiatry, Univ of Toronto, ON, Canada; 4) Dalglish Hearts & Minds Clinic for Adults with 22q11DS, UHN, Toronto, ON, Canada.

Background: 22q11.2 deletion syndrome (22q11.2DS) is a common human microdeletion syndrome known to be associated with high rates of psychiatric disorders. Attention deficit hyperactivity disorder (ADHD) has been found in up to 60% of children with 22q11.2DS and approximately 25% of adults with the syndrome suffers from schizophrenia. Mood and anxiety disorders are also common. There is however limited literature on the predictors of schizophrenia in this high risk population. Objective: To investigate the relationship between premorbid non-psychotic disorders and the subsequent development of schizophrenia in a group of young individuals with 22q11.2DS. Methods: Twenty-five children and adolescents with 22q11.2DS (10 M, 15 F; mean age at first assessment=14.4 years, SD=3.2 years) at a psychiatric genetics clinic who were found not to have a DSM-IV psychotic disorder on assessment were followed prospectively for the development of psychosis on an average of 10.8 years (SD 3.7 years) as part of a research study. All subjects were at least 20 years of age at last assessment. Six subjects (23.1%) have developed schizophrenia or schizoaffective disorder (SZD) so far, with an average age at onset of 19.3 years (SD=3.1 years). Rates of lifetime (for the non-psychotic group) or pre-morbid (at least one year prior to onset of SZD) non-psychotic psychiatric diagnosis were compared between the two psychosis outcome groups. Results: Subjects who eventually developed SZD had similar rates of lifetime/premorbid ADHD, major depressive disorder, anxiety disorder, substance use disorder or an intellectual disability. They also had similar rates of prodromal positive and negative symptoms. However, subjects who eventually developed schizophrenia had a significantly higher rate of oppositional defiant disorder than those who remained psychosis-free (50.0% vs 5.3%, p<0.01). Conclusions: Although the sample size is small, results from this study would suggest that behavioural problems in childhood and adolescence may be predictive of the subsequent development of schizophrenia in 22q11.2DS, as for schizophrenia in the general population. Further research into this area is needed.

1350T

Association between advanced paternal age and early onset of schizophrenia among sporadic cases. *S. Wang[1], L. Yeh[2], C. Liu[3], C. Liu[3], T. Hwang[3], M. Hsieh[3], Y. Chien[3], Y. Lin[3], S. Chandler[4], S. Glatt[5], N. Laird[6], S. Faraone[5], M. Tsuang[4], H. Hwu[3], W. Chen[1].* 1) Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan; 2) Department of Healthcare Administration, College of Health Science, Asia University, Taichung, Taiwan; 3) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 4) Center for Behavioral Genomics, Department of Psychiatry, University of California San Diego, La Jolla, California, USA; 5) Departments of Psychiatry and Behavioral Sciences and Neuroscience and Physiology, Medical Genetics Research Center, SUNY Upstate Medical University, Syracuse, New York, USA; 6) Department of Biostatistics, Harvard University, Boston, Massachusetts, USA.

Background: Advanced paternal age is associated with increased risk of schizophrenia, and the association has been attributed to the increased risk of de novo mutations in paternal germ cells. Age at onset is an important component phenotype for schizophrenia. Patients with early-onset schizophrenia have a higher incidence of structural genomic variation than those with later onset. If early-onset schizophrenia could be associated with genetic factors, the increased number of de novo mutations along with paternal age could be associated with not only the elevated risk of schizophrenia but also the earlier onset of the disorder. Aim: This study aims to explore whether increased paternal age is associated with early onset in schizophrenia among sporadic cases. Methods: A total of 2450 patients with schizophrenia with no first-degree relatives affected with psychiatric disorders were recruited from the Schizophrenia Trio Genomic Research in Taiwan (S-TOGET) project. Early onset was defined as those below 18 years of age of the first psychotic episode. The association between paternal age and early onset in schizophrenia was estimated by a logistic regression model adjusting for confounders. Results: A U-shape relationship was observed between paternal age and proportion of early onset in schizophrenia. The proportion of early onset for patients with paternal age < 20 years, about 30%, is larger than that for patients with paternal age of 20-25 years, about 20%. As paternal age increased over 25, increased paternal age exhibited a linear increase in the proportion of early onset in schizophrenia: increased to about 35% for a paternal age between 25-30 and to about 45% for a paternal age greater than 45, with a statistical significance for the trend test adjusting for maternal age and other potential confounders. Conclusions: These findings indicate that paternal age greater than 25 and younger than 20 were both associated with early onset in schizophrenia among sporadic cases. The associations of advanced paternal age with both increased susceptibility to schizophrenia and early onset in schizophrenia are consistent with the rate of increases in spontaneous mutations in sperm as men age.

1351S

Cyclooxygenase-2 non-selective inhibitor prior to pentylenetetrazole-induced seizures increases the latency to seizure onset and decreased the number of seizures in zebrafish. *P. Barbalho, H.M Gomide, D.M Nakata, I.L Cendes, C.V Maurer-Morelli.* Department of Medical Genetics, State University of Campinas (UNICAMP)), Campinas, Sao Paulo, Brazil.

Introduction: Neuroinflammatory response may play a role in the pathophysiology of epilepsy. It has been demonstrated that cyclooxygenase-2 (COX-2) increases in response to an insult, as seizure. The aim of this study was investigated the effects of indomethacin (a COX-2 non-selective inhibitor) prior to pentylenetetrazole (PTZ)-induced seizure on mRNA expression of both cox-2 genes in zebrafish larvae brain. Methods: This study was approved by Animal Ethical Committee/UNICAMP (# 3098-1). At six dpf, zebrafish larvae were separated into Seizure+Indomethacin (SG+Indo; n=5) and Control+indomethacin (CG+indo; n=5) groups and incubated in indomethacin solution (110µg/ml) for 24 hours. After the incubation, animals from SG+Indo were exposed to 15mM PTZ during 20 minutes and the number of seizure-like behavior and latency to seizure onset (Stage 3 of seizure) were analyzed. Animals from CG+indo were handled in PTZ-free water. Other groups: SG - only exposed to PTZ (n=5) and CG- control (n=5) were also investigated. Each sample was composed by pooling 20 heads. Immediately after seizure, animals were anesthetized and their heads collected for reverse transcriptase quantitative-PCR amplifications that were carried out in triplicates with ef1α as endogenous controls using TaqManTM System. The relative quantification (RQ) was calculated by the equation RQ=2 -$\Delta\Delta$CT. Statistical analyses were performed by Mann-Whitney test with p<0.05. Results: The mean±SEM obtained were: (ii) cox2a: SG+indo 0.5±0.06 vs SG 1.3±0.12 (p=0.004); (ii) cox2b: SG+indo 0.73±0.06 vs SG 1.73±0.18 (p=0.004). Interestingly, when exposed to PTZ, animals pre-treated with indomethacin showed longer latency to reach seizure: SG+indo: 4.6±0.33 vs SG: 2.92±0.17 (p=0.0004) and presented less number of seizure-like behavior response when compared to SG (SG+indo: 11.2±1.5 vs SG: 38.16±4.5; p=0.003). Conclusion: Indomethacin treatment prior to PTZ-induced seizure reduced the cox2a and cox2b mRNA expression levels compared with non-treated animals (SG). Besides, the pharmacological cox-2 inhibition increased the latency to seizure onset and significantly decreased the number of seizures during PTZ exposure compared to SG. Our findings support evidence that zebrafish is a valuable model for further investigations of the main role of inflammation in seizure, as well as a valuable model for anti-inflammatory screening of compounds that are potentially therapeutic for seizures. Support: FAPESP and CNPq.

miR-1202: A Primate Specific and Brain Enriched miRNA Involved in Major Depression and Antidepressant Treatment. *J.P. Lopez[1,2,3], R. Lim[4], C. Cruceanu[1,2,3], L. Crapper[2], C. Fasano[3], B. Labonte[2], G. Maussion[2], J.P. Yang[2], V. Yerko[2], E. Vigneault[3], S. El Mestikawy[3], N. Mechawar[2], P. Pavlidis[4], G. Turecki[1,2,3].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec; 3) Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 4) Department of Psychiatry, University of British Columbia, Vancouver, B.C, Canada.

Major depressive disorder (MDD), is a prevalent mood disorder that associates with differential prefrontal brain expression patterns. Treatment of MDD includes a variety of biopsychosocial approaches, but in medical practice, antidepressant drugs are the most common treatment for depressive episodes, and not surprisingly, they are among the most prescribed medications in North America. While they are clearly effective, particularly for moderate to severe depressive episodes, there is important variability in how individuals respond to antidepressant treatment. Failure to respond has important individual, economic and social consequences for patients and their families. Several lines of evidence demonstrate that genes are regulated through the activity of microRNAs (miRNAs), which act as fine-tuners and on-off switches in gene expression patterns. Here we report on complementary studies using postmortem human brain samples, cellular assays and samples from clinical trials of depressed patients, and show that miR-1202, a miRNA specific to primates and enriched in the human brain, is differentially expressed in depressed individuals. Additionally, miR-1202 regulates the expression of the Metabotropic Glutamate Receptor 4 (GRM4) gene and predicts antidepressant response at baseline. These results suggest that miR-1202 is associated with the pathophysiology of depression and is a potential target for novel antidepressant treatments.

The NINDS Repository Biomarker Discovery Collection is a Public Resource for Neurodegenerative Disorders. *G. Balaburski[1], S. Heil[1], A. Green[1], C. Kopil[3], M. Fraser[3], M. Sutherland[2], K. Gwinn[2], R. Corriveau[2], C. Tarn[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD; 3) Michael J Fox Foundation for Parkinson's Research, NY, NY.

Neurological diseases present numerous challenges: they are devastating to patients and their families, present unique research, diagnostic and clinical difficulties and are an increasing burden on health care systems. Biomarkers for diagnosis, disease onset, disease progression and therapeutic response are urgently needed to improve research, as well as clinical and diagnostic outcomes of patients with neurodegenerative diseases such as Parkinson's and Huntington's disease. The mission of the NINDS Repository is to provide genetic support for scientists investigating pathogenesis of the central and peripheral nervous systems through submission and distribution of biomaterials and de-identified clinical data. Moreover, the NINDS Repository facilitates identification and validation of biomarkers for neurological diseases by virtue of being the centralized facility for storage, processing and distribution of biofluids (cerebrospinal fluid, plasma, serum, whole blood, urine) and nucleic acids (DNA and RNA) extracted from whole blood. The Repository minimizes pre-analytical variables by establishing unified standards for sample collection and shipping, securely stores samples with real time monitoring and recording systems, performs standardized laboratory processing with validated operating procedures and maintains the highest levels of quality control and quality assurance. To further incite the investigation and discovery of novel biomarkers the NINDS Repository is establishing large, long term longitudinal collections of biological samples obtained from affected and neurologically healthy individuals, as well as from individuals with known genetic mutations. Currently, the NINDS Repository collects samples under either NINDS sponsored biomarker initiatives as well as in collaboration with partners such as the Michael J. Fox Foundation. Current biomarker discovery studies include: Parkinson's Disease Biomarkers Program (PDBP), Neurobiological Predictors of Huntington's Disease study (PREDICT-HD), Frontotemporal Dementia MAPT Carrier Study and the Fox Investigation for New Discovery of Biomarkers (BioFIND). Thus, the NINDS Repository is a public resource that freely distributes biomaterials for research, discovery and validation of biomarkers for neurological disorders. Samples are available upon request from the NINDS Repository web catalog (http://ccr.coriell.org/NINDS), or via NIH-sponsored resources with links to the online catalog.

1354S

SP1 inhibitors as modulators of APP and BACE1 levels in human cells: A novel drug target in Alzheimer's disease. *B.L. Bayon[1,2], J.A. Bailey[2], B. Ray[2], K. Sambamurti[3], N.H. Greig[4], D.K. Lahiri[1,2].* 1) Medical & Molecular Genetics, Indiana University School of Medicine , Indianapolis, IN; 2) Laboratory of Molecular Neurogenetics, Department of Psychiatry, Neuroscience Research Building, Indiana University School of Medicine, 320 W 15th St. Indianapolis, IN, USA; 3) Department of Neurosciences, Medical University of South Carolina, Charleston, South Carolina, USA; 4) National Institute on Aging, National Institutes of Health Translational Gerontology Branch, Intramural Research Program, District of Columbia, USA.

According to the amyloid hypothesis, abnormalities in AD are believed to result from the over-production of amyloid-β peptide (Aβ), a product of Aβ precursor protein (APP). Dysregulation of proteins involved in the production of Aβ such as APP and β-site APP-cleaving enzyme (BACE1), may contribute to excessive Aβ deposition. The rate-limiting step in the production of Aβ is the processing of APP by BACE1. Understanding how expression of these proteins is regulated will eventually expose new drug targets. The transcription factor specificity protein 1 (SP1) coactivates the expression of the APP and BACE1 gene. We tested SP1-mediated regulation of APP with Mithramycin A, a selective inhibitor of SP1, and Tolfenamic acid, an inducer of SP1 degradation in human glioblastoma cells U373 and in human neurosphere (NSP) cultures. NSPs were cultured in Neurocult basal media plus differentiation supplement (Stem Cell Technologies). U373 (ATCC) cells were cultured and transfected, and Western blot analysis was performed as previously described (Long et al., JBC-2014). Mithramycin A (Santa Cruz) and Tolfenamic acid (Sigma Aldrich) were prepared in 1 μM and 5 μM doses. After 72-hour treatment or transfection, cell viability was assessed using CTG assay (Promega), and protein lysates made. Western blot analysis reveals a significant decrease in the expression of APP in U373 and NSP treated with Mithramycin A. NSP treated with Mithramycin A also exhibit a decrease in BACE1 expression. Treatment with Tolfenamic acid, however, does not significantly decrease APP or BACE1 expression in either cell model. APP siRNA effectively knocks down APP expression in U373 and NSP cultures. BACE1 siRNA and SP1 siRNA did not significantly affect APP levels. CTG showed no significant changes in cell viability among treatment groups in U373 and NSP. We show that expression of APP is decreased after treatment with the SP1 inhibitor Mithramycin A in both U373 and human neurospheres cells. However, APP expression is not affected by treatment with Tolfenamic acid, perhaps due to the differences in the mechanisms between these SP1-inhibiting drugs. We also show that transfection with siRNAs can effectively change the expression of APP and BACE1 in both the human cells. It is essential to ascertain whether drugs or small RNAs targeting this transcription factor could be used to effectively decrease amyloid load and possibly the symptoms of AD in patients.

1355M

Association of Serotonin 2c Receptor Polymorphisms with Antipsychotic Drug Response In Schizophrenia. *J. Li[1], H. Hashimoto[2], H.Y. Meltzer[1].* 1) Psychiatry, Northwestern University Feinberg School of Medicine, Chicago, IL; 2) Graduate School of Pharmaceutical Sciences, Osaka University, Japan.

The serotonin (5-HT)2C receptor (HTR2C) has been implicated in schizophrenia and response to antipsychotic drugs (APDs) through its regulatory effect on dopamine release, interaction with scaffolding proteins at the synapse, and other unknown mechanisms. Evidence from genetic association studies also implicates HTR2C in a variety of neuropsychiatric diseases. We tested the association between HTR2C polymorphisms, Cys23Ser, -759C/T, and -697G/C, and treatment response in 171 schizophrenic patients after treatment with APDs, mostly clozapine, for 6 months. We confirmed that -759C/T, but not Cys23Ser, was a *cis*-eQTL for HTR2C according to Braincloud data, an integrated database of genome-wide gene expression and genetic control in human postmortem dorsolateral prefrontal cortex (DLPFC) of normal subjects. Ser23 was significantly associated with treatment response at 6 months (positive symptoms, $X^2 = 7.540$, $p = 0.01$; negative symptoms, $X^2 = 4.796$, $p = 0.03$) in male, but not in female patients. Haplotype analysis showed that -759C-Ser maintained the same level of significant association with positive symptom improvement ($X^2 = 6.648$, $p = 0.01$) but additive association with negative symptom improvement ($X^2 = 6.702$, $p = 0.01$). Logistic regression after controlling for covariates showed these haplotypic associations remained significant with the same direction. Finally, a meta-analysis was performed on six studies with accessible genotyping data for rs6318 and treatment outcome. The overall odds ratio under fixed effect model is 2.00 (95%CI, 1.38-2.91, $p = 0.0003$) and under random effect model is 1.94 (95%CI, 1.27-2.99, $p = 0.0024$). In conclusion, HTR2C polymorphisms were associated with treatment response to clozapine in male schizophrenic patients. HTR2C could be relevant to a broad range of the psychopathology which responds to clozapine in schizophrenia.

First case of Spinocerebellar Ataxia type 1 in a Mexican female. *I. Cervantes[1], C.M. Morán[2], J. Sanchez[2], G. Castañeda[4], D.M. Sanchez[5], M.H. Orozco[1,2], N.Y Nuñez[1], J.A. Alcaraz[1,2], I.P. Dávalos[3], N.O. Dávalos[1], S. Ramírez[6], J. Corral[7], H. San Nicolás[7], L. de Jorge[7], V. Volpini[7], D. García[1].* 1) Instituto de Genética Humana, CUCS, Doctorado en Genética Humana Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) División de Medicina Molecular, CIBO, CMNO, IMSS, Guadalajara, Jalisco; 3) División de Genética, CIBO, CMNO, IMSS, Guadalajara, Jalisco; 4) Servicio de Neurocirugía, UMAE Hospital de Especialidades, CMNO, Jalisco; 5) Psicología, ITESO, Tlaquepaque, Jalisco; 6) Universidad de la Sierra Sur, Mihuatlán de Porfirio Dïaz, Oaxaca; 7) Centro de Diagnóstico Genético Molecular, IDIBELL, Barcelona, España.

Introduction. Spinocerebellar ataxia type 1 (MIM ID #164400) is an autosomal dominant disease caused by expansion of the CAG trinucleotide repeats in the ataxin-1 gene. Clinically characterized by cerebellar signs, upper motor neuron signs and extensor plantar responses, scanning speech, incoordination, slow motor-nerve conduction and choreiform movements in some instances. Material and Methods. A female aged 24 year-old was studied clinically due to SCA with 10 years of evolution which presented gait ataxia, dysmetria, dysarthria, disdiadochokinesis, scanning speech, loss of deep tendon reflexes, mild hypotonia, hypermetric bilateral saccades and normal ocular fundus; the electromyography reported sensorimotor polyneuropathy with segmental demyelination. Brain MRI scans revealed olivopontocerebellar atrophy. Laboratorial studies were performed with 5mL of peripheral blood were used to isolate patient's DNA by GeneCatcher Kit (invitrogen). The molecular analysis was made by PCR. Results. Molecular analysis revealed a number of expansion repeats of 32/*exp. Discussion. In previous studies done in Mexican population there was not detected any patient with SCA1, so its frequency is unknown. This is the first time that is described a patient affected by SCA1 in Mexico.

1357S

Allelic distribution of the normal ATXN10 gene in a sample of a Peruvian Amerindian population: an exploratory study. *D. Veliz-Otani[1], O. Ortega[1], M. Cornejo-Olivas[1,2], K. Milla-Neyra[1,3], K. Espinoza-Huertas[1], S. Lindo-Samanamud[1], M. Inca-Martinez[1], V. Marca[1], I. Tirado[1,3], M.L. Saraiva-Pereira[4,5], L. Jardim[4,5], P. Mazzetti[1,6], Rede Neurogenetica.* 1) Neurogenetics Research Center, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 2) Northern Pacific Global Health Research Training Consortium, Bethesda, MD; 3) Genetics and Biotechnology School, Universidad Nacional Mayor de San Marcos. Lima, Peru;; 4) Laboratório de Identificação Genética - Centro de Pesquisa Experimental e Serviço de Genética Médica, HCPA;; 5) Programa de Pós-Graduação em Genética e Biologia Molecular, UFRGS; 6) School of Medicine, Universidad Nacional Mayor de San Marcos. Lima, Peru.

Background: SCA10 is caused by an ATTCT abnormal expansion (locus 22q13.31.) of the *ATXN10* gene , and has been diagnosed only in patients from North and South Americas. Up to now, for instance, we have diagnosed SCA10 in 16 Peruvian SCA families, becoming the most frequent dominant ataxia reported in this population, which has an average of 70% of Amerindian ancestry. Normal alleles range from 10 to 29 ATTCT repeats, and the mutant ones are from 800-4500 ATTCT repeats. Large normal alleles of other SCA-related genes seem to be prone to expanding to a pathogenic range, acting as natural sources of *de novo* mutations. **Objective**: To describe the normal allelic distribution as well as the frequency of large normal alleles (≥17 repeats) in the *ATXN10* gene in healthy controls of an Amerindian "Quechua" community. **Methods**: Observational exploratory study collecting DNA samples from 49 healthy individuals from an Amerindian "Quechua" population from Puno, Peru. ATTCT repeats of the *ATXN10* gene were genotyped by conventional PCR followed by polyacrylamide gel electrophoresis; ATTCT repeat counting was carried out by means of a lineal model based on normal controls of known repeat size previously measured by capillary eletrophoresis. The probability of sampling low-frequency alleles was estimated using Minsage software. **Results**: We included a total of 98 alleles from 49 individuals. The sample size yielded a 95% probability of sampling an allele with 5.8% population frequency under H-W equilibrium or 10.1% frequency assumming no H-W equilibrium. The allele distribution ranged from 11 to 17, the mean was 14.1 ATTCT repeats . The most frequent allele was 14 (45.92%), and the frequency of large normal alleles (≥17 repeats) was 3 (3.06%) under no H-W equilibrium (P-value=0.018). **Conclusion**: This preliminary data shows a low frequency of large normal alleles in this population, suggesting that frequency of large normal alleles is not related to the high prevalence of SCA10 in Peruvian population. Further analysis with larger sample size and complimentary approaches are required to confirm these results.

1358M

Molecular characterization of genes modifying the age at onset in Huntington's Disease in a group of patients from Uruguay. *P. Esperon Percovich[1], M. Vital Coppa[1], E. Bidegain Culasso[1], V. Raggio Risso[2].* 1) Molecular Biology Unit Clinical Biochemistry Department School of Chemistry, General Flores 2124Ave, Montevideo, Uruguay; 2) Genetic Department School of Medicine, General Flores 2124Ave, Montevideo, Uruguay.

Background: Huntington's disease (HD, OMIM #143100) is a neurodegenerative disorder with an autosomal dominant inheritance mode, complete penetrance and variable clinical expressivity. The genetic cause of HD is an expansion of a sequence of CAG trinuc leotide repeats located in the first exon of the *IT*15 gene (region 4p16.3). Though the number of CAG repeats can largely explain the age at onset (AAO), a percentage of variation on AAO persists and can be attributed to modifier genes. Aim: To evaluate the influence on the AAO of HD of: the CAG repeats number and del2642 in the *IT*15 gene; the E2, E3 and E4 *APOE* gene alleles, and *ADORA2A* rs5751876, *HAP*-1 rs4523977, *PGC*-1 rs7665116 and *UCHL*-1 rs5030732 gene polymorphisms. Patients and methods: 21 patients were recruited from different national institutions. The CAG repeat number determination and gene polymorphisms were done by polymerase chain reaction and High Resolution Melting assays, respectively. Informed consent was obtained from all patients. The study follows the Code of Ethics of the World Medical Association (Declaration of Helsinki). Results: A 63.3% variation in the AAO resulted from the CAG repeat number. The genotype for the aforementioned gene polymorphisms was analysed together with the CAG repeat number and the AAO. No influence of the del2642 of *IT*15 gene, *UCHL*-1, and *APOE* gene polymorphisms was found. Out of seven patients with solely the *ADORA2A* polymorphism, four presented anticipation on the AAO. Inversely, a delay on the AAO in two patients was observed, one carrying the T allele of *HAP*-1 and one the C allele of *PGC*-1α gene. Conclusions: For the first time, in our population, the molecular diagnostic of HD was done. For a more extensive study of molecular aspects, a determination of polymorphisms strongly involved in the variation of the AAO was also performed. Considering a HD disease prevalence of 5/100.000, in a country with only a 3.3 million inhabitant population, the recruitment of a large group of patients is a big challenge. Our results, albeit qualitative, showed a novel approach to the molecular analysis of HD patients.

1359T

Deregulation of specific microRNAs in whole blood and skeletal muscle of Myotonic Dystrophy type one patients. *K.K. Ambrose, I. Taufik, I.H. Lian, K.J. Goh, K.T. Wong, A. Ahmad-Annuar, M.K. Thong.* University of Malaya, Kuala Lumpur, Malaysia.

MicroRNAs (miRNAs) are short RNA molecules of approximately 22 nucleotides that function as post-transcriptional regulators of gene expression. They are expressed in a tissue specific manner and show different expression patterns in development and disease, and hence can potentially act as disease specific biomarkers. Several miRNAs have been shown to be deregulated in plasma and skeletal muscles of myotonic dystrophy type one (DM1) patients. Here we further expand the miRNAs associated with DM1, report the differential expression of particular miRNAs in whole blood and skeletal muscle samples of DM1 patients, and discuss the potential of these miRNAs as DM1-specific biomarkers. Eleven candidate miRNAs were analysed using quantitative real-time PCR in whole blood (n=10) and muscle biopsy samples (n=9) of DM1 patients, as well as normal control samples (whole blood, n=10; muscle, n=9). In DM1 whole blood samples, miRNA 133a, 29b, and 33a were significantly up regulated, whereas miRNA 1, 133a and29c were significantly down regulated in DM1 skeletal muscle samples compared to controls. Our findings are aligned to those shown in other studies and point towards pathways that potentially contribute towards pathogenesis in DM1. However currently available data is not sufficient for these miRNAs to be made biomarkers for DM1, as they seem to be common to many muscle pathologies, hence lacking specificity. This reinforces the need for DM1 biomarker study to be further explored as we move towards less invasive, economical, disease-specific, and timely methods of biomarker detection and analysis.

1360S

FMR1-based "Double Hit" model and genomic studies in premutation carriers. *R. Lozano[1], R. Hagerman[1], M. Duyzend[2,3], E. Eichler[2,3], F. Tassone[4].* 1) MIND Institute, Dept. of Pediatrics, UC Davis Medical Center; 2) Department of Genome Sciences, University of Washington School of Medicine; 3) Howard Hughes Medical Institute Seattle; 4) Dept. of Biochemistry, UC Davis.

The FMR1 premutation is defined as having 55 to -200 CGG repeats in the 5' untranslated region of the Fragile fragile X Mental mental Retardation retardation 1 gene (FMR1). The clinical involvement has been well characterized for Fragile fragile X-associated Tremortremor/Ataxia ataxia Syndrome syndrome (FXTAS) and Fragile fragile X-associated Primary primary Ovarian ovarian Insufficiencyinsufficiency (FXPOI). The behavior/psychiatric and other neurological manifestations remained to be specified as well as the molecular mechanisms that will explain the phenotypic variability observed in individuals with the FMR1 premutation. We describe a pilot study of copy number variants (CNVs) in 56 participants with a premutation ranging from 55 to 192 repeats. The participants were divided into 4 four different clinical groups for the analysis: those with behavioral problems but no autism spectrum disorders (ASD), those with ASD but without neurological problems, those with ASD and neurological problems including seizures, and those with neurological problems without ASD. Results: We found 12 rare CNVs (8 eight duplications and 4 four deletions) in 11 cases (19.6%) that were not found in about approximately 8,000 controls. Three of them were at 10q26 and two at Xp22.3, with small areas of overlap. The CNVs were more commonly identified in individuals with neurological involvement and ASD. The frequencies were not statistically significant across the groups. There were no significant differences in the psychometric and behavior scores among all groups. Further studies are necessary to determine the frequency of second genetic hits in individuals with the FMR1 premutation; however, these preliminary results suggest that genomic studies can be useful in understanding the molecular etiology of clinical involvement in premutation carriers with ASD and neurological involvement in an FMR1-base "Double Hit" model.

Determination of the origin of Huntington disease based on haplotypes in a Peruvian population. *I. Tirado[1,2], C. Kay[3], M. Cornejo-Olivas[1,4], J.A. Collins[3], M.E. Ketelaar[3], S. Lindo-Samanamud[1], M. Inca-Martinez[1], O. Ortega[1], V. Marca[1], D. Veliz-Otani[1], K. Espinoza-Huertas[1], G. Sotil[2,5], P. Mazzetti[1,6], M.R. Hayden[3].* 1) Neurogenetics Research Center, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 2) School of Genetics and Biotechnology, Universidad Nacional Mayor de San Marcos, Lima, Peru; 3) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, University of British Columbia, Vancouver, Canada; 4) Northern Pacific Global Health Research Training Consortium, Bethesda, MD; 5) Department of Genetics and Cell Biology, Universidad Nacional Mayor de San Marcos, Lima, Peru; 6) School of Medicine, Universidad Nacional Mayor de San Marcos, Lima, Peru.

Introduction. Recent studies have associated specific *HTT* haplotypes with the CAG expansion causing Huntington disease (HD) in Caucasian, Asian and African populations. In Europe, HD chromosomes are predominantly associated with haplogroup A while in East Asian populations and the black subpopulation of South Africa, they are associated with haplogroups C and B respectively. There is a reported hotspot of HD cases in Peru, a Latin American country of admixed population with predominance of Spanish European and Amerindian ancestry. **Aims.** To determine the origin of HD in the affected Peruvian population based on *HTT* haplogroups and the relative admixture of Amerindian, European, Asian and African genetic background. **Methods.** Haplotypes of 44 HD chromosomes and 90 control chromosomes from Peruvian HD pedigrees were reconstructed from genotypes at 91 SNPs across the *HTT* gene region, IRB approval was obtained at Instituto Nacional de Ciencias Neurologicas. **Results.** HD chromosomes were found mainly on haplogroup A (85%), most specifically on the variant A1 (75%). HD occurs on A1 at the highest frequency (>90%) in the regions of Lima and Central Peru. By contrast, a small proportion (14%) are associated with haplogroup C, which occurs at the highest frequency in the South of the country, where Amerindian ancestry predominates. **Conclusions.** HD chromosomes from the Peruvian population are predominantly associated with haplogroup A, suggesting a European Caucasoid origin. The locally high frequency of HD on A1 in Lima and Canete, exceeding the frequency of A1 in previously studied Caucasian cohorts, may indicate a founder effect of HD in these regions. The few Peruvian HD haplotypes on C, common among East Asian HD, are likely of Amerindian origin.

Event-level quantification of alternate splicing using junction reads identifies new splicing QTLs in RNA-seq data from 1000 Genomes Project samples. *T. Bhangale, L. Goldstein, B. Friedman, R. Gentleman, T. Wu, (TB and LG: equal contribution).* Bioinformatics & Computational Biology, Genentech Inc, South San Francisco, CA.

Common variants can lead to complex diseases by affecting RNA splicing; such splicing QTLs (sQTLs) have been shown to explain a considerable proportion of variation in isoform usage. Most current approaches to identifying sQTLs attempt to quantify differences in transcripts at the isoform level. However, since sequencing reads/fragments are much shorter than transcripts, isoform-level quantification involves either probability models of transcripts or mapping of reads to a reference transcriptome, instead of the reference genome. Both approaches introduce various challenges and pitfalls. Moreover most methods only detect sQTLs related to known isoforms. We therefore present a new approach that focuses on event-level quantification of splicing within a gene and apply it to the RNA-Seq data for the 1000 Genomes Project lymphoblastoid cell lines from Geuvadis Consortium (GC). We first map reads to the reference genome using our aligner GSNAP, which performs splice-junction-aware split-read alignments, using known splice sites as well as novel splice sites it predicts. Using known variants in the sample it also performs SNP-tolerant alignment and enables allele-specific expression analysis by eliminating the common problem of reference bias. These alignments are then analyzed by our new method exonfindR, which detects known and novel (i.e. ones that cannot be inferred from known transcript annotations) alternate splicing events and quantifies their expression levels in the sample. Quantification is in terms of local events e.g., skipped exon, retained intron etc, and only uses reads that provide unambiguous support for a given event i.e. splice-junction reads in most cases. Association tests are then performed to identify sQTLs. In the data from GC, we detected 37,121 known events in 14,527 genes and 3,703 novel events in 2,515 genes. At FDR cutoff of 5% in the 366 samples of European descent, we found 845 genes (known events) and 81 genes (novel events) with common (MAF $\geq$ 5%) cis sQTLs, where GC had previously reported 620 genes. Among our sQTLs, 38 (25 previously unreported) disrupt splice sites and likely provide a direct hypothesis for a mechanism and 35 overlap with SNPs in the NHGRI GWAS catalog. Advantages of our approach include greater power to detect association when the variant leads to an event-level change in splicing and the ability to detect novel events and sQTLs associated with them. Both tools, GSNAP and exonfindR, are freely available.

Detection and prediction of deleterious mutations affecting pre-mRNA processing. *D.S. Hanna, J.G. Underwood, J.D. Smith, M.O. Dorschner, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

Synonymous and intronic variation is often ignored during human genetic analyses although such variation is known to alter signals recognized by the spliceosome or its associated trans-acting factors. This variation can alter splice site choice or generate cryptic splice sites, both of which can result in aberrant splicing events that lead to nonfunctional coding sequence or nonsense-mediated decay. For the analysis of this underappreciated class of disease-causing variation, we present Spliceosaurus, a lightweight C++ codebase architected using the Standard Template Library (STL) for rapid analysis of variation on splicing signals. Spliceosaurus uses a novel scoring algorithm based on the maximum entropy principle further scaled by weighting cis-acting splicing enhancers and silencers by genomic distance and affinity to establish U1 and U2 snRNA recognition sites on pre-mRNAs. The algorithm iteratively searches not only for variation affecting existing splice sites, but also for variation contributing to the generation of cryptic splice sites. The model is trained on the non-canonical splicing variation found in DBASS that lead to aberrant mRNA isoforms allowing extreme specificity in the identification of variation highly impacting the splicing code. Potential irregular splicing events are interrogated by predicting new exon boundaries and the effects on the aberrant mRNA. Unlike existing splicing analysis suites, the input and output for Spliceosaurus is a standard VCF file that allows seamless integration into existing data analysis pipelines. Additionally, the code is capable of processing whole genome datasets in hours, permitting splicing analysis on the scale requjred for next generation sequencing approaches. We applied Spliceosaurus and correctly identified previously reported causal intronic and synonymous variants in several Mendelian disorders as highly disruptive to canonical splicing [i.e., Auriculo-condylar syndrome (ACS), hereditary nonpolyposis colorectal cancer (HNPCC) and X-linked parkinsonism with spasticity (XPDS)] The code is freely available for academic use on GitHub: https://github.com/davidhanna/Spliceosaurus.

1364T

An Integrative Approach to Identify Splice Factors and their Putative Upstream Regulators. *M. Subramaniam, SJ. Gosline, SK. Hughes, FB. Gertler, E. Fraenkel.* Massachusetts Institute of Technology, Cambridge, MA.

The rise of whole-genome expression analysis has demonstrated the power of understanding genomic-level changes in gene expression across diseases such as cancer. In addition to the large changes in whole gene expression observed in these genome-wide expression experiments via massively parallel pair-ended RNA sequencing, many novel splice isoforms of genes have been identified across different forms of cancer. However, identification of proteins that cause these splice isoforms is limited to *in vitro* competitive binding assays or high throughput binding experiments such as cross-linking immunoprecipitation. These assays have been helpful in identifying the space of possible protein-RNA interactions, but often fail to capture condition specific binding events. Here, we propose an integrative approach that uses sequence-level knowledge of alternative splicing events together with RNA-binding profiles and protein-protein interaction networks. We use paired-end sequencing data to identify differential splicing in a model of breast cancer, then apply a hypothesis driven scoring method that identifies putative RNA binding proteins that lead to differential splicing. We then factor in evidence from upstream protein interactions to identify the RNA binding proteins and their associated pathways implicated in the observed sequencing data. Using sequencing data collected from *Mena*-expressing epithelial breast cancer cells, we applied this method to identify and explain alternative splicing events as well as the metastatic phenotype related to the introduction of *Mena*. The results identified a network of protein interactions that connect *Mena* over-expression with key alternative splicing events unobserved in the control condition. The network results pinpointed specific splice factors likely responsible for causing splicing changes in response to activation by upstream regulators.

The Exome Coverage and Identification (ExCID) Report: a gene survey tool for clinical sequencing applications. *C. Buhay[1], R. Sanghvi[1], Q. Wang[1], K. Walker[1], H. Doddapaneni[1], J. Hu[1], M. Wang[1], Y. Han[1], H. Dinh[1], E. Boerwinkle[1,2], D. Muzny[1], R. Gibbs[1].* 1) Baylor College of Medicine - Human Genome Sequencing Center, Houston, TX; 2) 2Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

The Exome Coverage and Identification (ExCID) Report was developed at the Baylor College of Medicine Human Genome Sequencing Center (BCM-HGSC) to represent gene transcript and exon sequence coverage for samples analyzed with the VCRome Whole Exome sequencing (WES) reagent. Since March 2013, the report has been used to analyze more than 13,000 WES research samples for the BCM-HGSC and more than 1500 WES clinical samples at our Whole Genome Laboratory (WGL). ExCID assesses target sequencing coverage, annotates targets with gene, transcript and exon information and reports intervals below 20X. In addition, ExCID has batch analysis features that can compare data from hundreds of samples to reveal trends in the performance of large scale sequencing projects. Results can be visualized as 'coverage tracks' in popular browsers such as the Integrative Genome Browser and the UCSC Genome Browser. For a pilot survey, coverage data was examined from 34 WES samples from the WGL. This showed that the VCRome capture reagent covered (at $\geq$20X) more than 75 percent of the medically interesting genes listed in COSMIC, HGMD, GeneTests, and ACMG Incidental Findings lists. The analysis also identified gene regions that were currently below the 20X threshold. We also analyzed data from Whole Genome Shotgun (WGS) to compare sequence coverage in WGS versus WES. ExCID output was generated on 9 WGS (30X) and 9 WES (100X) to discover and aggregate coding regions below 20X in each method. The data show regions that are poorly covered irrespective of the sequencing strategy, as well as regions unique to each strategy. Ongoing analyses include the aggregation and characterization of poorly covered regions in 600 WGS and 1000 WES samples. Results will provide insight regarding regions of the human genome that require special consideration for the development of future clinical sequencing strategies. ExCID is available under public license in the GitHub repository: https://github.com/cbuhay/ExCID.

Scaled Sparse High Dimensional Tests for Localizing Disease Susceptible Sequence Variants. *S. Cao[1,3], H. Qin[2,3], J. Li[2,3], H. Deng[2,3], Y. Wang[1,2,3].* 1) Dept of Biomedical Engineering, Tulane University, New Orleans, LA; 2) Dept of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA; 3) Center for Bioinformatics and Genomics, Tulane University, New Orleans, LA.

Existing association tests are powerful to identify susceptibility variants in large samples. These tests, however, have low power in high dimensional set (HDS), which is a sample containing fewer study subjects than the number of variants tested. HDS are very common among recently deep sequencing data for human complex trait studies. Given the assumption that most of genetic variants are neutral, i.e., only a small portion of them are functional variants, sparse regression methods are powerful to select a promising sparse set of susceptible variants from numerous genetic variants. However, they are ineffective to control the Type I error rates of HDS without functional variants. In this study, we propose a novel scaled sparse regression approach for identifying disease susceptible variants set in high dimensional data. Our method focuses on constructing statistical tests for high dimensional data, based on scaled *Lp* ($0 < p < 1$) norm regularization. Basically, we propose two significance tests: marker wise test (single variant test) and HDS-based test (whole regional test). For marker wise test, we first apply sparse regression with scaled *Lp* norm regularization to generate a de-biased solution. Next, we utilize the asymptotical distribution of the de-biased solution to build the significance test. For HDS-based test, we integrate the marker wise statistics to identify susceptible genetic regions. In this step, the dependence among markers is incorporated to appropriately control set-based Type I error rates while maintaining certain statistical power gain. Under a wide range of simulations, the proposed approaches appropriately controlled Type I error rates and had improved detection power relative to several prominent methods such as SKAT, Global test and HDI test. When applied to a real DNA sequence data of Mexican Americans for studying hypertension, our HDS-based tests identified 8 additional significant susceptibility genes which were not reported by SKAT. Our promising results indicate that the marker wise test can pinpoint single suspected variants with higher resolutions, and the HDS-based test yields considerably high statistical power gain for the whole regional test, especially for high dimensional data. In addition, our methods also maintain substantial power for detecting susceptibility variants in low dimensional data or large samples. Last but not least, our method can detect both rare and common variants with almost equal efficiency.

Serapis: an archival system for large-scale genetic data. *I.G. Colgiu, N.A. Clarke, M.O. Pollard, J.C. Randall.* Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, CB10 1SA, United Kingdom.

As the volume of genome sequencing data has rapidly increased over the last few years, the need for high-performance systems that can cope with these storage demands and handle large datasets in an efficient way has become acute. Within the genetics research community, it is desirable to be able to easily access and retrieve large datasets from previous studies of interest. The Serapis archival system has been developed and is currently in use at the Sanger Institute to satisfy these requirements for human genetics research groups. It has been designed for the purpose of archiving large genetic datasets in a long-term storage system and facilitating search of the entire archive based on various criteria. The latter feature has been implemented by attaching relevant metadata to each archived file, stored in the form of key-value pairs. This metadata describes predefined attributes of the data, such as data source (e.g. whole exome/genome sequencing), sample id, associated publication, etc. Though it is possible to use Serapis as a general purpose system, the tool has been tailored to genetics, with built-in support for genetic file formats such as BAM and VCF. It has the ability to automatically collect metadata from within these types of files, by querying external resources, or via manual entry by users. In addition to this, the system also enforces access control restrictions, which is essential in the context of non-public human genetics datasets. In the configuration in use at the Sanger Institute, Serapis uses the iRODS system[1] for backing storage and performs all the work associated with data submission in a distributed way on the Sanger cluster. It is implemented using a distributed task management system (Celery[2]), metadata is assembled temporarily in a NoSQL database before it is permanently archived, and the submission system is accessible via a RESTful web interface. This architecture allows substantial flexibility so that it can be configured to suit the needs of a specific research team or an entire department. The current throughput of our system is 12TB of data archived per day (140MB/s), the limiting factor being the I/O performance of the backing store. All components of the system are available as open source code [3]. [1] http://irods.org/ [2] http://www.celeryproject.org/ [3] https://github.com/wtsi-hgi/serapis-web.

Leveraging Genome Mapping in Nanochannel Arrays and NGS for a Better Human De Novo Sequence Assembly. *H. Dai[1], A. Pang[1], W. Stedman[1], T. Anantharaman[1], A. Hastie[1], P.Y. Kwok[3], A. Ummat[2], E. Schadt[2], R. Sebra[2], B.A. Bashir[2], H. Cao[1].* 1) BioNano Genomics, San Diego, CA; 2) Mount Sinai School of Medicine, New York, NY; 3) University of California, San Francisco, CA.

Irys genome mapping technology provides direct analysis of extremely long genomic DNA (up to multi-megabases) without amplification. De novo assembly of these single molecules yields high-fidelity contiguous map information across long ranges. Its advantage over all other genome assembly methods is particular dramatic in highly repetitive regions. Genome maps thus greatly complement assemblies using relatively short second- and third-generation sequencing reads. We have constructed genome maps of human NA12878 (cell line derived from the daughter in the CEU trio) which resulted in a consensus assembly measuring 2.9 Gb and with an N50 of 4.6 Mb. With Pacific Biosciences sequence from the same cell line, we also created a sequence-based assembly with N50 length of 930 kb in parallel. By combining data from these two technologies with a custom-designed hybrid scaffolding pipeline, we were able to generate an assembly having scaffold N50 length of greater than 30 Mb covering more than 2.7 Gb of the human genome. At the same time, we were able to identify potential misassembles in the sequence assembly as well as in the genome maps by reviewing the inconsistencies between these two complementary technologies. The hybrid scaffolds also discovered additional long range structural variations not identified in sequence assembly.

1369M

Inference for high-dimensional feature selection in genetic studies. *C. Ekstrøm.* Biostatistics, University of Copenhagen, Copenhagen, Denmark.

Feature selection is a necessary step in many genetic applications because the biotechnological platforms provide a cheap and fast means for producing high-dimensional data. This need for dimension reduction is heightened further for example when data from different omics are combined into simultaneous integrated data analysis or when higher-level interactions among the available predictors are considered (which is the case for gene-gene or gene-environment interactions or in epigenetics).

Penalized regression models such as the Lasso or the elastic net have proved useful for variable selection in many genetic applications - especially for situations with high-dimensional data where the numbers of predictors far exceeds the number of observations. These methods identify and rank variables of importance but do not generally provide any inference of the selected variables. Thus, the variables selected might be the “most important” but need not be significant. We propose a significance test for evaluating the number of significant selection(s) found by the Lasso.

This method rephrazes the null hypothesis and uses a randomization approach which ensures that the error rate is controlled even for small samples. The ability of the algorithm to compute p-values of the expected magnitude is demonstrated with simulated data and the algorithm is applied to two dataset: one on prostate cancer and a full GWAS. The proposed method is found to provide a powerful way to evaluate the set of selections found by penalized regression when the number of predictors are several orders of magnitude larger than the number of observations.

1370T

An integrated framework for sequence variant prioritization. *B. Feng, D. Goldgar.* Department of Dermatology & Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Next generation sequencing has played a key role in genetic research and is now becoming integrated into clinical practice. A major problem in utilizing such information is in the interpretation of the large number of variants discovered from such sequencing, which have diverse characteristics and unknown clinical significance. Variant prioritization is the primary step leading to interpretation, based on which variants or genes or pathways can be filtered, tested or classified. Variant prioritization can be done by many criteria, including, but not limited to, sequence conservation, predicted effect on protein, frequency, co-segregation with disease, and gene/pathway relevance. However, it is not clear how to integrate all this information into a robust and quantitative system without arbitrary filtering or scoring. In this study, we propose a Bayesian framework to combine different lines of evidence for variant prioritization. The first part of this framework is a combined deleteriousness score using the weighted naïve Bayes model. By testing on a set of well classified BRCA1 and BRCA2 variants, this score has a higher area under the ROC curve than any component score such as PolyPhen2, SIFT, Mutation Taster, Mutation Assessor, LRT, GERP++, PhyloP, SiPhy, etc., or other combinatory scores such as CADD, MetaLR, and MetaSVM. Adding minor allele frequencies obtained from the NHLBI GO Exome Sequencing Project (ESP) to the model further improved its performance. The second part of the framework is co-segregation assessment using a modified version of that from Thompson et al., where such data is available. The third part, gene relevance, is inferred from guilt-by-association (GBA) in a protein-protein interaction network. The GBA score is computed by naïve Bayes label propagation on an InterConnectedness-transformed weight matrix, and then converted to an empirical Bayes factor. This method showed a high level of prediction accuracy among known disease genes. All these lines of evidences are combined into an overall Bayes factor, which can be used for variant selection and/or as a weight in a gene- or pathway-based burden test for association.

Omics Pipe: A Computational Framework for Multi-Omics Data Analysis. *K. Fisch, T. Meissner, L. Gioia, T. Carland, S. Loguercio, J.C. Ducom, A. Su.* Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA.

Next generation sequencing (NGS) has presented researchers with the opportunity to collect large amounts of sequencing data, which has accelerated the pace of genomic research with applications to personalized medicine and diagnostics. This has resulted in the development of a large number of computational tools and analysis pipelines, necessitating the creation of best practices and reproducible integrative analysis frameworks. Several automated pipelines have been developed to tie together individual software tools, although many of these tools focus on a single NGS platform (i.e. variant calling, RNA-seq), require computational expertise, and/or are poorly documented. The Nature Protocols journal has attempted to create one solution to establish best practices, by publishing step-by-step directions for well-established NGS analysis pipelines. In addition, other best practice pipelines exist, such as The Genome Analysis Toolkit (GATK). Omics pipe (https://bitbucket.org/sulab/omics_pipe) is an open-source, modular computational platform that automates best practice multi-omics data analysis pipelines. It currently automates and provides summary reports for two RNA-seq analysis pipelines, variant calling from whole exome sequencing, variant calling and copy number variation analysis from whole genome sequencing, two ChIP-seq pipelines and a custom RNA-seq pipeline for personalized cancer genomic medicine reporting. It also provides automated support for interacting with the The Cancer Genome Atlas (TCGA) datasets, including automatic download and processing of all of the samples in this database. We analyzed 100 TCGA breast invasive carcinoma data sets using Omics pipe with UCSC hg19 RefSeq annotation. Omics pipe automatically downloaded and processed the desired TCGA samples on a high throughput compute cluster to produce a results report for each sample. We aggregated the individual sample results to compare the results of our analysis with the original publications, which revealed high overlap between the analyses, as well as novel findings due to the use of updated annotations and methods. In conclusion, Omics pipe enables researchers to analyze next generation sequencing data with little development overhead to provide reproducible, open source and extensible use of established multi-omics analysis methods.

Tandem repeat sequencing error profiles and error correction models for short read sequencing data. *A. Fungtammasan[1,2], G. Ananda[1,3], S. Hile[4], C. Sun[5], R. Harris[2], P. Medvedev[3,5], K. Eckert[4], K. Makova[2].* 1) Integrative Biosciences, Bioinformatics and Genomics Option, Pennsylvania State University, Pennsylvania, 16802 USA; 2) Department of Biology, Pennsylvania State University, Pennsylvania, 16802 USA; 3) Department of Biochemistry and Molecular Biology, Pennsylvania State University, Pennsylvania, 16802 USA; 4) Department of Pathology, Gittlen Cancer Research Foundation, The Pennsylvania State University College of Medicine; 5) Department of Computer Science and Engineering, Pennsylvania State University, Pennsylvania, 16802 USA.

Profiling Tandem Repeats (TRs) from short read sequencing data is a big challenge because of sequencing and mapping errors. We developed a pipeline that can detect the full spectrum of TR lengths from short read data. We used our pipeline to estimate the TR error rates and patterns for PCR-containing and PCR-free Illumina sequencing libraries using both high-depth genome-wide data and ultra high-depth of plasmid data, which yielded very similar results. We found that the error rates increase with TR repeat number, A/T -richness of TR motives, and PCR step in library preparation. Contraction errors are more common than expansion errors, and the most common type of error is contraction by 1 motif. We used these error patterns to construct an error correction model for genotyping that can assign genotypes correctly for 97-100% of TR loci depending on repeat type. We also used our error models to recommend minimum sequencing depth for genotyping. We found that the minimum sequencing depth required for genotyping increases with TR length. Also, to obtain reliable genotypes, PCR-free data require lower depth than PCR-containing data. Our error correction model has the capacity to distinguish alleles even for TR with consecutive repeat numbers.

MITOCHONDRIAL DISEASE SEQUENCE DATA RESOURCE (MSeqDR) CONSORTIUM: A Centralized Genomic Resource for Analyzing Genetic Variants of Individuals with Suspected Mitochondrial Disease. *X. Gai[1], L. Shen[1], M.A. Gonzalez[2], M. Attimonelli[3], A. Stassen[4], D. Navarro-Gomez[1], J. Leipzig[5], M. Lott[5,9], D.C. Wallace[5,9], D. Krotoski[6], P.E. Yeske[7], S. Zuchner[2], M.J. Falk[8,9].* 1) Department of Ophthamology, Massachusetts Eye and Ear Infirmary, Boston, MA; 2) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Dipartimento di Bioscienze, Biotecnologie e Biofarmaceutica, UniversitÃ di Bari, Bari, Italy; 4) Department of Clinical Genetics, Maastricht University, The Netherlands; 5) Center for Mitochondrial Medicine and Epigenomic Medicine, The Children's Hospital of Philadelphia , Philadelphia, PA; 6) NICHD, NIH, Bethesda, MD; 7) The United Mitochondrial Disease Foundation, Pittsburgh, PA; 8) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 9) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

Mitochondrial diseases are highly heterogeneous with pathogenic variants in many genes from both the nuclear and mitochondrial genomes. While whole exome sequencing (WES) greatly empowers the discovery of novel disease genes and the diagnosis of mitochondrial disease patients, it also magnifies the associated bioinformatics challenges. The later include the highly fragmented and limited nature of the current mitochondrial resources, and also the lack of a convenient and standardized way to share data across the community. Since June 2012, we have established a grass-roots effort supported by the United Mitochondrial Disease Foundation (UMDF) called the "Mitochondrial Disease Sequence Data Resource (MSeqDR) Consortium". A centralized mitochondrial genomic resource has been developed (https://mseqdr.org/) by engaging and working with more than 100 disease experts across the globe. Major components of MSeqDR include: a) A Mitochondrial Disease Locus Specific Database (MSeqDR-LSDB) hosting 3,560 potentially disease-causing genetic variants in 1,332 genes, extracted and fully integrated from multiple resources, such as ClinVar, Ensembl, POLG database, and contributions from various diagnostic laboratories; b) A genome browser (MSeqDR-GBrowse) that allows convenient searching, browsing, and visualization of genomic variant annotations of known and potential mitochondrial disease genes, especially the mitochondrial genome, again extracted from, integrated with, and contributed by all major mtDNA genomics resources, namely MitoMap, HmtDB, and PhyloTree; c) Web-based variant annotation and analysis tools, namely HBCR, MT.AT, and MitoMaster@MSeqDR; d) Phenotype-centric search and browse of genetic variants, fully integrated with MSeqDR-LSDB and MSeqDR-GBrowse; and last but most importantly e) powerful web-based WES analysis of individual patients, families, and cohorts via GEM.app (https://genomics.med.miami.edu/gem-app). The resource is fully functional with more functionalities to be added. Together, we believe this resource will support reliable genetic diagnosis in individual cases, facilitate identification of additional cases of rare genetic disorders, provide evidence to exclude from consideration sequence variants of unknown significance that are unlikely to be disease-causing, permit identification of modifier genetic factors underlying disease variability, and even identify genetic variants that are likely to alter response to emerging therapies.

1374S

Using RNA-Seq to improve sensitivity/specificity of CNV calls made from whole-exome sequencing data. *R. Golhar, J. Glessner, E. Liu, H. Hakonarson.* The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Whole-Exome sequencing is being used to study human disease primarily by cataloguing single-nucleotide variants (SNVs). Copy-number variants (CNVs) are another form of genetic alterations that have been associated with several disease phenotypes and are harder to detect in whole-exome sequencing data due to the discontiguous nature of the target regions (exons) sequenced. Several algorithms have been published to detect rare CNVs in whole-exome sequencing data, including XHMM, Conifer and Canoes. All three methods work by normalizing read depth data, followed by using a hidden Markov Model to detect CNVs. In one dataset consisting of approximately 2000 samples, we were able to positively verify CNVs of at least 5 kb in size called by XHMM in 189 probands while CNVs in 48 probands were negative resulting in an 80% verification rate. In the second dataset consisting of 650 samples, we validated CNVs in 30 samples using qPCR where 15 CNVs (50%) were positively verified, 9 (30%) were negative, and remaining 6 (20%) could not be validated due to the quality of DNA or short length of the exon involved. In order to increase sensitivity and specificity of called CNVs, we are investigating the use of RNA-Seq to provide additional supporting evidence of CNV calls made from whole-exome sequencing data.

Branch: An interactive, web-based tool for building decision tree classifiers. *B.M. Good, K. Gangavarapu, V. Babji, M. Nanis, A.I. Su.* Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA.

A crucial task in modern biology is the prediction of complex phenotypes, such as breast cancer prognosis, from genome-wide measurements. Machine learning algorithms can sometimes infer predictive patterns, but there is rarely enough data to train and test them effectively and the patterns that they identify are often expressed in forms (e.g. support vector machines, neural networks, random forests composed of 10s of thousands of trees) that are highly difficult to understand. In addition, it is generally unclear how to include prior knowledge in the course of their construction.

Decision trees provide an intuitive visual form that can capture complex interactions between multiple variables. Effective methods exist for inferring decision trees automatically but it has been shown that these techniques can be improved upon via the manual interventions of experts. Here, we introduce Branch, a new Web-based tool for the interactive construction of decision trees from genomic datasets. Branch offers the ability to: (1) upload and share datasets intended for classification tasks, (2) construct decision trees by manually selecting features such as genes for a gene expression dataset, (3) collaboratively edit decision trees, (4) create feature functions that aggregate content from multiple independent features into single decision nodes (e.g. pathways) and (5) evaluate decision tree classifiers in terms of precision and recall. The tool is optimized for genomic use cases through the inclusion of gene and pathway-based search functions.

Branch enables expert biologists to easily engage directly with high-throughput datasets without the need for a team of bioinformaticians. The tree building process allows researchers to rapidly test hypotheses about interactions between biological variables and phenotypes in ways that would otherwise require extensive computational sophistication. In so doing, this tool can both inform biological research and help to produce more accurate, more meaningful classifiers.

A prototype of Branch is available at http://biobranch.org/.

Computational evaluation of the pathogenicity of noncoding sequence variants in autism spectrum disorder. *A.J. Griswold[1], D. Van Booven[1], N. Dueker[1], E.R. Martin[1,2], M.L. Cuccaro[1,2], J.R. Gilbert[1,2], J.L. Haines[3], J.P. Hussman[4], M.A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of MIami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 4) Hussman Institute for Autism, Baltimore, MD, USA.

Massively parallel whole exome sequencing, whole genome association, and copy number analyses in thousands of individuals have implicated hundreds of genetic loci, including dozens of genes with rare, *de novo* loss of function and inherited damaging missense variants, in the genetic risk for autism spectrum disorder (ASD). A largely unstudied hypothesis is that rare variants in noncoding regions of the genome functionally contribute to ASD. As part of an ongoing project, we have sequenced evolutionarily conserved regions upstream, downstream, and within introns of 689 ASD associated genes and 942 ASD associated intergenic loci in 2099 ASD cases and 812 controls of European descent. We identified 545,916 single nucleotide variants (SNVs), 519,950 of which are noncoding. To assess which SNVs might contribute to the ASD and to prioritize them for molecular studies, we utilized three bioinformatic tools to annotate and score their functional potential. 1) FunSeq assesses the SNV against the 1000 Genomes database and prioritizes on evolutionary selection and effect of the variant on protein binding motifs. 2) GWAVA (Genome Wide Annotation of Variants) is based on annotation of SNVs with ENCODE and on genome-wide properties such as evolutionary conservation and GC-content. 3) CADD (Combined Annotation Dependent Depletion) integrates multiple functional categories and contrasts variants that survived natural selection with simulated mutations and scores them relative to all possible mutations in the genome. 7,223 variants were in the top 10% of both GWAVA and CADD. Of those, 137 also had a score greater than 3 in FunSeq, the top 2% of FunSeq scores, making these our most likely functional noncoding SNVs. Among these are case specific rare variants (MAF<0.01) in highly conserved transcription factor binding sites upstream of ASD candidate genes including five upstream of *NRXN1* and two upstream of *CTNND1*. In addition, promoters of other neurodevelopmental genes *FGFR2*, *SGK1*, and *SETD7* contain case unique high scoring SNVs. Molecular experiments to determine the underlying effect of these variants on protein binding and gene regulation are underway. This evolving approach of applying computational methods to noncoding variation will enhance our ability to classify SNVs as functional and broaden our understanding of the underlying genetic factors in ASD. This approach can be applied to other disorders generating large scale beyond exome sequencing data.

Similarity metrics for comparing exome sequence variants. *V. Heinrich[1], P.N. Robinson[1,2,3,4], S. Mundlos[1,3], P.M. Krawitz[1,2,3].* 1) Institute for Medical Genetics and Human Genetics, Charité Universitätsmedizin Berlin, Germany; 2) Berlin Center for Regenerative Therapies (BCRT), Charité-Universitätsmedizin Berlin,; 3) Max Planck Institute for Molecular Genetics Berlin, Germany; 4) Institute for Bioinformatics, Department of Mathematics and Computer Science, Freie Universität Berlin, Germany.

Removing frequently detected variants is one of the most effective approaches to reduce the number of candidate mutations in the data analysis of next-generation sequencing studies. The incidence of a rare disorder in a population serves as an upper bound for the allele fre- quency or genotype frequency that can be used as a filter for dominant or recessive disorders. However, the frequentist inference requires that genotypes of a single individual are repre- sented in the database only once. With many and decentralized data submitters the probability increases that samples of the same individual are sequenced multiple times and are contributed independently under differ- ent pseudonyms. We compare two different metrics that compute the similarity between any two exome samples in a defined target region. Each similarity value can be used to assess whether a list of sequence variants has already been submitted and provides information about the relationship between samples. This allows the identification of replicates from different enrichment procedures, sequencing platforms and bioinformatic pipelines.

Novel Integrative Genomics Approach for the Discovery of MicroRNA and mRNA Signatures and target Pathways in Prostate Cancer. *C. Hicks[1,2,3], R. Jangiti[1], R. Ramani[1], T. Koganti[1], S. Giri[3], S. Vijayakumar[1,3].* 1) Cancer Institute, University of Mississippi Medical Center, Jackson, MS; 2) Department of Medicine, University of Mississippi Medical Center, Jackson Mississippi; 3) Department of Radiation Oncology, University of Mississippi Medical Center, Jackson Mississippi.

Background: Prostate cancer is the most common solid tumor and the second most common cause of cancer death in men in the United States. Advances in high-throughput transcription profiling have made possible molecular classification of prostate cancer. However, although these primary analyses have provided valuable insights about the molecular basis of prostate cancer, they have been unsuccessful in determining which genes have causative roles as opposed to being consequences of the prostate cancer state. Advances in genotyping and reduction in genotyping costs made possible identification of single nucleotide polymorphisms (SNPs-herein called genetic variants) associated with an increased risk of developing prostate cancer using genome-wide association studies (GWAS). However, many of the identified genetic variants (>80%) map to noncoding regions with unknown functions. Recently, microRNAs (miRNAs) a class of noncoding RNAs have gained prominence in oncology research as potential clinically actionable biomarkers. However, the functional relationships between genetic variants, miRNAs and their mRNA and pathway targets are not well defined. The objective of this investigation was to leverage GWAS information with miRNA and mRNA expression data for the discovery of MicroRNA and mRNA oncogenic signatures and pathways in prostate cancer. Methods: We used a combination of bioinformatics tools to integrated disparate genomics data in our analysis. First, we developed a comprehensive catalogue of genetic variants and associated genes from GWAS and a comprehensive catalogue of miRNAs and their mRNA targets. Next, we analyzed miRNA and mRNAs expression data to identify miRNA and mRNA signatures enriched for genetic variants. Subsequently we performed network and pathways analysis to identify target molecular networks and biological pathways enriched for genetic variants. Results: The analysis revealed miRNAs and mRNA oncogenic signatures. We identified molecular networks and pathways enriched for genetic variants and targeted by miRNAs. Among the identified target pathways included the androgen, androgen biosynthesis, IGF-1, JAK, STAT and prostate cancer signaling pathways. Conclusions: Our investigation demonstrates that integrative genomic analysis provides a powerful and unified approach for establishing putative functional bridges between GWAS findings, miRNAs and their mRNA and pathway targets.

Medical re-sequencing analysis pipeline provides one-stop solution for identifying disease-causing mutations of Mendelian disorders. *H. Hu[1], T.F. Wienker[1], L. Musante[1], V. Kalscheuer[1], P.N. Robinson[2], H.H. Ropers[1].* 1) Max Planck Institute for Molecular Genetics, Berlin, Germany; 2) Universitätsklinikum Charité, Berlin, Germany.

Next-generation sequencing has greatly accelerated the search for disease-causing defects, but even for experts the data analysis can be a major challenge. To facilitate the data processing in a clinical setting for Mendelian disorders, we have developed a novel Medical Re-sequencing Analysis Pipeline (MERAP). MERAP assesses the quality of sequencing, and has optimized capacity for calling variants, including Single Nucleotide Variants, insertions and deletions, Copy Number Variation, and other structural variants. MERAP identifies polymorphic and known causal variants by filtering against public-domain databases, and flags non-synonymous and splice-site changes. MERAP uses a logistic model to estimate the causal likelihood of a given missense variant. MERAP considers the relevant information such as phenotype and interaction with known disease-causing genes. MERAP compares favorably with GATK, one of the widely used tools, because of its higher sensitivity for detecting indels, its easy installation, and its economical use of computational resources. Upon testing more than 1,800 individuals with mutations in known and novel disease genes, MERAP proved highly reliable, as illustrated here for 5 families with disease-causing variants. We believe that the clinical implementation of MERAP will expedite the diagnostic process of many disease-causing defects for Mendelian disorders.

1380S

A novel integrated analysis framework for detecting genome-wide changes in gene expression or regulation with next-generation sequencing data. *W. Huang, D.M. Umbach, L. Li.* Biostatistics, NIEHS, NIH, Research Triangle Park, NC.

The cost-effective next-generation sequencing has quickly become a popular assay method for studying gene expression and genetic/epi-genetic regulation. The development of corresponding data analysis tools, as demanded by these sequencing applications, has also been fast paced, particularly in the last five years. The sequencing technologies continue to evolve so quickly, however, that the development of analysis tools still lags far behind the need. In particular, sequencing is now being used for more complicated or more challenging studies, and existing tools are no longer sufficient for these new and more advanced applications. In fact, data analysis and interpretation is becoming the bottleneck that limits more widespread sequencing applications. The main inadequacies of existing tools include: 1) ineffective at detecting true biological changes, especially when number of biological replicates is small, 2) high false positive rates, typically resulting from unrealistic underlying statistical assumptions, 3) little capability for analyzing data from more advanced experimental designs, 4) limited data visualization capability, and 5) typically restricted to one type of sequencing application. We present a new computational framework, based on our previous work (EpiCenter), to address the above challenges. Instead of using a single procedure or statistical test for every application, our new framework employs different statistical tests and filters to analyze data from different kinds of study. Specifically, our framework makes the choice according to the experimental design, number of biological replicates, type of data (e.g., histone ChIP-seq or mRNA-seq gene expression), and the organism/species (genome complexity and annotation can differ dramatically among organisms) used in the study. In addition, our framework, unlike existing methods that treat individual genes/regions separately, considers individual genes/regions as an integrated part of a genome-wide study to improve overall detection accuracy. Furthermore, our framework extends EpiCenter's data visualization capability including the generation of the UCSC hub track data. Evaluation on both simulated and actual sequencing data showed the superior performance of our framework over that of some popular existing tools.

1381M

Database of disease-associated genomic polymorphisms based on assessment of reproducibility between or within human populations. *T. Imanishi[1,2], Y. Nagai[1], Y. Takahashi[1].* 1) Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) National Institute of Advanced Industrial Science and Technology, Tokyo, Japan.

Genome-wide association studies (GWASs) have identified numerous single nucleotide polymorphisms (SNPs) that are associated with development of common diseases. However, because GWAS uses statistical evaluation, we cannot completely eliminate false positives that may contaminate to a certain extent. On the other hand, it is becoming clearer that genetic risk factors of common diseases are not totally universal but heterogeneous among human populations. We thus developed a new database of genomic polymorphisms that are *reproducibly* associated with disease susceptibilities, drug responses and other traits for each human population, and released it as "VarySysDB Disease Edition (VaDE)". Using PubMed and NHGRI GWAS catalog, we collected 1806 GWAS papers and curated them manually. We extracted information of associated SNPs, odds ratios, p-values, study design, nationality of subjects, and many others. Also, extensive manual curation has been carried out separately for hypertension and rheumatoid arthritis. Then, we assessed the reproducibility of each association in multiple, independent studies for each human population. Finally, we could obtain 4675 and 790 reproducible associations for 427 and 151 traits in the European and East Asian populations, respectively. Furthermore, to support finding functional SNPs in the VaDE database, we integrated data of ChIP-seq, DNaseI hypersensitivity experiments, regulatory motifs, RefSeq genes, H-Inv transcripts, and linkage disequilibrium data in three major human populations that have been obtained from Haploreg v2, VarySysDB, and Univ Michigan. We also installed a genome browser to visualize these data in VaDE. From the VaDE database, we searched for pleiotropic SNPs that are associated with multiple traits. As a result, we could identify 802 pleiotropic SNPs, such as those affecting metabolic traits and autoimmune diseases, which provides a clue to solve hidden relationships among various phenotypes. The VaDE database is publicly available from http://bmi-tokai.jp/VaDE/. We believe that our database will contribute to the future establishment of personalized medicine and understanding of genetic factors underlying diseases.

Semantic Similarity Analysis of Patient Phenotypes for Genome Wide Genetic Diagnostics. *R. James, M. Bainbridge, C. Eng, C. Shaw.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

The clinical implementation of genome wide diagnostics is increasingly important in the molecular diagnosis of human disease. However, these genome wide approaches are challenged by the large number of variants observed in individual patients. We hypothesize that efficient integration of available clinical data characterizing patient indications for genetic testing can improve the implementation of diagnostic workflows and, ultimately, prioritization of variants. We have developed scalable quantitative analysis tools for mining indication content. Fundamentally, our approach exploits semantic similarity computed on patient phenotypes to comprehensibly represent patient features in simple composite scores. Our tool can help to elucidate cohort substructure by segmenting large, heterogeneous groups of subjects into subgroups based on shared multidimensional phenotypes. Identification of this structure can help to identify and establish cohorts for associative or experimental study, accelerating the investigation of genetic variation. Identification of cohorts can also lead to discovery of novel functional variants that drive complex phenotypes. We have also developed a prototype graphical interactive data viewer exploiting our computational toolkit. This viewer can aid decision support through visual query and analysis of structured input data. This tool can help simplify identification of clinically relevant variants by facilitating indirect matching of patient phenotypes to cataloged variants already known to be associated with semantically similar patients or reported OMIM diseases. We use our tools, in the context of the Human Phenotype Ontology representation of patient indications, to analyze a pilot cohort assembled from retrospective data from the Whole Genome Laboratory at Baylor College of Medicine. We demonstrate the performance of our method for matching to known diseases by comparing our computational OMIM disease matches for subjects against the findings reported in exome reports. These tools can help improve the quality of clinical care by more effectively utilizing available indication data, increasing the value of the electronic health record (EHR), and better illuminating the correspondence between the requisition content and the ultimate genetic diagnosis.

1383S

Efficient and accurate multiple phenotypes regression method for high dimensional genomic data considering the population structure. *J.W. JOO[1], E.Y. Kang[2], E. Eskin[1,2,3].* 1) Bioinformatics IDP, UCLA, Los Angeles, CA; 2) Computer Science Dept, UCLA, Los Angeles, CA; 3) Human Genetics Dept, UCLA , Los Angeles, CA.

Typical GWAS test correlation between a single phenotype and each genotype one at a time. However, it is often very useful to analyze multiple phenotypes simultaneously. Especially, high-dimensional multiple phenotypes analysis is preferable with the advent of high-throughput technologies that produce a huge amount of data everyday. For example, researchers may want to detect variants associated with many phenotypes such as a profile of gut microbiota which contains tens of thousands species. Another useful application of high-dimensional multiple phenotype analysis is for detecting regulatory hotspots in eQTL studies. Many genes are known to be regulated by a small number of genomic regions called regulatory hotspots and those are very important evidence of the presence of master regulators of transcription. In addition, due to clinical overlap and correlation between many phenotypes, high-dimensional multiple phenotype analysis may boost the power to detect variants. There are several multivariate approaches that try to detect variants related to multiple phenotypes. However, none of them consider population structure and may result false positive identifications. Here, we introduce a new methodology referred to as GAMMA that could both simultaneously analyzes many phenotypes as well as corrects for population structure. In simulated study, GAMMA accurately identifies true genetic effects without false positive identifications. While other methods either fail to detect the true effects or result many false positive identifications. We further apply our method to a real Hybrid Mouse Diversity Panel data and show that GAMMA identifies several variants that are likely to have a true biological mechanism.

Using a Pan-Genome Reference for Sequence Alignment and Accurate Haplotype Discovery. *D. Kural.* Research & Development, Seven Bridges Genomics, Cambridge, MA., Select a Country.

Currently, the human reference genome is the anchor point against which new variants are discovered, and annotations are made. This approach relies on accurate matching placement of short reads generated by high throughput sequencing to the reference genome, leading to the development of aligners and variant detection (including SV/CNV) algorithms suited for these new high throughput technologies with an emphasis on speed. We develop an approach capable of aligning against a population genome, removing many of the biases traditionally associated with re-sequencing that rely on a singular reference genome. We accomplish this by removing the restrictions imposed by a linear reference sequence, and by incorporating known variants. A graph genome (pan-genome) representing known variants enables the accurate alignment of short sequences containing these regions - thus boosting discovery rates of known variants in new samples, compared to existing methods, most significantly in regions containing Structural Variants. Additionally, we've developed an SV genotyper that can operate directly on graph genomes. We present results demonstrating accurate genotyping of Structural Variants, that were previously undiscovered, deriving from direct alignments to a reference graph containing both hg19 and HuRef, based on Craig Venter. Our approach enables correct alignment of reads to complex regions, leading to a more accurate determination of the personal genome queried against an enhanced graph genome representing a reference population, compared to traditional methods. We believe that the reference genome will keep serving a useful purpose in providing a common coordinate system. This approach also enables more accurate analysis of tumor/normal pairs, by incorporating the normal genome into the reference graph. This enables determining and genotyping the clonal complexity around translocations and fusion genes.

Predicting functional regulatory variants from DNA sequence. *D. Lee[1], M.A. Beer[1,2], A. Chakravarti[1,3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Center for Complex Disease Genomics, Johns Hopkins University School of Medicine, Baltimore, MD.

Genome-wide association studies (GWAS), having identified > 12,000 single nucleotide polymorphisms (SNPs) significantly associated with > 900 phenotypic traits and diseases, have highlighted the challenge of identifying specific causal variants underlying these associations. ~90% of such SNPs are intergenic or intronic, and, thus, likely regulatory, so that integration of epigenetic data can reduce the number of candidate variants. However, the presence of linkage disequilibrium (LD) and the fact that not all variants in regulatory elements are functional does not lead to unequivocal discovery of causal sites.

We propose a novel framework, using sequence-based predictive models and epigenetic data (Lee et al. 2011, Genome Res), to address this challenge. The method involves: (1) building a support vector machine (SVM) classifier based on publically available ChIP-seq and DNaseI-seq data; (2) predicting functional regulatory SNPs based on changes in the SVM score (delta-SVM) between reference and alternative alleles; (3) validation. A major advantage of our method is that it provides specific testable hypotheses of the underlying molecular mechanism (binding site, transcription factor, transcriptional target). As proof of principle, we analyzed GM12878 lymphoblastoid dsQTLs (DNaseI Hypersensitivity Quantitative Trait Loci, Degner et al. 2012, Nature) using delta-SVM trained on the DNaseI-seq data set from the same cell line. We show that: (1) our SVM classifier can accurately predict GM12878 DNaseI hypersensitive sites (area under curve=0.94); (2) ~60% of dsQTLs (~3,700 out of 6,070) are predicted to have at least one significant SNP determined by delta-SVM ($P < 0.05$); (3) ~34% of these SNPs (~1,250 out of ~3,700) are in strong LD ($r^2 > 0.5$) with their sentinel SNPs (i.e. SNP with the most significant association with DNaseI hypersensitivity); (4) these SNPs are mostly predicted to disrupt or to create transcription factor binding sites (TFBSs) known to play roles in the relevant cell type (i.e. NFKB1, RUNX1 and IRFs), as well as general and promoter specific TFBSs (i.e. AP-1, CREB, YY1, NFYA, SP1 and ETSs). Combined with association fine-mapping, our method can greatly help in the identification of causal and functional regulatory variants.

1386S

DISTMIX: Direct imputation of summary statistics for unmeasured SNPs from mixed ancestry population. *D. Lee, T. Bigdeli, B. Riley, A. Fanous, S. Bacanu.* Department of Psychiatry, Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA, USA.

Background: To improve signal detection power, many meta-analyses of genome-wide association studies use mixed-ancestry cohorts. To analyze these diverse cohorts while also increasing imputation accuracy, large multiethic reference panels are used. However, the ever increasing sizes of reference panels and study cohorts makes genotype imputation computationally unfeasible for moderately sized computer clusters. Moreover, due to modelling assumptions, the commonly used genotype imputation methods lack the ability to impute genotypes for family data. Besides, genotype imputation requires subject level genetic data, which unlike summary statistics provided by virtually all studies, are not publicly available.

Method: To overcome these limitations, we propose a novel method/software for Directly Imputing summary STatistics for unmeasured SNPs from MIXed ancestry population (DISTMIX) without imputing first subject level genotypes. Based only on the correlation matrix of allele frequencies from the study and the ethnicities in the reference panel, DISTMIX first infers the proportions of reference panel ethnicities in the study cohort. These proportions are subsequently used as weights in calculating the ancestry-weighted genotype correlation matrix as the mixture of ethnically-specific correlation matrices, as estimated from the mixed ethnicity reference panel. This mixture correlation matrix is subsequently used by DISTMIX to impute summary statistics of unmeasured SNPs using the conditional expectation formula for multivariate normal variates.

Results: Experiments based on our simulated null data sets with different types of ancestry shows that the proposed method controls the false positive rates. 1000 Genomes based imputation of summary statistics from the ethnically diverse Psychiatric Genetic Consortium Schzophrenia Phase 2 (PGC SCZ2) suggests that, when compared to commonly used genotype imputation methods, our method offers comparable imputation accuracy while requiring only a fraction of computational resources. We also present some new and interesting genetic findings for PGC SCZ2 cohort, which were obtained by increasing the size of the reference panel (and, likely, imputation accuracy) through the combination of the 1000 Genomes and UK10K reference panels.

Detecting complex fusion transcripts in pediatric cancer using a novel assembly-based algorithm CICERO. *Y. LI[1], T. Bo[2], M. Rusch[1], J. Easton[3], K. Boggs[3], B. Vadodaria[3], P. Gupta[1], G. Song[2], J. Ma[2], C.G. Mullighan[2], S.J. Baker[4], R.J. Gilberton[4], J.R. Downing[2], D.W. Ellison[2], J. Zhang[1].* 1) Department of Computational Biology, St Jude Children's Research Hospital, Memphis, TN; 2) 2Department of Pathology, St Jude Children's Research Hospital, Memphis, TN; 3) 3The Pediatric Cancer Genome Project Validation Laboratory, St Jude Children's Research Hospital, Memphis, TN; 4) 4Department of Developmental Neurobiology, St Jude Children's Research Hospital, Memphis, TN.

Fusion genes are important for cancer diagnosis, subtype definition and targeted therapy. Although RNAseq is useful for detecting fusion transcripts, computational methods to identify fusion transcripts arising from internal tandem duplication (ITD), that have multiple partners, low expression or non-template insertion are limited. We developed an assembly-based algorithm CICERO (CICERO Is Clipped-reads Extended for RNA Optimization) that is able to extend the read-length spanning fusion junctions for detecting complex fusions. Using test data that include RNASeq from 3 ependymoma (EPD), 39 low-grade glioma (LGG), and 128 acute lymphoblastic leukemia (ALL), we have shown that CICERO is able to detect multi-segment fusion transcripts resulting from chromothripsis, internal tandem duplication or rearrangement at a highly repetitive immunoglobulin (IG) locus; all of which would be missed by existing fusion analysis methods. The overall sensitivity and accuracy of CICERO are much higher compared with existing tools such as deFuse and Tophat-Fusion. Using CICERO, we analyzed >600 brain tumor and leukemia transcriptomes from the St. Jude/Washington University Pediatric Cancer Genome Project (PCGP) and detected recurrent C11orf95-RELA fusions in EPD, FGFR1 ITD in LGG, NTRK fusion in high-grade glioma and activating kinase fusions with multiple partners in ALL. CICERO also shows high sensitivity when detecting fusions with low expression, like BRAF fusions in LGG, making it useful for identifying subclonal lesions and for analyzing tumor specimens with low purity. Furthermore, the power of CICERO increases with the extended read-length enabled by improvement in next-generation sequencing (NGS) technology. Using paired-end 300bp RNAseq reads, CICERO shows the ability to assemble near full-length fusion transcripts and identify complex fusions with multiple segments.

Mixture modeling of next generation sequencing data and its application to estimating genotype frequency. *J. Lihm[1], S. Yoon[1], S.J. Finch[2].* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Stony Brook University, Stony Brook, NY.

Studying a probability of an individual having a variant, inherited or not, is of interest in genetic studies. We present a method for modeling the frequency of single nucleotide polymorphism variants in the exome capturing sequence data of an individual. Mixture modeling is used to model the proportion of alternative allele at a position under the biallelic single nucleotide polymorphism model. We suggested the application of this mixture modeling in this paper. We measured the proportion of alternative allele for positions in chromosome 1 exome sequencing data of two trios from pilot 3 study in the 1000 genomes project. The measurement was based on the counts of reference and alternative allele in the pileup file from SAMtools. We fit the proportions to mixture model of two point distributions and five continuous distributions. The fitted mixture model well described the properties of the distribution of the alternative allele proportions. The estimates of mixing proportions were used to estimate the fraction of each genotype in the data. Each individual had different estimates of parameters, but the estimates of genotype fractions were similar. We found the he estimated fractions of each trio clustered. We developed an expectation-maximization algorithm to obtain the maximum likelihood estimates of the mixture model parameters. Its application to estimate the fraction of each genotype was presented in this paper.

1389S

A high-performance database framework for fast and easy prioritization of disease related variants from Exome Sequencing data. *B. Linghu, F. Yang, R. Bruccoleri, J. Szustakowski.* Novartis Institutes for BioMedical Research, Cambridge, MA.

Exome sequencing (Exome Seq) has become a promising approach to identify disease related genetic variations. Pinpointing the small subset of pathogenic mutations amongst the thousands or millions of variants generated in an Exome Seq experiment remains a conceptual and computational challenge. One common approach is to use relational database systems to conveniently organize and query variant data for prioritization. However, traditional database systems often perform poorly when applied to such "Big Data". Recently, a number of high-performance database systems have been developed specifically to enable analysis of extremely large data sets. Here we describe applying one such system, namely Vertica, to prioritize disease variants. Our approach leverages Vertica's high performance capabilities to efficiently model, store, and query a comprehensive landscape of information including variant calls, variant quality metrics, predicted functional consequences, allele frequencies, disease prior knowledge, inheritance patterns, and clinical phenotypes. This framework enabled the convenient and efficient identification of candidate disease variants, with significant improvements over traditional databases. To our knowledge, this is the first demonstration that high-performance databases such as Vertica provide an efficient solution to prioritize variants from exome sequencing.

1390M

Analysis of Human neurodevelopmental disorders from the systems biology perspective using the Lynx Platform. *N. Maltsev[1], D. Sulakhe[2], D. Boernigen[1], B. Xie[1], A. Taylor[1], A. Paciorkowski[3], W. Dobyns[4], T.C. Gilliam[1].* 1) Human Genetics Department, University of Chicago, Chicago, IL., USA; 2) Computation Institute, University of Chicago, Chicago, IL, USA; 3) Departments of Neurology, Pediatrics, and Biomedical Genetics, University of Rochester Medical Center, Rochester, NY, USA; 4) Center for Integrative Brain Research, Seattle Children's Research Institute and Department of Pediatrics, University of Washington, Seattle WA, USA.

Understanding of genetic mechanisms underlying common heritable disorders (e.g. autism, schizophrenia, brain malformations) is one of the most important challenges of biology. Recent advances in biology provided new perspectives onto studies of complex heritable disorders, including: networks-based view of Human disorders; emergence of "phenomics" and a notion of interrelatedness of disease traits. However, the progress of biomedicine facilitated by these methodologies depends on availability of the new bioinformatics platforms supporting the development of integrative models of genetic disorders and identification of their characteristic multidimensional patterns of inheritance. We present an approach and a supporting computational platform Lynx (http://lynx.ci.uchicago.edu/) for analysis of common heritable disorders from the systems biology perspective. Our approach is three-fold and includes tools for the enrichment analysis, gene prioritization and the development of the networks-based models of biological processes in health and disease. These tools utilize genomic, functional, clinical and experimental information from the Lynx knowledge base integrating over 35 public and proprietary databases and information derived from the literature using advanced text mining. We will illustrate our approach using analysis of brain connectivity disorders (e.g. agenesis of corpus callosum, autism, schizophrenia) as an example. While interest in the biological mechanisms that lead to heritable brain disorders such as autism, infantile epilepsy and brain malformations has been high, discovery of the underlying genetic mechanisms has proven elusive despite some recent advances. Previous studies of developmental brain disorders has led to understanding that "interrelatedness" between molecular components postulated by the systems approach will be essential for understanding both individual susceptibilities and possible biological interventions. The presented work is based on comparative analysis of a group of developmental brain disorders that often co-occur and share at least a subset of causative genes (e.g. autism, agenesis of corpus callosum, mid-hindbrain malformations). Our analysis allowed uncovering some of the common molecular mechanisms that underlie these disorders. This knowledge will eventually lead to the development of efficient diagnostic and therapeutic strategies.

Identification of differentially expressed genes and somatic mutations in esophageal adenocarinoma cancer patients. *M. Matvienko[1], B. Øster[2], A. Joecker[2], A.-M. Hein[2], P. Dekker[2], R. O'Neill[3], A. Krejci[4], A. Arens[2], N. Thomson[1], C. Boysen[1], S. Mønsted[2], R. Forsberg[2], B. Knudsen[2], T. Knudsen[2], T. Hupp[3].* 1) CLC bio, a Qiagen Company, Davis, CA; 2) CLC bio, a QIAGEN Company, Silkeborgvej 2, Aarhus, 8000, Denmark; 3) 2p53 Signal Transduction Group, University of Edinburgh Cancer Research Centre in the Institute of Genetics and Molecular Medicine, Crewe Road South, Edinburgh EH4 2XR, United Kingdom; 4) Regional Centre for Applied Molecular Oncology, Masaryk Memorial Cancer Institute, þlutý kopec 7, 656 53 Brno, Czech Republic.

High throughput sequencing technologies are currently revolutionizing the cancer research area with rapid improvements in sequencing capacity and time consumption. As a result the most time consuming step has moved from being the sequencing process itself to being the bioinformatic data analysis. RNA sequencing (RNA-Seq) is used in an increasing number of transcriptomic studies. The great advantage of using RNA-Seq is its ability to precisely quantify transcript levels and identify novel transcripts, isoforms, and splice junctions, while further providing information of the mutational landscape down to single base resolution. To ease the hurdles associated with RNA-Seq data analysis there is an increasing demand for tools that are specifically tailored to RNA-Seq data. Here we describe how the newly developed CLC Cancer Research Workbench can be used to analyze and visualize RNA-Seq data with ready-to-use workflows that automatically map, quantify, and annotate transcriptomes. We identify differentially expressed genes and transcripts in Illumina HiSeq transcriptomic data from matched tumor and normal samples from four esophageal adenocarinoma cancer patients, and compare the mutational patterns in the samples with the expression values of the corresponding genes. Results are visualized in a track based genome browser view, which provides the means for quick and easy navigation as well as allowing the user to simultaneously view and annotate multiple samples and different data types (e.g. genes, transcript expression levels, and detected variants).

1392S

A Simple Method of Generating Reproducible NGS Workflows. *M. Mikheev, A. Taffel, G. Ganebnii, D. Leca, A. Lisnik, M. Hohlovich, A. Dobretsov, V. Shakin, M. Gollery.* Biodatomics, Bethesda, MD.

A core tenet of biological study is that research by one scientist or organization must be reproducible -- and thereby verified -- by third parties. The NGS analyses that are now dominating genomic research commonly employ open-source, command line algorithms. While these algorithms are powerful, flexible and readily accessible, they have a drawback when it comes to creating research pipelines that can be identically reproduced and verified by other researchers. Specifically, each algorithm has its own options, variables and formats that govern the manner in which it is executed. Furthermore, the algorithm's executable code itself may go through multiple variations and versions. When these algorithms are then combined into a pipeline, the same variability applies exponentially. Unless all of these factors can be held constant across datasets, locations, and users, research will not be reproducible and verifiable by third parties. Several groups have developed software systems with Graphical User Interfaces designed to ease the manipulation of open source algorithms; however, none embodies a mechanism to enable reproducible research. BioDatomics set out to design and create a mechanism to facilitate reproducible research for its BioDT analytics platform. The solution turned out to be surprisingly simple. Once the original researcher has "locked in" an algorithm or workflow, they can assign it a version number. The version captures all relevant metadata about the algorithm or set of algorithms. When the algorithm or workflow is shared with colleagues, the originator has the option of forcing downstream executions to run as described in the version number. In this way, research can be recreated without regard for who is running the analysis, where it is being run, or even the passage of time. This poster will explain the need for reproducible research, the inherent obstacles within open source algorithms, and will present the simple solution to the problem.

1393M

Clinical whole-exome and whole-genome sequencing in dystonia: a key role for UMD knowledgebases. *M. Miltgen[1,2], A. Blanchard[1,2], L. Barré[1,2], C. Palacin[1,2], C. Guien[1,2], A. Pinard[1,2], A. Roubertie[4,5], C. Béroud[1,2,3], G. Collod-Béroud[1,2].* 1) Aix-Marseille Université, GMGF, 13385, Marseille, France; 2) Inserm, UMR_S910, 13385, Marseille, France; 3) APHM, Hôpital Timone Enfants, Laboratoire de Génétique Moléculaire, 13385, Marseille, France; 4) Département de Neurologie Pédiatrique, Hôpital Gui de Chauliac, 34295, Montpellier, France; 5) Inserm U1051, Institut des Neurosciences de Montpellier, 34091, Montpellier, France.

As the cost of genome sequencing falls, the clinical use of whole exome sequencing (WES) in first line of molecular testing becomes widespread. These approaches can facilitate the work-up of disorders like dystonia that present large clinical variability and clinical overlapping for the different involved genes. WES is also the technique of choice for clinical practice as newly identified genes can be easily added to the bioinformatics pipeline. Nevertheless, because of the huge amount of data generated by such technology, access to reference knowledge base system is central for accurate data analysis and interpretation. To date, several kinds of primary dystonia have been characterized: "pure", "plus", "paroxystic" and "heredodegenerative" covering 23 forms of these diseases and 17 genes have been identified. Our team has developed the UMD (Universal Mutation Database) reference system allowing not only creating locus specific databases, but also analyzing and interpreting data through various algorithms like a pathogenicity of missense and synonymous mutations prediction system (UMD-Predictor®) or algorithms to evaluate the impact of mutations on splicing signals. In order to exhaustively collect, validate and annotate molecular and clinical data for patients presenting with dystonia we have created locus specific databases for genes currently known for being involved in these diseases: *ANO3, ATP1A3, CIZ1, GCDH, GCH1, GNAL, MR1, PRKRA, PRRT2, SGCE, SLC2A1, SPR, TH, THAP1,* and *TUBB4a.* Due to a founder effect for *TAF1* and the lack of genetic heterogeneity for *TOR1A* (four mutations reported to date), they were not included in this project at present. Most of the 15 genes show a wide clinical spectrum that is not restricted to dystonia but is also associated with several other diseases for which data are also included. These databases contain mutations collected from literature and through direct collaborations with diagnostic laboratories representing 1,719 entries to date. The main goals of this work are to provide an exhaustive collection of clinical and molecular data associated with dystonia and to facilitate WES data analysis in the context of dystonia. We believe that these resources could play a pivotal role in such heterogeneous diseases and decrease the diagnostic wavering by facilitating WES integration in clinical practice.

A high-fidelity simulation validation framework for high-throughput genome sequencing with cancer applications. *J.C. Mu[1,2], M. Mohiyuddin[2], J. Li[2], N. Bani Asadi[2], M.B. Gerstein[3], A. Abyzov[4], W.H. Wong[5,6], H.Y.K. Lam[2].* 1) Department of Electrical Engineering, Stanford University, Stanford, CA; 2) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 3) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 4) Department of Health Sciences Research, Mayo Clinic, MN; 5) Department of Statistics, Stanford University, Stanford, CA; 6) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

High precision simulation and computational validation are essential in characterizing and assessing the accuracy of NGS analysis. We present VarSim, an integrated computational framework that leverages state-of-the-art read simulation and vast annotation databases to generate realistic high-throughput sequencing reads for normal and tumor samples and report detailed accuracy statistics. It also has the ability to isolate the analysis to specific regions of interest, such as disease genes.

For each normal or disease sample, VarSim first generates a phased diploid genome using variants, including various types of structural variations, from existing annotations and novel sites. Next, reads are simulated from this diploid genome using empirical error models. After alignment and variant-calling on the simulated reads, VarSim reports detailed statistics on the accuracy of the results in an HTML document. These statistics include alignment accuracy and variant-calling accuracy for different variant types and sizes, as well as for different categories of genomic regions, e.g., genes and repeats. Since VarSim generates a diploid genome, genotyping accuracy is also reported. For tumor samples, VarSim also uses COSMIC annotations to generate the tumor variant set. To simulate the impurity and heterogeneity of tumor samples, the reads for a tumor sample are constructed by mixing the reads generated from multiple sets of tumor variants with the reads generated from normal variants in a specified proportion. After running somatic mutation callers on the reads, VarSim then generates a report on the accuracy of the somatic variant calls.

To demonstrate its utility and enable rapid validations, we generated three synthetic genomes and their reads at high coverage (100x): one a normal female sample, another a male sample with a rare disease and finally a tumor-normal sample pair. We compared the accuracy statistics generated by VarSim for these genomes on popular secondary analysis tools including aligners, small variant callers, structural variant (SV) callers and somatic mutation callers. One of these tools includes our multi-algorithm SV caller, MetaSV, which improves both sensitivity and specificity of SV calling. No other simulation framework offers such a comprehensive validation of secondary analysis over a variety of whole genome sample types.

Accurate estimation of transcript isoform expression from RNA-Seq data by improved variational Bayesian inference. *N. Nariai, K. Kojima, T. Mimori, Y. Sato, Y. Kawai, Y. Yamaguchi-Kabata, M. Nagasaki.* Tohoku University, Sendai, Miyagi, Japan.

RNA sequencing (RNA-Seq) technologies have been widely used for quantification and identification of transcripts at single-base resolution. However, in many cases, short reads can be aligned to more than one location of reference sequences, which complicates quantification of transcript isoforms from RNA-Seq data. Previously, graphical models have been proposed to handle isoform abundances as parameters, and unknown alignment states as hidden variables. By using the expectation maximization (EM) algorithm, maximum likelihood estimate can be obtained through an iterative update of parameters. However, the EM algorithm poses a risk of overfitting because of noise, such as sequencing errors, introduced in RNA-Seq data. Also, its rate of convergence is known to be slow. We have previously proposed a Bayesian approach, TIGAR (https://github.com/nariai/tigar), in which model parameters are handled as the posterior distribution and are estimated by variational Bayesian inference in order to avoid the overfitting problem and control the model complexity (the number of transcript isoforms). Here, we have implemented an improved algorithm to eliminate unnecessary calculations in each iteration of variational Bayesian inference, which significantly speeds up the convergence of the iterative computations. We apply our method to both simulation data and real data and evaluate performance in comparison to existing methods. Our method performs better than existing methods for both single-end and paired-end reads.

Phy-Mer: A novel alignment-free and reference-independent mitochondrial haplogroup classifier. *D. Navarro-Gomez[1], J. Leipzig[2], M. Lott[2], L. Shen[1], A. Stassen[3], D.C. Wallace[2,4], M. van Oven[5], M.J. Falk[4,6], X. Gai[1].* 1) Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA; 2) 2Center for Mitochondrial Medicine and Epigenomic Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Clinical Genetics, Maastricht University, The Netherlands; 4) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 5) Department of Forensic Molecular Biology, Erasmus MC - University Medical Center Rotterdam, The Netherlands; 6) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Accurate mitochondrial haplogroups determination is critical for population genetics, anthropology, and forensics. It is equally if not more important for clinical genetics as mitochondrial haplogroup associations with human diseases have been identified. Despite this, there is a lack of computational tools to facilitate automated classification starting with mitochondrial sequences. A mitochondrial sequence has to be aligned to a mitochondrial reference genome in order to identify the polymorphisms, which are then compared individually and frequently manually to the haplogroup determining polymorphisms, such as those summarized in Phylotree (http://www.phylotree.org/). What complicates more is that the choice of optimal mitochondrial reference genome remains controversial as some researchers pointed to various limitations with the commonly used Revised Cambridge Reference Sequence (rCRS) and proposed to replace rCRS with Reconstructed Sapiens Reference Sequence (RSRS) instead. There is a strong need therefore for an alignment-free mitochondrial haplogroup classifier that is hence agnostic to the reference sequence of choice. Results: Using a k-mer approach, we developed a Python software package called Phy-Mer that determines the associated haplogroup of a mitochondrial sequence to the highest resolution currently feasible based on Phylotree without having to align it. Comparisons with other available manually curations, and existing haplogroup tools such as HaploGreb and Mitomaster, revealed superb performance of our tool, in terms of accuracy, sensitivity, as well as the ease to use. Phy-Mer has an added functionality such that next-generation sequence data can be used directly as input. Accurate haplogroup call can be obtained in less than 1 minute per sample with FASTA input and about 2 minutes per sample with BAM file of either whole-exome or whole-genome sequencing data sets on a desktop computer. Availability: The source code and sequence library is being made freely available on GitHub (https://github.com/), as well as the websites of the Mitochondrial Disease Sequence Data Resource Consortium (http://mseqdr.org) and PhyloTree.org (http://www.phylotree.org/).

1397T

Application of Machine Learning Techniques to Next Generation Sequencing Quality Control. *S.M. Nicholls[1,2], A. Clare[2], J.C. Randall[1].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Aberystwyth University, Aberystwyth, Wales, United Kingdom.

Advances in genetic sequencing hardware have introduced the concept of massively parallel DNA sequencing, reducing both the time and cost involved in performing genetic analysis. However, these "next-generation" processes are complicated and open to error, thus quality control is an essential step to ensure confidence in any downstream analyses carried out.

As part of the Sanger Institute's human genetics informatics pipeline, a system called *auto_qc* is responsible for applying quality control to samples within the pipeline. It does this by comparing a subset of quality metrics output by *samtools stats* to hard-coded thresholds, determining whether a particular sample has reached a level that requires a warning, or has exceeded the threshold and failed a test entirely. Whilst this catches most of the very poor quality outputs, a large number of samples are flagged for manual inspection at the warning level; a time consuming task which can invite inefficiency and error.

Using a set of 13,455 lanelets (each containing data from one indexed sample extracted from a single lane of multiplex sequencing) drawn from 4,915 DNA samples we investigate the accuracy of a range of machine learning classifiers for a series of quality control data sets and show it is possible to generate minimal yet accurate models, creating decision trees which closely resemble the behaviour of an already existing manually curated QC system -- using stratified cross-validation, a method which measures the proportion of samples that were correctly classified as indicated by the manually curated training set, our models were able to gain scores of 95% and above. To support this work we have developed *Frontier*, a Python package which provides users with interfaces for the reading, storage and retrieval of *samtools stats* data for the purpose of working with a machine learning framework. *Frontier* is freely available open-source software hosted at https://github.com/SamStudio8/frontier.

Computational Medicine for Investigation the functional Sterol Regulatory Element Binding Protein-1 gene Polymorphism: a new challenge for Glucose-6-phosphate dehydrogenase deficiency biology. *A. Palasuwan.* Faculty of Allied Health Sciences, Chulalongkorn University, Bangkok, Thailand.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the genetically hemolytic disease and commonly presents in Southeast Asia particularly Thailand. The severity and pattern of clinical manifestation vary greatly both among individuals with G6PD deficiency and among people of different ethnic backgrounds. Although the relevance of G6PD variants and clinical manifestations have extensively described in various populations, the association of G6PD variants and enzymatic activity is not clearly understood. Recently the expressions of G6PD have been shown to be regulated by Sterol Regulatory Element Binding Protein-1 (SREBP-1) gene. To uncover the primary causative SNP of SREBP-1 gene related to human phenotypic variation in statistical effectiveness with large sample set, the new inventory technology such as high throughput genome sequencing, DNA chip technology are the promising tools. In order to reduce the cost and time consuming in a large cohort genetic association study. Computational genetics approach facilitates the selection of potentially functional genetic polymorphisms and the plausible biological explanation of genetic association study results. In this study, the in-silico genetic analysis approach has been used for uncovering the potential functional genetic polymorphisms of SREBP-1 gene. The genetic polymorphism mining technique, functional effect prediction, linkage disequilibrium(LD) approach of SREBP-1 gene polymorphisms were extensively studied in reference populations from HAPMAP project. Many candidate single nucleotide polymorphisms (SNP), a nucleotide substitution, localized in regulatory region have been identified as a functional SNP. However nonsynonymous SNPs also demonstrated the possible functional effect. The large haplotype block obtained from LD analysis indicated a high nonrandom association in this region. We therefore proposed the usefulness of computational genetic approach for analyzing SREBP-1 gene and demonstrated the fascinating results of high potentially functional SNPs which can be a good candidate marker for human genetic association study. The utilization of computational genetic approach is the meaningful tool in the field of life science both in pre-and post-experimental study.

1399M

Computational tools for discovery of patterns and associations in genetic and genomic data. *P. Pavlidis, E. Portales-Casamar, G. Charathsandran, E. Chong, C. Kwok, C. McDonald, N. St. Georges, P. Tan, A. Zoubarev, S. Rogic.* Psychiatry / Centre for High-Throughput Biology, University of British Columbia, Vancouver, British Columbia, Canada.

We present three free, open source integrated computational systems designed to aid researchers who are analyzing complex genetic and genomics data sets. They address common challenges in functionally characterizing and prioritizing experimentally obtained gene lists or genetic variants.

Phenocarta (phenocarta.chibi.ubc.ca) is a curated gene-phenotype knowledgebase consolidating information from over 15 data sources. Phenocarta currently holds more than 120,000 lines of evidence linking over 12,000 genes to nearly 3000 different phenotypes. We are introducing a novel evidence scoring scheme that will further enhance the utility of the data. Phenocarta data can be downloaded for use in other tools such as ErmineJ (gene set analysis).

Gemma (gemma.chibi.ubc.ca) is a database, analysis software system and web site for genomics data re-use and meta-analysis. Currently, Gemma contains analyzed data from over 6000 curated and re-analyzed expression profiling studies (microarrays and RNA-seq), yielding hundreds of millions of differential expression results and coexpression patterns (correlated expression) for retrieval and visualization. With optional registration users can save their own data and securely share it with other users. Gemma can be used to identify potential functional relationships among genes and with respect to phenotypes, and provides multiple search, analysis, browsing and visualization tools.

The newest tool, **ASPIREdb** (aspiredb.chibi.ubc.ca), supports the exploration, analysis and mining of complex phenome-genome datasets. The system has a powerful query engine for complex searches of genotype and phenotype characteristics in conjunction with data from external sources, such as DGV and DECIPHER. We will describe analysis tools to mine the data, including the ability to perform enrichment analysis of phenotypes in user-identified subject subgroups. ASPIREdb provides graphical representations, including an interactive ideogram, heat map views and genome browser integration. Through integration with Gemma and Phenocarta, ASPIREdb provides information on gene networks, differential gene expression and gene-phenotype associations.

Sparse structural equations for joint phenotype-genotype network analysis. *M.L. Rahman, P. Wang, M. Xiong.* Human Genetics Center, University of Texas Health Science center at Houston, Houston, TX.

Multivariate lineal model is the most widely used statistical method for genetic studies of multiple phenotypes. However, multivariate linear model for genetic studies of multiple phenotypes has several serious limitations. First, it ignores the correlations among the phenotypes. In practice, the most clinical phenotypes are often correlated. Overlooking correlation information of phenotypes will compromise identification of genetic architecture of multiple phenotypes. Second, it cannot be used to estimate the causal effects of genetic variants on the phenotypes and causal relationships among phenotypes. To overcome these limitations, we propose sparse structural equations for modeling the phenotype-genotype networks. In other words, the multiple phenotypes are presented as endogenous variables and genetic variants are modeled as exogenous variables in the structural equations. Since the current methods of parameter estimation for structural equations will lead to fully connected networks, we use regularization principal to reduce densely connected networks to sparse networks and develop alternative direction methods of multiplier to estimate parameters in the structural equations and identify the structure of phenotype-genotype networks. We formalize the causal inference in the phenotype-genotype networks using Peal's do operation. The directed acyclic graph (DAG) or its Markov equivalence class corresponding to the structural equation model is estimated from data and total causal effects of genetic variants on the phenotypes will be estimated by the DAG and Peal's back door operation. The proposed method was assessed by large simulations and applied to the NHLBI's Exome Sequencing data set with 12 phenotypes and 7,194 genes which were located in 234 pathways. We constructed phenotype-genotype network for each pathway and estimated their causal relationships. We used test statistics to formally test association of the SNPs in the networks with 12 phenotypes and identified a total of 89 genes significantly associated with at least one phenotype.

1401S

Human Splicing Finder: An invaluable system to annotate the impact of mutations on splicing signals. *G. RaÃ[1,2], D. Salgado[1,2,3], J.P. Desvignes[1,2], A. Blanchard[1,2], M. Miltgen[1,2], G. Blandin[1,2], C. Guien[1,2], A. Pinard[1,2], L. Barré[1,2], S. Olschwang[1,2,4], G. Collod-Béroud[1,2], C. Béroud[1,2,4].* 1) Aix-Marseille Université, GMGF, 13385, Marseille, France; 2) Inserm, UMR_S 910, 13385, Marseille, France; 3) EMBL Australia; Australian Regenerative Medicine Institute (ARMI), Monash University, Building 75, Clayton, Victoria 3800, Australia; 4) APHM, Hôpital TIMONE Enfants , Laboratoire de Génétique Moléculaire, 13385, Marseille, France.

The NGS technologies have dramatically changed our approach to rare human genetic diseases, leading to the identification of many disease-causing genes: the challenge is not anymore data production but data interpretation. It has been reported that many mutations (including intronic and up to 50% of missense) are not pathogenic because of their impact on the protein but rather because of their impact on the correct assembly of the pre-mRNA splicing machinery. Thus it is necessary to integrate this level of information in NGS bioinformatics pipelines. The Human Splicing Finder (HSF) system combines 12 different algorithms to identify and predict mutations' effect on splicing motifs including the acceptor and donor splice sites, the branch point and auxiliary sequences known to either enhance or repress splicing: Exonic Splicing Enhancers (ESE) and Exonic Splicing Silencers (ESS). If the HSF system has quickly become an international reference, the complexity of splicing signals often result in a flow of information preventing correct interpretation by non-specialists. To make this information accessible to all we have created an expert system for data interpretation. This algorithm uses a decision tree based on mutation position: intronic vs. exonic, localization or not in wild type splice sites or branch point. Based on these criteria, context-irrelevant signals are automatically ruled out to focus on relevant ones to evaluate the potential impact of mutations. To evaluate the data-interpretation expert system, we selected two datasets: 200 mutations reported to affect splicing (150 intronic and 50 exonic); 70 mutations (intronic and exonic) reported as having no effect on splicing signals. We then compared predictions with the manually interpreted data and with the in vitro results. The first comparison gives a 100% concordance, while the second demonstrate accuracy >0.96 for donor and acceptor splice sites; 0.95 for branch point but only 0.57 for ESE/ESS. This last result was expected, as the prediction of such signals is still difficult because of insufficient experimental data. Furthermore, to allow implementation of the HSF system in NGS pipelines, we created a dedicated webservice. In the NGS era, the HSF system could now be used both in research and clinical practice by non-experts thanks to its new data-interpretation expert system and its dedicated webservice. It could be combined with other systems such as the UMD-Predictor for WGS.

1402M

Plot: A tool to automatically summarise single variant analyses. *N.W. Rayner[1,2,3], N. Robertson[1,2], M.I. McCarthy[1,2,4].* 1) Wellcome Trust Centre for Human Genetics, Nuffield Department of Medicine, University of Oxford, Oxford, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Oxford, UK; 3) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 4) Oxford NIHR Biomedical Research Centre, Oxford University Hospitals Trust, Oxford, UK.

With the continued drop in the costs of genotyping chips and sequencing, along with the increasingly diverse number of phenotypes collected on cohorts, the number of genome wide association analyses and meta-analyses being performed has increased dramatically in recent years. The analyses are generally amenable to automation via scripting: however it is time consuming and error prone summarising the many output files. To address this problem we have developed a program, Plot, which automates this process providing a quick and easy way to generate a single Portable Document Format (PDF) document of multiple single variant analyses. The program runs as a two stage process, the first stage creates a Manhattan plot, adding chromosome and position information if required, and a Quantile Quantile (QQ) plot as well as a table of all independent variants, currently defined as distance >100kb, with a p value $<10^{-5}$. The table is annotated with predicted variant effect, if any, and whether the variant is within or near genic features. Other user definable metrics such as minor allele frequency, alleles and effect allele can also be included. The top 20 independent variant signals are also plotted using LocusZoom, its standard PDF output is automatically converted to jpeg files for inclusion in the next stage. The second stage compiles the stage one outputs into an eXtensible Markup Language (XML) DocBook document. This is formatted into an eXtensible Stylesheet Language - Formatting Object (XSL-FO) which describes a two page per analysis report comprising the Manhattan and QQ plots on the first page and the top 20 table and the top 4 variant's locusZoom plots on the second. Finally the XSL-FO is rendered using Apache™ Formatting Objects Processor (FOP) into a single PDF. The program can cope with up to two files per analysis and supports many different summary file formats from both sequencing and genotype chip based single variant analyses and meta-analyses, such as SNPtest, METAL, GWAMA and EPACTS. New formats can easily be added to the program via the properties file. To date the program has been used successfully by a number of analysts working within some of the large consortia such as SUMMIT, DIRECT, ENGAGE and UK10K running on up to ~150 different analyses at a time.

1403T

Network Modeling of Transcriptional Response to Influenza Vaccination. *A. Renwick, J. Belmont, C.A. Shaw.* Baylor College of Medicine, Houston, TX.

Although genome wide data has become common in biomedical science, fully exploiting the mutlivariate character of the data has remained a challenge. Instead of using the data more holistically to form and test systems level hypotheses, the data are frequently used as a massively parallel screening tool to identify individual candidates. When more systems level analyses are performed on data, they are often introduced sequentially. In this approach, data are analyzed first in a massively parallel fashion, and then the filtered results (the "hits") from the parallel analyses are introduced to content-based enrichment analyses. A potentially more powerful approach is to analyze the data from the systems level in the primary analysis. A number of methodological tools potentiate this analysis approach. One method is the Gaussian Lasso, which we use to infer an undirected bayesian network among changes in transcript levels. We have performed a comparative analysis of a sequential gene content approach vs the network approach using our primary data for human influenza vaccine response. Human response to vaccination invites a multivariate approach as it is a complex phenomenon involving signals between cell types and migration of cells between tissues. The inferred network identifies expression modules that respond coordinately to vaccination. Our analysis shows the interferon signaling system is extremely important in the first day after vaccination. Our results highlight the similarities and differences as well as the additional power of the multivariate content analysis approach.

1404S

A Novel Family-based Approach for Analysis and Interpretation of Exome Sequencing Data in Pedigrees. *R. Robison, M. Zhu, J. Zhu, L. Dobias, M. Brown, T. Richards, C. London, B. Beebe, T. Lefler, G. Simon, K. Wang.* Tute Genomics Inc. 150 S. 100 W. Provo, UT 84601.

Introduction: The widespread use of exome sequencing has created the need to rapidly understand the functionality of identified variants and evaluate their consequences on human phenotypes. One key way to address this is by using a family-based statistical approach to analyze the data in order to more rapidly identify causal variants for clinical syndromes. Methods: We developed a web application called Tute Genomics for comprehensive and user-friendly annotation and interpretation of genomic data, including a case-control and family-based analyses. Analysis was completed using the following approach: (1) comprehensive variant annotation with over 100 annotation types (2) variant filtering using default or user-specified criteria (3) probabilistic modeling of variants, using a machine-learning algorithm to rank all variants in a genome by their likelihood of having functional consequences with respect to a specific phenotype of interest (known as the Tute Score). Pedigree information and optional phenotype information were incorporated in the analysis as prior information, and variants were identified with labels such as inherited, de novo, compound heterozygous and shared with sibling. This information, along with Tute Score, was then used to calculate the family adjusted variant scores and gene scores in a probabilistic approach. Results: In an exome sequencing study on a pedigree where one subject was discovered to have idiopathic hemolytic anemia (IHA), we identified two heterozygous variants in *PKLR* gene, a gene previously confirmed to be associated with IHA, ranked 7th (c.1022G>C) and 11th (p.R569Q) out of all variants based on Tute Scores. When applying a recessive model where the effect of compound heterozygosity or homozygosity was considered, the *PKLR* gene ranked 3rd based on the Tute Gene Scores. When further applying a phenotype label of 'anemia' in the analysis, the *PKLR* gene ranked 1st based on adjusted Tute Gene Scores. This analysis demonstrates that our pipeline can effectively prioritize disease-causing mutations and genes in pedigrees with exome sequencing data. Conclusion: Tute can rapidly interpret large volumes of sequencing data, including family-based datasets, via a web-based clinical genome interpretation platform, with comprehensive annotation types and user-friendly interface for conducting analyses. Our results demonstrate the effectiveness of this family-based approach to support disease gene discovery.

1405M

Improving Computational Prediction of Clinically Relevant Genome Variation. *A. Rychkova, C. Bustamante.* Genetics Department, Stanford University, Stanford, CA.

Rapid, accurate, and inexpensive genome sequencing promises to transform medical care. A critical hurdle to enabling personalize genomic medicine is predicting the functional impact of novel genome variation. This is a particularly pressing problem at "clinically relevant genes" where some mutations are already known to impact phenotype (such as the BRCA1/2 cancer susceptibility genes), but where we have a very incomplete map of how genotype impacts clinical phenotype. Differentiating "benign" from "pathogenic" genetic variants is far from an exact science and, oftentimes, a doctor is left with the frustrating and inconclusive result that a patient carries a "Variant of Unknown Significance" (VUS). Existing computational approaches to variant classification all suffer from low overall accuracy rates. Their poor performance limits the general utility of these tools in the determination of whether a novel genetic variant at a "clinically relevant gene" is actually related to the disease of interest or whether incidental findings ought to be returned and when. In this project we considered variants located in the coding region of the genome, in particular missense mutations, which cause the amino acid change in the protein. Such mutations might lead to diseases by interrupting protein folding and decreasing its overall stability. Protein stability is a fundamental property affecting function, activity, and regulation of biomolecules. It is measured by the folding free energy, the free energy difference between the folded and unfolded states of proteins. Therefore, estimated folding free energy should give valuable information about the functional consequence of missense mutations. Here we develop a machine learning method that combines the predictor of protein stability with other predictors based on amino acid sequence, structure and evolutionary information. As a first pilot experiment, we focused on the Clinical and Functional TRanslation of CFTR (CFTR2) database, which assembles clinical data and accompanying CFTR variants from individuals with cystic fibrosis (CF). We used variants found in this database along with 1000 Genomes data to train and validate our method. Along with the NCBI ClinVar and NHGRI ClinGen databases we are helping develop, we will use other Locus Specific Data Bases to evaluate functional consequences of variants in clinically actionable genes reported by ACMG, and those used in newborn screening.

Cancer is a Zero Sum Game between Cells and Cells! *A.R. Salehi Chaleshtori[1], S. Bamohabbat Chafjiri[2].* 1) Medical Genetic Center of Genome, Isfahan, Iran; 2) Information and Security LAB, Sharif University of Technology, Tehran, Iran.

Cancer is the major problem of our age and massive efforts performed to solve this problem. Cancer is very variable and tumor heterogeneity is documented for many characters, including the production of growth factors, one of the hallmarks of cancer. Combined interactions within the tumor can maintain heterogeneity for the production of growth factors and explain short term effectiveness of some therapies like RNAi. Alternative strategies for evolutionarily stable treatments are discussed, but this study propose that these strategies must be completed by mathematical principles like Game theory. Game theory is a social science whose aim is to understand the behavior of interacting decision-makers. We propose that determination of equilibrium point between growth factors and apoptosis inducers can be very effective in cancer treatment as well as cancer prediction. Cancer is recognized by uncontrolled growth, invasion, metastasis and death in the end. This process is initiate by defect in equilibrium point and defeating the whole system finally. Cells that overexpressing oncogenic products elevate their growth and divisions to access the impermanent success but this process led to whole system defeat permanently. Regarding to the game theorem, we propose that tumorigenesis is a zero sum game (or competitive game) in which canceric cells elect the same strategy (further growth and division), controlling the game and finally win the game. If other cells select a definite strategy to play against cancerous cells, this cause to control the game by these healthy cells and winning the game eventually. These selfish canceric cells prefer their success to the system but if these cells possess their balance, don't exceed from equilibrium point through normal expression of oncogenes and apoptosis inducers and select stable strategy against cancerous cells, system can access the permanent success entirely. It is concluded that game theory is an applied issue in cancer treatment and prediction. Normal cells can control the cancer if these normal cells operate stable and choose the right strategy. These cells require to be trained in this field, win the game and controlling the cancer.

UMD-Predictor: A variant annotation masterpiece for NGS pipelines. *D. Salgado[1,2,3], J.P. Desvignes[1,3], G. Rai[1,3], A. Blanchard[1,3], M. Miltgen[1,3], A. Pinard[1,3], G. Collod-Béroud[1,3], C. Béroud[1,3,4].* 1) Aix-Marseille Université, GMGF, 13385, Marseille, France; 2) EMBL Australia; Australian Regenerative Medicine Institute (ARMI), Monash University, Building 75, Clayton, Victoria 3800, Australia; 3) Inserm, UMR_S 910, 13385, Marseille, France; 4) APHM, Hôpital TIMONE Enfants , Laboratoire de Génétique Moléculaire, 13385, Marseille, France.

Whole Exome Sequencing (WES) technologies are increasingly applied to clinical practice and medical research. Those experiments generate 50 to 90,000 variations per individual from which only one or two are pathogenic mutations responsible for Mendelian diseases. It is thus crucial to differentiate non-pathogenic from pathogenic mutations to limit downstream analysis. To do so, we created the UMD-Predictor system (http://umd-predictor.eu) to annotate all coding variations for their potential pathogenic effect. UMD-Predictor contains all nucleotide substitutions from human protein coding transcripts annotated through a combinatorial approach that aggregates: data related to splicing signals, evolutionary data, biochemical substitutions matrices, mutant position, and frequency in the general population. Scoring values range from 0 to 100 and correspond to 4 classes: <50 = polymorphism; ≥50 <65 = probable polymorphism; ≥65 <74 = probably pathogenic, and ≥74 = pathogenic mutations. To evaluate UMD-Predictor's efficiency we used 4 datasets containing pathogenic (P) and non-pathogenic variations (NP): Varibench with dbSNP (19,335 P; 7,897 NP), Uniprot (20,821 P; 36,825 NP), Clinvar (10,669 P; 1,817 NP) and PredictSNP (24,082 P; 19,800 NP). We then compared our system to the commonly used systems SIFT 5.1.1, PolyPhen 2.2.2, Provean 1.1.3, Mutation Assessor 2, CONDEL 1.5, MutationTaster 2 (MT2) and CADD. Various statistical parameters were calculated including ROC curves and Diagnostic Odds Ratio (DOR) which measures the effectiveness of a diagnostic test and the log(DOR) to study the trade-off between sensitivity and specificity. For all parameters, UMD-Predictor gave the best results. For example, with the VariBench/dbSNP dataset it displayed a: ROC AUC of 0.954 vs. 0.834 for CADD; DOR of 86.6 vs. 12.6 for MT2 and a log(DOR) with a 2-logs increase vs. all others. In the NGS context, UMD-Predictor's webservice analysis time was 45s (± 4s) per dataset vs. 420-9740s for other systems. If all systems accurately annotate the pathogenic mutations, UMD-Predictor gave the shortest list of candidate mutations with an average of 739 versus 2027 for other tested predictors (64% reduction of false positives). We believe that the UMD predictor system will be a masterpiece in NGS pipelines both through its very high specificity (0.95), its availability through webservices and speed. It could be combined with other systems such as Human Splicing Finder for WGS.

SUGAR: high-resolution refinement of high-throughput sequencing reads considering their spatial organization in flowcells. *Y. Sato, K. Kojima, N. Nariai, Y. Yamaguchi-Kabata, Y. Kawai, M. Nagasaki.* Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan.

To obtain valuable insights from high-throughput sequencing data, it is essential to control low-quality portions of the data affected by technical errors like air bubbles in sequencing fluidics. As a part of quality control pipeline in the Tohoku Medical Megabank Project, we developed a software SUGAR (subtile-based GUI-assisted refiner) which can handle full data of Illumina HiSeq and MiSeq machines with user-friendly GUI interface and interactive analysis capability. The SUGAR generates high-resolution quality heatmaps of the flowcell (maximum 100×100 per tile), enabling users to find signals of technical errors during sequencing. In addition, the sequence read/nucleotide data generated from the error-affected regions of a flowcell can be selectively removed by automated analysis or GUI-assisted operations by the SUGAR. This automated cleaning operation based on the sequencing quality scores (Phred) was applied to a public human genome sequencing data, and we proved that the overall mapping quality (MapQ) was improved (29.5 to 30.1; an average MapQ of the discarded reads was 25.0). Such a high-resolution data cleaning enabled by the SUGAR would improve the subsequent variant analyses that require high-quality sequence and mapping results. Consequently, this software will be especially useful to control the quality of variant calls of the low population cells, *e.g.*, cancers, and improve the analyses of somatic mutations, mitochondrial micro-heteroplasmy, etc.

RaMWAS: Analysis software for rapid methylome-wide association studies. *A.A. Shabalin, K.A. Aberg, E.J. van den Oord.* Center for Biomarker Research and Personalized Med, Virginia Commonwealth University, Richmond, VA., USA.

DNA methylation plays important role in a variety of biological processes. It is critical in tissue differentiation and development and has been implicated in several diseases including cancer. High-throughput sequencing technologies allow for genome-wide measurement of DNA methylation at high resolution, up to the level of individual CpGs. Methylation measurements from about 30 million CpGs across hundreds to thousands of samples comprise billions of values. Analysis of such data is computationally complex and requires special tools to avoid excessive memory requirements and to allow for parallelization. We present a new R/Bioconductor package, RaMWAS, which has been developed to streamline methylome-wide association studies (MWAS). Starting with aligned reads, RaMWAS can perform all steps to conduct MWAS. First, it obtains the location of target CpGs from the human genome. Next, if not known in advance, the DNA fragment size distribution is estimated using the location of mapped reads around isolated CpGs. The estimate of DNA fragment size distribution is then used to calculate read coverage at the target CpGs. The full set of CpGs can later be reduced by exclusion of non-methylated sites and combining adjacent CpGs with highly correlated coverage estimates. The data reduction step decreases computational complexity of the association study and eases the multiple testing problem. Next, RaMWAS can perform principal component analysis to identify common sources of variation, such as from population substructure. Finally, RaMWAS can perform association testing between methylation coverage estimates and phenotypes of interest accounting for known covariates and the calculated principal components. RaMWAS can also perform eQTL-like analysis by testing methylation coverage estimates against gene expression or genotype measurements. Although RaMWAS is primarily designed for analysis of data from MBD-seq, MeDIP-seq, and similar technologies, it can also be used with whole genome bisulfite sequencing data. We tested RaMWAS on MBD-seq measurements from 1,500 samples with an average of 68 million reads per sample. Using RaMWAS we estimated methylation coverage at about 30 million CpGs, which were then collapsed to about 5 million CpG sites. Using the R package MatrixEQTL, RaMWAS performed methylation QTL analysis with 5 million SNPs, a total of 25 trillion statistical tests, in 1.5 days on a computing cluster with 50 nodes.

Genome and Transcriptome Free Analysis of RNA-Seq Data (GT-FAR) using cloud computing. *T. Souaiaia[1], K. Vahi[2], R. Mayani[2], J. Herstein[1], O. Evagrafov[1], T. Chen[3], E. Deelman[2], J. Knowles[1].* 1) Zilkha Neurogenetic Institute, USC, Los Angeles, CA., USA; 2) Information Science Institute, USC, Los Angeles, CA., USA; 3) Dept of Molecular and Computation Biology, USC, Los Angeles, CA., USA.

Despite being the current gold-standard for the evaluation of gene expression, alignment studies involving RNA-seq data frequently suffer from low-mapping rates and incorrect estimation of gene models, especially for model organisms with poorly annotated transcriptomes. To overcome these shortcomings, we have developed a cloud-based version of GT-FAR, our transcriptome optional RNA-seq analysis pipeline to bring accurate expression analysis to researchers without significant computational resources. GT-FAR consists of three independent modules which (1) Annotate a reference transcriptome and infer possible splice locations, (2) Filter, trim, and align reads to reference transcripts, introns and novel splice junctions and (3) cluster unmapped or raw reads into a compact sequence preserving index to facilitate to detection of significant sequence differences between samples and provide queries to multiple homology databases. The steps in each of these modules consist of multiple tasks with variable runtime and memory requirements; often local campus resources preclude the availability of nodes capable of providing knowles@med.usc.eduan efficient combination of CPU and memory availability. Additionally, even when resources are available, the need for on-demand computation may overwhelm the necessary computational tasks carried out by many small research groups. To minimize the financial and logistical strain necessary to run a state-of-the-art analysis pipeline we have modeled GT-FAR as a Pegasus workflow, enabling it to be a deployed as a virtual machine in the Amazon EC2 cloud. We are currnelty developing a custom web interface over Pagasus WMS for the virtual machine are developing a virtual machine which will allow users to upload custom datasets, track computational progress, and be alerted when their output is available for download. The Pegasus WMS represents the workflow in an abstract form that is independent of computational resources or file location resulting in executable workflows that can be deployed on local resources, remote clusters, or computing clouds. The Pegasus WMS also provides the additional wherin the event of a fatal error or hardware failure, a rescue workflow is created that performs only the tasks not yet completed.

Pedigree Reconstruction by PRIMUS using Exome Sequencing Data. *J. Staples[1], M.H. Cho[2], D. Qiao[2], E.K. Silverman[2], U.W. Center for Mendelian Genomics[1], D.A. Nickerson[1], J.E. Below[3].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Brigham and Women's Hospital, Boston, MA; 3) Epidemiology, Human Genetics & Environmental Sciences, University of Texas Health Science Center, Houston, TX.

We have developed a software program known as PRIMUS designed to reconstruct pedigrees from variant genotypes generated by genotyping arrays, exome sequencing, or whole genome sequencing. It quickly verifies that the provided samples match the expected pedigrees and helps to correct inconsistencies. PRIMUS is an efficient algorithm for accurate pedigree reconstruction, and is particularly useful in the analysis of Mendelian diseases. In this report, we validate the performance of PRIMUS on thousands of simulated pedigrees and demonstrate its utility in reconstructing, validating, and correcting expected pedigrees using simulated and clinical pedigrees obtained from the University of Washington Center for Mendelian Genomics (UW CMG). To investigate the performance of PRIMUS on a broad range of known pedigrees, we simulated pedigree structures of varying sizes, structures, genotypes, and combinations of missing data for individuals in the pedigrees. Our analysis revealed that PRIMUS reconstructs the true pedigree in 93.1% of the simulations and a partial pedigree for an additional 6.3%. PRIMUS is an essential tool for quality control within the UW CMG, and is used to reconstruct clinically obtained pedigrees submitted to the UW CMG. One dataset consisted of 49 pedigrees containing 351 individuals with Early Onset Chronic Obstructive Pulmonary Disease (EOCOPD). Using only the variants captured by exome sequencing, we calculated genome-wide identity-by-decent (IBD) estimates with PLINK and reconstruct each pedigree with PRIMUS. These results confirm that 43 of the 49 pedigrees matched the expected pedigree information collected in the study. Among the remaining pedigrees, PRIMUS identified and corrected a combination of non-paternity errors, unintentional sample swaps, and duplicate samples, which are common issues among all large pedigree datasets. Using PRIMUS, we completed validation and error correction of these pedigrees in under a minute of runtime and a few minutes of visual inspection. PRIMUS has detected inconsistencies in other submitted pedigree data that have altered the disease model used to identify the disease causing gene—ultimately, leading to the identification of the causal gene. Using only genotype data from arrays or exome sequencing data to verify and correct expected pedigrees, PRIMUS saves time and effort that would otherwise be spent on manual verification. Funding: NSF, NHGRI, and NHLBI.

DbGaP Phenotype Quality Control. *A. Sturcke, Y. Jin, S. Pretel, N. Popova, M. Lee, L. Ziyabari, M. Feolo.* National Center for Biotechnology Information (NCBI), National Library of Medicine, National Institutes of Health, Bethesda, MD.

NCBI's dbGaP (database of Genotypes and Phenotypes) has distributed over 5,800 phenotype datasets constituting ~4.8 billion phenotypic values to more than 2,000 approved investigators since 2007. The phenotype data consists of subject consents, subject-sample mapping (SSM), subject phenotypes, and sample attributes. The SSM links IDs found in phenotype data to IDs found in molecular genetic data, such as SNPs, expression, methylation, and sequence data. The phenotype data submitted to dbGaP often contains inconsistencies or missing information, which may skew subsequent analyses of associations between phenotypes and genotypes. We have created a dbGaP submission guide to standardize the formats of all submitted datasets and data dictionaries. All submitted files are initially checked by QC scripts for formatting inconsistencies and data integrity across subjects and samples, subject consents, and the mapping of subjects and samples. The QC process also identifies conflicts in subject gender, affection status, pedigree structure, and unexpected duplicates. Potential HIPAA violations are identified by QC scripts developed to detect the presence of visit dates, birth dates, zip codes, and ages over 89. The potential HIPAA violations reported by the QC scripts are further checked manually to identify true violations. Most of the HIPAA violations detected are dates. Datasets that meet criteria are then compared to their data dictionary to assure that every variable contains a description, that every encoded data value contains a code meaning, and that the values match the units listed and fall within the logical min/max. After the submitted data have passed the pre-loading QC tests, phenotype data are loaded into dbGaP databases. Variable summaries are generated and value distributions are displayed on a preview website for review by the submitter. Statistical summaries are further manually checked to detect missing code meanings and extreme data values that could potentially be used to identify individual participants and their families. Additional ID and gender checks are conducted between phenotype and molecular genetic data. This presentation will describe the phenotype quality control process designed to ensure the integrity and accuracy of the phenotype data distributed by dbGaP.

A case study for high throughput analysis of NGS data for translational research using Globus Genomics. *D. Sulakhe[1], A. Rodriguez[1], K. Bhuvaneshwar[2], Y. Gusev[2], R. Madduri[1], L. Lacinski[1], U. Dave[1], I. Foster[1], S. Madhavan[2].* 1) Computation Institute, University of Chicago, Chicago, IL; 2) Innovation Center for Biomedical Informatics, Georgetown University Medical center, Washington, DC.

Next generation sequencing (NGS) generates massive amounts of data and its analysis requires access to powerful computational infrastructure, high quality bioinformatics software, and personnel skilled to operate the tools. We present a practical solution to this data management and analysis challenge by using the Globus Genomics platform that simplifies large-scale data handling and provides advanced tools for NGS data analysis. Globus Genomics uses Globus Transfer to allow seamless data transfer from distributed data endpoints such as sequencing centers into its analytical platform for immediate analysis. It hosts an enhanced Galaxy instance on Amazon Web Service (AWS) resources with hundreds of widely used NGS analysis tools and many pre-defined best practices pipelines for whole genome/exome, RNA-seq, or ChIP-seq data analysis. Unlimited scalability and enabling simultaneous analysis of numerous data sets is possible due to the platform's ability to provision on-demand compute clusters on AWS and submit workflows to that cluster from Galaxy. Globus Genomics allows tool specific provisioning of Amazon EC2 nodes, thus accommodating a wide range of CPU and memory intensive analytical tools that require varying compute capabilities that helps in dramatically reducing execution times and costs. This platform has been prototyped successfully for the Innovation Center for Biomedical Informatics (ICBI) to enhance translational research at Georgetown University Medical Center. We have created exome and whole genome analytical workflows, a RNA-seq workflow, and have demonstrated the analysis at scale for multiple samples. We setup Globus Online data endpoints at ICBI's local storage and S3 based storage to provide easy access to the sequence data and to seamlessly transfer the input data into Globus Genomics for analysis. The analysis of a single 80gb whole genome (paired-end) took ~12 hours using memory intensive and compute intensive AWS cluster instance (cr1.8xlarge). To test scalability, we ran the exome analysis pipeline on a batch of 78 samples from a lung cancer study obtained from EBI's SRA (ERP001575) and it was completed in parallel in 40 hours. We also ran the RNAseq workflow on a batch of 21 samples of TCGA's ovarian cancer samples downloaded from Cancer Genomic Hub (CGhub) archive. The analysis of these RNA samples was completed in 24 hours. We will present detailed results, best practices and common bottlenecks overcome by using Globus Genomics.

Targeted alignment and end repair elimination increase alignment and methylation measure accuracy for reduced representation bisulfite sequencing. *Z. Sun[1], R. Kanwar[1], S. Baheti[1], M. Goelzenleuchter[2], J.P.A. Kocher[1], A.S. Beutler[1].* 1) Mayo Clinic, 200 1st ST, Rochester, MN 55906; 2) Charité - Universitaetsmedizin Berlin, Berlin, Germany.

Background DNA methylation is an important epigenetic modification involved in many biological processes. Reduced representation bisulfite sequencing (RRBS) is a cost-efficient method for studying DNA methylation at base level on a genomic scale, yet analyzing the RRBS data is challenging. Although several programs/pipelines are available for the data analysis, it is not clear which strategy performs the best and there has been no much attention to the contamination issue from artificial cytosines incorporated during the end repair step of library preparation. To address these, we have developed Targeted Alignment and Artificial Cytosine Elimination for RRBS (TRACE-RRBS), which aligns bisulfite sequence reads to MSP1 digitally digested reference and specifically removes the end repair cytosines before CpG methylation summarization. We have tested and compared the algorithms on a simulated and a real dataset in terms of alignment speed, accuracy, and accurate methylation estimate with 7 other RRBS tools and Illumina 450K microarray platform. **Results** By aligning RRBS reads only to the genomic regions where Msp1 digests, TRACE-RRBS demonstrated as the fastest, most sensitive and specific alignment tool among the 7 compared for a simulated dataset. For the real dataset with ~50 million of reads, TRACE-RRBS took about the same time as RRBSMAP, a third to a sixth of time needed for Bismark and Novoalign. TRACE-RRBS aligned more reads correctly than most of other tools and achieved the highest correlation with 450k microarray data. The end repair artificial cytosine removal increased correlation between nearby CpGs and methylation quantification. **Conclusions** TRACE-RRBS is a fast and accurate alignment and methylation quantification tool for DNA methylation from RRBS. It is implemented using platform independent Java programming language. The package is available for public use (http://bioinformaticstools.mayo.edu).

Unraveling epistatic causal genes of diseases with hyper-sensitive multiple testing procedure. *A. Terada[1,2], K. Tsuda[3,4,5], J. Sese[1].* 1) Department of Computer Science, Ochanomizu University, Tokyo, Japan; 2) Research Fellow of the Japan Society for the Promotion of Science; 3) Department of Computational Biology, The University of Tokyo, Chiba, Japan; 4) Computational Biology Research Center, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan; 5) JST ERATO Minato Discrete Structure Manipulation System Project, Hokkaido, Japan.

Epistatic interactions are key to unraveling the genetic contributions to complex diseases and traits. However, most of the analyses in genome-wide association study (GWAS) perform a statistical test for single SNP or gene. As the reason, the existing multiple testing procedures that are widely used to avoid false discoveries in GWAS, including the Bonferroni correction and the Benjamini-Hochberg procedure, are too conservative to detect such interactions, and finding any statistically significant combinations after applying such corrections is hopeless. We propose a novel multiple testing procedure to identify the epistatic effects of complex diseases, which is called the Limitless Arity Multiple-testing Procedure (LAMP). The LAMP can list any statistically significant combinations without any limit and can be substituted for the Bonferroni correction by rigorously calculating the family-wise error rate (FWER). We demonstrated that the LAMP compute the adjusted P-value by multiplying by a value that is 250 times smaller than the value by the Bonferroni correction or Holm procedure, while maintaining the FWER under the threshold. We also showed that the LAMP could identify significant combinations from existing GWAS data that have the potential to cause diseases, and that were overlooked by the Bonferroni correction. This procedure may contribute to the discovery of new combinatorial effects by the reanalysis of existing data.

1416S

Graphical algorithm for integration of genetic and biological data: Proof of principle using psoriasis as a model. *L.C. Tsoi[1], J.T. Elder[2,3], G.R. Abecasis[1].* 1) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Dermatology, University of Michigan, Ann Arbor, MI; 3) Ann Arbor Veterans Affairs Hospital, University of Michigan, Ann Arbor, MI.

Pathway analyses to reveal biological mechanisms for genetic association studies have great potential to better understanding of complex traits with major human disease impact. However, current approaches have not been optimized to maximize statistical power to identify enriched functions/pathways, especially when the genetic data derives from studies using platforms (such as Immunochip and Metabochip) customized to focus on markers near previously identified top-ranking loci. We present here a novel approach, called MEAGA (Minimum distance-based Enrichment Analysis for Genetic Association), with the potential to address both of these important concerns. MEAGA performs enrichment analysis using graphical algorithms to identify subgraphs among genes and measure their closeness in an interaction database. It also incorporates a statistic summarizing the numbers and total length of subgraphs, depicting the overlap between observed genetic signals and defined function/pathway gene-sets. MEAGA uses sampling techniques to approximate empirical and multiple testing-corrected p-values. We show in simulation studies that MEAGA has more power than count-based strategies to identify disease-associated functions/pathways, and the increase in power is influenced by the shortest distances among associated genes in the interactome. We applied MEAGA to the results of a meta-analysis of psoriasis using Immunochip datasets, and showed that associated genes are significantly enriched in immune-related functions and closer with each other in the protein-protein interaction network. Count-based strategies failed to identify functional enrichment in the same data.

1417M

A population- and pedigree-aware alignment strategy for Next Generation Sequencing data. *E. Valkanas[1], E. Flynn[1], T. Gall[2], J. Elson[3], A. Brandt[1], P. Pemberton[1], L. Carmichael[4], J. Osman[4], S. Leighton[4], M. Groner[4], D. Adams[1, 5], W. Gahl[5], T. Markello[1].* 1) NIH Undiagnosed Diseases Program Translational Laboratory, Bethesda, MD; 2) Walter Reed National Military Medical Center, Bethesda, MD; 3) Microsoft Research, Redmond, WA; 4) Appistry Inc., St. Louis, MO; 5) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

Next Generation Sequencing (NGS) data is conventionally aligned to a standard human reference sequence that provides a common reference for understanding genetic variation. However, since the standard human reference is derived from a limited number of samples, it cannot account for all non-pathogenic variations arising in the human population. This problem confounds alignment and genotyping of NGS data. The NIH Undiagnosed Diseases Program has developed a Diploid Alignment pipeline in order to increase the accuracy of short read alignment and improve variant calling. This strategy applies pedigree information in the form of genome-wide family SNP Chip data and imputes population data using SNP Chip data and HapMap information from the 1000 Genomes Project. The result is a set of three reference sequences for alignment: a maternal, paternal, and concatenated parental reference. The short reads from NGS were then aligned to each of these individualized references and the results were lifted over to the standard reference coordinates. The lift over enables results from the diploid alignment to be annotated with information from common databases. To determine the efficacy of this alignment strategy, we aligned a cohort of 70 individuals using this novel diploid strategy and compared the results to those obtained using a standard alignment pipeline. Using the diploid alignment strategy, there was a significant decrease in gapped alignments as well as in the number of differing variant calls. Results that differed between the two pipelines were Sanger validated; of the interpretable sequences, the diploid alignment strategy correctly called genotypes six times more frequently than the standard alignment strategy. These results suggest that an aligner that is both pedigree and population aware will call genetic variants with greater accuracy than an aligner that relies only on information from the standard human reference sequence.

My-Forensic-Loci-queries (MyFLq) BaseSpace application for analysis of forensic STR data generated by massive parallel sequencing. *F. Van Nieuwerburgh[1], C. Van Neste[1], D. Van Hoofstat[1], W. Van Criekinge[2], D. Deforce[1].* 1) Lab of Pharmaceutical Biotechology, Ghent University, Ghent, Belgium; 2) Biobix, Ghent University, Ghent, Belgium.

Forensic DNA profiles of short tandem repeat (STR) loci are currently obtained using PCR followed by capillary electrophoresis (CE). Massive parallel sequencing (MPS) technologies do not rely on size separation and thus relieve the limitations on locus multiplexy. MPS therefore creates extra possibilities within forensics for analyzing degraded samples, mixed samples, etc. Data analysis of raw sequencer reads, resulting in a reliable and usable forensic human identification report is still in early development. Only a couple of bioinformatics methods have been published. Unfortunately, all of these methods are command-line based and thus unsuitable for use by forensic analysts without a bioinformatics training. Recently, we published an open-source bioinformatic framework My-Forensic-Loci-queries (MyFLq) for analysis of MPS forensic data in a generic, platform independent way. The MyFLq framework was successfully applied on an Illumina MiSeq dataset generated from a multi-locus STR PCR on both single contributor samples and multiple person mixture samples.

We now present the newest developments on MyFLq. We created an application with an easy to use graphical user interface in which we have incorporated the MyFLq algorithms. Several new features have been added such a electropherogram style visual representation of the results, allowing for backward compatibility with CE results. To our knowledge, we are the first to present an open-source GUI application for forensic MPS data analysis. It can run as a standalone web application, or run embedded in the Illumina BaseSpace environment. In the latter, analysis is only a matter of running the samples on an Illumina machine and starting the MyFLq app to obtain a finished, graphical and interactive human identification report.

Identification of Somatic Mutations at Single-Cell Resolution. *X. Wang, K. Szulwach, P. Chen, G. Sun, M. Unger, R. Ramakrishnan.* R&D, Fluidigm inc, South San Francisco, CA.

Cancer genomes are extremely complex and diverse. When cells accumulate low-frequency mutations to form polyclonal cell populations, they co-exist with normal cells. It is difficult to identify these somatic mutations and the underlying clonal architecture from bulk cell populations, which mask the underlying heterogeneity of these rare cell types. DNA sequencing that incorporates the C1™Single-Cell Auto Prep System from Fluidigm provides a streamlined, upstream workflow for single-cell capture, lysis, and whole genome amplification. We have applied this workflow to 100 cancer/normal single-cells derived from the same individual [CRL-2338 (HCC1954) ductal carcinoma cells and CRL-2339 (HCC1954BL) normal B-lymphoblasts]. We subsequently performed whole-exome sequencing at an average of 27x coverage per cell. In order to facilitate the interpretation of variants identified in single cells, we developed an analysis workflow to identify somatic mutations and clonal architecture at single-cell resolution. In the analysis, we first determined the false discovery rate (FDR) of single cell genotyping based on high confidence homozygous sites in bulk genomic DNA, and then we applied the FDR to a binomial test (a cumulative distribution function) to determine the probability of observing a variant in a given number of cells among the total number of cells tested. A set of mutation filters, including the minimum number of single cells with mutations, variant allele frequency in tumor single cells, and the p-value of Fisher's Exact test of normal/tumor (and so forth), were used to eliminate false somatic mutations caused by random errors from whole genome amplification and sequencing. Our results demonstrate that the single-cell mutation analysis workflow can accurately detect somatic mutations in single cells and match results from the TCGA/ICGA "somatic mutation" calling benchmark study. The above analysis workflow has been integrated in an R package (SINGuLAR™Analysis Toolset 4.0) for free public use.

Sparse functional graphical model for joint analysis of RNA-seq and DNA sequencing data. *P. Wang[1,2], S. Guo[1,2], L. Jin[2], M. Xiong[1].* 1) University of Texas School of Public Health, Houston, TX., Select a Country; 2) Fudan University, Shanghai, China.

A focus of systems biology is to combine multiple types of genomic and epigenomic data and generate large networks of intermolecular interactions including physical associations underlying protein-protein and functional association measuring relationships between genes and correlated expression between genes. The growing availability and application of the high-throughput methods based on next-generation sequencing (NGS) stand as key players in systems biology, but the analysis and the interpretation of the vast amount of genomic and epigenomic NGS data poses great conceptual and computational challenges. The current methods for RNA-seq and DNA sequencing data integration are originally designed for microarray platforms. These methods either overlook position level and isoform information in RNA-seq or unable to deal with rare variants in NGS data of DNA. To overcome these limitations and multicolinearity in NGS data, instead of modeling the genome as a collection of separated individual loci, we model the genome as a continuum. To fully capture expression variation at the level of exon, chromosomal position, allele, splicing isoform provided by RNA-seq, and use entire spectrum of allelic information, we develop sparse functional graphical model for joint analysis of RNA-seq and NGS generated genotypes where the position-level read counts of expression or the number of risk alleles within a gene is taken as a function of genomic position. Alternative direction methods of multiplier was used to estimate the parameters in the penalized functional graphical model. Its goal is to simultaneously construct a sparse Gaussian graphical model and detect association of genes with the gene expressions. The proposed method was applied to RNA-seq data of ovarian cancer with 158 tumor samples from TCGA dataset. We jointly analyzed 64 genes in mTOR signaling pathway and 9 genes with somatic mutations. We reconstructed networks of expressions and somatic mutations with 54 edges. We identified association of mutated TP53 with PIK3CG, PCK3B, RRAGB, CAB39 and TSC1 expressions, the mutated TTN with the expressions of genes RICTOR, EIF4E1B and RPS6KA6, and the mutated DST with the expressions of gene PRKCA. In summary, the proposed method will shift the paradigm of systems biology research from multivariate data analysis to large scale penalized and functional data analysis and stimulate both theoretical and practical researches in systems biology with NGS data.

1421T

Swiss: a bioinformatics tool for identifying overlap between novel loci in GWAS scan results and a GWAS catalog. *R.P. Welch, T.M. Teslovich.* Biostatistics, University of Michigan, Ann Arbor, MI.

We present here a bioinformatics tool to scan genome-wide association study (GWAS) results and identify overlap between significant variants and previously identified variants in a GWAS catalog. This is a necessary step to identify novel associations, but to our knowledge there is no publicly-available software to automate the task. To this end, Swiss performs two primary functions. First, it identifies lead variants by clumping GWAS results, either by using measures of linkage disequilibrium (D', r2) to keep only the most significant variant per set of variants in LD, or by keeping the most significant variant within windows defined by physical distance. LD-based clumping is particularly useful for meta-analysis results, when it is not always possible to perform conditional analyses to identify statistically independent signals. The user must supply genotype data (in VCF format) to be used in LD calculations if LD-based clumping is desired; study-specific genotype data or files available from the 1000 Genomes Project FTP server may be used. Second, Swiss will attempt to find overlap between lead variants and a GWAS catalog, which can be generated by the user, or downloaded directly from the NHGRI GWAS Catalog website. Allowing the user to specify a customized catalog is critical, as many research groups maintain internal catalogs tailored to their traits of interest and/or including unpublished associations. Swiss identifies variants in the catalog that are in LD with each lead variant. The user can provide a different VCF for LD calculation in this step, for example when study-specific genotype data used for clumping of initial findings do not include all published GWAS variants. Swiss will also identify GWAS catalog variants within a user-specified distance of each lead variant, regardless of LD, thereby facilitating identification of known associations as well as secondary signals at the same loci. Swiss can be run in parallel on results from multiple traits, which is becoming increasingly important in metabolomics and eQTL studies with hundreds or thousands of traits. In the near future, we plan to integrate Swiss with LocusZoom, providing an easy way to identify significant lead variants from GWAS results and create LocusZoom plots highlighting both novel and previously known associations. We also plan to add built-in support for LD calculations using 1000 Genomes data for multiple ancestry groups.

Churchill: An Ultra-Fast Analysis Pipeline for the Discovery of Human Genetic Variation in Clinical and Population Scale Genomics. *P. White[1,2], B. Kelly[1], J. Fitch[1], D. Corsmeier[1], H. Kuck[1], A. Naik[1].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) The Ohio State University, Columbus, OH.

Next generation sequencing (NGS) has revolutionized genetic research, enabling dramatic increases in the discovery of new functional variants in syndromic and common diseases. This technology has been widely adopted by the research community and is rapidly being implemented clinically, driven by recognition of NGS diagnostic utility and enhancements in quality and speed of data acquisition. Compounded by declining sequencing costs, this exponential growth in data generation has created a computational bottleneck. Current analysis approaches can take weeks to complete, resulting in bioinformatics overheads that exceed sequencing costs and represent a significant limitation. Churchill is a computational approach that overcomes these challenges, fully automating the analytical process required to take raw sequencing data through the complex and computationally intensive processes of alignment, post-alignment processing, local realignment, recalibration and variant discovery. Compared with alternative analysis pipelines, Churchill is simpler, faster, deterministic and 100% reproducible. Through implementation of novel parallelization techniques, Churchill enables computationally efficient whole genome sequencing analysis in less than two hours, ideal for clinical applications where turnaround time is paramount but data quality cannot be sacrificed. The algorithm enables population scale genome analysis to be performed cost-effectively using cloud resources. Churchill is able to effectively utilize distributed clusters of computers to allow the processing of data sets that would have otherwise been too large to process at a reasonable cost in a practical time frame. To demonstrate this we analyzed 1,088 whole genome raw data sets available from the 1000 Genomes Project Consortium (1KG) utilizing AWS resources. Despite the large number of samples, population variant frequencies were produced in less than 7 days for ~$11 per genome. We achieved a high degree of correlation to the 1KG SNP allele frequencies and discovered ~3 million INDELS not reported in the original 1KG analysis. As we look to the future, cloud computing will become indispensable in the analysis of human genome sequencing and the $1000 genome will soon be a reality. Churchill solves the sequence analysis computational bottleneck and through use of cloud computing resources enables rapid analysis of population scale sequencing datasets.

1423M

Neat-optimal whole genome reconstruction by a small set of genomic variants. *M. Xiong, N. Lin, J. Yu, L. Ma, J. Jiang, P. Wang, S. Guo.* Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX.

The emerging genomic technologies will produce so large genomic and epigenomic data that traditional technologies and tools are unable to storage, transfer, manage and analyze them when the number of sequenced genomes exceeds ten thousands. It is urgent to develop novel concepts, theory and computational algorithms to filter out irrelevant and redundant genomic variants and select a set of sufficient genomic variants which can optimally recover whole genome information in the genomic data analysis. To meet these challenges, we propose to formulate genomic and epigenomic data as genomic matrices and selection of an essential set of genomic variants for the whole genome reconstruction as a subset selection problem for matrices. We develop matrix approximation theories and error estimation methods as powerful tools for optimal genomic matrix column and row selection. Both deterministic and randomized algorithms are designed to select genomic variants with provable guarantees that whole genome reconstruction by selected genomic variants can reach prespecified high accuracy. This nice property is due to the fact that matrix information largely depends on the rank of matrix. We show that selection of genomic variants is independent of phenotypes. To evaluate their performance, the proposed genome subset selection algorithms were assessed by large-scale simulations and applied to sparse principal component analysis in population genetics with 1000 genome data, quantitative trait prediction with sequencing data from the NHLBI's Exome Sequencing Project, cluster analysis of RNA-seq data from NIH TCGA project, prediction of a coronary artery disease (CAD) with GWAS data from WTCCC study. Our results show that the most genetic analysis using selected subset of genomic variants can reach the performance as good as using original whole genome datasets. For example, in CAD risk prediction study where 1,929 cases and 2,938 controls were sampled and the total number of SNP markers is 393,473. Using 65 SNPs out of 393,473 SNPs can reach average accuracy of 81.04% in the test datasets by 10 fold cross validation evaluation. However, using original dataset and traditional logistic regression, we can only reach 62.25% accuracy in the test datasets. In summary, the genomic matrix approximation theory and optimal column and row subset selection algorithms will have important implication in big genomic and epigenomic data analysis.

1424T

Detecting Nuclear Receptors Using a Finite Mixture Model. *M. Xu[1], D. Umbach[2], Y. Yao[1], L. Li[2].* 1) Intramural Research Program, National Institute of Menthal Health, Bethesda, MD; 2) Intramural Research Program, National Institute of Environmental Health Sciences, Bethesda, MD.

Motivation: Nuclear receptors are a special BiPartitie structure which binds to DNA sequences to regulate transcription. The typical orientations of the two BiPartitie structure includes direct repeat, reverse direct repeat, inverted repeat, and evert repeat. A large-scaled ChIP-seq data may contain all or some of these orientations of nuclear receptors as well as half-sites. It is a challenging task to identify those nuclear receptors and their binding sites from a large-scaled ChIP-seq data with potential enrichment of all the orientations. Results: In this paper, we develop a tool NRMotif which can be used to 1) estimate the position weight matrix (PWM) of the embedded nuclear receptors and distribution of the gap between the two half-sites of nuclear receptors from a large-scaled ChIP-seq data set; 2) predict the location of the nuclear receptor binding site; 3) estimate the proportion of each orientation of nuclear receptors. We propose a mixture model frame work to model all the orientation of the embedded nuclear receptors and consider Markov model for the background. An EM-based iteration algorithm is used to maximized the complete data likelihood. We conducted simulation study and applied the algorithm to real datasets. Comparing with other available tools, our software has been able to identify all the orientations of the bipartite structured dimers as well as monomers from large-scaled ChIP-seq data set.

Bayesian inference for tumour heterogeneity using the Hamming Ball Sampler. *C. Yau[1,3], P. Kirk[1], M. Titsias[2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxon, United Kingdom; 2) Department of Informatics Athens University of Economics and Business (AUEB) Patision 76, 10434, Athens, Greece; 3) Department of Statistics, University of Oxford, 1 South Parks Road, Oxford, United Kingdon.

The characterization of sub-clonal structure from whole genome sequencing of heterogeneous tumors is a computationally challenging problem due to the large number of mutations and unknown number of tumor sub-populations. Many recent approaches have adopted methods based on Bayesian nonparametric models (the Dirichlet or Indian Buffet Process) but standard computational methods for inference for these models can be slow as they rely on inefficient Markov Chain Monte Carlo methods. We have developed a novel Markov Chain Monte Carlo sampling algorithm that allows efficient and exact Bayesian inference for multiple membership models that is scalable to massive datasets. While standard approaches use asymmetric updates that are prone to becoming trapped in local modes. Our algorithm uses locally symmetric modes that allows joint updating of the latent variable structure. We illustrate the utility of the sampling algorithm for tumor deconvolution problems and demonstrate its advantage over standard computational alternatives using in vitro mixtures of tumor DNA.

1426M

LVpicker: picking up true, low-frequency variants for studying cancer heterogeneity. *J. Zhang[1,2], J. Majewski[1,2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Genome Quebec Innovation Centre, Montreal, Quebec, Canada.

Low-frequency, somatic mutations due to cancer subclones are common and important for studying the heterogeneity within a tumour mass that shed light on cancer biology and preventing the recurrences and progresses of tumours. Several bioinformatics tools, such as MuTect, are designed to call low frequency variants from paired normal and tumor samples. However, it is difficult to distinguish true, low-frequency variants (LFV) from background noise, etc. sequencing and mapping errors. Here we present an algorithm, LVpicker, to pick up true mutations from LFV. This approach uses a binomial test to calculate the probability of observing certain number of mutant reads in total reads in the test sample, given the site-specific error rate that can be generated from pooled control samples. The program also filters variants if all reads supporting the variant (including controls) have mapping quality lower than 30. Using LVpicker, we firstly studied a patient with the blood sample and saliva sample that underwent exome sequencing. Among 117 low-frequency variants called from the blood and saliva sample comparison, LVpiker rejected ~60% of the calls after Bonferroni correction. This demonstrated the ability of LVpicker to reject false positives from LFV. We then used LVpicker to study five spatially distinct biopsies from a primary glioblastoma multiforme (pGBM) tumour and the matched blood sample. LVpicker picked several true LFVs that potentially contributed to tumour evolution, including a known driver mutation in gene PIK3CA, which showed increased frequency during progression. We also used MiSeq to validate the false positives. Finally we manually decreased the frequencies of some high-frequency driver mutations in ATRX and H3.3 genes and demonstrated that those mutations did not have high site-specific error rate and could be picked by our program. Our work suggests that LVpicker is a useful tool to study cancer heterogeneity and should be applied after raw variant calling.

1427T

Efficient and accurate de novo assembly algorithm for paired-end reads and its application in indel calling. *L. Zhao[1], Y. Guan[1,2,3].* 1) USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine , Houston, TX., US; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX. US; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX., US.

De novo assembly of paired-end reads into long contigs has been demonstrated to have markedly greater power in solving genetic related problems. Unfortunately, existing assemblers either suffer from high time complexity or low repeat tolerance. In this study, a novel assembly algorithm is presented to overcome these difficulties, and the power of this method in indel calling is demonstrated as well. Giving the input of paired-end reads, the model partitions these reads into overlapping groups. Within each group, a Smith-Waterman type of alignment algorithm is designed to align paired-end reads, accounting for the random insert lengths. The alignment forms a temporary assembly object that usually consists of two short contigs. By repeating this procedure, a few temporary assembly objects are assembled. These temporary assembly objects are then aligned together by using a Smith-Waterman type alignment algorithm incorporating seeding to form a larger temporary assembly object. The process continues until a single, gap filled, and long contig is obtained. This bottom-up procedure of assembling contigs from paired-end reads are carried out in parallel to produce many long contigs that span 2000 - 3000 base pairs. Our method assembles haplotypes, but it retains two/multiple alleles caused by various situations at specific regions, such as the region with different paternal and maternal haplotypes, the repetitive region having multiple alleles, and the region containing paralogs. Based on the assembled contigs, we are able to call indels by mapping the long contigs to a reference genome. To evaluate the power of this method, we have simulated 2000 indels with size ranging from 1 base to 5 bases at the major histocompatibility complex (MHC) region of the Homo sapiens. Preliminary experimental results show that the true discovery rate of our method is 0.88 with the false discovery rate under 0.0025, while at the same false discovery rate level the true discovery rates of Fermi and velvet (two well-known assemblers) are only 0.37 and 0.23, respectively. Besides the greater indel calling performance, our method is superior to existing ones in the parallelizability *per se*. These observations indicate that our method has great potential in variants calling and clinical genetic diagnoses.

PGS: a tool for association study of high-dimensional microRNA expression data with repeated measures. *Y. Zheng[1], Z. Fei[2], W. Zhang[3], J. Starren[4], L. Liu[5], A. Baccarelli[6], Y. Li[2], L. Hou[5,7].* 1) Institute for Public Health and Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 3) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL; 4) Northwestern University Biomedical Informatics Center, Northwestern University, Chicago, IL; 5) Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 6) Department of Environmental Health, Harvard School of Public Health, Boston, MA; 7) The Robert H. Lurie Comprehensive Cancer Center, Feinberg School of Medicine, Northwestern University, Chicago, IL.

MicroRNAs (miRNAs) are short single-stranded non-coding molecules that usually function as negative regulators to silence or suppress gene expression. Due to interested in the dynamic nature of the miRNA and reduced microarray and sequencing costs, a growing number of researchers are now measuring high-dimensional miRNAs expression data using repeated or multiple measures in which each individual has more than one sample collected and measured over time. However, the commonly used univariate association testing or the site-by-site (SBS) testing may underutilize the longitudinal feature of the data, leading to underpowered results and less biologically meaningful results. We propose a Penalized regression model incorporating Grid Search method (PGS), for analyzing associations of high-dimensional microRNA expression data with repeated measures. The development of this analytical framework was motivated by a real-world miRNA dataset. Comparisons between PGS and the SBS testing revealed that PGS provided on average 9% smaller phenotype prediction errors and 57% higher enrichment of phenotype-related biological pathways than SBS testing. Our extensive simulations showed that PGS provided more accurate estimates (root-mean-square-error=0.02, compared to 0.18 using SBS testing) and higher sensitivity (sensitivity=0.86, compared to 0.67 using SBS testing) with comparable specificity (>0.95). PGS is suitable for high-dimensional microRNA expression data with repeated measures in that, by exploiting underlying dependent structures, it relies on variable selection in the context of a multiple regression model, which circumvents multiple testing issues, enhances statistical power, and yields more biologically meaningful results. PGS is also applicable to other longitudinally collected high-dimensional quantitative data, such as, epigenomics, mRNA transcriptomics, proteomics, metabolomics, etc. The growing number of studies conducting high-dimensional profiling dataset using different platforms requires a more comprehensive evaluation of PGS in various study settings. (Availability: R source code for PGS tool is available for download at https://github.com/feizhe/PGS).

FExSeq: A familial exome sequencing discovery pipeline. *C. Chung[1,2], Z. Wang[1,2], X. Zhang[1,2], M. Wang[1,2], W. Luo[1,2], S. Suman[1,2], L. Burdett[1,2], M. Cullen[1,2], B. Hicks[1,2], M. Yeager[1,2], J. Boland[1,2].* 1) Leidos Biomedical Research, Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Rockville, MD.

Whole-exome sequencing has become a popular approach for disease-causing and/or disease-predisposing variant discovery. Analysis of massive amount of exome sequence data requires efficient bioinformatic approach. Although a number of state-of-art variant calling algorithms enabled accurate variant callings, a reproducible, streamlined pipeline for discovering biologically significant variants in the phenotype of interest is scarce. We have developed a pipeline called FExSeq discovery pipeline that utilizes familial exome sequencing data to 1) perform effective filtration by multiple parallel comparisons to public datasets; 2) to perform segregation analysis to identify variants that are family/disease group specific and/or shared among disease group; 3) to prioritize functional variants based on multiple annotation scheme. Here, we present the results from analyzing ~1,500 whole-exome sequenced samples from 710 families of 27 different cancer types. Our comprehensive FExSeq discovery pipeline effectively prioritize list of variants for follow-up functional studies.

1430T

A novel approach to methylation-Seq data analysis based on functional principle component analysis (FPCA). *S. Guo[1,2], L. Li[1], J. Jiang[1], N. Lin[1], M. Chen[2], L. Jin[2], M. Xiong[1].* 1) Human Genetics Center, Division of Biostatistics, University of Texas School of Public Health, Houston, TX 77030, USA; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, Shanghai 200433, China.

Methyl-CpG binding domain (MBD) protein-enriched genome sequencing (MBD-seq) has been considered as one of the most important approaches for methylome-wide association studies (MWAS). However, the present MBD-seq statistical analysis methods for differential methylated region (DMR), including 1) average reads in certain region or 2) to estimate methylation center (MACS2) are designed for analysis of methylation that is measured by microarray. Such methods have ignored the spatial characteristic in the function of DNA methylation, which would greatly decrease the power to detect the disease associated differential methylation region (DMR). In our present study, we propose a novel method for the analysis to the MBD-seq data in which the methylation profiles were taken as random functions andfunctional principle component analysis (FPCA) was introduced to fit the methylation profile for CpG island, CpG shore and CpG shelves. We develop FPCA-based statistics to test for differential methylation. We used spares hierarchical and K-means clustering to discover biologically meaningful pattern. Genome-wide DNA methylation-seq profile of 24 pairs of colorectal cancer (CRC) and normal tissues were used to validation the performance of the method. Simulation results showed that our proposed method substantially outperforms the traditional methods for testing differential methylation. In real data analysis, our method identified 3,425 hyper-methylation regions (HEMR) and 692 hypo-methylation regions (HOMR) in tumors, in which, 738 HEMR and 224 HOMR cannot be identified by traditional methods, among which the most important CRC associated CpG island methylator phenotypes (CIMP) such as CACNA1G, IGF2, NEUROG1, RUNX3, SOCS1, UCHL1, ADAMTS1 and AOX1 were identified. DMRs identified by FPCA showed significant consistency with the distribution of DMR in tumor and normal tissues. We found more than 39.3% of DMR were distributed in CpG shore and CpG shelves, which suggest the important biological role of CpG shore and CpG shelves in cancer development and progression. In summary, we provided an effective novel method to analyze next-generation MBD-Seq dataset based on Functional PCA (FPCA), which can identify aberrant DMR in colorectal cancer.

1431S

Next-generation sequencing reveals the presence and positions of novel duplications in clinical samples. *M. Kennemer[1], V. Semenysty[2], N. Patil[1], C. Hartshorne[1], M. Rabideau[1], A. Agbarya[2], Y. Kaplan[3], A. Dvir[3], L. Soussan-Gutman[3], K. Jacobs[1], M. Powers[1], J. Paul[1], S. Topper[1].* 1) Invitae Corporation, San Francisco, CA., United States; 2) Rambam Health Care Campus, Haifa, Israel; 3) Teva Pharmaceuticals Industries, Petach-Tikva, Israel.

Germline copy number variants (CNVs) account for a significant fraction of hereditary cancer pathogenic mutations. For example, approximately 5-10% of BRCA1 and BRCA2 pathogenic variants involve large deletions and duplications. Traditional analysis for these rare events was performed by multiplex ligation-dependent probe amplification, quantitative PCR or comparative genomic hybridization. Although germline CNVs can be detected from next-generation sequencing (NGS) data generated using targeted DNA capture technologies (e.g. exomes and other panels), methods for doing so must overcome many technical challenges. Several algorithms have been published to detect CNVs in such data, though they may not yet be adequate for use in diagnostic testing laboratories, particularly for detection of small single-exon CNVs. We have previously described a new method, CNVitae which is designed to detect single-exon CNV as well as larger regions sequenced using NGS with sensitivity and specificity of >99%. We have tested clinical samples where we performed NGS on 29 genes associated with hereditary cancer syndromes where CNVs were detected. One case is a 38 year-old Christian Arab woman diagnosed with invasive ductal carcinoma at 30 years of age. A duplication involving exons 5-11 of BRCA2 was identified from NGS read count data using CNVitae. To understand the impact of this duplication on the BRCA2 protein we analyzed sequence alignments from this region for either split-reads or discordant mate pairs and were able to confirm that this duplication occurred in tandem within the gene. The duplication is predicted to cause a Met to Arg change at codon 1594 followed by a frame-shift that ends with a premature truncation at codon 1597. The truncated protein is expected to result in a loss-of-function; a well-documented mechanism for BRCA2 inherited breast cancer susceptibility. In addition to being a novel duplication, this is the first clinically reported duplication in BRCA2 using these new methods of detecting CNVs. We have found additional examples of clinical cases where CNVs were detected using our methods of NGS and CNVitae software. This demonstrates the ability of NGS to not only detect single nucleotide sequence changes but also CNVs in a cost-effective scalable single assay for clinical genetic testing.

OncoRep: An n-of-1 reporting tool to support genome-guided treatment for breast cancer patients using RNA-sequencing. *T. Meissner, K.M. Fisch, L. Gioia, A.I. Su.* Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA, USA.

Introduction Breast cancer is the leading cause of cancer among females. Being a heterogeneous disease, it comprises multiple tumor entities associated with distinctive histological patterns, different biological features and clinical behaviors. Next generation sequencing allows us to study this heterogeneous disease in multiple dimensions. This provides in depth insight into tumor pathogenesis on the individual patient level paving the path to individualized medicine. The advent of individualized medicine introduces a shift in how cancer patients will be treated in the future, away from the one drug-one disease paradigm towards the idea of bringing the right drug to the right patient. **Problem** Challenges that arise with this paradigm shift are i) preprocessing and analyzing sequencing data in the n-of-1 setting ii) extracting relevant information from various layers of omics data iii) integrating omics data with drug databases, (iv) presenting the information to the clinician in an understandable manner, and (v) completing these steps in a timely manner to provide clinically relevant and actionable targets to a tumor board or the treating physician. **Results** To address these challenges, we present the extensible and customizable open-source framework OncoRep, an RNA-Seq based n-of-1 reporting tool for patients with cancer. We have applied it to breast cancer, including prospective molecular classification, detection of altered genes, and pathways, identification of gene fusion events, clinically actionable mutations and it reports suitable drugs based on identified actionable targets. It presents integration and visualization of these omics data in an approachable html based interactive report as well as a PDF based summary report, providing the clinician and tumor board with a tool to guide the treatment decision making process.

1433T

Identification of transcriptional regulators associated with breast cancer risk. *K.B. Meyer[1], M.A.A. Castro[2], F. Markowetz[1], B.A.J. Ponder[1].* 1) Cancer Research UK Cambridge Institute, Li Ka Shing Centre, Cambridge CB2 0RE, Cambridgeshire, United Kingdom; 2) Department of Biochemistry, Federal University of Rio Grande do Sul (UFRGS), Rua Ramiro Barcelos, 2600, Anexo, 90035-003 Porto Alegre, Brazil.

Over 70 breast cancer risk loci have been identified at formal genome-wide significance, but there may be many more loci with small effect. The challenge is to understand how these risk loci synergise to influence disease risk, and to find read-outs of the combined risks. We are seeking evidence of common mechanisms by mapping the genes associated with these loci onto breast cancer gene regulatory networks. We have examined the regulatory network in breast cancer for enrichment of genes associated with breast GWAS loci[1]. First we used ARACHNe[2] to assign potential target genes, so-called regulons, to transcription factors (TFs) using gene expression data from Metabric[3]. A second step examined whether these regulons are enriched for genes associated with breast cancer GWAS loci, by applying an extended variant set enrichment[1,4] (EVSE) that uses eQTLs to define the genes associated with the known breast cancer risk loci[5]. We have implemented EVSE on a genome-wide basis and identified 36 TFs significantly associated with risk in both cohorts (995 and 997 samples) of Metabric. Interestingly four master regulators of FGFR2 signalling, previously defined as a risk-associated pathway[1], were found as risk TFs (ESR1, GATA3, FOXA1 and SPDEF). We extensively validated our EVSE results: (1) Negative control GWAS signatures e.g. bone mineral density or random SNPs do not yield a positive association. (2) EVSE with random but size matched regulons does not find a significant association. (3) Lastly, we demonstrate that the eQTL step in the analysis strongly influences the results: eQTLs from ER+ and ER- tumours identify different sets of risk associated TFs. By studying the correlation of gene expression between regulons, we found that risk TFs fall into two distinct, but internally highly correlated groups, each of which may represent a group of TFs relating to a common mechanism. Using the TCGA data set we find that 33% of the risk TFs showed somatic alteration in more than 3% of tumours, while only 0.3% of a set of control TFs were altered to the same extent, providing independent validation of our results and suggesting that similar pathways may be responsible for risk as well as disease progression. 1. Molecular docking simulations provide insights in the substrate binding sites and possible substrates of the ABCC6 transporter. *O. Vanakker[1], M.J. Hosen[1,2], A. Zubaer[2], S. Thapa[2], B. Khadka[2], A. De Paepe[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Genetic Engineering and Biotechnology, Shahjalal University of Science Technology, Sylhet 3114, Bangladesh.

The human ATP-binding cassette family C member 6 (ABCC6) gene encodes an ABC transporter protein (ABCC6), primarily expressed in liver and kidney. Mutations in the ABCC6 gene cause pseudoxanthoma elasticum (PXE), an autosomal recessive connective tissue disease characterized by ectopic mineralization of the elastic fibers. The pathophysiology underlying PXE is incompletely understood, which can at least partly be explained by the undetermined nature of the ABCC6 substrates as well as the unknown substrate recognition and binding sites. Several compounds, including anionic glutathione conjugates (N-ethylmaleimide; NEM-GS) and leukotriene C4 (LTC4) were shown to be modestly transported in vitro; conversely, vitamin K3 (VK3) was demonstrated not to be transported by ABCC6. To predict the possible substrate binding pockets of the ABCC6 transporter, we modeled a 3D homology model, qualified for molecular docking and virtual screening approaches. By docking 10 reported in vitro substrates in our 3D homology model and using VK3 as a negative control, we were able to predict two substrate binding sites for this protein. Further, virtual screening of 4651 metabolites from the Human Serum Metabolome Database in our model disclosed a prediction of possible substrates for ABCC6, which are mostly lipid and biliary secretion compounds, some of which are found to be involved in mineralization. Virtual screening expands this possibility to explore more compounds that can interact with ABCC6, and may aid in understanding the mechanisms leading to PXE.

1435M

A method for the discovery of long-range genomic interactions from 3C-seq experiments. *T. Yuan, M. Du, R. Dittmar, S. Xia, Y. Guo, L. Wang.* Pathology, Medical College of Wisconsin, Milwaukee, WI.

Abstract: Integration of chromosome conformation capture (3C) with high-throughput sequencing (HTS) (3C-seq) enables us to detect long-range genome-scale chromatin interactions between two genomic regions through counting the ligated fragments co-localized into these regions. However, the signals from real chromatin interactions are often overshadowed by a large number of the signals from short-range interactions or accident interactions. It is difficult to determine specific long-range chromatin interactions by setting a threshold of read counts (RC). Here, we present a new algorithm known as Tscore calculation. The algorithm assumes that the most chromatin interactions detected by sequencing are non-specific and randomly distributed, of which density functions can be fitted. For a specific genomic region (viewpoint) on a chromosome, the cumulative probabilities of the other genomic regions along this chromosome interacted with this viewpoint (cis-interactions) are calculated through the density function of the normal distribution fitted by multiplying the count numbers of cis-localizations and the distance between the viewpoint and the other regions, and the cumulative probabilities of the regions on the other chromosome interacted with the viewpoint (trans-interactions) are calculated through the density function of the exponential distribution fitted by the counting of trans-localizations between the viewpoint and these regions. The scores (Tscore), the conversion of the cumulative probabilities, can be used for measuring frequency of cis-/trans-interactions. WIn addition, by comparing various factors, e found that background noise and counting methods have significant effects on the detection of chromatin interactions. We therefore develop a tool known as 3C-analyzer in order to apply this algorithm into 3C-seq data analysis. 3C-analyzer integrated all analytic work from raw data in FASTQ format to the detection of significant chromatin interactions from 3C-seq experiments. It provides a user-friendly experience by including graphic user interface, sample management, and primary enzyme setup. The ability of parallel processing is optimized for large data analysis. Our case studies show that 3C-analyzer enable us to detect significant genomic interactions across different 3C technologies (Capture-C and 4C).

1436T

Using a reference panel to increase coverage in pooled sequencing experiments. *H. Al-Asadi, M. Stephens.* University of Chicago, Chicago, IL.

Pooled sequencing is an increasingly popular technique for assessing genome-wide population allele frequencies. Increasing the sequencing depth- or coverage - improves the accuracy of these allele frequency estimates but requires additional cost. Reference panels are often available in pooled sequencing applications and provide additional information about a sample -namely SNP correlations- which allows you to borrow information from linked SNPs. In this study, we demonstrate use of an LD-based model which incorporates information from a panel to increase the effective coverage for each SNP. For example, with two perfectly correlated SNPs, our approach doubles the coverage because reads from both SNPs can be used for any one SNP. We test our method on two evolve and re-sequence experiments.

1437S

The DNA Integrity Number: A novel approach for objective integrity classification of genomic DNA samples. *M. Gassmann[1], E. Schmidt[1], A. Inche[2], I. Pechtl[1], R. Salowsky[1], B. McHoull[2].* 1) Agilent Technologies, Waldbronn, Baden-Würtemberg, Germany; 2) Agilent Technologies UK Limited, Edinburgh, United Kingdom.

Genomic DNA (gDNA) is used as starting material in the experimental workflow of many applications in molecular biology. The integrity of the DNA critically affects the success of many downstream experiments like array CGH or sequencing. Initial electrophoretic analysis of the sample is highly recommended as the respective downstream applications can be expensive and time consuming. The Agilent Genomic DNA ScreenTape Assay has been primarily developed for the electrophoretic analysis of genomic DNA samples. A ScreenTape is a pre-packaged microfluidic device designed for performing electrophoretic applications in a microscale format. It is used in combination with the Agilent 2200 TapeStation instrument. Degradation of gDNA is typically a gradual process in which high-molecular weight DNA is fragmented into smaller species. It can occur either enzymatically, chemically or mechanically. Judging the integrity of DNA by visual evaluation of the electropherogram trace is subjective and can be error-prone. In order to standardize this a novel algorithm was developed to score gDNA samples on the 2200 TapeStation. The DNA integrity number (DIN) is calculated from several features obtained from the electrophoretic trace and ranges from 1 to 10. Here we show data demonstrating the reproducibility, scalability and linearity of the DIN. The DIN is independent from instrument, reagent and sample concentration variability and can be used as objective measure for determining the integrity of gDNA.

Genomic susceptibility for cancer prediction by supervised machine-learning methods on SNP-syntax. *S. Kim[1], M. Kim[2].* 1) Chemistry, University of California, Berkeley, Berkeley, CA., USA; 2) Computer Science, University of California, Davis, CA, USA.

It has been widely assumed that human genomic variations are associated with individual's susceptibility to complex diseases such as cancer. However, extensive genome-wide association studies so far had limited success in that the results have low predictive value of practical utility to individuals. We present a prediction process where two supervised learning methods are applied to two different descriptors of each individual's common genomic variations to predict an individual's susceptibility to each of 8 major cancer traits plus healthy trait. The accuracy of the prediction ranges from 33 to 57% depending on cancer type, significantly better than 11% for a random prediction, with probability estimates that may be useful for making practical health-decisions for individuals or for a population.

1439T

A composite classifier for prioritizing somatic SNVs based on predicted functional impact, protein disorder, and gene expression. *W. Liao, B.J. Chen, K. Wrzeszczynski, K. Arora, T. Bloom, N. Robine, V. Vacic.* Bioinformatics, New York Genome Center, New York, NY.

The majority of observed somatic variants are thought to be passengers and distinguishing them from true functional drivers of cancer remains an ongoing challenge. While great strides have been made in predicting the impact of variants in the context of inherited disease, only recently have tools specifically designed for annotating somatic variants been developed. One clear cause for this delay has been the lack of reliable datasets for training, but the growing availability of cancer genome data is helping to address this problem. Following the strategy utilized in previous work where recurrence and well-characterized gene lists were used to distinguish putative driver mutations from passengers, we composed a collection of positive and negative examples comprised of variants from the COSMIC, ICGC, TCGA, and UniProt repositories. Using these datasets to evaluate several annotation tools, we observed that while cancer-specific methods performed reasonably well, by and large they were outperformed by a composite of predictions from several tools—most of which were intended to assess variants associated with inherited disease, not cancer. Second, because most of current methods rely on sequence conservation as a proxy for function, we found them to be less sensitive in regions of intrinsic protein disorder. Finally, after applying these tools to variants predicted from TCGA glioblastoma samples where RNA data was also available, we found that sample-specific expression context provided valuable information, allowing us to deprioritize unexpressed genes while raising the priority of mutations in genes that were overexpressed or exhibited allele-specific expression—two notable examples being EGFR and TP53. This suggested that RNA-seq can be useful for inferring functional impact of somatic variants. In light of these observations, we developed a novel composite classifier that incorporates several cancer-focused prioritization algorithms in conjunction with well-established methods. Additionally, it considers a disorder prediction score, and examines over- and allele-specific expression at a per sample level. Taken together, our novel cancer-focused somatic variant prioritization method performed better than existing algorithms and represents a tool that can facilitate interpretation of somatic variants and understanding of cancer etiology.

1440S

Barcode-based template identification of KIR region in human genomes. *C. Lo[1], S. Zakov[1], S. Kim[1], B. Halldorsson[2], V. Bafna[1].* 1) Computer Science and Engineering Dept, University of California, San Diego, San Diego, CA; 2) Biomedical Engineering, School of Science and Engineering, Reykjavík University Reykjavik University. Reykjavik, Iceland.

The immunospecific regions of the human genome, such as the region encoding the killer cell immunoglobulin- like receptors (KIRs) on Chromosome 19 and the region encoding the major histocompatibility complex in humans (HLAs) on Chromosome 6, are among the most important regions functionally, but their hypervariability, in gene copy number and mutations, makes it difficult to assemble and characterize these regions. Previous methods characterizing these regions rely on laboratory methods using traditional and quantitative PCR primers and probes. Here, we propose a computational method to type the KIR region and to determine various allele groups of KIR genes directly from whole genome sequencing data. Our method is based on barcoding (deriving signatures) known KIR templates as well as sequenced fragments, and comparing the two sets of signatures.The method is alignment-free and efficient, and easily scales to large populations of individuals. We demonstrate the robustness and accuracy of our method over simulated data, trios from various populations in the 1000 genomes project as well as 298 Icelandic trios. The results indicate that this method can resolve all KIR types up to an equivalence that can only be broken by long range haplotyping or inheritance patterns.

1441M

Network-Augmented Genomic Analysis (NAGA) applied to Cystic Fibrosis studies. *S. Loguercio[1], D. Martino-Roth[2], D. Hutt[2], A. Su[1], W. Balch[2].* 1) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 2) Department of Cell Biology, The Scripps Research Institute, La Jolla, CA.

Cystic fibrosis (CF) is an early onset disease characterized by a defect in the apical chloride channel, CF transmembrane conductance regulator (CFTR). The most common disease causing mutation is a 3 base pair deletion resulting in loss of Phe 508 (F508del), which leads to misfolding, endoplasmic reticulum (ER) retention and efficient ER associated degradation of the protein. To elucidate the molecular networks influencing the folding and function of CFTR in CF, we recently screened CFBE41o- cells containing F508del-CFTR against a siRNA library of 2500 targets known to be involved in protein homeostasis. In parallel, we generated a high confidence CFTR interactome of F508del-CFTR in the same cell line. Given a list of high-scoring siRNA hits for CFTR rescue of function, and a set of CFTR binding proteins, we sought to connect these datasets through an integrated protein-protein interaction network, and use shortest path analysis to uncover the minimal network structure consistent with both the CFTR interactome and siRNA data. The goal of this approach is to prioritize proteins connecting CFTR with siRNA hits that may act as central “hubs” in cellular processes required for CFTR functional rescue. For each protein in the subgraph, it computes the number of distinct siRNA hits that utilize the protein on its shortest path to CFTR. In order to filter out nonspecific protein hubs, this computation is repeated using a random selection of hits from the original siRNA library. The analysis identified several novel candidates for CFTR rescue of function that could be validated through targeted siRNA screens. In summary, we present here a novel network-based method to integrate functional genomics data (e.g. siRNA screens) with interactomics datasets (e.g. AP-MS, MudPIT), useful for prioritizing novel functional targets and for identifying relevant network modules. It leverages publicly available information on protein-protein interactions and thus is readily applicable to many scenarios where a connection between functional and biochemical data is sought.

1442T

Whole-Exon Haplotype Calling for Clinical Next-Generation Sequencing. *J. Maguire, A. Gibiansky, M. Rasmussen, E.A. Evans, I.S. Haque.* Counsyl, 180 Kimball Ave, South San Franciso, California.

In the last two years, NGS has begun to make significant inroads into the clinic via a set of screening and diagnostic applications such as carrier screening for recessive disease, and testing for heritable cancer risk. Research tools such as BWA, GATK, FreeBayes, and others make up the current best practices in sequence analysis, but it is rarely appreciated that they are built with various implicit design decisions that are highly specific to the research regime and not appropriate in a clinical setting. We describe in detail KCall, our whole-exon (155bp-4kb) diploid haplotype caller, which is based on diploid HMM inference over a De Bruijn graph. We describe its performance in various clinical testing applications, using data generated from our own patient stream of thousands of samples per month. KCall was designed to address the differences between the high-volume clinical and research regimes -- Clinical test designs focus on small genomic regions of ~0.5-1Mb targeted at specific medical questions, rather than whole exome/genome coverage in typical research studies; Clinically relevant variants are often “hard” sites for NGS and must be called correctly in every patient; research protocols often optimize the average genome-wide accuracy rather than local accuracy at specific sites; Clinical protocols are unbounded in number of potential samples and have strict turnaround-time requirements; finally, research protocols are funding-limited in sample count and can batch-process all samples at once. KCall leverages these differences to call whole-exon (155bp-4kb) haplotypes using 100bp reads in 100x depth sequencing data. Additionally, KCall replaces heuristic tuning of variant calling parameters with a hands-off calibration procedure using calibration flowcells totaling >30,000x depth in our target area (4 HiSeq flowcells). This eliminates heuristic tuning by modeling error processes site-by-site down to a frequency of 1/1000. The end result of these changes is a tool that behaves with a consistent level of quality across all targets, requires zero subjective tuning steps, and provides a complete and accurate view into the patient’s DNA.

1443S

JADE: A tool for comparative analysis of spatially smooth genomic data. *J. Morrison, D. Witten, N. Simon.* Biostatistics, University of Washington, Seattle, WA.

Multiple quantitative genomic data types such as methylation proportion and copy-number are now commonly collected as part of studies seeking to investigate the genetic architecture of human disease. These data types are often extremely high-dimensional with thousands of measurements per subject and can possess a spatial structure with respect to genome position. The presence of these patterns leads naturally to treating the entire profile as the explanatory variable of interest when comparing groups rather than using measurements at single sites. This task can be challenging because profiles must be estimated from the data and are more complicated data types than un-smoothed site-level measurements. We have developed a penalized likelihood approach, Joint Adaptive Differential Estimation (JADE) for simultaneously preforming smoothing, estimation, and cross-group comparison of genomic profiles for quantitative data types with spatial patterns. The method is motivated by a model in which groups have a shared average profile over some of the genome but to differ in a few biologically relevant regions. JADE utilizes the similarity between groups to improve accuracy of group profile estimation while allowing for regions in which the profiles are different. We are also able to create adaptive clusterings which vary along the genome for joint comparison of more than two groups. By taking a unified approach we avoid many of the ad-hoc decisions made in multi-step techniques as well as the challenges of multiple-testing correction and window-size and region pre-selection. JADE is implemented through an efficient dual gradient descent algorithm. We have applied it to the task of identifying differentially methylated regions between different cell types available in the ENCODE database of reduced representation bisulfite sequencing experiments. In these experiments methylation level is obtained as a binomial proportion at millions of closely spaces sites. These data have previously been modeled using splines and other smoothing techniques allowing us to compare results using JADE and other methods.

Identifying causal noncoding variants using tissue-specific gene regulatory networks. *K. Tan[1], X. Ma[1], B. He[2], L. Teng[1].* 1) Internal Medicine, University of Iowa, Iowa City, IA; 2) Interdisciplinary Graduate Program in Genetics, University of Iowa, Iowa City, IA.

Characterization of noncoding variants poses a significant challenge in human genetics. Among the different classes of noncoding regulatory sequences, transcriptional enhancers represent the primary basis for differential gene expression, with many human diseases resulting from altered enhancer action. Here, we term SNPs located in enhancers eSNPs. To predict causal eSNPs, current practice has been to overlap various types of functional genomics data (chromatin accessibility, transcription factor binding, epigenetic modification, gene expression) with individual GWAS SNPs. The rationale for such approaches is that causal SNPs should alter TF binding affinity and consequently gene expression. While biologically intuitive, there are a number shortcomings for current approaches. First, most studies attempt to interpret GWAS results agnostically instead of using cell/tissue types that are relevant to the diseases. Cell type-specific information has strong predictive value, and can overcome certain limitations in population-based association studies (e.g. reduced power for weak alleles and low-frequency variants). Second, current approaches do not take into account the complex interactions among the genes affected by regulatory variants. Molecular networks have been used to improve the inference accuracy of causal coding variants. This potential has not been examined for noncoding variants. We have developed a general computational framework for identifying causal noncoding variants that affect a specific trait. By casting the causal inference problem into a subnetwork identification problem, our approach considers all candidate eSNPs simultaneously, thus increasing the power of the inference. Further, our network-based approach naturally provides a pathway content for the resulting causal eSNPs. Compared to existing methods, our method achieves significant improvement. We have applied our novel method to SNPs documented in the NHGRI Catalog of Published Genome-Wide Association Studies.

ClinSeK: targeted clinical variant identification from high-throughput sequencing data. *W. Zhou, H. Zhao, Z. Chong, A. Eterovic, K. Shaw, F. Meric-Bernstam, G. Mills, K. Chen.* The University of Texas MD Anderson Cancer Center, Houston, TX.

The current paradigm of clinical sequencing data analysis employs a lengthy discovery approach: aligning reads to the human reference assembly, discovering mutations from base to base and identifying mutations that are likely actionable. Although widely practiced, such a paradigm is not optimal for clinical applications, which demand rapid acquisition of clinically relevant, sensitive, and unambiguous molecular profiles. We developed ClinSeK based on a knowledge-driven inversely-operating paradigm that directly tests well-characterized, clinically-relevant variants from high-throughput sequencing data, without exhaustively aligning and comparing sequencing reads to the human reference genome. We overcome challenges in analyzing repetitive regions and duplicated reads under this new paradigm. Applying ClinSeK to characterize the molecular profile of over 600 deeply sequenced cancer samples indicated that this new approach increases sensitivity in detecting low frequency variants with over 50-fold reduction in processing time than existing approaches that perform sequential alignment and variant calling. ClinSeK can test point mutations, indels and structural variations in single or paired samples. It supports the analysis of both DNA and RNA sequencing data. It can also serve as a quick and independent cross-validation in complement to existing variant discovery pipelines.

1446S

Detection, Characterization, and Biological Analysis of Long Tandem Repeats Detected in Human Genomes Using Nanochannel Technology. *S. Chan, X. Zhou, Z. Dzakula, A. Hastie, H. Cao.* Research and Development, BioNano Genomics, San Diego, CA.

A large portion of the human genome is known to be composed of long tandem repeats that can span several hundred kilobases to multiple megabases. Although the repeat motifs can be sequenced and the amount of repeat material can be approximated by conventional sequencing technologies, it is often difficult or impossible to assemble them into long contigs, so the exact locations and copy numbers of these repeats often remain elusive, especially when the unit length exceeds the read lengths. Without knowing the genomic context of these repeats or the amount of repeat material, it is difficult to attach any biological relevance to them. Thanks to the recent developments in nanochannel technology which allow us to image intact megabase-scale molecules of DNA, repeat regions can be more accurately characterized and put into biological context. Using Irys® technology and novel algorithms designed specifically to investigate long repeat arrays, we were able to find and characterize previously enigmatic repeat regions in the human genome. The genomic positions of these repeats were found by aligning non-repetitive portions of repeat-containing molecules or consensus *de novo* assemblies to the reference genome. The genomic context then provides insight into the biological significance of the repeats. Here, we have found that molecules containing a prominent 5.6-kilobase tandem repeat are derived from the Lipoprotein(a) (Lp(a)) coding region on chromosome 6, which is linked to atherosclerotic diseases such as heart disease and stroke. Furthermore, since the array is contained on single molecules, we can measure allele array lengths, showing that Irys® technology has potential for aiding in quick, accurate, and cost-efficient prognosis of these and other genetic diseases which are influenced by copy number variations.

1447M

novoBreak: comprehensively characterizing somatic structural breakpoints in cancer genomes. *Z. Chong[1], M. Gao[2], J. Ruan[3], X. Fan[1], W. Zhou[1], T. Chen[1], H. Zafar[1], J. Chen[2], G. Mills[4], K. Chen[1].* 1) Department of Bioinformatics & Computational Biology, The University of Texas MD Anderson Cancer Center, Houston, TX; 2) Department of Experimental Radiation Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX; 3) Agricultural Genomes Institute at Shenzhen, Chinese Academy of Agricultural Sciences, Shenzhen, China; 4) Department of Systems Biology, The University of Texas MD Anderson Cancer Center, Houston, TX.

Somatic structural variations (SVs) are a major source of genomic variations in cancer genomes and may play a driving role in cancer genome evolution. However, current algorithms for detecting SVs using Next-Generation Sequencing (NGS) data could not achieve a high sensitivity and specificity. This is mainly due to the challenges in aligning and interpreting short reads spanning SV breakpoints. We have developed a novel algorithm, novoBreak, which minimizes the alignment issues to achieve a high recall rate and a low false discovery rate. novoBreak can characterize almost all types of SV breakpoints including deletions, duplications, inversions, insertions and translocations at base-pair resolution. It first clusters reads around potential breakpoints and then locally assembles the reads associated with each breakpoint into contigs. After aligning the contigs to the reference, it can identify the precise breakpoints and infer the types of SVs. novoBreak performs substantively better than other widely applied solutions, such as BreakDancer, CREST, etc., based both on simulation data and on the whole genome sequencing data in the tumor genome atlas (TCGA) and the 1000 Genomes project. In the recent NCI ICGC-TCGA DREAM 8.5 somatic mutation calling challenge, novoBreak ranks as one of the best-performing methods. The higher sensitivity of novoBreak makes it possible to uncover more novel and rare SVs, which could delineate a more comprehensive landscape of variations in cancer genomes and shed light on cancer genome evolution. The algorithm of novoBreak can be easily extended to germline SV discovery, which could be used to characterize genome evolution in a long-term view.

1448T

SG-ADVISER: CNV annotation pipeline. *G. Erikson, N. Deshpande, A. Torkamani.* Scripps Translational Science Institute, La Jolla, CA.

CNVs have been associated with a diverse array of diseases, especially cancer, autism, schizophrenia, and developmental delay. A large number of methods are available for the annotation and interpretation of SNPs and small indels, yet little is available for interpretation of CNVs. The Scripps Genome Annotation and Distributed Variant Interpretation Server (SG-ADVISER) CNV pipeline aims to fill this gap. The SG-ADVISER CNV pipeline is a web server developed at The Scripps Translational Science Institute for the annotation of CNVs. Annotation execution proceeds in highly parallel fashion and includes classes of variant annotations that are entirely independent of one another, serially dependent annotations whose execution are dependent upon the completion and status of prior annotations, and synthetic annotations that generate new information through the combination of multiple annotation outputs. The annotated file includes details regarding location, impact on the coding portion of genes, allele frequency information including allele frequencies from the Scripps Wellderly cohort, and overlap information with other reference datasets including ClinVar, DGV, known syndromes etc. The CNV pipeline accepts variant files in CNVnator, Complete Genomics, or plain tab delimited file formats. A variant classification is produced (ADVISER score) based on the American College of Medical Genetics (ACMG) scoring guidelines with categories 1-5. Variants of category 1 are most clinically relevant. The performance of ADVISER classification schema was evaluated using data from International Collaboration for Clinical Genomics (ICCG). We annotated both pathogenic and benign variants and the ADVISER classification schema showed accuracy of 89% specificity and 99% sensitivity. To facilitate the interpretation of the SG-ADVISER CNV pipeline output we added new functionality to the existing SG-ADVISER UI. The SG-ADVISER UI is a visualization tool that allows scientists with little or no programming experience to easily and quickly view, manipulate, sort, and filter the SG-ADVISER CNV output file. For example it is possible to sort or filter CNVs based on Known Disease, Coding Impact or Chromosome Position etc. At any point during the process the tool can provide summary statistics, and output the filtered results to a new file.

1449S

Challenges to CNV Detection in the Clinic using Targeted High Throughput Sequencing Data. *S. Sadedin, A. Oshlack.* Murdoch Childrens Research Institute, Parkville, Victoria, Australia.

High Throughput Sequencing (HTS) is rapidly gaining clinical acceptance as a cost effective solution for diagnosis of highly penetrant but genetically heterogeneous diseases. Despite this success, the analysis methods applied are usually limited to detection of point mutations and small insertions and deletions. Detection of larger structural variations, most notably deletions, is often omitted despite such variants being equally deleterious and common causes of many disorders. While many tools have been published in the literature, in practice, few laboratories are implementing them in their clinical sequencing pipelines. We speculate that this is due to a perceived lack of specificity and robustness. In this work we apply a novel simulation method to explore the reasons for this gap using real data spliced from X chromosomes of male samples into female samples to simulate single copy deletions. We find that real world performance of these methods appears to be highly sensitive to a range of factors including: method-specific tuning parameters, exact sequencing technology and methodology, variability in the quality of data, and the number and type of samples sequenced in a batch. We conclude that in order for HTS CNV detection to become clinically accepted, methods must be developed that can work in a highly robust, self-calibrating fashion and that are well tuned to popular sequencing platforms. Along these lines, we show results from our own method, Angel, which is specialized to achieve high accuracy and robustness on the HaloPlex targeted sequencing platform.

SAAS-CNV: A joint segmentation approach on aggregated and allele specific signals for the identification of somatic copy number alterations with next-generation sequencing data. *Z. Zhang[1,2], K. Hao[1,2].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY.

Motivation: Cancer genomes exhibit profound somatic copy number alterations (SCNAs). Studying tumor SCNAs using massively parallel sequencing provides unprecedented resolution and meanwhile gives rise to new challenges in data analysis, complicated by tumor aneuploidy and heterogeneity as well as normal cell contamination. While the majority of existing methods utilize total sequencing depth alone for SCNA inference, the allele specific signals are undervalued. We proposed a joint segmentation and inference approach using both signal dimensions to address some of the challenges. **Methods:** Our method consists of four major steps: 1) extracting read depth supporting reference and alternative alleles at each SNP/Indel loci and comparing the total read depth and alternative allele proportion between tumor and matched normal sample; 2) performing joint segmentation on the two signal dimensions; 3) correcting the copy number baseline from which the SCNA state is determined; 4) calling copy number variation (CNV) and copy-neutral loss of heterozygosity (LOH) for each segment based on both signal dimensions. The method is applicable to whole exome/genome sequencing (WES/WGS) data in a tumor-control study, and is readily extended to SNP array data and tumor-only setting. **Results:** We applied the method to a data set containing no SCNAs to test the false positive rate, created by pairing sequencing replicates of a single HapMap sample as normal/tumor pairs, as well as a large-scale WGS data set consisting of 88 hepatocellular carcinoma (HCC) samples along with matched normal samples. SNP array data is also available for the 88 samples to serve as benchmark. Compared with representative methods, such as ExomeCNV and CNAnorm, our method demonstrated high and consistent accuracy, scalability to large cancer studies, capability in handling a variety of platforms, and potential in improving the estimation of tumor ploidy and purity. **Availability:** An R package called saasCNV is available at zhangz05.u.hpc.mssm.edu/saasCNV/.

The new European Variation Archive Resource at EMBL-EBI. *I. Medina, D. Spalding, CY. Gonzalez, G. Saunders, J. Kandasamy, S. Ur-Rehman, V. Kumanduri, I. Lappalainen, J. Paschall.* European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Cambridge, United Kingdom, CB10 1SD.

The European Variation Archive (EVA; www.ebi.ac.uk/eva) is a new 'one-stop-shop' for all freely available variation data, for all types of variation, from all species. EVA will work with partner databases to guarantee free global access to genetic variation data. The EVA data model focuses on archiving and making available the results of large scale variant discovery and re-sequencing efforts, providing granular access to population specific allele frequencies paired with study meta-data. Data submitted to EVA in VCF format is closely linked with supporting BAM alignments where available in the ENA or EGA databases at the EMBL-EBI. EVA currently contains over 1.7 billion submitted variants, from a range of more than 15 large-scale projects including 1000 Genomes (phase 1 and 3), Exome Variant Server, Genome of the Netherlands and UK10K. We also mirror the data stored at both dbSNP and ClinVar permitting our users easy access to this data. As an example of our commitment to non-human species, EVA includes data from the NextGen project that has compiled more than 220 million livestock variants including rich meta-data on sub-strain and environment. With regards structural variation, EVA builds upon the existing Database of Genomic Variation Archive (DGVA; www.ebi.ac.uk/dgva) that, in collaboration with dbVar at NCBI, currently contains in excess of 10 million Supporting Structural Variants (SSVs) in 120 studies, covering a range of 28 species. The web portal of EVA aims to provide a dynamic and visually interactive set of queries and filters based on modern web technologies such as HTML5. Users can browse and explore our study or variation catalogue, visualize variations or search for a gene. This front-end is made modular and scalable through use of a RESTful web service interface to the backend data store, allowing EVA data to be accessible programmatically for a variety of applications such as annotation pipelines. To provide a high-performance and scalable solution EVA is based on NoSQL databases such as MongoDB and is designed to accommodate data derived from tens of thousands of whole genomes. Data mining and visualisation tools allow direct access to variation data at the granularity of a given submitted study. Complex queries can be built based upon entry points including gene, study, genomic location, variation type and consequence type. All software is released as open source. Please direct questions and submissions to eva-helpdesk@ebi.ac.uk.

PON-P2, PON-Diso and PON-MMR: tools for prediction of variation pathogenicity. *M. Vihinen, A. Niroula, S. Urolagin.* Department of Experimental Medical Science, Lund University, Lund, Sweden.

Reliable prediction methods are needed to analyze NGS datasets. Due to the large volume of identified variations only computational approaches can handle the datasets. Genomes contain millions of variants and typically over 10 000 of them lead to amino acid substitution. The applied methods have to be both reliable and fast. We have developed a completely new machine learning-based method PON-P2, which fulfills these criteria. It has excellent performance (accuracy 0.87, MCC 0.77) and it can predict very large datasets in reasonable time. It is more reliable and faster than our previous predictor, PON-P [1] and competing methods. PON-P2 is for amino acid substitutions. The method is based on extensive feature selection and training with a large benchmark dataset from VariBench [2]. The method is implemented with random forest. PON-Diso is a method for predicting effects of amino acid substitutions on order/disorder status of proteins [3]. Several proteins contain disordered regions or are completely disordered, i.e. without regularly ordered structure. Changes to the structure in these regions can be related to diseases. We tested the performance of a large number of existing disorder prediction methods, but they were found unsuitable for this task. We developed a novel tool that has a success rate on 70% in cross validation. A related tool was trained for mismatch repair (MMR) gene variations [4]. PON-MMR has accuracy of 0.87. When applied to 758 unclassified variants in InSiGHT database, it could classify 248 cases as pathogenic or benign. InSiGHT variation interpretation committee [5] classified 1370 variants out of 2360 investigated. 46 of those we had predicted to be either benign or pathogenic. 44/46 of them were correct (96%). These tools have been tested with independent benchmark datasets and they show the highest performance currently available. Available at http://structure.bmc.lu.se/ . References: 1. HLA-Genotyper Prediction of HLA Genotypes from Next Generation Sequencing Data. *J. Farrell[1], G. Jun[1], L.A. Farrer[1], A. DeStefano[2], P. Sebastiani[2].* 1) Biomedical Genetic- Evans 218, Boston Univ Med, Boston, MA; 2) School of Public Health, Boston University, Boston, MA.

Background: HLA genotyping of next generation sequencing data would be useful for testing the association of HLA alleles with adverse drug reactions, auto-immune diseases, infectious diseases and age-related diseases. **Methods:** We have developed HLA-Genotyper for the prediction of HLA genotypes from next generation sequencing data. HLA-Genotyper is a software tool which performs 4-digit HLA allele prediction using a novel Naïve Bayes algorithm. The evaluation of the novel algorithm for MHC I and II Classical HLA loci (A, B, C, DRB1, DQA1, and DQB1) was conducted using whole genome, whole exome and RNA-Seq data from 51 European and 50 Yoruba samples from the 1000 Genomes Project. To validate the predictions, the precision and recall of the predicted HLA genotypes were compared to a "gold standard" based on SSOP and SBT HLA typing. **Results:** For 560 HLA alleles predicted in 51 low coverage (3-7x) European samples, the precision was 0.96 with a recall of 0.59. For the 597 HLA alleles predicted in 50 low coverage Yoruba samples, the precision was 0.90 with a recall of 0.49. For the 51 European samples with whole exome sequencing (50-100x coverage), the precision of the HLA genotype predictions increased to 0.97 with a recall of 0.96. For the 50 Yoruba samples with whole exome sequencing, precision increased to 0.90 with a recall of 0.90. In 45 European samples, the predictions of 518 HLA alleles from RNA-Seq data were near complete concordance with the "gold standard" with a precision of 1.0 and recall of 0.99. The RNA-Seq validation results of 453 assayed alleles from 38 Yoruba samples also had very high precision and recall rates of 0.98. **Conclusion:** With modest coverage and read lengths between 75 and 101bp, the HLA-Genotyper software accurately predicted HLA genotypes from next generation sequencing data commonly used for research. The predictions were best from the RNA-Seq data with near concordance with the gold standard and better than PCR-SSOP accuracy. Using HLA-Genotyper, researchers may readily unravel the association of HLA alleles with many diseases from next generation sequencing experiments without the expensive and laborious HLA typing of thousands of subjects in diverse ethnic populations. This will improve researchers ability to understand biological roles of HLA loci in infection, inflammation, auto-immunity, aging, mental illness and adverse drug reactions.

1454T

A Statistical Approach that Simultaneously Perform Variant Calling and Local Haplotyping Based on Phase-Informative Reads. *K. Kojima, N. Nariai, T. Mimori, Y. Yamaguchi-Kabata, Y. Sato, Y. Kawai, M. Nagasaki.* Integrative Genomics, Tohoku University, Sendai, Japan.

Next generation sequencing (NGS) technologies enable the detection of novel rare variants in genome wide scale. Haplotype phasing of these variants is important for rare variant association studies because variants are often grouped into exon or gene level. Effects of multiple variants and phase-dependent interactions such as compound heterozygosity and cis-effect are considered for the analysis. In addition, phased haplotype information is required for estimating population genetic parameters by considering a coalescent tree or an ancestral recombination graph based inference. In the process of haplotype phasing, various approaches have been proposed by considering the linkage disequilibrium between variant sites. These types of approaches can provide accurate phasing results for common variants, but their accuracies for low-frequency variants or variants around recombination hotspots tend to be low. The other type of approach uses NGS reads spanning multiple heterozygous variant positions (called phase-informative reads). Although this approach is promising for phasing low-frequency variants, the applicable length of the estimated haplotypes is limited due to the current length of NGS reads (around hundred bases). However, since length of sequence reads is growing rapidly, the rate of heterozygous sites phased by phase-informative reads is expected to increase. The quality of estimated variants is crucial in haplotype phasing based on NGS reads, while accurate variant calling is still challenging due to errors on sequencing and read mapping. Since some of such errors can be corrected by considering haplotype phasing, simultaneous estimation of variants and haplotypes is important. Here, we introduce a statistically unified approach for variant calling and haplotype phasing named HapMonster, in which haplotype phasing information from phase-informative reads is used for improving the accuracy of variant calling and the improved variant calls are used for more accurate haplotype phasing. From the comparison with other existing methods on simulation and real sequencing data, we confirm the effectiveness of HapMonster in both variant calling and haplotype phasing.

Kragle: a new local *de novo* assembler and genotype caller for short tandem repeats and other complex variations. *K. Konvicka, K.B. Jacobs, K. Nykamp, N. Patil, M. Cargill, C. Kautzer, S.A. McCalmon.* Invitae Corporation, San Francisco, CA.

BACKGROUND: Structural variation in the genome can have a profound effect on gene function. In particular, short tandem repeat (STR) expansions are implicated in a wide array of genetic disorders, such as Huntington Disease. We developed software able to call genotypes of complex variations from next generation sequencing (NGS) with short paired-end reads that current software packages fail to assemble and call. These failures have two causes: 1) most *de novo* sequencing algorithms utilize De Bruijn graphs and are not well-suited to assembling low-complexity sequences due to k-mer limitation, and 2) *de novo* sequencing algorithms often utilize sequence error correction techniques that remove information from low-complexity sequences and interfere with STR sequence assembly. **METHODS**: We developed Kragle, software that combines and adapts three known algorithms: paired-end aware read recruitment, consensus-overlap *de novo* sequence assembly and a statistical framework for genotypes. These components were combined to take full advantage of the reads and assemble low-complexity sequences with repetitive content as long as the read length. The statistical framework then allows us to call diploid genotypes from the assembled haplotype sequences and assign confidence based on alternative genotype hypotheses. **RESULTS**: We processed and analyzed 31 positive control samples representing 11 distinct STR-related loci and inherited conditions in technical duplicate. We used Kragle to genotype the samples at 9 of these 11 loci (2 loci failed PCR) and at 10 additional STR loci. The resulting matrix of 31 samples x 19 genotypes showed complete agreement with the reported genotypes, giving only one false positive result (in 1 of 2 replicates). This translates to 100% sensitivity and 99.2% specificity. The reproducibility of genotype calls between technical replicates was 97% when alleles were allowed to differ by +/-1 repeat. These genotyped loci include STR's in the following genes: *AR*, *ATN1*, *ATXN1*, *ATNX2*, *ATXN3*, *ATXN7*, *DMPK*, *FXN*, and *HTT*. In another experiment we were able to call a heterozygous large deletion in *BRCA1* gene, and confirm it with PCR. **CONCLUSIONS**: The above experiments confirmed that Kragle is capable of assembling and genotyping STR sequences up to the length of an NGS read, and assembling junctions resulting from deletions, insertions and chromosomal rearrangements. This will enable clinical diagnosis of many genetic conditions using short-read NGS data.

Pipeline and Varant annotation tool for identifying causal variants in inherited rare disorders. *K. Kundu[1], S. Rana[1], A. Chellappan[1], U. Sunderam[1], J.M. Puck[2], S.E. Brenner[3], R. Srinivasan[1].* 1) Innovation Labs, Tata Consultancy Services, Berkeley, CA; 2) Department of Pediatrics, University of California, San Francisco, Box 0519, CA, USA; 3) University of California, Berkeley, CA 94720, USA.

We have developed a pipeline for the analysis of genomic variant data, whose distinctive features enabled solving numerous clinical cases related to SCID (Severe Combined Immunodeficiency) and related diseases. The first several steps of the pipeline employ standard tools for mapping and processing of the mapped data in preparation for variant calling, but integrate three different carefully-tuned callers, to yield high quality sets of variants. Quality metrics for mapping, gene coverage, and called variants are generated throughout the run to ensure confidence in downstream analyses. Our Varant tool (available under an open source license) provides extensive variant annotations, such as genes and transcripts affected by the variant, the type of effect, possible functional consequences including pathways that may be affected by the variant, known disease associations from a variety of data sources such as ClinVar, OMIM, GAD, the mouse phenotype database. We have carefully benchmarked Varant to ensure that it not only has all the features present in other widespread tools, such as Annovar and snpEff, but also overcomes the errors made by other tools and is more liberally licensed. For cases where pedigree or phasing information is available the Varant tool classifies variants as following a compound heterozygous model, *de novo*, uniploidal disomy, or X-linked recessive with potential clinical importance. The annotations are combined with predictions from programs such as ToppGene and Endeavour to further prioritize short-listed variants.

Our pipeline was able to identify likely causal variants in several cases where routine protocols would have been expected to fail. In one example of a patient with abnormal T-cell receptor excision circles (TREC) we were able to identify and later confirm mutations in the *NBN* (nibrin) gene that led to a diagnosis of Nijmegen breakage syndrome. In another example, literature-based haploinsufficieny annotations of the *BCL11B* gene allowed us to propose a role for a heterozygous *de novo* variant in this gene in the case of a child with low T-cell counts and absent corpus callosum. Finally, we identified causal compound heterozygous variants in the *PRKDC* gene in a patient with SCID; other tools missed a key variant because the reference genome incorporates a frameshift mutation.

SVSI: A Fast and Powerful Set-Valued System Identification Approach to Identifying Rare Variants in Sequencing Studies for Ordered Categorical Traits. *W. Bi[1], G. Kang[2], Y. Zhao[1], Y. Cui[3], S. Yan[4], Y. Li[4,5], C. Hartford[6], W. Leung[6,7], J. Zhang[1].* 1) Key Laboratory of Systems and Control, Academy of Mathematics and Systems Science, Chinese Academy of Sciences; 2) Department of Biostatistics, St. Jude Children's Research Hospital, Memphis, Tennessee; 3) Department of Statistics and Probability, Michigan State University, East Lansing, Michigan; 4) Department of Genetics, Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 5) Department of Computer Science, University of North Carolina, Chapel Hill, NC; 6) Department of Bone Marrow Transplantation and Cellular Therapy, St. Jude Children'sResearch Hospital, Memphis, Tennessee; 7) Department of Pediatrics, University of Tennessee Health Science Center, Memphis, Tennessee.

For phenotype-genotype association studies that involve a phenotype with ordered multiple response categories, we usually either regroup multiple categories of the phenotype into two categories ("cases" and "controls") and then apply the standard logistic regression(LG) model, or apply non-parametric method of spearman rank correlation or parametric method of ordered logistic (oLG) regression model which accounts for the ordinal nature of the phenotype. However, these approaches may lose statistical power or may not control type I error rate if the underlying genetic variants are rare or sample size is limited.Here we propose a set-valued (SV) system model, which assumes that the underlying continuous phenotype follows a normal distribution, to identify genetic variants associated with an ordinal categorical phenotype. We couple this model with a set-valued system identificationmethod to identify all the key underlying system parameters. Simulation studies show that SVwell controlled the Type I error rate. In the comparison among LG, SV and oLG methods, LG had significantly lower power than SV and oLG due to disregarding of the ordinal nature of the phenotype, and SV had similar or higher power than oLG. Additionally, the SV association parameter estimate was 2.7-28.7 fold less variable compared to the oLG association parameter estimate. Less variability in the association parameter estimate translates to greater power and robustness across the spectrum of minor allele frequencies. These advantages are most pronounced for rare variants or even common variants when sample size is small. For instance, in a simulation with data generated from an additive oLG model with odds ratio of 7.4 for a phenotype with three categories, a single nucleotide polymorphism with minor allele frequency of 0.75% and sample size of 999 (333 per category), the power of SV, oLG and LG models were 70%, 40% and <1%,respectively, at a significance level of 10-6.When applied to one real data, the testing p-values forSV are smaller than those forLG. Thus, SV can be a competitive alternative to LG or oLG in genetic association studies for ordered categorical phenotype.

1458S

A comprehensive empirical evaluation of linear mixed models for GWAS. *D. Heckerman[1], C. Widmer[1], O. Weissbrod[2], N. Fusi[1], C. Kadie[3], R. Davidson[3], J. Listgarten[1], C. Lippert[1].* 1) Microsoft Research, Los Angeles, CA; 2) Computer Science Department, Technion, Israel; 3) Microsoft Research, Redmond, WA.

The linear mixed model (LMM) has recently emerged as the model of choice to correct for confounding structure, including population structure and family relatedness, in GWAS. At their core, mixed models rely on the estimation of a genetic similarity matrix (GSM), which encodes the pairwise similarity between every two individuals in a cohort. These similarities are estimated from SNPs or other genetic variants. Traditionally, the GSM for an LMM has been estimated from all available variants. Recently, however, it has been proposed that only a subset of variants should be used. The motivation behind this suggestion is based on a mathematical equivalence between the LMM and linear regression. In particular, an LMM is equivalent to a form of linear regression in which the variants that determine the GSM in the LMM view are covariates in the linear-regression view. Thus, taking the linear-regression view, one should only estimate the GSM using variants that are relevant to the phenotype. When all variants have an influence on the phenotype, this understanding leads to the traditional approach of including of all variants in the GSM. When some variants have absolutely no influence on the phenotype, then they should be omitted. But what happens when some variants are only minimally relevant, either having an extremely weak causal effect on the phenotype or an extremely weak association with the phenotype through confounding factors? We investigated variant selection with an empirical study of synthetic data sets spanning a wide range of population structure, family structure, and polygenicity, measuring performance in terms of control of type I error and power. Generally, we find that, when population and/or family structure is present, variant selection alone does not perform well. In particular, when population structure is present, the inclusion of principal components (PCs) as covariates to the model improves performance. When family structure is present, variant selection improves performance only when it is used to create a second GSM in addition to a GSM based on all variants, yielding a dual GSM. When population structure and family structure are both present, a combination of PC covariates and dual GSM is best. Finally, we find that, when population and/or family structure is present, use of variant selection is only beneficial when there are a relatively small number of causal SNPs with relatively large effect sizes.

1459M

Accelerating curation of the catalog of GWAS by automatic text mining. *C. Hsu.* UC San Diego, La Jolla, CA.

The Catalog of GWAS is an important resource containing published association between SNPs and phenotypes identified by Genome-Wide Association Studies (GWAS), a well-defined study approach. GWAS studies have been successfully producing discovery and replication of many new disease loci. The number of GWAS is growing rapidly. There is a need for a database that allows researchers to easily query and search for previous results. Such database has been created and maintained by the National Human Genome Research Institute (NHGRI), called "A Catalog of Published Genome-Wide Association Studies" (Catalog of GWAS). The catalog has led to interesting characterization of previous results in GWAS and NHGRI has continued to update and curate the catalog regularly. However, curation of the catalog is current performed by expert curators. Though this will ensure the quality but new publications in GWAS really outpace any human curation team can possibly handle. The goal of the project GWASTool is to develop a new tool to automatically extract the information from research articles for the curation of the catalog of GWAS. Our proposal is to use the curated data currently available from NHGRI as the training examples and apply novel machine-learning algorithms to train information extractors to allow accurate automatic extraction. Machine learning is particularly suitable for this project because a sufficiently large set of training examples is avail-able from the Catalog of GWAS. The idea is to match the records to the text of the article to mark where they were mentioned and should be extracted from. Moreover, data fields for GWAS studies are relatively well defined, unlike other biological text mining tasks, such as extracting protein-protein interaction. The information extractors to be developed will consist of a tagging module to tag the information in full-text of GWAS research articles and a link module to link the tagged values into entries. A special tagger, based on template matching, will be developed to tag and link the information given in tables. We will demonstrate how the automatic information extraction tool works through a Web-based online tool and present remarkable statistics of the GWAS studies from the extracted data.

GACT: A Tool for Predicting and Converting Genome Build and Allele Definition during Imputation and Meta-analysis of SNP Genotype Data. *A. Sulovari[1,2], D. Li[1,3,4].* 1) Department of Microbiology and Molecular Genetics, University of Vermont, Burlington, VT; 2) Cell, Molecular and Biomedical Sciences Graduate Program, University of Vermont, Burlington, VT; 3) Department of Computer Science, University of Vermont, Burlington, VT; 4) Neuroscience, Behavior and Health Initiative, University of Vermont, Burlington, VT.

Meta-analysis is one of the commonly used methods in genetic studies of complex diseases as it can increase the statistical power to identify new disease-associated variants by combining genotypes from multiple GWAS. This approach requires same allele definition and genome build among individual studies. Similarly, genotype imputation, commonly used prior to meta-analysis, requires the same consistency. However, the genotypes from various GWAS are generated using different genotyping platforms, arrays or SNP-calling approaches, resulting in use of different genome builds and allele definitions. Incorrect assumptions regarding allele definition among combined GWAS will lead to a large portion of discarded genotypes or incorrect association findings. We have developed a tool that predicts and inter-converts between any of the common SNP allele definitions and the major genome builds. In addition, we measured the effect of several factors on imputation quality, and our results indicated that inclusion of singletons in the reference had detrimental effects while ambiguous SNPs had no measurable effect. Unexpectedly, exclusion of genotypes with missing rate > 0.001 (40% of our study SNPs) showed no significant decrease of imputation quality (even significantly higher when compared to the imputation with singletons in the reference), especially for rare SNPs. Based on our GWAS data, an approximate number of 600 thousand well-typed SNPs are likely to be sufficient for high quality genome-wide imputation of rare SNPs (high quality assayed SNPs may compensate for low true-genotype density). In conclusion, we have developed a new, powerful, and user-friendly tool with both command-line and interactive online versions that can accurately predict, and convert between any of the common allele definitions and between genome builds for genome-wide meta-analysis and imputation of genotypes from SNP-arrays or deep-sequencing. Availability: GACT (http://www.uvm.edu/genomics/software/gact).

Applying compressed sensing to genome-wide association studies. *S. Vattikuti[1], J.J. Lee[2,4], C.C. Chang[3,4], S.D.H. Hsu[4,5], C.C. Chow[1].* 1) Mathematical Biology Section, Laboratory of Biological Modeling, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD; 2) Department of Psychology, University of Minnesota Twin Cities, 75 East River Parkway, Minneapolis, MN 55455, USA; 3) BGI Hong Kong, 16 Dai Fu Street, Tai Po Industrial Estate, Tai Po, Hong Kong; 4) Cognitive Genomics Lab, BGI Shenzhen, Yantian District, Shenzhen, China; 5) Office of the Vice President for Research and Graduate Studies, Michigan State University, 426 Auditorium Road, East Lansing, MI 48824, USA.

The aim of a genome-wide association study (GWAS) is to isolate DNA markers for variants affecting phenotypes of interest. This is constrained by the fact that the number of markers often far exceeds the number of samples. Compressed sensing (CS) is a body of theory regarding signal recovery when the number of predictor variables (i.e., genotyped markers) exceeds the sample size [1]. Its applicability to GWAS has not been investigated. Using CS theory, we show that all markers with nonzero coefficients can be identified (selected) using an efficient algorithm, provided that they are sufficiently few in number (sparse) relative to sample size. For heritability equal to one ($h^2 = 1$), there is a sharp phase transition from poor performance to complete selection as the sample size is increased. For heritability below one, complete selection still occurs, but the transition is smoothed. We find for $h^2 \sim 0.5$ that a sample size of approximately thirty times the number of markers with nonzero coefficients is sufficient for full selection. This boundary is only weakly dependent on the number of genotyped markers. Practical measures of signal recovery are robust to linkage disequilibrium between a true causal variant and markers residing in the same genomic region. Given a limited sample size, it is possible to discover a phase transition by increasing the penalization; in this case a subset of the support may be recovered. Applying this approach to the GWAS analysis of height and using approximately 12,000 subjects, we show that 70-100% of the 20 selected markers are strongly correlated with height-associated markers identified by the GIANT Consortium [2].

Cross-Phenotype Analysis of GWAS (CPAG): A powerful tool for detecting shared genetic architecture among human traits and underlying shared pathways. *L.Y. Wang[1], D.C. Ko[1,2,3].* 1) Duke University, Department of Molecular Genetics & Microbiology, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC; 3) Center for Human Genome Variation, Duke University, Durham, NC.

Recent large-scale meta-analyses of GWAS have demonstrated that cross-phenotypic associations and pleiotropy are abundant among GWAS hits for various diseases and traits. However, the degree of disease similarity as well as the underlying genetic basis driving such connections remains poorly understood. By integrating GWAS results, we developed a novel approach to estimate the degree of disease similarity, identify informative disease clusters, and highlight the potential underpinning pathways. A probability-based method was used to estimate similarity of traits by correcting unobserved shared genetic components and is therefore less sensitive to small and/or uneven shared similarities. Comparing nearly a dozen similarity methods, we determined which was most optimal and robust. Unlike previous methods such as polygenic score, linear mixed-effect model and network model, our approach is based on analyses of summary statistics without requiring more genotype/phenotype data. Using data from the NHGRI GWAS Catalog, we constructed human disease trees with more than 600 traits by using similarity matrices based on either SNPs, SNPs corrected for linkage disequilibrium, and implicated genes among pairwise diseases. For pairwise comparisons that showed significant similarity, we implemented gene set enrichment analysis to identify possible associated pathways. Our method categorized related diseases into disease clusters well consistent with pre-defined groups but also revealed novel and unexpected disease connections. We validated the cross-phenotype analysis of GWAS (CPAG) method computationally using two different approaches by comparing the CPAG generated categorization to pre-defined categories. All of this functionality for disease similarity, visualizing clustering, and pathway analysis has been implemented into a flexible stand-alone software program, named CPAG. CPAG also accepts user-defined datasets to predict potential disease connections and shared pathways. Our approach will become increasingly powerful with the ever-expanding identification of novel causal genetic variation attributed to different traits, and lead to further understanding of the genetic architecture of complex traits and additional insights into the pathophysiology of diseases. Indeed, we are currently experimentally testing novel human trait connections discovered from our analysis using zebrafish.

GeneHeal: An Online Resource for Mutations and Associated Phenotypes in Deafness. *A. Mehta[1], G. Bademci[1], A. Lakum[1], G. Beecham[1], S. Blanton[1], X. liu[2], M. Tekin[1].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics and John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL 33136, USA; 2) Department of Otolaryngology, Miller School of Medicine, University of Miami, Miami, FL 33136, USA.

The success of genomic medicine depends on many factors, including the availability of well characterized genotype-phenotype correlations. We have developed a web-based resource GeneHeal, which links auditory phenotypic information of the deaf individuals enrolled in our study to the respective pathogenic genomic variants. To display the relationship between deafness gene variants (genotypes) and their respective phenotype, diagnostic categories for each participant (based on age at onset, progression and severity, including average hearing levels, audiogram shape, and associated findings) are stored in the Hearing Loss (HL) Phenotype Database. Causative mutations in deafness genes for the enrolled individuals are stored in the HL Genotype Database. Both databases are accessible through the Miami Genetics of HL Resource (GeneHeal) at http://hihg.med.miami.edu/deafness/geneheal and are open for researchers who would like to contribute their data. It provides search capabilities to end users making it an efficient data repository and query tool for the researchers around the world. The front end of the website is an HTML form running on PHP scripts. Predefined scripts are provided to query the database and relay information seamlessly. Both variant and phenotype oriented queries are available. An output table is generated that contains all the information listed in both databases for the individuals identified with the query. Both databases are updated on a regular basis. Quality assurance and data integrity checks are performed on a regular basis by HIHG personnel as well as daily data backups. Our tool links molecular variation with its detailed auditory phenotypic features for a comprehensive approach to the diagnosis, management, and risk assessment of individuals with HL.

1464S

A fast and accurate method for detection of IBD shared haplotypes in genomewide SNP data. *D. Bjelland[1], U. Lingala[1], N. Lapinski[1], M. Jones[2], M. Keller[1,2].* 1) Institute for Behavioral Genetics University of Colorado, Boulder, CO; 2) Department of Psychology University of Colorado, Boulder, CO.

Several programs have been developed to detect shared identical-by-descent haplotypes between individuals using SNP data. For detecting short shared haplotypes (e.g., 2-3 cM) in large datasets (e.g., > 10,000 individuals), the performance of these programs suffers either in terms of accuracy or in computational time. With this in mind, we developed a program, FISHR, that utilizes initial shared haplotype output from GERMLINE, quickly post-processes this data, and more accurately discovers the true shared haplotypes. FISHR was compared to GERMLINE and BEAGLE Refined IBD by simulating 15 megabases of genotypic data for 8,000 individuals with realistic levels of SNP and phasing errors. GERMLINE was the fastest program analyzed, with times of 9.0, 34.7, 152.3, and 601.0 seconds for samples of 1,000, 2,000, 4,000 and 8,000 individuals, respectively. Run times on equivalent sample sizes were 13.0, 48.3, 189.7, and 753.0 seconds for FISHR (including the initial GERMLINE runs) and 400.3, 2064.0, 29,840.0, and 921,602.7 seconds (or 10.6 days) for BEAGLE Refined IBD. When discovering shared haplotypes with lengths between 2 and 3 cM, FISHR consistently had ~ 8% higher positive predictive value for matched sensitivity when compared to GERMLINE and ~18% higher positive predictive value for matched sensitivity when compared to BEAGLE Refined IBD. Similar results occurred when analyzing shared haplotypes between 3 and 4 cM. Thus, FISHR is more accurate than both GERMLINE and Refined IBD, and is fast enough to be usable for detection of identical-by-descent shared haplotypes in very large genome-wide datasets.

HapFerret: A flexible haplotype inference program, determining blocks of haplotype inferability. *G. Nelson, S. Limou, C. Winkler, M. Carrington.* Basic Research Program, Leidos Biomedical Corp/FNLCR, Frederick, MD.

The Expectation-Maximization (EM) algorithm for haplotype inference has been superseded for accuracy by newer programs, e.g. PHASE and SHAPEIT, but remains useful for rapid analysis. We have developed an EM implementation, "HapFerret", that is characterized by flexibility and ease of use, notable its use of a natural format for input genotypes and output haplotypes. Genotypes may be input as lines of comma separated alleles, where the alleles may be any alphanumeric; i.e. for HLA data, for the loci MogCA—DQA1—rs9273349—DQB1—rs1894407—TAP2—TAP1, a hypothetical genotype input line: 9,12 101,301 C,T 302,503 A,A 3.2,4.2 3.1,3.1 might yield an output line of haplotype calls 12-301—C—302—A—4.2-3.1; 9-101—T—503—A—3.2—3.1. Input can also be by one locus genotype per line, with the same allele format. Critically for the inference of HLA haplotypes, an arbitrary number of alleles are allowed at each locus.

A special feature is the ability to infer haplotypes for all subsequences with a specified range of lengths. This has the particular purpose of finding blocks in which haplotypes are inferred with relatively low ambiguity. The program measures the ambiguity of haplotype inference with an entropy measure, where a completely unambiguous inference has entropy 0. We propose this measure as an alternate, pragmatic criterion for haplotype blocks, that predicts the effectiveness of inferred haplotypes for association analysis. Since no coalescence calculation is used (being incompatible with the EM algorithm) this inferability is purely a function of the genotype/haplotype combinatorics, and the underlying LD. In general inferability is a function of higher order LD; we conjecture that a necessary and sufficient condition for unambiguous haplotype inference for n loci is that D' = 1 for LD of some order ≤ n. A limitation is that the EM algorithm may give an unambiguous prediction even where the inference is uncertain. To catch such errors, HapFerret contains a bootstrapping procedure; comparing inference between successive bootstrap replicates catches some cases of spurious precision. We show with data with known haplotypes that bootstrapped inference from HapFerret has an accuracy intermediate between standard EM and PHASE. HapFerret may be downloaded from: https://ccrod.cancer.gov/confluence/display/BCGC/BCGC+Software.

A novel approach to craniofacial gene discovery: *SysCLFT* (Systems tool for Cleft lip/palate gene discovery). *I. Saadi[1], D. Anand[2], D. Djordjevic[3,4], J.W.K. Ho[3,4], S.A. Lachke[2].* 1) Anatomy & Cell Biol, Univ Kansas Med Ctr, Kansas City, KS; 2) Biological Sciences, Center for Bioinformatics and Computational Biology, University of Delaware, Newark, DE; 3) Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 4) Faculty of Medicine, The University of New South Wales, Sydney, NSW, Australia.

Although study of mammalian craniofacial (CF) development has resulted in a detailed functional understanding of several genes associated with orofacial clefts (OFCs), many additional loci remain unsolved. We recently developed an innovative systems approach that is highly effective in identifying genes critical to the development and/or homeostasis of specific tissues. Successful application of this approach identified several novel genes with functional significance in eye tissue and associated defects (Lachke *Science* 2011 331:1571). Here, we expand this approach to develop *SysCLFT* (Systems tool for Cleft lip/palate gene discovery), a new interactive web resource for efficient prioritization of candidate genes associated with OFCs and construction of CF developmental GRN. We analyzed 67 microarray gene expression datasets of various CF tissues, available publicly in FaceBase and NCBI-GEO, using *in silico* subtraction with embryonic whole body (WB) reference datasets. This approach generates systematic gene ranks based on CF-tissue enrichment - instead of simply high expression - and offers a new method of prioritization of candidate genes associated with OFCs. Indeed with WB subtraction, the top 500 highly ranked genes from the palate, frontonasal, mandible or maxillary process datasets are highly enriched in gene ontology (GO) categories for palate development, cell adhesion, cell proliferation, epithelium development and skeletal system development. In contrast, without WB subtraction, *i.e.* data as currently available on FaceBase and NCBI-GEO, the most highly enriched GO categories among the top 500 candidates mainly comprise of housekeeping genes (translation, glycolysis, nucleic acid biosynthetic process, *etc.*). WB-subtraction identifies 41 of 45 (91%) OFC-linked genes at higher expression ranks, compared to only 4 of 45 (9%) genes without WB-subtraction. Major genes with established role in CF development, including *Irf6, Pax7, Pax9, Pbx2, Pbx3, Msx1, Runx2, Satb2, Tbx22*, are highly enriched in WB-subtracted datasets from different facial tissues. Most significantly, we show that the *in silico* subtraction method successfully identifies a majority (85%, *n*=45) of known OFC genes within the top 5 minRank genes in mean chromosomal intervals of 13Mb, each containing 106 genes on average. Thus, *SysCLFT* is a new, highly effective approach to facilitate prediction of genes and prioritization of variants in GWAS and exome-based CF gene discovery efforts.

1467S

Phenolyzer: prioritizing candidate genes from disease/phenotype descriptors. *H. YANG, K. WANG.* Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA.

Whole-genome/exome sequencing and copy number variation studies can generate many candidate genes for specific diseases or phenotypes. However, to best prioritize these candidate genes, traditional approaches typically do not consider the prior knowledge on associations between genes and specific phenotypes. To address this problem, we developed an integrative tool named Phenolyzer, which takes as input a discrete list of phenotype terms and generate a list of candidate genes weighted by the chance of being associated with the phenotype, even in the absence of any genotype data. Phenolyzer works by following a biologist's logic - 1) search databases in CTD's (Comparative Toxicogenomics Database) disease vocabulary and Disease Ontology for a certain disease/phenotype term, interpret the term into multiple specific disease names, find all the associated genes and related information in OMIM (Online Mendelian Inheritance in Man), Orphanet (a journal for rare disease), NCBI's ClinVar, GeneReviews (an expert-authored, peer-reviewed disease descriptions) and GWAS (Genome Wide Association Studies) databases, then generate the seed gene set with conditional probability as scores, 2) grow the seed gene set in the HPRD (Human Protein Reference Database) protein interaction, NCBI's Biosystem, HGNC (HUGO Gene Nomenclature Committee) gene family, and HTRI (Human Transcriptional Regulation Interactions) databases and retrieve an augmented gene set, 3) integrating all the information to score genes. The input can be one or several disease/phenotype terms, while users can optionally supply a gene list or genomic region to further trim down candidate genes. Additionally, Phenolyzer generates an intuitive visualization of gene-phenotype network and gene-gene network on the fly. Furthermore, combined with ANNOVAR, users can prioritize disease variants from whole-genome/exome sequencing data, significantly expediting discovery of disease causal genes. The efficiency and accuracy of Phenolyzer were validated by extensive benchmarking studies using phenotype terms associated with several Mendelian diseases, and also with test datasets on complex diseases. The great performance of Phenolyzer was also compared with other similar tools like Phevor and PosMed. In addition to a command line software tool, we implemented Phenolyzer as a user-friendly web server to facilitate easy access for users without informatics skills. The server is available at http://phenolyzer.usc.edu.

Determining the Number of Contributors using Forensically Relevant STRs: Effects of Template Mass and Complexity on the Ability to Correctly Identify the Number of Contributors. *L. Alfonse[1], H. Swaminathan[2], D.S. Lun[2], M. Medard[3], C.M. Grgicak[1].* 1) Biomedical Forensic Sciences, Boston University School of Medicine, Boston, MA; 2) Department of Computer Science, Rutgers University-Camden, Camden, NJ; 3) Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, MA.

The objective of this project was to evaluate NOCIt - a software that can assess the number of contributors (NOC) to DNA samples. The likelihood that n unrelated individuals contributed to a sample is computed via a Monte Carlo process during which genotypes for the n contributors are randomly chosen based on the allele frequencies, and the ratio of the n contributors to the mixture is randomly selected from a uniform distribution. Modeling of baseline noise, reverse and forward stutter proportions, dropout rates, and allele heights is performed. The likelihood of observing the peak heights at each locus given the genotypes of the contributors, the mixture ratio, and the template DNA mass is computed using single source calibration samples of known genotypes; likelihood values are 'averaged' between iterations and multiplied across loci to give the overall likelihood given n contributors. The output is presented as the probability distribution over 0 to 5 contributors. The performance of NOCIt was tested on 1-, 2-, 3-, 4- and 5-person mixtures of various contributor ratios, amplified with the AmpFlstr® Identifiler® Plus Amplification kit (29 cycles). Samples were amplified at target masses ranging from 0.25 to 0.008 ng and analyzed at 1 RFU. Artifacts such as -A, dissociated dye, bleed through, and spikes were manually removed. Allele frequencies from the Caucasian population provided in the AmpFlstr® Identifiler® Plus manual were utilized. The accuracy of NOCIt, computed by comparing the software's output to the known NOC, was dependent upon 1) the true NOC in the sample and 2) the total mass of DNA in the sample. For example, the accuracy decreased from 100% to 20% for the 1- to 5-person mixtures, respectively. However, when sufficient levels of DNA were amplified, i.e. 0.25 ng, the accuracy was 100% for 1- to 4-person mixtures and 67% for the mixtures containing DNA from 5 persons. The minimum from any one contributor required to correctly estimate the NOC was ~10 cells. These preliminary results suggest that NOCIt is a valuable analysis tool and results in high accuracy rates for samples with sufficient DNA quantities. Furthermore, these data indicate that samples containing low-target quantities may need to be interpreted using multiple or different assumptions on the number of contributors. Future studies will test NOCIt's accuracy with an additional 360 samples and provide data regarding the number of samples needed to calibrate NOCIt.

Detection of autozygous segments in exomes of inbred individuals. *M. Vigeland[1], K.S. Gjøtterud[2].* 1) Dept of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Dept of Chemistry, Biotechnology and Food Science, Norwegian University of Life Sciences, Ås, Norway.

We present AutEx, a new algorithm for detecting autozygous segments directly from whole-exome variant files. Our approach is based on the hidden Markov model developed by Leutenegger et al. (2003), taking as input the level of inbreeding, allele frequencies, variant distances and sequencing error probabilities. Using both simulated data and real inbred exomes we compare our method to existing software detecting runs of homozygosity, including PLINK. Overall AutEx performs better, in particular when the level of inbreeding is accurately known. The AutEx algorithm is implemented as part of FILTUS, a lightweight GUI program aimed at non-bioinformaticians, providing a framework for filtering, exploring and statistical analysis of exome data. Combined with these features, AutEx becomes an effective and easy-to-use tool for narrowing down the search for causal variants in exomes of inbred individuals with recessive disorders.

1470S

A systems biology approach for enriching genetic association studies of metabolite profiles with pathway knowledge. *K. Willems van Dijk[1], H.K. Dharuri[1], P. Henneman[2], A. Demirkan[3], A. Isaacs[3], C.M. van Duijn[3], P.A.C. 't Hoen[1], J.B. van Klinken[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, Zuid Holland, Netherlands; 2) Clinical Genetics, Academic Medical Center, Amsterdam, Netherlands; 3) Genetic Epidemiology Unit, Epidemiology, Erasmus Medical Center, Rotterdam, Netherlands.

Plasma metabolite levels have been proposed to reflect the interaction of the genome with the environment and may thus provide insight into the etiology of complex metabolic disorders. Genome-Wide Association Studies (GWAS) on plasma metabolite levels have led to the discovery of many novel loci, but they have been relatively unsuccessful in providing insight into the etiology of complex metabolic disorders. Here, we propose Elementary Flux Mode (EFM) analysis as an approach to assist in the functional interpretation of GWAS results on metabolomics data and to explain the mechanistic link between genotype and metabotype. EFM analysis consists of enumerating the complete set of steady state fluxes that are possible in a metabolic network, thus providing a comprehensive picture of the network's functional capacity. We assessed the potential of EFM analysis to explain a set of genetically determined metabotypes (GDMs) concerning amino acid metabolism in humans that were reported in the OMIM and GWAS catalogue database. We performed EFM analysis on a condensed version of the genome-scale stoichiometric model (GSMM) of the hepatocyte developed by Gille et al. (2010). The resulting model yielded 8.5•10^9 EFMs that were involved in the degradation, synthesis or conversion of amino acids. Subsequently, for each reaction and amino acid, we determined the essentiality of that reaction in the metabolism of the amino acid by counting the number of EFMs that both contained the reaction and were involved in the conversion of the amino acid. Comparing these results with the selected GDMs, we found that the known genotype-metabotype relationships could be predicted with a high degree of accuracy (ROC curve AUC = 0.93). In contrast, predictions that were made based on co-occurrence of the gene and metabolite in KEGG pathway gene sets or on the shortest distance between the gene and the metabolite in the metabolic network had a low degree of specificity and were less accurate (AUC = 0.79 and 0.74 resp.). In conclusion, we present a novel strategy for analysing metabolomics data in a genome-wide setting using a Systems Biology approach. A workflow has been developed to 1) compute the EFMs in a GSMM, 2) map GWAS results to the EFMs, and 3) visualise enriched EFMs. Our approach integrates genetic association analysis with mathematical models of human metabolism and has the potential to provide new mechanistic insights into the causes of metabolic disease.

1471M

Integration of transcriptome, bioinformatics and model organism studies to gain insight into microRNA function. *S. Banfi[1, 2], I. Conte[1], S. Merella[3], J. Garcia-Mantega[3], C. Migliore[4], D. Lazarevic[3], S. Carrella[1], R. Avellino[1], N. Davidson[1], E. Stupka[3].* 1) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 2) Department of Biochemistry, Biophysics and General Pathology, Second University of Naples, Naples; 3) Center For Translational Genomics and Bioinformatics, San Raffaele Scientific Institute, Milan, Italy; 4) CBM Scrl, c/o Area Science Park, Trieste, Italy.

Vertebrate organogenesis is critically sensitive to gene dosage and even subtle variations in the expression levels of key genes may result in a variety of tissue anomalies. MicroRNAs (miRNAs) are fundamental regulators of gene expression and their role in vertebrate tissue patterning is just beginning to be elucidated. To gain further insight into this issue, we analysed the transcriptomic consequences of manipulating the expression of miR-204 in the Medaka fish model system. We used RNA-Seq and an innovative bioinformatics approach, which combines conventional differential expression analysis with the behaviour expected by miR-204 targets after its overexpression and knockdown. With this approach combined with a correlative analysis of the putative targets, we identified a wider set of mir-204 target genes belonging to different pathways. Together, these approaches confirmed that miR-204 has a key role in eye development and further highlighted its putative function in neural differentiation processes, including axon guidance as supported by in vivo functional studies. Together, our results demonstrate the advantage of integrating next-generation sequencing and bioinformatics approaches to investigate miRNA biology and provide new important information on the role of miRNAs in the control of axon guidance and more broadly in nervous system development.

1472T

Enhanced statistical methods to detect cross-population heterogeneity at GWAS risk loci. *M. Roytman[1], B. Pasaniuc[1, 2, 3].* 1) Bioinformatics Interdepartmental Program, UCLA; 2) Dept of Human Genetics, David Geffen School of Medicine, UCLA; 3) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA.

GWAS have identified thousands of disease-associated variants to date, many of which have successfully been used to identify biological pathways for drug targets. However, a large majority of these risk alleles were identified in individuals of European ancestry making their transferability to other ethnic groups uncertain. Here we present methods for quantifying how well the known GWAS risk variants extend to individuals of non-European ancestry. We introduce methods that quantify the difference in effect size of a particular risk variant across two populations and propose a log likelihood ratio test for assessing the presence of heterogeneity at a given risk locus. We investigate the power of our approach at different levels of heterogeneity and show that our methods has high power of detecting realistic differences in effect size, while maintaining well-calibrated statistics, closely following a chi-squared distribution with one degree of freedom under null data simulations (where effect size does not differ between the populations). We extend our approach to admixed populations (e.g. African American) and show how locus-specific can be integrated to detect heterogeneity in the allelic effect across different ancestries.

1473S

Regulatory network constructed from the epigenome of normal cells reveals functional connections between disease genes. *R.F. Lowdon[1], G. Elliott[1], B. Zhang[1], J.B. Cheng[2], S.J. Fisher[3], J.F. Costello[4], T. Wang[1].* 1) Genetics, Washington University School of Medicine, Saint Louis, MO. 63108; 2) Department of Dermatology, University of California San Francisco, CA 94143; 3) Department of Obstetrics, Gynecology & Reproductive Sciences, School of Medicine, University of California San Francisco, San Francisco, CA, USA; 4) Dept. of Neurological Surgery, Helen Diller Family Comprehensive Cancer Center, UC-San Francisco, CA 94143.

It is a daunting but critical challenge to understand the functional connection between human disease genes and the function of disease-associated non-coding variants. Uncovering the connections between these genes and variants are crucial for understanding normal and aberrant regulation of human disease genes. We hypothesized that cell type-specific gene regulatory instructions for a transcription factor and its target genes are encoded in the epigenomic landscape around the genes. To test this hypothesis, we developed a regulatory analysis pipeline to construct gene regulatory networks based on a cell's epigenome. Our regulatory analysis approach has the following components: first, by profiling and contrasting epigenomes of different cell types, we defined cell type-specific regulatory elements. Then, we identified enrichment of binding site motifs of specific transcription factors in these regulatory elements. Next we used custom region-gene association tools to identify candidate genes for each element. We also used co-variation of transcription factor expression and target gene expression to increase the confidence of our prediction. Finally, we queried publicly available TF-target gene interaction data to quantify the connections among our TFs and target genes. This approach allowed us to construct a gene regulatory network of a cell type of interest. We successfully captured many known connections in our reconstructed networks, as well as predicted novel connections. Surprisingly, this approach revealed functional connections across disease genes, predicted potential key genes that are not yet implicated in disease, and explained functional consequences of some non-coding, disease associated variants. In our first test, we constructed a gene regulatory network of the embryonic surface ectoderm using epigenomes of cell types of shared developmental origin. We confirmed co-regulation of six genes that encode hemidesmosomes, a structural complex in the epidermis of the skin. Mutations occur in any one of five of these genes in the inherited blistering skin disease, epidermolysis bullosa. In our second test, we constructed a gene regulatory network of the placenta cytotrophoblast cells. The network revealed genes highly connected to the placental disease pre-eclampsia and predicted a master regulator of these genes. Thus our analysis pipeline was robust across biological systems and connected non-coding regulatory elements in human disease.

Dynamic changes in RNA modifications (epitranscriptome) localization drives new regulation of cancer cells. *Y. Saletore[1,2,3], T. Fernando[4], A. Melnick[4], L. Cerchietti[4], C. Mason[1,2].* 1) Department of Physiology and Biophysics, Weill Medical College, Cornell University, New York, NY 10065, USA; 2) The HRH Prince Alwaleed Bin Talal Bin Abdulaziz Alsaud Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY 10065, USA; 3) Tri-Institutional Training Program in Computational Biology and Medicine, New York, NY 10065, USA; 4) Department of Hematology and Oncology, Weill Cornell Medical College, New York, NY, USA.

The epitranscriptome is a very nascent, exciting field that has revealed a complex middle layer of cellular regulation that is mediated by modified RNA bases. Methylated RNA ImmunoPrecipitation-Seq (MeRIP-Seq) utilizes an antibody specific for the RNA modification methyl-6-adenosine (m^6A) to enrich for RNA fragments that contain the epitope. Combined with next-generation sequencing (NGS), these immunoprecipitated fragments (IP) are sequenced with RNA-Seq controls to identify peaks: genomic regions of interest where putative m^6A sites exist. However, the original MeRIP peak-finding methods (like MeRIPPeR) utilized the non-parametric Fisher's exact test to find peak regions that were statistically significant in enrichment for the IP relative to the control. While this was successful in identifying thousands of peaks in both human and mouse samples, m^6A is known to be a dynamic modification and m^6A sites and methylation levels change in response to cell stimuli. Here we introduce MeRIPPeR 2.0, which uses the negative binomial distribution to better model the high dispersion in the RNA-Seq data and applies a probabilistic graphical model to elucidate peak methylation from the IP efficiency. This not only enables better identification of epitranscriptomic peaks, but also more accurate characterization of how those peaks change between conditions.

We then applied MeRIP-Seq and MeRIPPeR 2.0 to Ly1 diffuse large B cell lymphoma samples to further examine the dynamic nature of m^6A in the context of cancer, using normal cells, proliferating cells, and those cells after heat shock, as well as investigating nuclear and cytosolic fractions separately. Heat shock has previously been demonstrated to have an impact on m^6A sites and also simulates B-cell activation. Previous epitranscriptomic studies have demonstrated an enrichment of peaks near the stop codon, but here, we find that some samples exhibit a striking enrichment in the 5' UTR. In concordance with these results, we identified thousands of m^6A peaks throughout the transcriptome and an enrichment near the stop codon. However, we also discovered a small set of m^6A peaks in the 5' UTR that are more highly regulated more dynamic than those found enriched at the stop codon. This indicates that not only the degree of RNA methylation, but also the coordinates of foci within genes can shift, allowing a completely different regulatory avenue for m^6A that has not been seen before.

An integrated method to predict functional impact of non-synonymous SNVs in human genome. *M. Wang[1], L. Wei[1,2].* 1) Center for Bioinformatics, State Key Laboratory of Protein and Plant Gene Research, School of Life Sciences, Peking University, Beijing, P.R. China; 2) National Institute of Biological Sciences, Beijing, P.R. China.

Correct interpretation of large scale genome variants functional impact and implications in human disease is essential for modern biomedical research and clinical genetics. In silico methods predicting whether a non-synonymous SNV is deleterious or neutral facilitate the discovery of disease causal mutations and classification for SNVs of unknown clinical significance. Most of these tools are built upon machine learning approaches, which classify the two types of SNVs mainly based on conservation information, sequence features and protein structures. However, correct assessment of disease relevance for a SNV requires informative and comprehensive evaluation, which should take various sources of evidence into consideration. We proposed a method to predict functional impact of non-synonymous SNVs in human genome by integrating multiple sources of evidences. Genetic evidence including co-segregation of a SNP with disease phenotype in a family and population case-control associations provide direct evidence linking SNPs to phenotype. Such heterogeneous factors were integrated in our tool by a unified Bayes model, which gives a combined posterior probability that the SNV is pathogenic given all the evidences. Performance evaluation on benchmark data sets showed the integrated method outperforms those widely employed tools. We also demonstrated its utility in disease causal gene discovery from next-generation whole exome sequencing. This method would facilitate rapid annotation and reliable classification for SNPs discovered by NGS in a large scale.

1476S

Identifying the master regulators of complex autoimmune disease susceptibility in Alopecia Areata with reverse-engineered regulatory networks. *J.C. Chen[1,2], A.M. Christiano[2,3].* 1) Systems Biology, Columbia University, New York, NY; 2) Genetics and Development, Columbia University, New York, NY; 3) Dermatology, Columbia University, New York, NY.

Alopecia areata (AA) is an autoimmune disease affecting the hair follicle in which T-cell infiltrates aberrantly localize to and destroy the follicle, resulting in hair loss. While most research has focused on the immunologic etiology of the disease, little has been done to investigate the contributing genetics of the affected end organ e.g. the skin and hair in AA, yet this is an indispensable driver to the etiology of this autoimmune disease. Patients with autoimmune disease do not uniformly present with symptoms across multiple tissues, indicating that genetic components in the end organ specific to a disease are required for autoimmune response. We have taken a systems biology approach to the study of acquired autoimmunity in AA, and modeled it as a genetic, regulatory disease phenotype using reverse-engineered cellular networks. The goal of this study was to take a global, unbiased approach to understanding the regulation of key molecular programs mediating the AA autoimmune response by microarray profiling of scalp biopsies from 60 individuals across three categories of AA clinical presentation and unaffected controls. Through integrating our network-based analysis, with Gene Set Enrichment analysis and unsupervised clustering, we have identified that varying presentations of AA are mediated by the unique expression of six key regulators, with increased severity in presentation coinciding with the involvement of a higher fraction of these regulators. The manipulation of these master regulators is sufficient to induce cytotoxicity in cultured human dermal papillae cells and keratinocytes. This approach has given us a novel means to study the mechanistic regulation behind the complex gene expression networks associated with aberrant autoimmune response in the context of AA.

1477M

Global profiling of condition specific transcription factor binding with ATAC-seq. *R. Pique-Regi, D. Watza, M. Estill, F. Luca.* Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI.

Deciphering the regulatory sequences which control gene transcription is a critical step in understanding both cellular and condition-specific regulatory programs encoded in the human genome. Transcriptional response is typically regulated by transcription factors (TFs) which are known to bind specific regulatory sequence motifs. Profiling the environmental binding activity of these factors can be quickly accomplished at a genome-wide scale with the recently developed technique ATAC-seq, which utilizes the Tn5 transposase to fragment and tag accessible DNA. When coupled with an advanced computational method such as CENTIPEDE binding models for TFs with known motifs can be generated across the genome. To date, there are no methods that efficiently incorporate the information provided by paired-end sequencing which allows both the identification of the library fragment length as well as the two cleavage locations that generated the fragment.

First, we have extended CENTIPEDE to utilize fragment length information, and we are working on extending the model to include the joint statistics of cleavage pairs. Our results indicate that paired-end sequencing provides a more informative footprint model for ATAC-seq libraries which leads to greater accuracy in predicting TF binding. These results were validated with ChIP-seq data (ENCODE Project) for multiple factors including CTCF, NRSF, NRF-1, and NFkB.

We then assayed TF activity in lymphoblastoid cell-lines (LCLs) across multiple treatments (selenium, copper, retinoic acid and iron) for which we previously determined significant differences in gene expression levels. From our initial sequencing results we were able to resolve 383 actively bound motifs (Zscore > 5) across all conditions. We were also able to characterize 5236 regions that have significantly changed chromatin accessibility (FDR < 10%) in response to both copper and selenium. No major change in accessibility was detected for retinoic acid but condition-specific differential binding was detected in a small subset of motif instances. Ongoing analyses focus in integrating the changes in TF binding together with the transcriptional response. These results demonstrate that ATAC-seq together with an improved footprint model are excellent tools for rapid profiling of transcription binding factor activity to study cellular regulatory response to the environment.

1478T

A comprehensive and highly accurate RNA-Seq pipeline using a hybrid sequencing and algorithm approach. *P.T. Afshar[1], G. Gibeling[2], M. Mohiyuddin[3], R. Sebra[4], A. Sethi[6], L.T. Fang[3], J.C. Mu[1], H. Tilgner[5], N. Bani Asadi[2,3], M.B. Gerstein[6], M. Snyder[5], E. Schadt[4], W.H. Wong[7,8], K.F. Au[9], H.Y.K Lam[3].* 1) Department of Electrical Engineering, Stanford University, Stanford, CA; 2) Department of Engineering, Bina Technologies, Redwood City, CA; 3) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 4) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 6) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 7) Department of Statistics, Stanford University, Stanford, CA; 8) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA; 9) Department of Internal Medicine, University of Iowa, Iowa City, IA.

Emergence of next generation sequencing has brought a new era in transcriptome analysis with RNA-Seq. Although Second Generation Sequencing (SGS) is a high-throughput and high-fidelity technology, full-length isoform analysis is still a challenging problem due to the relatively short read length of SGS, the imperfect performance of existing tools, and the complexity of alternative splicing. Recent studies have suggested to use Third Generation Sequencing (TGS) to improve isoform detection, but it is missing the essence of the analyses enabled by SGS.

Here we present a comprehensive transcriptome profiling pipeline, the RNA-Seq Cocktail pipeline, integrating both SGS and TGS RNA-seq data along with a number of best-of-breed algorithms. TopHat2, SpliceMap, and STAR are used to align RNA-Seq reads from SGS and detect splice junctions. A novel algorithm we developed is used to merge alignments and junctions from multiple mappers and assign confidence level to the merged junctions. It also uses Cufflinks2 for isoform assembly, Cuffdiff for differential expression analysis, and GATK3 for variant detection. To address the high error rate of current TGS, it uses LSC for error correction followed by IDP for RNA-Seq analysis, including fusion gene detection.

We processed 7 human embryonic stem cell (hESC) datasets from the ENCODE project with our pipeline. The merged junction set from our algorithm has up to 33% more detected junctions compared to the junctions from a single tool. In addition, 94% of junctions reported by all the three tools were validated by the EST dataset compared to 25% validation rate for junctions reported by only one tool. We also compared the assembled isoforms from Cufflinks2 based on ~50K TopHat2 alignments to RefSeq and Ensembl. We observed that a higher percentage of singletons was reported by Cufflinks2 (51%) compared to the aforementioned databases (<10%), suggesting limitations in the use of short read SGS data for detecting long isoforms. Our previous study has already shown that at the same specificity (5% FPR), IDP had a much higher sensitivity (62% TP) than Cufflinks (20% TP). We have also applied our pipeline to other RNA-Seq data, including the MCF-7 breast cancer cell line. Our RNA-Seq Cocktail pipeline is by far the most comprehensive RNA-Seq pipeline with very high accuracy.

1479S

Typing of PRDM9 in childhood cancers from Next Generation Sequencing data. *A. Ang Houle[1,2], P. Awadalla[2].* 1) Bioinformatics Dept, University of Montreal, Montreal, Quebec, Canada; 2) Sainte-Justine Research Center, Montreal, Quebec, Canada.

Childhood cancers differ remarkably from those seen in the adult population, and their unique biology suggests that the genetic factors underlying the malignant transformation in the developing tissues differ from those generally identified in adults. The identification of these genetic factors may promote the development of biomarkers contributing to early cancer detection. Prior work from our research group suggests that patients affected with childhood acute lymphoblastic leukaemia show a higher frequency of the rare C allele of PRDM9, which is found in only ~1% of the European population. PRDM9 protein are composed of a repetitive zinc finger array at their C terminal tail, which binds to specific motifs of the DNA during meiosis, and determines the location of double-stranded breaks during recombination. This type of repetitive structure confers instability to the genetic sequence and has been shown to evolve rapidly, explaining partially the extreme polymorphism of the PRDM9 gene in the human population. Moreover, this structure poses important challenges in typing PRDM9 alleles from Next Generation Sequencing (NGS) data, and current computational typing methods are unsuccessful at identifying novel alleles. Here, we present a computational method to accurately type PRDM9 alleles from NGS data, and therefore make possible the identification of alleles in childhood cancer NGS patients. This study provides a method for the challenge of typing PRDM9 alleles from NGS data. Furthermore, the association of rare PRDM9 alleles with particular childhood cancer types may shed light on the unique molecular mechanisms underlying these diseases.

Integrated Variant Comparison Using Three Different DNA-seq Analysis Methods. *H. Beale, D. Kearns, B. Lee, D. Bailey, T. Lowe, P. Chan.* Maverix Biomics, Inc., San Mateo, CA.

Technology advancement and increased adoption of next generation sequencing has introduced a large amount of raw data that requires extensive analysis to obtain relevant biological information. However, the costs and duration of the subsequent bioinformatic steps including read mapping, variant calling and contextualization can rarely be pre-determined and often cannot be accurately assessed until a substantial portion of the analysis is complete. Here we demonstrate an approach with pre-defined costs and extensive scalability that uses the most highly considered, peer-reviewed, open source techniques and generates complete documentation of the process. The new DNA sequencing analysis pipeline on the Maverix Analytic Platform incorporates three best-in-class algorithms for variant analysis: GATK, FreeBayes, and SAMTools. We illustrate the few steps required to upload FASTQ files and to configure and launch an analysis. All data are extensively protected with security standards that are HIPAA compliant. The key results are summarized in graphs, while individual variants are annotated and presented in an interactive tabular format that is linked to a private version of the UCSC Genome Browser which can display statistics or supporting reads for a selected variant call. The common and distinct variants calls by different analysis methods are visually displayed, and the resulting variants can be extensively filtered on many characteristics. Results can also be downloaded in the tabular format or exported in VCF format for use in other downstream applications. The intermediate results, processing logs, and command lines as executed are available for those who wish to review each step of the pipeline in detail. Use of this approach accelerates the availability of the findings contained in the sequencing results without a loss of quality or control.

Predicting splicing mutations by information theory-based analysis in rare and common diseases: performance and best practices. *N.G. Caminsky[1], E.J. Mucaki[1], P.K. Rogan[1,2].* 1) Biochemistry, Western University, London, Ontario, Canada; 2) Cytognomix, London, Ontario, Canada.

Disease-causing mutations that affect pre-mRNA splicing are common. We review the literature citing information theory-based mRNA splicing mutation analyses (n=376). This type of analysis has been applied by many groups to study both common Mendelian conditions, and rare syndromes. While the Shannon entropy framework remains the foundation of these analyses, the software for performing these studies has rapidly progressed. Currently, the Automated Splice Site and Exon Definition Analysis server (splice.cytognomix.com) is used to comprehensively analyze single splicing and regulatory mutations. The Shannon pipeline (shannonpipeline.cytognomix.com) analyzes mutations in exomes, genomes, and targeted gene sets. These resources compute individual or total exon information contents (R_i, or $R_{i,\text{total}}$, in bits) of normal and mutant sequences, which correspond to thermodynamic differences that account for splicing effects. Primary applications include interpretation of novel variants, distinction of benign nucleotide alterations, deleterious alleles (including leaky, inactivating, and cryptic sites), and quantitative evaluation of changes in R_i, or $R_{i,\text{total}}$ that account for phenotypic variability and disease severity. Our results, based on a sample of these studies (n=106) report 157 natural splice sites, 19 activate cryptic sites, and 9 are regulatory splicing mutations. Of those affecting natural splice sites, 20 cause leaky and 50 inactivate splicing. Canonical dinucleotide mutations in splice sites comprised 28% but adjacent positions occurred at 41% and 31% within introns and exons, respectively. 82.7% of the studies (n=29) that validated predicted mutations with *in vitro* or *in vivo* expression assays confirmed the information theory-based analyses. Genome-scale information analyses of complete cancer genomes (3 cell lines) detected 17 to 31 splicing mutations, of which 6 to 17 abolished natural splicing, 1-5 were leaky, and 9-13 activated cryptic sites. In 447 tumors of breast cancer patients, on average, 11.8 splicing mutations were present per exome, where 3.1 were inactivating, 6.2 were leaky and 2.6 activated cryptic splicing. Splicing mutations in these tumors have been validated with RNA-Seq data by automating this process (veridical.org). In summary, we propose guidelines for detection of splicing mutations, distinction of polymorphisms, interpretation of constitutive and regulatory binding site mutations, and exon definition of splice isoforms.

PedigreeAnnotator: a GATK walker to annotate variants based on pedigree information. *B.K. Cornes, J. Patel, T. Bloom, A.V. Abhyankar.* New York Genome Center, New York, NY.

Family-based exome/genome analyses have been effectively used to identify genetic defects in rare Mendelian disorders. Several available tools, with their own advantages/disadvantages, have the ability to either integrate pedigree information or add genomic annotations but no single tool combines all the steps required to make biologically/clinically relevant variant prioritization. Previously we have described a set of R-scripts and a workflow to perform pedigree-aware analyses of next-generation sequencing data. To improve the accuracy and performance of our existing method we reimplemented our R code and workflow with the open-source version of GATK. PedigreeAnnotator accepts, as input, a PLINK format pedigree file and a VCF file containing multiple samples from a single or several families. The pedigree information is used to predict the mode of inheritance, recalibrate genotypes, compute Mendelian error probabilities & inbreeding coefficients and classify variants accordingly (e.g. denovo). Compound heterozygosity and loss of heterozygosity (LOH) annotations are also computed. All available families can be analyzed simultaneously in a computationally efficient way. Additionally, detailed QC is performed including confirmation of family relationships, gender check and cross-sample contamination. Family data is then integrated with publicly available annotation resources (e.g. OMIM, ENCODE). Furthermore, to aid variant prioritization, a scoring scheme is implemented, taking into account different attributes of the annotated variant. A summary report is generated to include QC, variant statistics and a short list of variants based on the prioritization score. PedigreeAnnotator is designed to perform extended variant analysis accurately and efficiently while being user-friendly.

GenAP workbench: aiding variant classification in clinical diagnostic settings. *M.C. Eike[1], E. Skorve[2], T. Håndstad[1], H. Fontenelle[1], K.S. Gjøtterud[1], J. Børsting[2], M. Aanestad[2], A.L. Culén[2], T. Grünfeld[1], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Department of Informatics, University of Oslo, Oslo, Norway.

Classifying genetic variants in terms of clinical significance is a complex process where multiple sources of information of variable quality are reviewed, weighted and combined. With the introduction of high-throughput sequencing technologies into the clinic, this process can quickly become a daunting task without the help of supporting tools. We have therefore developed a workbench for rules-based, semi-automated analysis of sequence variation data for diagnostic use, as part of the project *Norwegian clinical genetic Analysis Platform* (genAP).

The underlying system allows rich annotation of sequence variants from external and internal resources, and the workbench displays this information in a series of structured tabs, highlighting key information and guiding the analyst through an analysis workflow based on standard operating procedures at our department. This includes frequency data, mutation databases and prediction tools for missense variants, as well as tools for splice sites. In addition, we have developed a literature evaluation module, where relevant references are classified by the analyst according to quality and conclusions. For the final report, the system uses the annotation information and analyst input to generate suggested classifications for each variant. Approved results may be exported and added to the in-house database.

We are currently testing a prototype of the workbench, with the aim to introduce it for full scale use by the end of 2014. This presentation will demonstrate the logic of the system, with specific examples and some of our experiences from user testing.

Hadoop Acceleration of Bioinformatics Algorithms. *M. Gollery, A. Taffel, G. Ganebnii, D. Leca, A. Lisnik, M. Hohlovich, A. Dobretsov, V. Shakin, M. Mikheev.* BioDatomics, Bethesda, MD.

Genomic data production now has the pace, volume, and variety to be considered 'Big Data'. As a result, the processing of genomic data can be improved by applying lessons and techniques from other industries that have worked successfully with Big Data. One of these techniques, now in common use within multiple industries--Energy, Financial Services, Online Commerce, and Telecommunications, for example--is the use of a Hadoop-based analysis infrastructure. Hadoop is an open source software framework whose roots lie in the original Google search engine. The framework is a collection of software modules that manage the storage and processing of large datasets on clusters of commodity hardware. Because Hadoop segments and distributes data across a theoretically infinite number of compute nodes, the framework has the potential for virtually unlimited scalability and a speed increase of multiple orders of magnitude compared to legacy approaches. These developments make it hypothetically possible to accelerate the analytical processing of NGS data. The execution speed of NGS data analysis directly impacts the speed at which research findings become available. Currently, analysis of a large dataset via a complex workflow can take days--in some cases weeks. This represents a significant impediment to research productivity. The goal of this project was to reduce these protracted analysis times by optimizing bioinformatics algorithms for Hadoop and executing them on Hadoop-compatible software and a Hadoop-optimized cluster. At project initiation, BioDatomics optimized several standard bioinformatics analysis tools to take advantage of Hadoop's parallel processing capability. The resulting pipelines were then executed via the BioDT software platform, which is built on Hadoop, running on a Hadoop-optimized hardware cluster. The effect on pipeline run times, compared to standard-version tools running on a comparably-sized non-Hadoop platform, was dramatic. This poster will explain the basics of a Hadoop system, the mechanisms used to optimize bioinformatics algorithms and bioanalytic software for Hadoop, and will present data comparing Hadoop vs. legacy clusters as applied to bioanalytics.

Benchmarking of Strand NGS variant caller using a whole genome sample NA12878 and data from Genome in a bottle consortium. *R. Hariharan, R. Gupta, P. Gupta, A. Narayanan, S. Aditya, S. Katragadda, V. Veeramachaneni.* Strand Life Sciences, Bangalore, Karnataka, India.

Background and Objectives: To realize the potential and promise of Next Generation Sequencing (NGS) technology towards research and clinical applications, computational approaches are essential to call variants and translate them into actionable knowledge. Many algorithms are developed for variant calling, however often times they differ on multiple variant call predictions. In this work, we'll present Strand NGS (formerly Avadis NGS) variant calling approach and benchmarking results on a 1000 genomes CEU female sample, NA12878. Strand NGS is capable of calling different types of variants including SNPs, InDels, structural variations (SVs) and copy number variations (CNVs). We compare our variant calls (SNPs and InDels) with those from GATK UnifiedGenotyper and highly confident variant call set from NIST - Genome in a Bottle Consortium. **Results:** Strand NGS and GATK identified a total of 6,393,054 and 6,105,466 variants respectively with very similar Het/Hom and Ti/Tv ratios. We observed a high overlap (93%) in these variant calls. When variant calls from Strand NGS are filtered using quality metrics like % supporting reads, variant score, read coverage, stand bias and other PV4 biases, the overlap between the variant calls increases to ~98%, making Strand NGS and GATK very similar. We also compared the Strand NGS variant call set to highly confident variants from Genome in a bottle consortium and found a significant overlap between them. We observed that application of the filters based on the above mentioned quality metrics helps to selectively reduce false positive variant calls, there by increasing both sensitivity and specificity. **Conclusions:** Due to several issues with the raw sequencing data, variant calling is still a challenging problem. Although numerous open-source and proprietary algorithms are available, assessing how well these algorithms perform on different data sets remains a challenge. Assessment of different quality metrics like supporting reads %, variant score, read coverage, strand bias and other PV4 biases, provides a useful way to filter the likely false positive variant calls. The benchmarking results presented in this paper suggest that Strand NGS variant caller is a powerful and flexible approach to call variants and provides a visually appealing way to assess their quality using a variety of quality metrics.

1486M

Accurate detection of low-representation alleles in tumor DNA through augmented exome and transcriptome sequencing. *E. Helman, M. Clark, S. Boyle, A. Patwardhan, D. Church, M. Pratt, S. Luo, N. Leng, C. Haudenschild, R. Chen, J. West.* Personalis, Inc, Menlo Park, CA.

Somatic mutations present at a low allelic fraction have been implicated in tumor progression, recurrence, metastasis and drug resistance. The ability to detect these mutations via next-generation sequencing is crucial but often impaired by small sample size, low cellularity, and tumor heterogeneity. In order for sequencing to aid in directing personalized cancer therapies, these low-representation alleles must be accurately identified and interpreted. We sought to determine the sequencing depth and analytical parameters required to detect small variants in cancer by completing exome and transcriptome sequencing of four cancer cell lines. These lines contain a large number of known mutations in *EGFR*, *KRAS*, *BRAF*, and more than 20 other cancer genes at well defined levels of allelic representation, with some mutations at fractions as low as 1%. We completed high-depth exome sequencing with our ACE exome assay, which augments and improves coverage of over 1200 cancer genes, increasing our sensitivity for cancer variants. We utilized modified bioinformatics approaches and integrated whole-transcriptome sequencing to validate our findings. We identified all 36 known cancer mutations present within these cell line mixtures with our ACE exome and somatic pipeline. To gauge our limit of detection, we computationally down-sampled the aligned sequence files to varying depths of coverage. We find that our method is highly sensitive at moderate depths, detecting mutations present at 1% allelic fraction, and show how the limit of detection changes as depth of coverage changes. We also find high concordance between our estimated allelic fractions and known values. Notably, we recapitulate canonical *EGFR* mutations, such as T790M, which has been shown to confer acquired resistance to treatment with *EGFR* TKIs. Finally, we confirm the expression of coding mutations as well as the predicted effect of regulatory mutations by integrating results from our transciptome sequencing pipeline. Important cancer mutations are often present at small allelic fractions because of tumor heterogeneity and low purity samples. For effective cancer exome analysis, accurate detection of these variants is of paramount importance. Existing assays report limits of detection in the 5-10% range. Here, we use mixture experiments to quantitatively determine the detection limits of our enhanced exome protocol and analysis pipeline and report its sensitivity to low-representation cancer mutations.

1487T

Genomic Analysis of Blood-mediated Disorders in African Americans. *L. Jackson[1], F.L.C. Jackson[2].* 1) Biomedical Engineering, Science, and Health System, Drexel University, Philadelphia, PA; 2) Department of Biology, Howard University, Washington DC.

African-American populations are disproportionately affected by stroke, hypertension, skeletal diseases and renal disorders. This increased disease prevalence is thought to arise, in part, from population specific genetic variation at genes involved in disease phenotypes. We have developed a method of identifying the significant underlying genetic polymorphisms curated from NCBI gene sets. The resulting literature curated gene sets can be used to identify modules and pathways mediating the intersection of stroke, hypertension, renal disease, and skeletal diseases. Stroke, hypertension, renal disease, and skeletal diseases gene sets(N= 2521 genes) were obtained from NCBI Gene and then projected onto the genome, annotated with their gene ontology categories and cellular pathways to draw a bioinformatics portrayal of the overlap between these diseases with disproportionate effect in African American populations. Hotspot regions were then identified in the Human genome diversity panel populations and further characterized in HapMap populations. Mapping addiction genes onto the human genome resulted in eight gene clusters, with at least 15 disease genes (Range: 15-31 genes, pV <0.005) within a 1.5Mb contiguous distance along the genome. Hotspot genes were involved in blood circulation, cell migration, and regulation of phosphorus. Analysis of Human genome diversity panel populations with Sub-Saharan African ancestry showed population differences to non-African populations. We found eight regions of the genome that are strongly involved in complex disorders overrepresented in African American populations. Functional annotation of these hotspots identifies new candidate genes previously uncharacterized in the literature. Finally comparisons of polymorphism data point to 10 strong candidate variants that merit further characterization.

1488S

In silico prediction of splice-altering single nucleotide variants in human genome. *X. Jian[1], X. Liu[1,2].* 1) Division of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX; 2) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX.

Purpose *In silico* tools have been developed to predict mutations that may have an impact on pre-mRNA splicing. The major problem that prohibits the use of these tools in research and clinical practice is the difficulty in interpreting the output, partially due to lack of large-scale evaluation analysis of these tools. We aimed to compare some of these tools on a much larger scale and to provide a more accurate and directly interpretable prediction score for splicing mutations. **Methods** Two groups of single nucleotide variants (SNVs) within splicing consensus regions (-3 ~ +8 at the donor site and -12 ~ +2 at the acceptor site) that have known impact on splicing from public databases were used to evaluate eight *in silico* tools by receiver operating characteristic (ROC) analysis with ten-fold cross-validation. Two ensemble learning methods, adaptive boosting and random forests, were used to construct new models that take advantage of individual tools and to compute an ensemble prediction score for a given mutation. An additional test set was used to validate the new models. **Results** We collected 2,959 SNVs, among which 1,164 were positive and 1,795 were negative. Four tools were excluded from ROC analysis due to high missing rate. Among the remaining four tools, the Position Weight Matrix model and MaxEntScan outperformed other tools. We combined scores of these four tools as well as four conservation scores using two ensemble methods to construct two new models. Both models significantly improved the predictive performance (area under the curve > 0.97, accuracy > 93%) and were further validated by an additional test set with 45 labeled splicing mutations. We pre-calculated our ensemble scores for all possible SNVs within splicing consensus regions across the human genome and applied them to the mutations from the Catalogue of Somatic Mutations in Cancer database. Analysis showed that predicted splice-altering variants are enriched in both recurrent mutations and known cancer genes. **Conclusions** Our results demonstrated that some *in silico* methods are powerful tools in predicting the impact of splicing mutations, and ensemble learning methods can further improve prediction. Providing a directly interpretable prediction score for all possible SNVs within splicing consensus regions across the human genome shall significantly facilitate splicing defect prediction and detection, and thus contribute to providing new targets for gene therapy and newborn screening.

1489M

High-accuracy imputation for HLA class I and II genes based on genome-wide SNP data of population-specific references. *S. Khor[1], W. Yang[2], M. Kawashima[1,3], S. Kamitsuji[2], X. Zheng[4], N. Nishida[1,5], H. Sawai[1], H. Toyoda[1], T. Miyagawa[1], N. Kamatani[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) StaGen Co., Ltd. Statistical Genetics Analysis Division. Tokyo, Japan; 3) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo, Japan; 4) Department of Biostatistics, University of Washington. Washington, United States; 5) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan.

Statistical imputation for genotypes of human leukocyte antigen (HLA) genes is becoming an indispensable tool in the fine-mappings of disease association signals from case-control genome-wide association study (GWAS). However, most of the HLA imputation tools available are based on European descendents and not suitable for the direct application to non-European populations. Among the HLA imputation tools, HIBAG R package is a flexible tool equipped with a wide range of population based classifiers and accommodate for the building of custom classifiers. Using Japanese healthy control datasets, Japanese-based classifiers were built. HLA imputation accuracy in five HLA genes (*HLA-A, B, DRB1, DQB1, DPB1*) increased considerably to 95.1-99.5%, as compared to 90.5-98.7% when HIBAG Asian reference and 82.5-98.8% when HIBAG multi-ethnic reference were used. We also compared data from different platforms (Illumina Omni 2.5, Affymetrix 6.0, Affymetrix Axiom ASI), but there was little difference in the results. Call threshold of 0.4 is recommended for Japanese classifier in contrast with 0.5 recommended by HIBAG. Our results showed that population matched reference panel is essential to impute common HLA alleles and especially important for specific HLA alleles in individual populations.

1490T

LNCScore: a machine-learning approach for novel lncRNA discovery from RNA-Seq data. *J.H. Kim[1], O. Evgrafov[1,2], J. Knowles[1,2,3], K. Wang[1,2,3].* 1) Zilkha Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Department of Psychiatry and Behavioral Sciences, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Division of Bioinformatics, Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

RNA-Seq techniques are widely used in biomedical research to investigate the transcriptional landscape of different tissues or conditions on human and other species. Although most studies focused on the analysis of protein coding genes, the importance of non-coding transcripts, especially long non-coding RNAs (lncRNAs) has been increasingly recognized as important regulators of transcriptional activity and the category of them could be substantially larger than previous thought. Despite the increased interests on lncRNA, our understanding on ncRNA is still at rudimentary and studying known lncRNA and identifying novel lncRNA are challenging problems without ideal solutions yet. Typical features of lncRNA include the longer size of transcript length >200bp, the likely genomic location between genes, and the lack of complete ORF, but these features alone cannot be used to infer lncRNA confidently. To address this issue, we developed a called LNCScore for predicting novel lncRNA directly from alignment files from RNA-Seq data sets. Our strategy is based on a scoring system using multiple features for lncRNA, and use well known/annotated lncRNA to train a statistical model to identify optimized parameters to separate candidate lncRNA from random noises. We incorporated most of the commonly used features used for lncRNA prediction and added more criteria to score the likelihood of a predicted transcript to be a genuine lncRNA, such as phylogenetic modeling and comparison with related species, the use of SNPs that may result in new open reading frames, the epigenetic markers from ChIP-Seq experiments where available, the gene family information of neighboring genes, and comparison to well established database like NONCODE and LNCipedia. This can be used on poorly studied tissues from model organisms with rich annotation data and also can be applied to newly sequenced species with limited functional annotations on genes. The input of our software is the alignment files in BAM format generated with reference-guided assembly, and the output is a list of possible novel lncRNA, each with LNCScore (a confidence score for the likelihood of being a genuine lncRNA) as well as FPKM values and read counts, to facilitate downstream analysis such as differential expression or splicing. Our method will help researchers identify novel lncRNAs and help determine the potential functional significance of these novel non-coding RNAs.

Biomarker Discovery From RNA-seq Data Using a Biologist-Friendly Analysis Platform. *B. Lee, D. Kearns, D. Bailey, T.M. Lowe, P. Chan.* Maverix Biomics, Inc., San Mateo, CA.

The analysis of large-scale next-generation sequencing data requires both increasing amounts of computing power and exponential growth in storage. In many cases, the data may be generated by multiple laboratories at distant locations, which complicates the management, processing, and collaboration required to interpret the data. To enable hands-on exploration of RNA-seq data sets by a much larger community of biologists, we have developed the Maverix Analytic Platform. This cloud-based platform, that is built for the biologist, performs quality assessment, leverages best-in-class analysis methods, and provides an integrated UCSC-genome browser endpoint to enable visualization and interpretation of results. In this case study, we will present an automated RNA-seq pipeline that helps improve gene expression analysis by providing results from two common algorithms, Cufflinks and DESeq. This automated pipeline provides multiple sample sorting and filtering capabilities to maximize analysis flexibility in interpreting results. A comparison between the two methods is displayed in a Venn diagram for quick assessment of highly concordant differentially expressed genes in addition to downloadable gene lists and expression results. With the genome browser, we will show a comparison to microarray data through customizable data tracks. The results include examples of potential biomarkers identified by using this integrated analysis approach that illustrates the untapped opportunities for discovery in large-scale RNA-seq analysis.

1492M

PARADIGM-SHIFT predicts the functional impact of 'driver modules' in multiple cancers using pathway impact analysis. *S. Ng[1], C. Benz[2], D. Haussler[1], J. Stuart[1].* 1) Biomolecular Engineering, UC Santa Cruz, Santa Cruz, CA; 2) Buck Institute for Research on Aging, Novato, CA.

The major mechanism by which cancer arises is through genomic alterations. These alterations can lead to changes in gene regulation, protein structure, and function. Individual tumors can contain hundreds to thousands of alterations. It is critical to distinguish alterations that have an important role defining the cancer - drivers - from alterations that are unimportant to the tumor - passengers. Driver genes can lead to significant changes in their pathways; however, alterations in a single gene may not be sufficient to explain all the pathway perturbations across patients. Additional alterations could range from DNA copy number changes, gene-fusions, or even lesser understood non-coding mutations. Identifying these 'driver modules' is essential for understanding cancer disease mechanisms, which can help guide treatment decisions as well as identify novel targets for treatment.

We have developed a functional impact prediction method called PARADIGM-SHIFT based on integrated pathway analysis to discriminate loss-of-function, neutral, and gain-of-function alterations. Utilizing the set of regulatory interactions annotated for a given gene, we can detect a shift in the downstream effects of an altered gene compared to what is expected from its upstream influences. Additionally, since these shifts in pathway signal can be detected for all samples, PARADIGM-SHIFT can be used to identify additional genomic alterations that lead to similar changes to the altered pathway to form 'driver modules.' Application of our method to the TCGA Pan-Cancer cohort identifies many genes with significant alterations that lead to loss- and gain- of function. PARADIGM-SHIFT then identifies several additional genomic alterations, including gene-fusions and non-coding mutations, which are significantly implicated in these pathway changes. This analysis offers insight into the mechanism of gene-fusions and non-coding mutations that cannot be assessed by most conventional methods.

1493T

Geneious R7: a bioinformatics platform for biologists. *C. Olsen[1], K. Qaadri[1], R. Moir[2], M. Kearse[2], S. Buxton[2], M. Cheung[2], B. Milicevic[2], W. Hengjie[2], J. Kuhn[2], S. Stones-Havas[2], C. Duran[2].* 1) Biomatters, Inc. Newark, NJ; 2) Biomatters, Ltd. Auckland, New Zealand.

Biomatters' Geneious R7 is a bioinformatics software platform that allows researchers the command of industry-leading algorithms and tools for their genomic and protein sequence analyses. Using a glass-box approach for software design, Geneious R7 offers a comprehensive suite of peer-reviewed tools that enable researchers to be more efficient with their bioinformatic workflows. Researchers at all levels can easily manage, analyze, and share their sequence data via a single intuitive software application. R7 provides tools for next-generation sequence analysis, sequence alignment, molecular cloning, chromatogram assembly, and phylogenetics. New features for this major version release include tools for Gibson & TALEN assembly, TOPO cloning along with algorithms for RAxML, FastTree, Garli, LastZ, Bowtie2, as well as a number of new plug-ins. R7 affords real-time dynamic interaction with sequence data and empowers biologists to produce stunning publication quality images to increase the impact of their research. By utilizing Geneious R7, biologists can easily improve their sequence analysis workflow efficiencies to free up more time for their research. This poster aims to demonstrate the new features and benefits of the highly integrated Geneious R7 tool-suite.

1494S

Assembly Hubs and Genome Browser in a Box Makes Viewing Private Annotations and Custom Sequences Easy. *B.J. Raney, M. Haeussler, A.S. Hinrichs, A.S. Zweig, D. Karolchik, H. Clawson, J. Casper, M. Speir, B. Lee, T. Dreszer, G. Barber, P. Fujita, D. Haussler, W.J. Kent.* University of California at Santa Cruz, Center for Biomolecular Science and Engineering, School of Engineering, Santa Cruz, CA, USA.

The UCSC Genome Browser is one of the most popular resources in genomics, allowing users to view a large collection of annotations on human, mouse and many other vertebrate assemblies released by NCBI. The Genome Browser also allows users to upload their own annotations as custom tracks, or more recently, to create stand-alone Track Hubs which can contain thousands of tracks of custom annotations.

Two new features of the UCSC Genome Browser facilitate its use in situations where privacy is a priority, and where the sequence being visualized is not part of UCSC's standard set of assembly browsers.

The first technology is called Genome Browser in a Box (GBiB) which uses virtual machine technology to allow users to easily mirror the genome browser on a protected network, or in situations when private annotation cannot be uploaded to UCSC for privacy reasons. To install GBiB one need only download VirtualBox, which is freely available for all major operating systems, and the GBiB virtual image which is a pre-installed copy of the UCSC Genome Browser. The Genome Browser is open source and free for non-commercial users.

The second new feature of the UCSC Genome Browser is Assembly Hubs, an extension of the Track Hub mechanism introduced in 2012. Track Hubs allow users to create their own annotation on assemblies supported at UCSC. Assembly Track Hubs allow users to provide their own DNA sequence on which the Track Hub annotation can then be viewed. Assembly Track Hubs require only a network accessible location where the sequence and annotations are stored in a flat-file directory hierarchy. Currently Track Hubs support the following annotation formats: BigBed, BigWig, BAM, HAL, and VCF/tabix.

These two technologies combined make it possible for an end-user to create a UCSC browser instance with custom sequence and annotations without passing sensitive data over the Internet. Using GBiB and Track Hubs, users can view their own annotations aligned with other annotations curated at UCSC.

1495M

Comparative transcriptome analysis reveals a proangiogenic compensatory mechanism for increased placental vascularization in women with reduced vasodilation. *L.M. RODRIGUEZ[1], L. RISHISHWAR[2], L. WANG[2], A.C. AGUILAR[1], K. JORDAN[2], A. CASTILLO[1].* 1) UNIVERSIDAD DEL VALLE, CALI, VALLE DEL CAUCA, COLOMBIA; 2) GEORGIA INSTITUTE OF TECHNOLOGY, ATL, GA, USA.

Purpose: The activation of angiogenic pathways is essential for placental development in pregnant women. Flow mediated dilation (FMD) is a metric commonly used to measure endothelial response to the increased blood flow characteristic of placental vascularization during pregnancy. We are taking a number of approaches to compare cohorts of high- versus low-FMD pregnant women in an effort to understand how endothelial response to vasodilation relates to the process of placental angiogenesis and vascularization during pregnancy. For this study, we used a genome-wide expression (i.e. transcriptome) analysis approach to identify genes that may help to mediate the link between endothelial response and the construction of the placental vascular network during pregnancy. Methodology: RNA-seq was used to characterize genome-wide expression levels from placental tissue for cohorts of pregnant women that had either high versus low-FMD in order to identify differentially expressed genes that may be involved in angiogenesis pathways. We focused our differential expression analysis on down-regulated targets of proangiogenic miRNAs previously shown to be up-regulated in low-FMD individuals. Results: We applied a novel transcriptome analysis approach (GFOLD) that allows for characterization of differentially expressed genes using low sample sizes; in this case, we had sample sizes of n=2 each for the high and low-FMD cohorts. Using this approach, placenta samples from women with low-FMD showed significantly down-regulated expression for the igfbp1 (GFOLD score = -1.164) and lep (GFOLD score = -0.079) genes, which encode for the Insulin-like growth factor (IGF)-binding proteins (IGFBP1) and Leptin (LEP) respectively. These genes are both expressed in placenta and participate in the activation of the proangiogenic Insulin Receptor Signaling (IRS) pathway. Conclusion: These preliminary results are consistent with a role for IGFBP1 and LEP in a process of placental hypervascularization that may help compensate for reduced endothelial response to vasodilation in low-FMD women. This would account for the fact that the low-FMD women in our cohort do not show any apparent pregnancy complications related to placental vascularization. However, the down-regulation of these genes, and the effect on their pathways, may lead to subsequent problems with predisposition to diabetes and macrovascular disease in low-FMD women.

1496T

Pilot data from the Virtual Genomics Clinic (VGC). *J.V. Thakuria[1, 2, 3].* 1) Massachusetts General Hospital, Boston, MA; 2) Theopolis, Cambridge, MA; 3) Veritas Genetics, Cambridge, MA.

While the number of published reports demonstrating medical utility of exome sequencing in patients suspected of monogenic disease continues to grow, data are still limited on the medical utility of exome sequencing in healthy, asymptomatic individuals. Over the past year, ACMG recommendations to return results on a panel of 56 genes in both adult and pediatric cases whenever clinical exome or whole genome sequencing is performed, highlights the importance of gathering this data. Initial reports on the number needed to screen (NNS) in the general population before a suspected pathogenic mutation is identified varies widely from <1% to >20%, but is usually reported in the 1.5%-5% range (excluding potential reproductive utility from knowledge of carrier status for recessive disorders) - and is highly dependent on variant filtering stringencies. Preliminary pilot phase data from over 80 exomes with ~60X average on target coverage from the Virtual Genomics Clinic (VGC) study parsed against the 56 ACMG IF (incidental findings) genes and undergoing secondary individualized analyses based on voluntarily provided personal and family medical histories, is reported. The pilot cohort was primarily recruited from the Young Presidents' Organization (YPO). Study consent, pre- and post-test genomic counseling, as well as return of results, are generally performed remotely via tele- or videoconferencing. All study participants are given the option to receive an easily portable, compressed copy of their exome data on thumbnail drive and may opt in for indefinite biobanking of their samples for ongoing research and clinically focused reanalysis of data on a yearly basis on average and guided by evolving medical genomics knowledge. Alternatively, participants may opt to have their samples discarded and backup data deleted after receiving their compressed data and initial medical interpretation of results. Data privacy is enhanced using several "off the grid" features such as hybrid systems utilizing onsite bioinformatics infrastructure for storage and processing while leveraging cloud-based analyses tools on pooled, de-identified data. Future efforts, including the use of physical decryption keys such as Giambattista della Porta modified Alberti cipher disks for off-site collaborators (eg, for access to corresponding phenotype data), will add additional layers of data security in the VGC.

Mega2: data reformatting for facilitating genetic linkage and association analyses. *D.E. Weeks[1, 2], R.V. Baron[1], C. Kollar[1], N. Mukhopadhyay[3].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA.

A comprehensive genetic study of a complex disease invariably requires reformatting the data into the precise input format required by each of many analysis programs used. Our Mega2 software facilitates this process by automating common data reformatting tasks, thereby markedly reducing the chance of data reformatting errors, making data setup much less error-prone, and saving the user the time of writing, debugging, and maintaining data conversion scripts. We have recently extended the capabilities of Mega2 in a number of ways. In addition to accepting LINKAGE-format input files, it now accepts VCF, BCF, and compressed VCF files and can apply common 'VCFtools' filters. While continuing to support conversion to commonly-used formats like Merlin, Mendel, SimWalk2, and SOLAR, PLINK, Cranefoot, IQLS, FBAT, MORGAN, BEAGLE, Eigenstrat, and Structure, Mega2 has now been extended to support data conversion to PLINK/SEQ format. Mega2 can now pass through non-numeric alleles to analysis programs that will accept them, instead of recoding them to numeric alleles as was done previously. For some output options, Mega2 can generate high-quality plots of the results using our nplplot R package, as well as generate custom track files for use within the UCSC genome browser. When controlled by a batch file, Mega2 can be used in an automated manner within data analysis pipelines. Mega2 also supports organisms other than humans. Mega2 is open source and freely available and has extensive documentation and a tutorial, available on our http://watson.hgen.pitt.edu/register web site. This work was supported by NIH grant R01 GM076667 (PI: Weeks). Earlier contributions to our initial code base were made by Lee Almasy, Mark Schroeder, and William P. Mulvihill.

1498M

Single Cell RNA-Seq analysis of Tumor Composition. *I. Ragoussis[1,4], Y-C. Wang[1,4], E. Iacucci[1,4], L. Letourneau[4], P. Savage[2], A. Monast[2], N. Bertos[2], A. Omeroglou[3], M. Park[2].* 1) Department of Human Genetics & McGill University and Genome Quebec Innovation Centre, McGill University, Montreal, Quebec, Canada; 2) The Rosalind and Morris Goodman Cancer Research Centre, McGill University, Montreal, Quebec, Canada; 3) Department of Pathology, McGill University, Montreal, Quebec, Canada; 4) McGill University and Genome Quebec Innovation Centre, McGill University, Montreal, Quebec, Canada.

Single-cell RNA-Seq experimentation and analysis represents an advanced and powerful tool for cutting-edge human genetics research as we can now monitor the whole transcriptome at the single-cell level. The ability to interrogate control and disease states of single cells allows for specific and unadulterated characterization of these conditions. Here we examine the issues surrounding the analysis of individual and bulk breast cancer cells derived from a tumor biopsy. In brief, live single-cell mRNA to cDNA libraries were prepared using the Fluidigm C1 Single-Cell microfluidic system. cDNA libraries were then converted to sequencing ready libraries using the Illumina Nextera XT kit and sequenced on the HiSeq2500 using Rapid Paired End 150bp mode. In parallel, control cDNA libraries were prepared from extracted total RNA and 200 cells serving as benchmarks to systematically evaluate the sensitivity and accuracy of our single-cell RNA-seq approach. We sequenced > 100 cells from a Her2 + ve breast tumor and detected between 4501 and 7168 genes in the single cell samples and between 8782 and 13512 genes in the bulk samples. The analysis was carried out via a process which included filtering, clustering, as well as various comparative and pathway analysis. Clustering (based on read counts and FPKMs) revealed three distinct and state-related expression profile groups (clusters). Statistical analysis between these groups of cells revealed several significant genes, of which five were known breast cancer stem cell markers (CD44, TGFBR2, MUC1, KRT5, and ITGA6). Pathway analysis provided greater detail into the mechanisms (such as cell-cycle checkpoint and apoptosis) believed to be responsible for the cellular states of the groups as mediated by known cancer associated genes (BCAS2, BRIX1, BRE, and TRIAP1). These approaches demonstrate our ability to classify single cell samples, identify potential biomarkers, and elucidate which pathways were involved in the aberrant cell growth. Complementary to this, single-cell samples showed cell state specific clustering leading to the conclusion that this approach allows for the characterization of cellular heterogeneity, both important steps in the understanding of tumor biology. Within this setting, we have been able to move towards distinguishing between different cell populations in the tumor sample, characterizing the tumor purity, and identifying distinct expression patterns.

1499T

Standardized phenotyping enables rapid and accurate prioritization of disease-associated and previously unreported sequence variants. *W.P. Bone[1], D.R. Adams[1], M.J. Davis[2], D. Draper[1], E.D. Flynn[1], R.A. Godfrey[1], C. Groden[1], M. Haendel[6], E. Lee[1], A.E. Links[1], T. Markello[1], C. Mungall[4], M. Nehrebecky[1], P.N. Robinson[5], M. Sican[1], D. Smedley[3], C.J. Tifft[1], C. Toro[1], E. Valkanas[1], C. Wahl[1], N.L. Washington[4], L. Wolfe[1], C.F. Boerkoel[1], W.A. Gahl[1].* 1) Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD; 2) National Institute of Allergy and Infectious Diseases, Bethesda, MD, USA; 3) Mouse Informatics group, Wellcome Trust Sanger Institute, Hinxton, CB10 1SA, United Kingdom; 4) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720, USA; 5) Institute for Medical and Human Genetics, Charité-Universitätsmedizin Berlin, Augustenburger Platz 1, 13353 Berlin, Germany; 6) University Library and Department of Medical Informatics and Epidemiology, Oregon Health and Sciences University, Portland, Oregon 97239, USA.

The NIH Undiagnosed Diseases Program (UDP) uses exome analysis for generating hypotheses of potential genetic causes of disease. This approach, which incorporates Mendelian segregation and population frequency filters and prioritizes on rarity and predicted deleteriousness, has enabled several diagnoses. However, this method is laborious, even when the variants are in known disease-causing genes. Therefore, we hypothesized that use of patient phenotype data recorded in Human Phenotype Ontology (HPO) terms would enhance the efficiency of diagnosing known diseases. To this end, we used the Exomiser 2.0 algorithm, which queries human, mouse, and zebrafish phenotypic data as well as protein-protein association data. The algorithm prioritizes variants based on variant allele frequency, predicted deleteriousness, and phenotypic relevance. For eleven solved UDP cases, Exomiser 2.0 ranked all eleven diagnostic variants within the top ten candidates; five ranked as the top candidate. When applied to a cohort of 23 undiagnosed UDP patients, Exomiser 2.0 aided in the diagnosis of three cases by prioritizing variants for two known diseases and for one new disease. We conclude that use of standardized phenotyping in combination with purely genomic exome analysis provides a rapid and effective method of screening for variants in known disease causing genes and possibly for identification of new disorders.

Discovery and validation of mechanistic underpinnings of *cis*-regulatory variants underlying *FTO* association with type 2 diabetes and obesity risk. *M. Claussnitzer[1, 2,3], LD. Ward[1], YH. Hsu[2], H. Hauner[3], M. Kellis[1].* 1) Computer Science and Artificial Intelligence Lab, Massachusetts Institute of Technology, Cambridge, MA; 2) Institute for Aging Research, Harvard Medical School, Boston MA; 3) Institute for Nutritional Medicine, Technical University München, Munich Germany.

Genome-wide association studies (GWAS) have revealed numerous risk loci associated with type 2 diabetes (T2D) and obesity. However, GWAS signals are rarely traced to the disease-causing variants, given the still incomplete annotation of the human genome, especially for non-coding variants that account for the majority of disease associations. This is particularly complex given the uncertainty on the specific causal variant (given numerous variants in linkage disequilibrium, LD), the uncertainty on the cell type of action, the target genes and upstream regulators of non-coding variants. Here, we overcome these challenges using a combined computational and experimental approach. We use regulatory annotations across 127 tissue/cell types to prioritize functional non-coding variants in regulatory regions, and a comparative genomics across multiple species to recognize likely driver regulatory motifs. We next use diverse experimental assays to validate the cell-type specific regulatory activity for 16 predicted variants and their binding regulators. In particular, for the *FTO* obesity/T2D risk locus, we report multiple lines of evidence supporting that the intronic variant rs1421085 is causal for the FTO association, acts in adipocytes, affects ARID5B binding, and alters *IRX5* gene regulation. Briefly: 1) rs1421085 harbors a functional regulatory ARID5B motif based on conservation of a ARID5B-CART-GATA motif cluster across species; 2) rs1421085 is located in a candidate adipocyte enhancer based on chromatin state analysis across 127 reference epigenomes; 3) rs1421085 shows allele-specific binding of ARID5B using electrophoretic mobility shift assays; 4) rs1421085 shows cell type-specific enhancer effects for SGBS adipocytes using luciferase assays; 5) the rs1421085 risk allele increases *IRX5* expression in human adipocytes, based on qRT-PCR; 6) Lastly, increase in *IRX5* mRNA levels depend on the risk allele and regulation by ARID5B, based on *ARID5B* siRNA knockdowns. This suggests that a non-coding variant acting in adipocytes underlies the FTO association which was previously thought to be mainly driven by the brain. More broadly, our results suggest a general method for the computational discovery and experimental dissection of disease variants and have important implications on the study complex traits, which can help bridge the genotype-to-phenotype gap between genetic variants, molecular mechanisms, and cellular and organismal phenotypes.

Fast and Accurate Site Frequency Spectrum Estimation from Low Coverage Sequence Data. *E. Han[1], J. Sinsheimer[1,2], J. Novembre[3,4].* 1) Biostatistics, UCLA, Los Angeles, CA; 2) Human Genetics and Biomathematics, UCLA, Los Angeles, CA; 3) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA; 4) Human Genetics, University of Chicago, Chicago, IL.

The distribution of allele frequencies across polymorphic sites, also known as the site frequency spectrum (SFS), is of primary interest in population genetics. It is a complete summary of sequence variation at unlinked sites and more generally, its shape reflects underlying population genetic processes. One practical challenge is that inferring the SFS from low coverage sequencing data in a straightforward manner by using genotype calls can lead to significant bias. To reduce bias, previous studies have used a statistical method that directly estimates the SFS from sequencing data by first computing site likelihood vectors (i.e. the likelihood a site has a each possible allele frequency conditional on observed sequence reads) using a dynamic programming (DP) algorithm. Although this method produces an accurate SFS, computing the site likelihood vector is quadratic in the number of samples sequenced. To overcome this computational challenge, we propose an algorithm we call the "adaptive K-restricted" algorithm, which is linear in the number of genomes to compute the site likelihood vector. This algorithm works because in a lower triangular matrix that arises in the DP algorithm, all non-negligible values of the site likelihood vector are concentrated on a few cells around the best-guess allele counts. We show that our adaptive K-restricted algorithm has comparable accuracy but is faster than the original DP algorithm. This speed improvement makes SFS estimation practical when using low coverage NGS data from a large number of individuals.

Parallelization of genome-wide local ancestry inference. *R. Johnson[1], G. Nelson[1], C. Winkler[2].* 1) BSP CCR Genetics Core, Frederick National Laboratory, Frederick, MD; 2) Basic Research Laboratory, Frederick National Laboratory, Frederick, MD.

Admixture linkage analysis has proven to be a powerful method to map disease genes and other phenotypic traits. The ALDsuite package in R uses a hidden Markov model (HMM) to infer local ancestry in both sparse and dense marker data, includes statistical tools to map disease genes in admixed populations and generates graphical output for visualizing results. One common drawback of HMM frameworks is their computational inefficiency, relative to other algorithms. While ALDsuite has been designed to maintain computational efficiency with marker sets of increasing density, the use of multiple Markov chains in parallel processes can offer significant time savings. During burn-in iterations, each independent chain's parameter state is combined and a global parameter state is maintained. At the completion of each iteration, each local parameter state is updated to be more like the global parameter state, using a weighted sum of the two. Early in the burn-in phase the global parameter state is more heavily weighted to push all chains to a more likely region of the parameter space. Later in the burn-in phase the local parameter state is more heavily weighted to allow more independent starting points for follow-on iterations. Each chain is then allowed to independently sample the parameter space until the desired number of samples has been reached. ALDsuite was developed to provide geneticists with easy to use software to augment admixture mapping studies with powerful insights gained from an analysis of admixture linkage disequilibrium in two-way and poly admixed populations. This parallelization scheme allows for a near-linear increase in speed per additional processor.

1503S

CliniCall - Bridging the Gap From High-Throughput DNA Sequencing to Actionable Variants. *S. McGee, G. Jimenez, T. Kolar, M.O. Dorschner, J.D. Smith, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

CliniCall is a stand-alone application that bridges the information gap between patient DNA sequencing data and clinical relevance. With the explosion of clinical DNA sequencing tests available there is a critical need for analysis tools to help filter and prioritize clinically actionable variants. This has created a significant challenge for clinical laboratories levering these new technologies, ranging from weighing the importance of rare variation to cross-referencing multiple annotation databases. To facilitate analysis, interpretation and reporting, we have developed a user-friendly tool to view sequence alignments, quality metrics and variant annotation. A combination of BAM and VCF files - or simply a GVCF file - can be easily imported for variant identification within user-defined gene sets. With CliniCall's new multi-sample display, variants can be easily compared across samples and filtered on a user-defined set of metrics such as allele frequency, conservation score, presence/absence in specific databases and annotation functionality or clinical-significance. The CliniCall platform clearly summarizes data quality for the sequenced samples, and simultaneously links to existing databases. In addition, CliniCall now not only graphically summarizes the data, but allows for filtering on a constantly-updated set of ClinVar variants. In addition it provides an up-to-date set of Targeted Gene Panels - such as the ACMG 56 Incidental Genes - that can be automatically pre-loaded into the analysis scheme for full reporting. This all is designed to make quantitative decisions regarding the validity and categorization of the identified variants easy for the clinical geneticist. This is done by utilizing an extensive set of exome sequences to report a statistical measure of confidence for each newly discovered rare variant based on the quality of all previous calls. The CliniCall tool provides an easy and efficient way to integrate a myriad of data into a single viewable format for clinical genetics.

1504M

A Comparison of Genomes and Exomes and the Impact on the Incidentalome. *E.G. Farrow[1], L.K. Willig[1], C.J. Saunders[1], K.J. Barger[2], G.P. Twist[1], N.A. Miller[1], S.F. Kingsmore[1].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospitals & Clinics, Kansas City, MO; 2) Endocrinology, Children's Mercy Hospitals & Clinics, Kansas City, MO 64108.

As the cost of genomic sequencing continues to decline, the comparison of data generated from whole genome versus whole exome sequencing becomes increasingly important. Adding another layer of complexity, the bioinfomatics tools utilized for analysis can have a large impact on the number and quality of variants. In order to establish the best practices within our center, data from a set of genomes and exomes was analyzed utilizing different filtering metrics, both with and without Variant Quality Score Recalibration (VQSR), notated as '.raw'. The comparison set included approximately 75 genomes and 1200 exomes. Genome samples were prepared for sequencing using the Illumina TruSeq PCR free sample kit. Exome samples were prepared utilizing Illumina's Expanded Exome kit with TruSeq library sample preparation. In order to minimize differences in variant calling, the entire set of exomes underwent variant calling as a single batch. As expected, removing filtering applied by VQSR led to an increase in the total number of variants detected; approximately 40% in genomes and 8% in the exome data set. When the analysis was restricted to rare ACMG category 1-3 variants, a similar increase was seen: approximately 30% in genomes and 5% in the exome data set; indicating that the increase in variants in the .raw files is not limited to non-coding regions. Surprisingly, although the total number of variants was higher overall in genomes, the average number of rare variants in ACMG categories 1-3 was only slightly different between genomes and exomes, both .raw and with VQSR (genome 936 and 687 variants, exome 904 and 858, p=.04 and .09 respectively). The incidentalome is also an important component of analysis for genomic data. When the analysis was further restricted to include only ACMG category 1 and 2 variants with a MAF<1% in the genes recommended for the incidentalome, the average number of variants per sample was not statistically different between genomes and exomes, .raw and filtered files (genome 1.6 and 1.3 variants, exome 1.3 and 1.3 variants, respectively). Taken together, our results demonstrate that eliminating VQSR results in higher sensitivity without a significant decrease in specificity and that whole genome analysis detects slightly more rare variants per sample than whole exome analysis. Further, our results indicate that the burden of the incidentalome, in both genome and exome, in our data set is approximately one variant per person.

1505T

Diploid Alignment of Whole Human Genome Data. *P.J. Pemberton[1], E. Valkanas[1], W.P. Bone[1], C.J. Markello[1], E.D. Flynn[1], A.E. Links[1], C.F. Boerkoel[1], D.R. Adams[1,2], W.A. Gahl[1,2,3], T.C. Markello[1,2], NIH Intramural Sequencing Center, NIH Genomics Core, and UDP Clinicial Team.* 1) Undiagnosed Diseases Program, NHGRI/NIH, Bethesda, MD; 2) Medical Genetics Branch, NHGRI/NIH Bethesda, MD; 3) Clinical Director, NHGRI/NIH Bethesda, MD.

A major problem in the analysis of human genome sequences is the miss-mapping of short read NextGen sequences to nearly equivalent gene loci, i.e. Loci homologous to the sequence miss-mapped. This is a function of the number and density of the difference between any one human sequence and the human reference genome used as the alignment template. In order for the alignment template to be a closer match to the sequence that the short reads were derived from, we customized the canonical reference sequence with high confidence differences from the canonical sequence that were derived from SNP chip hybridization results, BEAGLE imputed 1000 genome haplotypes, and results from one iteration cycle of the short read data results of genotyped calls by Haplotype Caller according to Broad Institutes' best practice pipeline. Diploid alignment exome data has already been performed in the UDP and is being run on a commercial platform (Appistry Inc.). We now describe this technique as applied to the whole genome sequencing, using low amplification 105bp Illumina HiSeq2000 short read data. This data is approximately 20x larger than exome data, and presents challenges to the current NIH Biowulf super cluster computing environment, and to the current generation of analytic and data storage resources of the UDP. We present our current results on the first 12 genomes and compare these to the exome data from the same family. With this further progress we plan to extend our analytic search for rare unknown disease causal variants beyond the exomic part of the human genome.

1506S

Evaluation of INDEL Callers for Next-Generation DNA Sequencing Data. *R.L. Goldfeder, E.A. Ashley.* Biomedical Informatics, Stanford University, Stanford, CA.

Small insertions and deletions (INDELs) in the human genome play a significant role in disease and genetic variation. In both research and clinical settings, the ability to detect INDELs is critical for disease understanding, diagnosis, and treatment. However, detecting INDELs from next-generation DNA sequencing data is still a major challenge. In order to better understand the current state of the art, we evaluated five commonly used INDEL-calling pipelines: Pindel, Dindel, SOAPindel, UnifiedGenotyper and HaplotypeCaller. To evaluate each pipeline, we generated a synthetic genome that contains INDELs of varying sizes. We created paired-end artificial sequencing reads for this genome, incorporating an error profile similar to that of a HiSeq2000 using ART. Finally, we processed the reads with each of the five pipelines using “best practice” parameters and filters and calculated recall and precision. We found greater variability in recall than precision across the pipelines. We also evaluated how robust each pipeline was to changes in alignment algorithms, read length, coverage, and variant type (homozygous vs heterozygous, with SNPs present or absent). In general, the pipelines perform better with Novoalign, longer reads, higher coverage, and homozygous INDELs. Our results suggest that longer reads and high coverage are necessary for clinical-grade INDEL detection.

1507M

Relationship detection with high-density SNP genotypes obtained from sub-nanogram amounts of fragmented DNA. *D.J. Witherspoon[1], J.C. Tackney[1,2], T.J. Parsons[3], L.B. Jorde[1].* 1) Dept. of Human Genetics, University of Utah, Salt Lake City, UT; 2) Dept. of Anthropology, University of Utah, Salt Lake City, UT; 3) International Commission for Missing Persons, Sarajevo, Bosnia and Herzegovina.

High-density SNP genotypes collected from DNA samples can be used to detect relationships between individuals with high power and accuracy. Such information is also valuable for identifying forensic DNA samples, such as those from crime scenes and from unidentified victims of disasters. High-density SNP genotyping platforms use short probes to quickly and cost-effectively collect genotypes at up to several million loci with ≥98% accuracy. However, they require substantial amounts (≥100 ng) of clean, unfragmented DNA (≥2kb length), which is then massively amplified by isothermal whole-genome amplification (WGA) prior to hybridization and genotyping. Forensic DNA samples are often severely fragmented and of limited amounts. Although microarray probe sizes (≤50 bp) are ideal for genotyping fragmented DNA, WGA fails for short DNA fragments, leaving most forensic DNA samples inaccessible to microarrays. To overcome this limitation, we used a high-throughput sequencing library preparation method developed for ancient DNA (Gansauge and Meyer Nature Protocols 2013). Biotinylated adapter oligonucleotides are ligated to single-stranded heat-denatured DNA, ligated to a dsDNA adapter after complementary strand synthesis, and further amplified by PCR to generate the sequencing library. However, we continue by ligating these library fragments to each other, creating concatemers long enough to amplify by isothermal WGA. The WGA product is then genotyped using the standard Illumina Infinium LCG protocol. To test this protocol, we acoustically fragmented human DNA to 100 bp length and removed fragments longer than 200 bp using SPRI beads. From 200 pg of this DNA, the library preparation and ligation generated 16 ng of product, which we used as input for genotyping on the Illumina HumanOmni2.5 platform (2.3 million SNPs). This yielded 1.3 million called SNP genotypes (57% call rate) of which 1.1 million genotypes were correct (80%, by comparison with genotypes from high-quality DNA of the same donor). Despite the 20% error rate, geographic ancestry of the sample donor is accurately estimated. Simulations demonstrate that even 10,000 SNP genotypes with a 20% error rate suffice to conclusively link a sample to first and second degree relatives with >95% power. Methods that explicitly model high SNP genotype error rates and use more SNPs should allow more distant relationships to be reliably detected. This research was supported by DOJ award 2012-DN-BX-K037 to LBJ.

1508T

Quantifying mitochondrial copy number using next-generation sequencing data. *P. Billing-Ross[1], K. Ye[2], A. Keinan[3], Z. Gu[2].* 1) Molecular Biology & Genetics, Cornell University, Ithaca, NY; 2) Department of Nutritional Sciences, Cornell University, Ithaca, NY; 3) Department of Biological Statistics & Computational Biology, Cornell University, Ithaca, NY.

The abundance of mitochondrial DNA (mtDNA) differs between cell types and changes in mtDNA copy number (mtDNA CN) have been associated with complex diseases such as cancer. Mitochondria are organelles responsible for the vast majority of energy production within the cell and are centrally involved with processes including signaling, calcium regulation, and programmed cell death. Mitochondria retain a small circular genome which codes for 13 genes, 22 tRNAs, and 2 rRNAs which are essential for respiration. A single cell contains hundreds to thousands of mtDNAs. Because of its central role in respiration, changes in mtDNA CN can have severe effects on metabolism and cellular function. In particular, drastic changes in mtDNA CN have been repeatedly observed in a variety of cancers. Measurement of mtDNA CN has traditionally been performed using real-time quantitative PCR; however, data generated from next-gen sequencing provides an opportunity to quickly and easily quantify mtDNA CN without the need for additional experimental techniques. Several methods have been described to measure mtDNA CN using sequencing data, but the accuracy of these methods has not been well verified. We use a simulation study to compare the accuracy of various methods for measuring mtDNA CN and determine an optimal approach for measuring mtDNA CN using next-gen sequencing data. Accurate estimation of mtDNA CN from sequencing data will provide a tool to incorporate mtDNA CN into association studies and measure changes in mtDNA CN during disease progression.

1509S

An accurate and integrative computational approach for cancer genome studies. *L.T. Fang[1], M. Mohiyuddin[1], J.C. Mu[2], P.T. Afshar[2], A. Kiani[3], N. Bani Asadi[1,3], L. Bullinger[4], A. Dolnik[4], C. Yau[5], W.H. Wong[6,7], H.Y.K. Lam[1].* 1) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 2) Department of Electrical Engineering, Stanford University, Stanford, CA; 3) Department of Engineering, Bina Technologies, Redwood City, CA; 4) Department of Internal Medicine III, University Hospital of Ulm, Ulm, Germany; 5) Wellcome Trust Centre for Human Genetics, Oxford University, Oxford, UK; 6) Department of Statistics, Stanford University, Stanford, CA; 7) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

Identifying somatic mutations is a key analysis and challenge in cancer research. Its complexity lies in the impure and heterogeneous nature of the samples, rendering each data set a unique problem. An algorithm in one mutation detector may work well for one data set but poorly for another. In this regard, we take an integrative approach to identify and rank the most clinically important mutations based on a combination of different algorithms, sequencing features, and prior knowledge.

We incorporate MuTect, SomaticSniper, VarScan2, and JointSNVMix2 in our cancer analysis pipeline for somatic SNP/Indel detection. For copy number aberration (CNA), we incorporate Control-FREEC, BIC-seq, and OncoSNP-SEQ. We have also developed a brand-new ranking method, OncoRank, which ranks the mutations in each tumor-normal study based on a number of features such as consensus calls, sequencing features (e.g. coverage, strand bias, and allele frequency) and knowledge base (e.g. dbSNP, COSMIC, and Cancer Gene Census). Here, we present our results for a breast cancer cell line (HCC1143) where the samples were pure, as well as two challenging leukemia (AML) data sets where heavy cross-contamination was expected.

For the HCC1143 study, a total of 189,142 somatic single-point mutation candidates were called, of which 90 candidates were COSMIC v54 entries and 38% (71,879) were dbSNP138 entries. Among those, 14,418 candidates were reported by all four detectors with 81 in COSMIC and 8.8% in dbSNP. Using our ranking method, we reported a similar size of call set with a score of at least 6/10. The call set had 13,146 candidates with 87 in COSMIC and 2% in dbSNP, indicating our method was more sensitive (with more COSMIC mutations) and more specific (with fewer known common calls) than the consensus of all four detectors. With our copy number analysis, we correctly detected the ploidy of the HCC1143 cell line as 3.8. Copy number gains were also detected by all the three detectors for breast cancer associated genes *GATA3*, *CCND1*, and *AKT1*. For the AML study, our pipeline successfully reported top-scored causative variants such as the *NPM1* insertion, *DNMT3A* mutation, and *KRAS* mutation in two leukemia patients. These results showed that our approach can increase both the sensitivity and specificity of somatic mutation detection, and is robust enough to handle vastly different data types from pure tumor cell line to challenging liquid cancers.

Accurate Randomized Dimension Reduction with Applications to Linear Mixed Model Corrections of eQTL Data. *G. Darnell[1], S. Georgiev[2], S. Mukherjee[3], B. Engelhardt[3,4].* 1) Computational Biology and Bioinformatics, Duke University, Durham, NC; 2) Genetics Department, Stanford University, Palo Alto, CA; 3) Department of Statistical Science, Duke University, Durham, NC; 4) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC.

Expression quantitative trait loci studies have power to detect many causal variants associated with gene expression. In many studies, particularly those of model organisms such as mice, complex population structure can overwhelm true signal and cause spurious associations. Linear mixed models have been shown to partition data in genome-wide association studies into fixed and random effects, accurately accounting for population structure and sample substructure (Zhou et al. 2012). Using sophisticated dimension reduction based on randomized singular value decomposition (SVD), we show it is possible to correct for confounding in many eQTL studies where computational burden made it previously infeasible. We show up to a 50% increase in speed when using our method for randomized SVD compared to optimized out of the box libraries for SVD, while maintaining accuracy above 99%. Our method applied to many eQTL datasets from the GTEx project yields results significantly faster than current methods such as GEMMA (Zhou et al. 2012).

1511T

Evaluation of a genotyping array design for tagging common variation across Africa. *T. Carstensen[1,2], GDAP Investigators.* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Cambridge University, Cambridge, United Kingdom.

Background: Most current genotype arrays have been ascertained largely on European populations, and are not designed to capture genetic variation across several populations in Africa. Designing genotype arrays to efficiently capture common genetic variation in Africa could have important implications for large-scale GWAS, including power to identify novel susceptibility loci in the region. Here, we explore the first such design to capture common genetic variation across Africa. Methods: For tagging, we used whole genome sequence (WGS) data generated through the African Genome Variation Project (320 samples sequenced at 4x coverage from Ugandans, Zulu in South Africa and Ethiopians) and phase 1 of 1000 Genomes (97 Luhya from Kenya and 88 Yoruba from Nigeria). To design the African SNP array we used a greedy pairwise tagging algorithm, written to be computationally efficient and scalable across the whole genome. Tagging was carried out across populations using a window size of 500kbp flanking each SNP, at an linkage disequilibrium (LD) threshold of 0.80 to capture variants with a MAF≥0.05. To examine efficiency of the genotype array, we carried out imputation using the tagged markers, and calculated the correlation between imputed genotypes and WGS genotypes. We calculated coverage across the genome as the proportion of common variants imputed with r2≥0.80 across all populations. Results: Using our tagging algorithm, we show that approximately 2.7 million SNPs are required to tag all common variation across the five African populations. With the most informative 1 million tagging SNPs identified using the tagging algorithm, we were able to tag more than 80% of common variation across 5 populations in Africa. Conclusions: We present the first exploration of a genotype array design to capture common variation across Africa. We show that while tagging common variation across Africa requires a reasonably large number of variants, even 1 million tagging variants can capture a substantial proportion of common genetic variation across African populations. Our findings suggest that designing a genotype array for large-scale GWAS in Africa is feasible, and can be made cost-effective so as to scale to large sample sizes. We envisage that using hybrid approaches for design that include cyclical tagging and imputation will further improve the efficiency of such an array.

StrandOmics: Accelerating clinical interpretation and reporting though integration of genomic, structural, functional and phenotypic information. *S. Agrawal, A. Ghosh, S. Krishna, S. Sankaran, A. Mannan, V. Veeramachaneni, R. Hariharan.* Strand Life Sciences, Bangalore, Karnataka, India.

Increasing demand for NGS tests in our clinical testing laboratory has driven the need for a clinical interpretation process with three key features. The first is *comprehensiveness*: handling of different types of panels, disease indications, variants, phenotypes, and family situations, a plethora of bioinformatics predictions and knowledge of genes and variants reported in literature. The second is *ergonomics*: the ability of an interpretation team to collaboratively assess literature and bioinformatics evidence, review it and then create accurate reports systematically on a large number of cases. The third is *efficiency*: minimising the time needed to go from reads to report. Thus StrandOmics, a clinical interpretation and reporting platform was created. We illustrate the clinical utility of this platform using some interesting cases comprising:

a) analysis of variants from whole-genome, whole-exome and targeted panel data

b) analysis of single individual as well as more complex multi-individual cases

c) molecular diagnosis for affected individuals and risk prediction for unaffected individuals

d) troubleshooting false negatives by Sanger sequencing

StrandOmics combines knowledge from our internal curated literature content with various publically available data sources and bioinformatics prediction tools to integrate genomic, phenotypic, structural and functional information. This integrated knowledge is then used to automatically prioritize a list of variants based on ACMG guidelines, the inheritance model and disease phenotypes. All the information needed for interpreting the clinical significance of a variant is displayed in a user-friendly manner, which greatly reduces the time for interpretation. Our team of clinical interpreters has thus far used StrandOmics to analyze over 500 cases with a variety of clinical indications and phenotypes. After its introduction, the average end-to-end time for interpretation, review and reporting was reduced by 67%. In addition, StrandOmics also supports the ability to share curated variant information with the medical community through an integrated interface for direct submissions to ClinVar. This feature not only makes our laboratory workflows comprehensive, ergonomic, and efficient, but also collaborative.

1513M

Performance survey of protein mutational prediction methods. *D.A. Baird[1], A. Bierzynska[2], I.N.M. Day[1], M.A. Saleem[2].* 1) Bristol Genetic Epidemiology Laboratories (BGEL), School of Social and Community Medicine, University of Bristol, Oakfield House, Oakfield Grove, Bristol, BS8 2BN; 2) Academic Renal Unit, School of Clinical Sciences, University of Bristol, Dorothy Hodgkin Building, Whitson Street,Bristol, BS1 3NY.

Point mutations are the most common form of variation within the human genome. Next Generation Sequencing (NGS) has accelerated research into the effects of these mutations in human disease. The major and fundamental challenge facing researchers in this area is determining the pathogenic mutations amongst a background of many neutral variants. Protein prediction tools are often used as a guide for this. Due to the diverse ways in which an amino acid residue change may impact protein structure, mutational prediction is challenging and a wide range of tools using a variety of computational approaches exist. There is a lack of literature jointly reviewing the performance of tools, with most comparisons done on an individual ad hoc basis during the development stage of the tool. This study extends and updates the surveys of Thusberg et al [1] and Shihab et al [2], by comparing the performance of 9 recent and commonly used web based prediction tools. Mutations annotated as neutral and pathogenic in SwissProt was selected as the benchmark for the performance comparison. The benchmark dataset was submitted to each prediction tool and performance statistics (accuracy, specificity, sensitivity and Matthews Correlation Coefficient (MCC)) and ROC curves calculated. The overall best performing tools were Condel 2 and FATHMM. 1.Thusberg, J., Olatubosun, A. & Vihinen, M. Performance of mutation pathogenicity prediction methods on missense variants. Hum. Mutat. 32, 358-368 (2011). 2.Shihab, H. A. et al. Predicting the Functional, Molecular, and Phenotypic Consequences of Amino Acid Substitutions using Hidden Markov Models. Hum. Mutat. 34, 57-65 (2013).

A bioinformatics approach to prioritizing candidate explanatory variants in whole genome sequences from patients affected with rare diseases. *D. Bodian[1], B. Solomon[1], A. Khromykh[1], R. Iyer[1], R. Baveja[2], J. Vockley[1], J. Niederhuber[1].* 1) Inova Translational Medicine Institute, Falls Church, VA; 2) Fairfax Neonatal Associates PC, Inova Children's Hospital, Falls Church, VA.

Nextgen sequencing technologies are making significant advances in the study of rare diseases, contributing both to the discovery of disease-associated genes and to the identification of likely causative genetic variants in affected individuals. A significant challenge in this approach is identification of the clinically relevant mutation(s) among the millions of variants uncovered by whole genome sequencing. As part of a research study of rare congenital anomalies, we are evaluating the effectiveness of publicly available bioinformatics methods in prioritizing causative mutations. Initially we are testing a genotype to phenotype approach, in which variants are filtered based on inheritance patterns, population frequency, and predicted deleteriousness. The highest ranked variants are then evaluated for congruency with the clinical phenotype. Significant reductions in the number of variants requiring manual assessment come from adapting the tools for combined quality filtering and inheritance-based analysis of family trios, and from comparison to our internal database of whole genome sequences from an ethnically diverse cohort of >1,500 healthy family trios representing >80 countries of birth. Implementation of this approach is in progress; preliminary analyses revealed causative variants for 5 probands enrolled in our congenital anomalies study, all of which have been validated.

Comparisons on whole exome capturing homogeneity among different versions of capturing kits and populations. *M.G. Borges[1,2], C. Rocha[1,2], B.S. Carvalho[1,2], I. Lopes-Cendes[1,2].* 1) State University of Campinas, Campinas, Sao Paulo, Brazil; 2) Brazilian Institute of Neuroscience and Neurotechnology - BRAINN, Brazil.

Coding regions of the genome, which correspond to less than 2% of its entirety, are known as exome: the portion of the human genome believed to concentrate most of the disease-causing mutations. It has been shown that when performing whole genome sequencing of a single individual we expect to find approximately three million variants; however, if one focus only on coding regions this number drops to less than twenty thousand. In this context, exome sequencing is thought to be a cost-effective strategy for high performance molecular diagnosis applied to genomic medicine and large scale population studies. However, to best apply this approach to different populations it is important to determine whether ethnic differences can affect sensibility and specificity of the method. These effects could have a significant negative impact in exome capturing efficiency and homogeneity among different populations, leading to the necessity of protocol adjustments when analysing patients from a mixed ethnic background. In order to investigate the impact of ethnicity in exome homogeneity, we selected 120 individuals from the 1000 Genomes Consortium. These exomes were sequenced and aligned at three different time-points. For each of those temporal subsets of data there are 40 individuals: ten of each of the four considered populations (ACB - African Caribbean from Barbados; GBR - British in England and Scotland; YRI - Yoruba in Nigeria; JPT - Japanese from Tokyo). We obtained the mean homogeneity for each exon within the human exome as well as the homogeneity at specific genes considered to be clinically relevant by the American College of Medical Genetics and Genomics, as presented at "ACMG Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing". After using multidimensional scaling to reduce dimensionality and capture variability, we identified patterns of exome homogeneity that can be related to time progression and, therefore, protocol advancement. We did not observe evidence for association between ethnicity and mean homogeneity at both levels of data analysis (whole exome and clinically relevant genes). Additionally we perceived that for the clinically significant genes the homogeneity density tends to assume a more normalized distribution as a newer version of capture kits is used. This heterogeneity over time can represent an important issue in large sequencing projects, which are to be developed over the next years.

1516M

Prediction consequences of amino-acid substitutions in the IDS gene using in silico tools. *A.C. Brusius-Facchin[1], R. Giugliani[1,2,3], S. Leistner-Segal[1,2].* 1) Hospital de Clinicas de Porto Aelgre, Porto Alegre, Brazil; 2) Programa de Pós-Graduação em Medicina: Ciências Médicas,UFRGS; 3) Departamento de Genética,UFRGS.

Computational methods are used to predict the molecular consequences of amino-acid substitutions on the basis of evolutionary conservation or protein structure, being relevant tools for establishing the consequences of novel mutations in heterogeneous genetic diseases such as Hunter Syndrome (MPS II).We used four different prediction computer programs that are based on evidence of evolutionary conservation of amino-acids, identification of amino acid positions, sequence homology, protein folding, crystal structure and information from a database of hotspot mutations in a specific protein, in order to analyze 17 novel missense mutations found in the IDS gene. PANTHER scores of -3 infer a 50% probability of being deleterious, while -12 is associated with a 100% probability of being deleterious. The POLYPHEN scoring predicts three outcomes for mutations: 'benign' (most likely lacking any phenotypic effect), 'possibly damaging' (may affect protein structure or function) and 'probably damaging' (high degree of confidence that protein structure function will be affected). The SIFT scores range from zero to one, with zero predicted to be the most deleterious mutation and one the least deleterious. PMUT classifies as neutral or pathological. The results obtained after in silico analysis was: PANTHER, mutations p.D45V; p.D45G; p.S61Y; p.Q80R; p.C84Y; p.160H; p.L314H; p.D308H; p.D334Y; p.D334V and p.H342P showed scores between -3 to -10 and the mutations p.Q81Y; p.R95S; p.H138Y; p.N265K; p.E344K and p.V503D, showed scores below -3, SIFT: The mutations p.D45V, p.D45G, p.S61Y, p.Q80R, p.C84Y, p.H138Y, p.P160H, p.L314H, p.D308H, p.D334Y, p.D334V and p.H342P were predicted as damaging and the mutations p.Q81Y, p.N265K, p.V503D, p.E344K were predicted as tolerated, Polyphen: the mutations p.D45V, p.D45G, p.S61Y, p.Q80R, p.Q81Y, p.C84Y, p.R95S, p.H138Y, p.P160H, p.L314H, p.D308H, p.D334Y, p.D334V and p.H342P were predicted as probably damaging and the mutations p.N265K, p.V503D, p.E344K were predicted as possibly damaging, PMUT: analysis predicted that all mutations were neutral except for p.C84Y that was predicted as pathological. Three softwares used showed agreement to predict the molecular consequences and can be considered good tools to characterize the novel alterations found in the IDS gene. The mutations p.N265K, p.E344K and p.V503D in all softwares did not show severe consequences in the protein which should be correlated with a specific (mild) phenotype.

1517T

Investigating the relationship between allele frequency of benign variants used in training mutation impact predictors and their stringency at calling deleteriousness. *A. Carroll[1], A. Sidow[2, 3].* 1) DNAnexus, Mountain View, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Pathology, Stanford University, Stanford, CA.

The growing use of sequencing to identify variants of interest in research and clinical data has generated large databases of well characterized mutations in the human population (e.g. dbSNP, OMIM, and ClinVar). In addition, due to the large amount of rare variation in the human population, variants of unknown, but potentially critical, significance are often identified. When novel variants are discovered, researchers and clinicians often look to mutation impact predictors to gain insight. A wide array of mutation impact predictors have been developed (for example SIFT, Polyphen, GERP, MutationTaster, MutationAssessor, or CADD, amongst many others). During the development of these predictors, scientists use sets of previously characterized benign variants as either explicit or implicit training sets to build their predictor models. Similarly, in the assessment of predictors, accuracy is assessed on sets of known disease-causing mutations and mutations existing in the human population considered to be benign. We demonstrate that the choice of benign (or negative) variants used in training and assessment of these models has a substantial impact on predictor results and accuracy assessments. Specifically, choosing a negative set of variants that exist in the population at a high allele frequency results in predictors that are more aggressive at calling variants as damaging, and give more favorable assessments to predictors which aggressively call damaging variants. Conversely, choosing a negative set of variants that exist at low frequencies results in more stringent prediction of damaging mutations and rewards more stringent callers. We show the fraction of variants predicted as damaging by a number of popular predictors across the human exome. In addition, we use machine learning approaches to take the output of a predictor and tune it new training sets. With this, we have generated results for each predictor that represents training using various negative sets with different allele frequencies. This allows investigators to choose predictors tuned for varying levels of stringency. These datasets are available for download and a tool to annotate a VCF with this data is available for use on DNAnexus.

1518S

Developing a new approach to transcriptomic characterization of mesial temporal lobe epilepsy models through next-generation sequencing. *B.S. Carvalho, A.H.B. Matos, A.S. Vieira, I. Lopes-Cendes.* Department of Medical Genetics, State University of Campinas - Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, SP, Brazil.

Mesial temporal lobe epilepsy (MTLE) is the most prevalent type of epilepsy in humans. It is a chronic condition characterized by recurrent seizures and caused by a number of factors, including genetic predisposition. It is often refractory to treatments, drawing a significant amount of attention from the medical community. In this study, we used recently described MTLE models (pilocarpine-treated rats without status epilepticus), whose lesions are better related to those found in patients, to improve our understanding regarding epileptogenesis in MTLE. We use results from high-throughput sequencing to describe gene expression and alternative use of exons. The statistical methodology is based on count tables, rather than on RPKM/FPKM measurements, combined with negative-binomial models to account simultaneously for technical and biological variabilities. This provides accurate estimates for changes in expression and alternative exon usage when comparing affected to control individuals. Through the use of statistics that were developed specifically to compare expression levels of individuals from distinct biological statuses, we improve our findings by using computational methods to explore sets of genes whose frequencies do not match expectations, being identified as systematically over- or under-represented (OR/UR). We investigate pathways and gene ontologies, allowing for a better understanding of gene networks and enhancing the findings obtained through the simplified models used for the gene expression estimation. We identified ontologies that presented significant association to epilepsy at different levels: 1) molecular (N-acetylglucosamine-phosphate-deacetylase activity/ATP binding); 2) biological processes (negative regulation of signal transduction/macromolecule catabolic process); and 3) cellular components (ion channel complex/intracellular organelles). Our data analysis strategy focuses on the use and development of open-source and high-performance tools, improving accessibility and allowing for greater opportunities of improvement and reproducible research. Combining these factors with the expertise of our group members, we believe to be in a unique position that entitles us to A) properly compare these to results generated with other models; B) confirm these findings through further experiments; C) contrast these findings to those identified on patients; and D) translate these results to the clinic. (Supported by FAPESP).

Comparative analysis of computational pipelines for RNA sequencing in genetical genomics studies. *J. Chen[1,2], C. Ye[1], A.C. Villani[1], M.N. Lee[1,3,4], T. Raj[1,3,5], P.L. De Jager[1,3,5], C. Benoist[3,5], T. Bhangale[6], W. Ortmann[6], T. Behrens[6], N. Hacohen[1,3,4], A. Regev[1,7,8].* 1) Broad Institute, Cambridge, MA; 2) Division of Health Sciences and Technology, MIT, Cambridge, MA; 3) Harvard Medical School, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Brigham and Women's Hospital, Boston, MA; 6) Genentech Inc., South San Francisco, CA; 7) Department of Biology, MIT, Cambridge, MA; 8) Howard Hughes Medical Institute.

RNA-sequencing (RNA-seq) has emerged as an important tool for profiling gene expression variation because it allows a comprehensive characterization of the transcriptome, including transcript levels, splicing, and allele specific events. Several large scale studies have now used RNA-seq to identify the genetic basis of gene expression variation in humans across different cell types and cell stimuli. Although a number of computational approaches have been developed to (i) align reads, (ii) assemble or annotate transcripts, and (iii) quantify transcript abundances, different computational pipelines aimed at defining quantitative traits from RNA-seq have not been systematically compared.

Here, we evaluate three pipelines for identifying the genetic basis of gene expression in humans. We: (1) align to the transcriptome and estimate fraction of transcripts using RSEM, (2) align to the genome, assemble and estimate fraction of transcripts using TopHat and Cufflinks, and (3) align to the genome, and directly count reads using HtSeq. We apply each pipeline to generate expression or isoform usage quantitative traits for three datasets: (i) the GEUVADIS lymphoblastoid cell line data across 462 individuals, (ii) whole blood across 922 individuals using single end RNA-seq, and (iii) ImmVar dendritic cell stimulation response in 576 samples. We evaluate the performance of each pipeline based on its ability to produce a reproducible set of genetic associations to expression (eQTL) or isoform ratio (irQTLs) within each dataset through cross validation or across datasets.

In the well annotated human genome, the simplest pipeline, which uses RSEM to estimate relative abundances from the annotated transcriptome, produced highly reproducible expression levels as compared to microarrays and Nanostring measurements on the same samples. Furthermore, within each pipeline, quantitative traits based on estimations of fraction of transcripts, such as transcripts per million and isoform ratio, produced highly reproducible eQTLs and irQTLs across all three datasets. Overall, our analysis highlights that a computational pipeline based on estimating fraction of transcripts from multiply mapped reads is a robust method for discovering variants that control expression and splicing from RNA-seq data.

1520T

Bioinformatic analysis of novel pathogenic missense mutation of ARSB gene in a colombian patient whit Maroteaux -Lamy. *G. Giraldo[1], P.A. Ayala[1], J. Acosta[2], R. García[2], J.C. Prieto[1], J. Gonzalez[3].* 1) Instituto de Genètica Humana, Pontificia Universidad Javeriana, Bogotà, Bogotà D.C, Colombia; 2) Instituto de Investigación en Nutrición, Genética y Metabolismo Universidad el Bosque, Bogotá D.C, Colombia; 3) Depto de bioquimica, Pontificia Universidad Javeriana, Bogotá D.C Colombia.

Introduction: Maroteaux -Lamy - MPS VI (OMIM# 253200) is a lysosomal storage disease characterized by systemic clinical manifestations and significant functional compromise. The reported worldwide incidence is 1:248.000 to 1:300.000 live births [1] and in Colombia 27 cases are known, 10 belong to indigenous groups [2]. To date, 133 mutations have been reported: 100 missense / nonsense, 9 in Splicing site, 17 small deletions, 3 small insertions in the Arylsulfatase B (ARSB) gene. The ARSB mutations cause loss of enzyme activity. To understand the structural basis for the disease, we approximated bioinformatics methods to analyze one ARSB missense mutations at both the sequence and structural level. Material and methods: In a previous study, 13 patients were analyzed, to date, sequencing for 4 exons in 7 patients have been performed, finding in one patient , a variant of exon 2, not previously reported , c.1618A > C (p.H111P). To evaluate the effect of mutation, different programs were run like Polyphen2, Mutation taster, Mustab, Panther and Provean. The amino acid sequence of human ARSB was taken from Uniprot entry P15848 and the crystallographic coordinates were obtained from the PDB database (ID: 1FSU) To prediction of the effect of point mutations on protein stability was performed using structural models generated by FoldX. The analysis of residue conservation was conducted with the ConSurf server and for illustration of conserved amino acids in the sequence we used MultiDisp. Results and discussion: We evaluated the effect of the change c.1618A>C (p.H111P) in the function on the protein, finding a highly deleterious and a potentially pathogenic variant. Histidine is a α-amino acid with an imidazole functional group and is considered a proteinogenic amino acid. This α-amino acid is involved in the catalytic reactions of enzymes. The proline change interrupts the habitual conformation of the side chain and makes the chain direction changes abruptly. The presence of proline disrupts the formation of any regular repeating structure Using bioinformatics programs was observed that this amino acid is conserved in all species; this variant causes a conformational change in the protein and affects the catalytic site seriously, responsible for the enzyme deficit.

1521S

Simultaneous detection of copy number variations (CNV) and point mutations with next generation sequencing (NGS) using Agilent HaloPlex custom designs. *C. Haag[1], K. Hauschulz[2], J. Strub[3], E. Schulze[1].* 1) Endocrine Practice and Medical Genetics Laboratory, Heidelberg, Germany; 2) Agilent Technologies Sales & Services GmbH & Co. KG, Germany; 3) JSI medical systems GmbH, Kippenheim, Germany.

Copy number variation (CNV) is a form of structural variation in the genome. Usually, CNV refers to the duplication or deletion of DNA segments larger than 1 kbp. Copy number variations have been recognized as pathogenic mutations for many years, for example in mental retardation disorders or Duchenne muscular dystrophy (DMD), where single or multiple exons are deleted or duplicated, respectively. Alterations in DNA copy number are also a common feature in different cancers and the detection of these changes shows promise for the diagnosis of a disease and also for therapeutic or prognostic purposes. Two different methods are traditionally used for mutation detection, one for CNVs and one for point mutations. For the detection of copy number changes in selected regions array Comparative Genomic Hybridisation (aCGH) or PCR-based methods such as Multiplex Ligation-dependent Probe Amplification (MLPA) are well established, whereas Sanger-based sequencing or next generation sequencing are the standard methods for the detection of point mutations and small deletions or insertions. We used the Agilent HaloPlex Target Enrichment system (on the Illumina MiSeq platform) for the combined detection of point mutations and copy number variations. Copy number variations are detected by comparing the coverage of regions in the sample of patients with control samples. The copy number variation analysis was performed with the CNV function of the Sequence Pilot software (JSI Medical Systems GmbH, Kippenheim, Germany). We used three different Haloplex custom designs including 21 genes for hereditary endocrine diseases like pheochromocytoma or multiple endocrine neoplasia for the validation of the Haloplex assay. Altogether, we analyzed 45101 bp covered by 2999 amplicons. The Haloplex assay was validated using known positive control samples comprising samples with point mutations, indels as well as exon duplications/deletions. All mutations were successfully identified with a high coverage (>1000 fold average exon coverage) and 99.2% of the targeted bases were covered with a least 50 reads. Regions with no coverage account for 0.5%. In summary, Haloplex custom designs can be used as a targeted NGS resequencing approach that facilitates the detection of point mutations, indels and duplications/deletions in parallel.

1522M

Gene-based burden analysis of imputed low frequency variants identifies associations with LDL in an African American cohort. *H. Hakonarson[1,2], A. Krämer[3], D.R. Richards[3], P.M.A. Sleiman[1,2].* 1) Center for Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine, University of Pennsylvania Philadelphia, PA, USA; 3) QIAGEN Silicon Valley, CA, USA.

Genome wide association studies (GWAS) have been very successful in identifying loci associated with complex disease, however, the genotyping arrays were not designed to capture low frequency and rare variation. As a result, the role of variants in that category of allele frequency remains largely unexplored in complex disease. One possibility would be to generate sequencing data on a large number of samples, however, the cost of large-scale studies remain prohibitively expensive. Genotype imputation presents a viable alternative for sample sets with existing genotypes from dense whole-genome arrays. Data generated from large sequencing projects such as the 1000 Genomes project and the NHLBI exome sequencing project (ESP) can be used as reference datasets to impute missing variation into the sample genotype data. Recent improvements in imputation algorithms and the expansion of reference datasets have improved the accuracy of imputation for even low minor allele frequency variants. Imputed variants can then be assessed against binary phenotypes or quantitative laboratory values derived from patients' electronic medical records. The Center for Applied Genetics (CAG) maintains a biorepository of over 150,000 genotyped samples, 45,000 of which are pediatric samples randomly recruited from the Children's Hospital of Philadelphia (CHOP) with complete electronic medical records. As a proof of principle, we imputed missing variants into a subset of just under 100,000 samples that had been previously genotyped on the Illumina BeadChips from the CAG biorepository. Imputation of untyped markers (~39M) was carried out using IMPUTE2 against the 1KGP Phase I integrated variant set after prephasing with Shapeit. Imputed genotypes were converted to a binary encoding and uploaded to QIAGEN's Ingenuity Variant Analysis platform for annotation and gene-based analysis using the SKAT algorithm. As proof of principle we carried out an association against EMR-derived LDL values from 2,500 African American children. The results of the gene-based analysis showed highly significant association of the APOE (P 3.44×10-10) and PCSK9 (P 3.34×10-7) genes both of which have recently been associated with LDL in African Americans through genotyping on exome array chips. Imputation of low frequency and rare variation into genotyped data thus represents a viable alternative to sequencing and re-genotyping on exome array chips for the study of this class of variation in complex disease.

NIH Genetic Testing Registry (GTR): A data mine available through programmatic access. *B. Kattman, A. Malheiro, J. Lee, D. Maglott, V. Hem, M. Ovetsky, G. Song, C. Wallin, K. Katz, R. Villamarin-Salomon, B. Gu, S. Chitipiralla, W. Rubinstein.* NCBI/NLM/NIH, Bethesda, MD.

The NIH Genetic Testing Registry (GTR; www.ncbi.nlm.nih.gov/gtr/) houses detailed information on more than 17,000 genetic tests voluntarily submitted by laboratory test providers. Interest in programmatic access to GTR data has burgeoned as GTR has become the world's most comprehensive repository of publicly available data about genetic tests. The GTR website supports interactive data access for a high volume of daily users. Recently the entire GTR dataset was made available through XML files from the ftp site, as well as summary data via NCBI's application programming interface, E-utilities.

The GTR includes germline and somatic tests using molecular, cytogenetic and/or biochemical methodologies. Tests for drug responses, and complex panels utilizing next-generation sequencing or array technologies, are in scope. As of June 2014, GTR has submissions from more than 400 testing laboratories from 39 countries. In the past 7 months there has been a 66% increase in the number of registered tests. Registered tests evaluate 4,456 conditions, with molecular tests targeting 3,014 genes (91% of clinically relevant genes reported by ClinVar). Submission of complex tests is also increasing, with 651 tests that evaluate 5 or more genes. Next-generation sequencing (NGS) is a component of 9.2% of molecular tests. Data surrounding the evidentiary basis of tests are available for a growing number of records: Analytical validity (100%), Target population (36%), Clinical validity (14%), and Clinical utility (15%). Information is also available about proficiency testing, FDA approval/clearance, laboratory certification and much more.

GTR has long maintained an FTP site to support unrestricted access to standard terminologies and provide summary data (ftp://ftp.ncbi.nlm.nih.gov/pub/GTR/_README.html). In response to stakeholders, GTR added the comprehensive extraction of test data as XML. In addition, data are accessible by NCBI programmatic tools (www.ncbi.nlm.nih.gov/gtr/docs/maintenance_use/).

GTR has a mission to improve transparency surrounding genetic testing, and is being sought by a wide variety of stakeholders interested in surveying the genetic testing landscape. This presentation will illustrate how to access GTR data for knowledge discovery.

Impact of statin on gene expression in human lung tissues. *J. Lane[1], B.Y. Aminou[1], S. vanEeden[2], D. Sin[2], M. Obeidat[2], S. Tebbutt[2], W. Timens[3], D.S. Postma[3], M. Laviolette[1], P. Paré[2], Y. Bossé[1,4].* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Quebec, Quebec, Canada; 2) University of British Columbia Center for Heart Lung Innovation and Institute for Heart and Lung Health, St. Paul's Hospital, Vancouver, Canada; 3) University of Groningen, University Medical Center Groningen, GRIAC research institute, Groningen, The Netherlands; 4) Department of Molecular Medicine, Laval University, Quebec, Canada.

Objectives: Statins inhibit 3-hydroxy-3-methylglutaryl-coenzyme A reductase which is involved in the synthesis of cholesterol and about a 1/3 of COPD patients are actively using statins. Statins may improve the respiratory health of patients with asthma, COPD and lung cancer by reducing the adverse impact of chronic inflammation and cardiovascular co-morbidities. We studied the effect of using statins on gene expression in human lung in order to identify new molecular pathways underpinning the effects of statins. **Methods:** Human non-tumor lung tissues were obtained from patients who underwent lung resection. Gene expression was measured on a custom Affymetrix array in a discovery cohort (n=408) and two replication sets (n=282 and 341). Genes differentially expressed between patients taking or not taking statins were tested by linear regression, adjusting for age, gender and smoking status. A propensity score or substitution variables also served as covariates as appropriate. The results of each cohort were combined in a meta-analysis and biological pathways were studied using Ingenuity Pathway Analysis, DAVID and Gene Set Enrichment Analysis. **Results:** The discovery set includes 267 statin users. Fifteen genes were found significantly up-regulated in the lungs of statin users (FDR < 0.05). Twelve of these genes were replicated in the first replication set, but none in the second (p-value < 0.05). The meta-analysis improved the significance of the 15 up-regulated genes. Biological pathways analyses provided 21 significant pathways (FDR < 0.05). The first pathway suggested that statins up-regulate expression of genes involved in cholesterol synthesis by activating the sterol regulatory element-binding protein. The top 10 pathways affected by statins included genes involved in isoprenoïds synthesis and genes regulated by the cytochrome P450 reductase. Genes in the insulin receptor substrate/protein kinase B pathway were also affected by statins. **Conclusion:** To our knowledge this is the first study to report the effect of statins on the transcriptome of the human lung. The results suggest that statins may improve respiratory health by modulating pulmonary expression of genes involved in biological pathways associated with asthma, COPD and lung cancer.

1525M

A network approach to investigate the respective roles of common and rare variants in Attention-Deficit/Hyperactivity Disorder. *L.A. Lima[1,2], A.C. Feio-dos-Santos[3], D.B. Mariani[2], S.N. Simões[2,4], R.P. Silva[1], R.F. Hashimoto[2,5], L.A. Rohde[6], H. Hakonarson[1], H. Brentani[2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Programa Interunidades de Pós-Graduação em Bioinformática, Universidade de São Paulo, São Paulo, SP, Brazil; 3) Instituto de Psiquiatria, Faculdade de Medicina, Universidade de São Paulo, São Paulo, SP, Brazil; 4) Instituto Federal do Espírito Santo, Serra, Espírito Santo, Brazil; 5) Instituto de Matemática e Estatística, Universidade de São Paulo, São Paulo, SP, Brazil; 6) Departamento de Psiquiatria e Medicina Legal, Faculdade de Medicina, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil.

Attention-Deficit/Hyperactivity Disorder (ADHD) is the most common psychiatric disorder in infancy and adolescence, affecting 5.8% of children and adolescents in the world. Many studies have been applied trying to investigate the genetic susceptibility of ADHD. The present work aimed at examining the differences and similarities in rare and common variants in this disorder. We used previously published results of a GWAS meta-analysis and four copy number variation (CNV) studies of ADHD involving pediatrics/adolescent Caucasian samples. Using only genes expressed in brain (post-mortem pediatric samples from Brain Atlas), we constructed a protein-protein interaction (PPI) network as a background, using only physical interactions confirmed by at least two sources. Two sets of genes were defined based on the candidate hits from the GWAS meta-analysis and CNV analyses results. These sets of genes served as seeds to construct two independent networks: 1. related to common variants (from GWAS meta-analysis data) and 2. related to rare variants (CNV data). The two networks were constructed with the seed genes and their direct interactions on the background PPI network. The overlapping genes from common and rare variants networks confirmed some known functions involved with ADHD, such as Ubiquitin mediated proteolysis, Neurotrophin signaling pathway, Insulin signaling pathway, Focal adhesion and MAPK signaling pathway. The genes exclusively mapped in the rare network (CNV) were enriched with new candidate functions, as Spliceosome and Long-term potentiation. The network analysis approach can be easily applied to other diseases caused by both rare and common variants.

1526T

Optimizing an imputation panel for admixed Latin American populations. *W. Magalhães[1], N. Araujo[1], T. Leal[1], M. Machado[1], R. Moreira[1], M. Gouveia[1], F. Soares[1], M. Rodrigues[1], F. Kehdy[1], A. Horimoto[5], M. Barreto[2], B. Horta[3], M. Lima-Costa[4], A. Pereira[5], E. Tarazona-Santos[1], The Brazilian EPIGEN Consortium.* 1) Biologia Geral, Federal University of Minas Gerais, Belo Horizonte, Brazil; 2) Universidade Federal da Bahia, Brazil; 3) Universidade Federal de Pelotas, Brazil; 4) Fundaçao Oswaldo Cruz, Centro de Pesquiça René Rachou, MG, Brazil; 5) Instituto do Coracao, Universidade de Sao Paulo, Brazil.

As part of the largest Latin-American genomic initiative, we studied three Brazilian longitudinal population cohorts: Salvador-Bahia (n=1309), Bambui (n=1442) and Pelotas (n=3736) from Northeast, Southeast and Southern Brazil respectively. We genotyped the Omni2.5M-Illumina for the 6487 individuals, the Omni5.0M-Illumina for 265 individuals and sequenced 30 genomes (average coverage: 42X). Admixture is an important feature of the Brazilian population, which affects the genotype imputation process and must be considered as a key point, producing a changed linkage disequilibrium when compared to parental populations. In order to overcome the former point, using individuals with the same ancestry background, we combine our high-density array (Omni5.0M) and the whole genome dataset to propose a new reference imputation panel for Latin-American admixed populations. The software Shapeit for phasing followed by the software IMPUTE2 for imputation. We evaluated the accuracy of our panel with the public panel available by the phase I of the 1000 Genomes Project, wherein 1,092 individuals were genome and exome sequenced and genotyped to produce an integrated variant call set. Our preliminary results (CHR22) suggest that the effect of ancestry background and the size of the reference panel play important role on the accuracy of the imputed genotypes.

1527S

Functionally characterizing common variants associated with psychiatric disorders. *J. Moore, Z. Weng.* Program in Bioinformatics & Integrative Biology, UMass Medical School, Worcester, MA.

Schizophrenia, bipolar disorder, and major depressive disorder are psychiatric disorders that affect millions of people every year. The etiology of these disorders in unknown, though each have strong hereditary components. Genome wide association studies associated over 400 single nucleotide polymorphisms (SNPs) with these disorders with a majority of these variants lying in non-coding regions of the genome. In order to characterize the function of these non-coding SNPs, we used epigenomic data from the Encyclopedia of DNA Elements (ENCODE) Consortium and the Roadmap Epigenomics Project to define regulatory regions overlapping each of the variants. In agreement with previously reported results, we found a majority of variants and their linkage disequilibrium (LD) partners overlapped active epigenomic marks. While a majority of the SNPs intersected tissue specific marks, a subset of these variants overlapped marks from hundreds of cell lines. Additionally, we analyzed transcription factor binding motifs, which overlapped the associated SNPs and predicted the effect size of allele change. Most SNPs did not dramatically change the probability of observing the motif, but there were almost 500 loci with allele specific motifs. These motifs corresponded to transcription factors involved in neural pathways as well as inflammatory and immune response. Additionally, our functional predictions were validated by performing allele specific regulation analysis. We remapped reads from ENCODE and Roadmap datasets to observe whether the change in allele affected binding of transcription factors, DNase I hypersensitivity, and gene expression. We then predicted gene targets for these SNPs by correlating DNase I signal across multiple tissue types. These target genes were enriched in similar pathways as the motifs. Several of these pathways were connected through the regulation of cytokines such as transforming growth factor beta and interleukin 2, both of which were previously reported as dysregulated in psychiatric disorders.

A network-based approach to dissect the cilia/centrosome complex interactome. *M. Morleo[1], R. Amato[1], L. Giaquinto[1], D. di Bernardo[1,2], B. Franco[1,3].* 1) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Computer and Systems Engineering, University of Naples "Federico II", Naples, Italy; 3) Department of Medical Translational Sciences, Federico II University, Naples, Italy.

Background Cilia are microtubule-based organelles protruding from almost all mammalian cells that, when dysfunctional, result in genetic disorders called "ciliopathies". High-throughput studies have revealed that cilia are composed of thousands of proteins. However, despite many efforts, much remains to be determined regarding the biological functions of this increasingly important complex organelle. Results We derived an online tool from a systematic network-based approach to dissect the cilia/centrosome complex interactome (CCCI). The tool is able to integrate all current data available into a model which provides an "interaction" perspective on ciliary function. We generated a network of interactions between human proteins organized into functionally relevant "communities", i.e. a group containing genes that are both highly inter-connected and strongly co-expressed. We then combined sequence and co-expression data in order to identify the transcription factors responsible for regulating genes within their respective communities. Our analyses revealed communities significantly specialized for delegating specific biological functions such as mRNA processing, protein translation, folding and degradation processes that had never been associated with ciliary proteins until now. Conclusions CCCI will allow us to clarify the roles of previously unknown ciliary functions, elucidate the molecular mechanisms underlying ciliary-associated phenotypes, and apply our knowledge of the functional roles of relatively uncharacterized molecular entities and disease phenotypes to new clinical applications.

Identification and Clinical Assessment of Deletion Structural Variants in Whole Genome Sequences of Acutely Ill Neonates. *A.C. Noll[1,2], L.D. Smith[2], N.A. Miller[2], C.J. Saunders[1,2], I. Thiffault[2], A. Newton[1], K. Detherage[1], J. Hoang[2], L.K. Willig[2], L.D. Cooley[2], S.D. Fiedler[2], E.G. Farrow[2], S.F. Kingsmore[1,2].* 1) University of Kansas Medical Center, Kansas City, KS; 2) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO.

Effective management of acutely ill newborns with likely genetic diseases requires rapid and comprehensive identification of causative haplotypes. While whole genome sequencing (WGS) can identify pathogenic nucleotide variants in newborns in less than 50 hours, deletion structural variants (DSVs) >50 nucleotides are also an important component of the mutation burden for genetic diseases and are missed by many variant detection pipelines. Concomitant identification of DSVs in rapid WGS data for diagnosis of acutely ill newborns would be highly valuable. Here we describe the development of DSV detection methods that combine consensus calls from two WGS DSV detection tools (Breakdancer and GenomeStrip) with a novel filtering and clinical strategy. WGS simulation data demonstrated Breakdancer and GenomeStrip consensus calls had 83% sensitivity, 99% positive predictive value, and high precision. Upon inspection of read depth, and alignment distance of paired reads in the integrated genome viewer (IGV), DSV consensus calls overlapping with SNP array calls were found to be 95% true positive. Consensus DSV calling with parameterized filtering was implemented in an 8-hour computational pipeline called SKALD (Screening Konsensus and Annotation of Large Deletions). IGV evaluation of SKALD results in a tetrad demonstrated more than 80% were true positives, however the sensitivity was low. To assess the clinical utility of SKALD, WGS from 12 familial trios with an acutely ill newborn proband in which causative nucleotide variants had not been identified were analyzed. A heterozygous deletion of exons 1-3 of MMP21 (NC_000010.11 g.127,460,714_127,461,028del) was found in trans with a heterozygous frameshift deletion (p.Met122SerfsX55) in two siblings with transposition of the great arteries and abdominal heterotaxy (TGAH). These variants are expected to be deleterious to MMP21, resulting in a truncated or degraded protein. Mmp21 -/- mice exhibit TGAH, supporting MMP21 as a novel disease gene. In a newborn female with dysmorphic features, ventricular septal defect, and persistent pulmonary hypertension, SKALD identified the breakpoints of a heterozygous, de novo 1p36.32p36.13 deletion (NC_000001.11 g.4,848,728_18,503,068del). In sum, SKALD has the potential to increase the diagnostic yield of WGS in acutely ill neonates and to discover novel disease genes.

1530S

Protein functional domain annotation in single gene association in Parkinson Disease. *K. Nuytemans[1,2], V. Inchausti[1,2], L. Maldonado[1,2], A. Mehta[1,2], E.R. Martin[1,2], G.W. Beecham[1,2], L. Wang[1,2], W.K. Scott[1,2], J.M. Vance[1,2].* 1) Human Genomics, University of Miami, Miami, FL; 2) Miami Udall Center, University of Miami, Miami, FL.

Although whole exome sequencing (WES) allows identification of all variants in the coding regions of the genome, additional analyses are needed to assess the potential impact of any of those variants on the protein and thus potentially the disease mechanism. So far, many studies have used amino acid change prediction programs based on conservation or 3D structure (e.g. SIFT, POLYPHEN). Alternatively, filtering on presence in the protein's functional domains will augment the potential effect of variants to be included in the analysis. Most protein databases currently available, however, do not allow for annotation on the genomic level. As a proof-of-principle we used the Pfam database available as a UCSC track to filter variants for analysis. We performed WES in 410 PD patients and 229 controls. Functional annotation of identified variants for effect in protein and presence in protein functional domains (UCSC Pfam track) was performed through ANNOVAR. Rare variants (MAF<5%) were identified using the 1000Genomes and the NHLBI Exome Sequencing Project datasets. Association with risk for PD was assessed for sets of variants in genes using the optimal Sequence Kernel Association test (SKAT-O). Genes with p-value <0.01 were included in the enrichment analyses in KEGG pathways using WEB-based GEne SeT AnaLysis Toolkit (webGestalt). In total, 37,965 protein sequence altering variants (nonsense or missense) were annotated to a protein functional domain in 9736 genes. The top 10 genes ($p<0.002$) using rare or all variants were similar and included genes previously reported in PD (*SUMF2*) or involved in processes linked to PD (endosomal trafficking genes; *AP5M1*, *VPS4B*, axon guidance; *PPFIBP2*, cell-cell interaction; *PCDHB12*). No KEGG pathways were associated after correcting for multiple multiple testing. Top (nominally significant) pathways included "cell adhesion molecules" and "regulation of actin cytoskeleton", both previously reported in PD pathway analyses. These proof-of-principle analyses confirm the validity of using presence in a protein functional domain as a variant inclusion requirement. The analyses presented here are limited by the data available on genomic level for the Pfam (predicted) protein domain database. Therefore, we will set out to evaluate this approach of protein domain annotation for genomic variants including different algorithms (e.g. TIGR, PANTHER,..) to widen the search for potentially damaging variants.

1531M

Large pedigrees in human sequencing studies: toward a more resolved and accurate picture of genetic disease. *J.A. O'Rawe[1,2], Y. Wu[1,2], H. Fang[1], L.T.J Barrón[1,4], K. Wang[3,5], G.J. Lyon[1,2,3].* 1) Cold Spring Harbor Laboratory , Cold Spring Harbor, NY; 2) Stony Brook University, Stony Brook, NY; 3) Utah Foundation for Biomedical Research, Salt Lake City, UT; 4) Universidad Nacional Autonoma de Mexico, Cuernavaca, Morelos, MX; 5) Zilkha Neurogenetic Institute, Department of Psychiatry and Preventive Medicine, University of Southern California, Los Angeles, CA.

Introduction: While studying larger multi-generational families can increase the accuracy of "whole" genomes by reducing the effect of undetected sequence variation, using a variety of sequencing and analytical pipelines can generate a more comprehensive set of sequence variations. We describe a whole genome sequencing (WGS) study of one large multi-generational family containing two affected male children, aged 10 and 12, with severe intellectual disability, autism-like behavior and very distinctive facial features. Methods: WGS was performed on ten family members using the Illumina HiSeq2000 platform, with four (the two affected boys and their parents) being additionally sequenced using the Complete Genomics (CG) WGS and analysis platform. Illumina reads were mapped to the hg19 reference genome using BWA v.0.6.2-r126, and variant detection was performed using the GATK v. 2.4-9. Additional variant detection procedures included using Novoalign and the FreeBayes caller, Scalpel for insertion or deletion (INDEL) detection, RepeatSeq for INDEL detection in short tandem repeat regions, and the ERDS method for detecting larger copy number variations. Disease variant prioritization was performed using filtering techniques (ANNOVAR, Golden Helix SVS and GEMINI), and a statistical method for identifying disease variants (VAAST). Results: CG WGS covered >85% of the genome and >90% of the exome, both with 20 or more reads. Illumina WGS covered >90% of the genome with 30 reads or more and with >80% of the bases having a quality score of >30. We find a 2 to 5-fold difference in the number of variants detected as being relevant for various disease models when using different sets of sequencing data and analysis pipelines. We derive greater accuracy when more pipelines are used in conjunction with data encompassing a larger portion of the family, with the number of putative de-novo mutations being reduced by 80%, due to false negative calls in the parents. Conclusions: These data are particularly salient in terms of contrasting 'trio' or 'quad' studies with larger family studies, as both 'trio' and 'quad' study designs are limited in their power to resolve genetic variations contributing to disease. We demonstrate increased power to resolve putative disease related mutations using larger family based studies, and explore the feasibility and performance of using a wide variety of informatics methods to elicit a more complete "Whole Genome".

1532T

Novel bioinformatics driven imaging-genetics approach exploring the aetiology of Alzheimer's disease. *S. Patel[1,2,5], MT. Park[3], J. Pipitone[3], MM. Chakravarty[4,5,6], J. Knight[1,2,5], The Alzheimer's Disease Neuroimaging Initiative.* 1) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Canada; 3) Kimel Family Translational Imaging-Genetics Research Laboratory, the Centre for Addiction and Mental Health, Toronto, Canada; 4) Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, Canada; 5) Department of Psychiatry, University of Toronto, Toronto, Canada; 6) Douglas Mental Health University Institute, Verdun, QC, Canada.

Introduction: Alzheimer's disease (AD) is a devastating illness, affecting over 35 million people worldwide and expected to increase to 115 million by 2050. Our goal is to identify biomarkers for AD-progression based on structural magnetic resonance imaging (MRI) and genetic data using a systematic biological and bioinformatically-driven approach to shed light on the genetic burden associated with AD. **Methods**: T1 weighted MR images were obtained from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database. Hippocampus segmentation was carried out using the MAGeT Brain algorithm on 162 AD subjects, 317 with mild cognitive impairment and 183 healthy controls [Pipitone et al., 2014]. Hippocampal volumes were used for association testing with both genotypes from the Human 610-Quad BeadChip and imputed genotypes (n=5,706,974) and the following covariates were controlled for: gender, age, first principle component from multidimensional scaling, baseline diagnoses, APOE status and intracranial volume. Stratified false discovery rate (sFDR) [Sun et al., 2006] was used to prioritize SNPs in genes selected using Gene Ontology (GO) networks. A list of genes associated with AD was obtained from a previous study by Lambert et al., 2013. Common GO terms within the gene list were identified and Cytoscape was used to visualize the relationships of the GO terms in a network format. The GO network was then pruned to enrich for GO terms containing genes from our list. We then extracted all SNPs from genes associated to all the GO terms in the nervous system development GO network which formed our stratum for sFDR. **Results** : A total of 249,001 out of 5,706,558 SNPs were selected from 1146 genes from the nervous system development stratum to be up-weighted in sFDR. No significant SNPs were found to be associated with hippocampal volume. **Conclusion**: SNPs in the nervous system development stratum list were not significantly associated with hippocampal volume. SNPs in this stratum may not play a specific role in hippocampal volume, for example SNPs in gene region, growth arrest-specific protein 7 is involved in neuronal development and is mainly expressed in mature cerebellar Purkinje cells [Ju et al., 1998]. Further modifications to prune the nervous system development GO network by using the 'Extension' column of the GO database to extract genes annotated to GO terms with an extension of neuro-anatomical cells in the region of the hippocampus.

1533S

Non-coding RNAs and transcription expression underlying neuropathic pain following sciatic nerve injury. *H.B. Raju[1,3], E. Capobianco[3], N.F. Tsinoremas[1,2,3].* 1) Human Genetics, University of Miami, Miami, FL; 2) Department of Medicine, University of Miami, Miami, FL; 3) Center for Computational Science, University of Miami, Miami, FL.

Background: Neuropathic pain (NP) causes damage to the nervous system. It is vital to detect the targets underlying NP, essential for improving the health of millions of people affected. Cellular functions are likely associated with changes in gene expression causal to NP developing over time Objective: Identify, classify non-coding RNAs and detect transcriptional expression for the two different types of neuronal tissues (dorsal root ganglia (DRG) and proximal sciatic nerve (SN)) following sciatic nerve injury. Method: Microarray probe sequences for the differentially expressed genes at 4 0d, 1d, 4d, 7d and 14d post-sciatic nerve injury in rats were obtained for DRG and SN from the gene expression omnibus (GEO) generated by the Agilent-014879 Whole Rat Genome Microarray 4x44K G4131F. Using these datasets and the expression changes at different time points post-nerve injury, we identified and categorized different ncRNA for DRG and SN at 4 different time points nerve injury. In the primary analysis, the extracted probe sequences were aligned against mouse reference to identify the homologous sequences between the two rodent species. In t the secondary analysis, the raw microarray probe sequences were analysed using GeneSpring 12.6 GX to identify differentially expressed genes across the different time points and potentially, understand the gene regulatory effect related to nerve injury. Results: From the primary analysis, we detected increase in the expressions of ncRNAs such as antisense, lincRNA and pseudogenes in DRG tissues from 1d-14d post-injury. In SN tissues, we detected about 190 lincRNAs at 1d which increased to 310 lincRNAs at 7d post-injury. Comparatively in SN, more ncRNA categories (N=15) were identified than DRG (N=22). Discussion: To the best of our knowledge, this is the first report of the detection of different categories of ncRNAs and transcription expression underlying NP following sciatic nerve injury. Interestingly, the increase in the expression levels of long ncRNAs at extended day's post-injury raises many questions related to tissue repair or other mechanisms related to NP.

1534M

Unrevealing the genomic architecture of chromosomal breakpoint region using multiparametric computational approach. *R.M. Rawal.* Dept. of Cancer Biology, The Gujarat Cancer & Research Institute, Ahmedabad, Gujarat, India.

Recurrent non-random chromosomal translocations are hallmark characteristics of leukemogenesis however molecular mechanisms underlying these rearrangements are less explored. The fundamental question is, why and how chromosomes break and reunite so precisely in the genome. Meticulous understanding of mechanism leading to chromosomal rearrangement can be achieved by characterizing breakpoints. To address this hypothesis, a novel multiparametric computational approach for characterization of six most frequent leukemic translocations within and around breakpoint region was performed. To best of our knowledge, this study is unique in finding the presence of Segmental Duplications (SDs) flanking breakpoints of all major leukemic translocation. Breakpoint islands were also analyzed for other complex genomic architecture and physical properties e.g. SIDD, repetitive elements, recombination signal sequence, base composition, Topo-II binding site & restriction endonuclease cleavage site etc. Our study distinctly emphasizes on the probable role of SDs and various genomic features in the occurrence of breakpoints. Further, it also highlights what those potential features may be which play a crucial role in causing double-strand breaks leading to translocation.

1535T

Assessing the hidden genome architecture of structural variants with Globus Genomics Galaxy pipelines. *A. Rodriguez[1], S.G. Potkin[3], R. Madduri[1,2], F. Macciardi[3,5,6,7], S. Gaudi[8], G. Guffanti[4].* 1) Computation Institute, University of Chicago, Chicago, IL; 2) MCS, Argonne National Laboratory, Argonne, IL; 3) Department of Psychiatry & Human Behavior, University of California, Irvine, School of Medicine, Irvine, CA; 4) Division of Child and Adolescent Psychiatry, Department of Psychiatry, Columbia University/NYSPI, New York, NY; 5) Center for Autism Research and Treatment (CART), University of California, Irvine, California; 6) Center for Epigenetics and Metabolism, University of California, Irvine, California; 7) Department of Pharmacological and Biomolecular Sciences, University of Milan, Milan, Italy; 8) Department of Infectious, Parasitic and Immune-Mediated Diseases Istituto Superiore di Sanità Rome, Italy.

Next-generation sequencing (NGS) opened a new phase of discovery of structural variants. The list of programs and algorithms to assess insertions, deletions, duplications, inversions and mobile elements is in continuous expansion. To get a comprehensive picture of the structural variants genomic architecture, researchers need to use different programs with advanced programming-based query interface, which is often demanding due to the large number of required tools and considerable computational infrastructure and needs. We used cloud-based Globus Genomics platform for development of comprehensive pipeline for assessing the "hidden" genomic architecture of structural variants that includes all steps from processing and quality control of data generated by NGS to functional annotation and data visualization. Globus Genomics enabled us to share our analysis pipelines, collaboratively build the pipeline, share the results of the analysis with our collaborators and ultimately make our published results accessible to the research community at large thus promoting transparency and reproducibility. The research platform integrated Globus for data transfer and management, Galaxy for tool and workflow management and Amazon Web Services (AWS) for compute resources. In addition, we leveraged the Swift parallel language into the execution of tools for seamless parallelization of datasets at a chromosomal level. We optimized each tool to use best available Amazon Web Services resource based on memory and computation needs. Optimizations include identification of tools that can be parallelized to minimize execution time and costs which allowed us to reduce the execution time by a factor of 5. At the time of this writing, we implemented in our pipeline the most up to date, publicly available tools: ForestSV used for detection of deletions and duplications; INDELS and mobile elements insertions are detected using Retroseq and Tangram; reference-based mobile elements (LINE, ALUs and HERVs) are detected with RepeatMasker. Finally, we assembled the structural variants identified by each specific algorithm. The structural variants can be further visualized using circus plots for genome-wide scale summary graphs. In conclusion, we developed a comprehensive pipeline for structural variants analysis featuring a live online supplement (interface with UCSC) providing access to exact analyses and workflows.

1536S

Integrative Analysis of Cancer Genetic Data for Drug Discovery. *S. Saisanit, F. Milletti, Z. Albertyn, J. Cai.* Pharma Research and Early Development Informatics, Roche Innovation Center New York, New York,, NY.

Our objective is to perform integrative analysis of genetic variations such as mutations, gene fusions, copy number, and transcript abundance in tumor samples from patients and cultured tumor cell lines. We envision that these analyses will help identify cancer cell lines best represent a given primary tumor type. We will also discover candidates for biomarkers and therapeutic targets. We process saw RNA sequencing data for identification of gene fusion events. We obtain other processed genetic data from TCGA Firehose and from ICGC Data Portal. We devise mapping strategies specific to each sequencing data type; differential mutation and differential gene and transcript expression (from RNA sequencing data); identification of genetic variations shared by patient samples and cell lines representing the corresponding primary tumor; compound screening panels on cancer cell lines for selected tumor types. Where applicable, we utilize in silico analysis pipelines to handle mapping and variant calling (RNASeq and WXS), gene fusion detection, splice junction detection, transcript-level expression, and isoform usage (RNAseq). Our effort leads to several candidate biomarkers and targets. Experimental validations will be needed to confirm the utility of these candidates. We can also use our integrated data for selecting cell lines to use in compound screenings.

1537M

Identification of differentially methylated genes potentially associated with neurological diseases. *W. Souza, B. Carvalho, D. Dogini, I. Lopes-Cendes.* Department of Medical Genetics, UNICAMP, Campinas, Brazil.

Epigenetic marks, including DNA methylation and histone modifications could play a role in neurological disorders with complex inheritance, such as epilepsy and stroke. However, this issue has not been sufficiently investigated. In this context, our aim was to perform an epigenome-wide association study (EWAS) using a public dataset (http://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE37579), to assess methylation profile across distinct tissues of patients with neurological disorders and compared this to that obtained from a control group. We used principal component analysis (PCA) for data quality control and empirical Bayes methods to adjust for systematic differences allowing better comparisons between tissues and disease-related conditions. Our results show a latent variable that stratified control samples into two subgroups and could represent a potential source of bias for downstream analyses. After further investigation we observed that the two clusters were tightly related to the different ethnicities of the individuals in the control group. After correcting for this variable we applied recent methods for methylation profiling using bumphunter Bioconductor package, which allows one to search for differences in methylation at the regional level rather than at the single-CpG level. We identified differentially methylated regions (DMR) when comparing DNA methylation profiles from different tissue groups. Finally, we compared the list of differentially methylated regions to a curated list of genes known to be associated with neurological disorders. We found that regions of a set of genes related with epilepsy and stroke (including *RELN*, *ARHGEF9* and *BDNF*) were differentially methylated. In conclusion, we identified and corrected a source of bias in the dataset, performed an analysis for differential methylation and identified DMRs that included genes potentially associated with epilepsy.

Genome-Wide Association Study Of Cerebrospinal Fluid Prostatic Acid Phosphatase Levels. *L.A. Staley[1], P.G. Ridge[1], M.H. Bailey[1], C. Cruchaga[2], A. Goate[3], J.S.K. Kauwe[1].* 1) Biology, Brigham Young University, Provo, UT. USA; 2) Biology and Biomedical Sciences, Washington University in St. Louis, St. Luis, MO. USA; 3) Psychiatry, Washington University School of Medicine in St. Louis, St. Luis, MO. USA.

Prostatic Acid Phosphatase(PAP) is an enzyme that is produced in the prostate in males, and it's physiological function is thought to deal with the liquefaction process of semen. Understanding the genetics of this enzyme is very important because this enzyme may be found in highly increased levels in men who have prostate cancer and moderately increased levels for bone diseases, such as Paget's disease or hyperparathyroidism and blood cell diseases, such as sickle disease, or multiple myeloma or lysosomal storage diseases, such as Gaucher's disease. For the initial association analysis in each series we used PLINK to perform linear regression and evaluated the association between the additive model for 5.8M SNPs and each phenotype. Age, gender, and the principle components from Eigensoft were included as covariates. Meta analysis was performed using default settings in METAL. Genomic inflation factor scores (GIF) were estimated using the R package GenABEL. The initial threshold for significance was P<5×10-8. SNPs that met this threshold were further filtered using the following criteria. First, we rejected markers where the direction of the effect was different in the Knight ADRC and ADNI datasets. Second, we removed all markers where the minor allele frequency was less than 5% (unless they were directly genotyped or had a clear functional annotation). Finally, we also rejected all associations with phenotypes where the genomic inflation factor was greater than 1.03 (GIF was calculated without SNPs where MAF is <0.05). We found 233 genome-wide significant markers(P<5×10^-8). We will analyze each of these markers individually and study the biological functions of each, to discover which is casual of the increased levels of this enzyme for men who have cancer or other diseases.

1539S

European Psoriasis Differences are Defined by Variation in the Epidermal Differentiation Complex. *C.E. Tanes, L. Jackson, A. Tozeren.* Biomedical Sciences, Engineering and Health System, Drexel University, Philadelphia, PA., USA.

Psoriasis is an autoimmune skin condition affecting 2-3% of Americans. Interestingly, European Americans are almost twice as likely to have psoriatic plaques as African Americans (3.6% and 1.9% respectively). Previous studies have shown that psoriasis has a strong genetic signature in human populations, leading us to examine the role that genetic variation might be playing in these prevalence differences. We harness the numerous curated genes identified through single gene and genome wide association studies to broaden the investigation of candidate polymorphisms in ethnic populations. Psoriasis genes curated through the National Center for Biotechnology Information (NCBI) Gene were mapped onto the human genome and regions with an overabundance of psoriasis genes were identified. These genomic hotspots were projected onto gene ontology categories and cellular pathways to draw a bioinformatics portrayal of psoriasis. HapMap (11 populations) and Human Genome Diversity Panel (51 populations) polymorphism data were analyzed for the psoriasis hotspot regions. Our analyses identify six psoriasis hotspots located on chromosomes 1, 2, 5, 6, 17 and 20. Functional annotation of these hotspots showed significant ($p<0.05$) biological processes consistent with keratinization, B cell proliferation and antigen presentation, core disruptions consistent with previous psoriasis studies. Population based polymorphic analyses identified a European specific pattern in genes making up the epidermal differentiation complex (1q21), which bear further investigation as the potential cause of population differences in psoriasis prevalence.

1540M

Exploiting whole exome-seq data for variant discovery from highly divergent regions in the human genome. *S.L. Tian, H.H. Yan, S. Slager.* Mayo Clinic, Rochester, MN.

Whole Exome Sequencing (WES) has been widely used to characterize genetic variations within human genes. However, mutation rate varies substantially across the human genome, which is a key determinant for variant calling. For example, human leukocyte antigen (HLA) region (6p21.3) contains the most polymorphic genes in the human genome and is associated with over 100 diseases. Accurate identification of variants from such highly divergent regions (HDRs) often relies on Sanger sequencing. While frameworks have been established for genome-wide variant calling for WES data, their feasibilities in HDRs have yet to be assessed. Using simulated and real data generated from our CLL (chronic lymphocytic leukemia) project, we have conducted a comprehensive assessment of numerous pipelines for variant discovery. We propose a strategy that achieves both high sensitivity and specificity over a wide range of divergence. Five short-read aligners were selected, including bwa, novoalign, gsnap, NextGenMap and stampy. From simulated data we found that four of the mappers were highly comparable in mapping accuracy (>99%) for reads with <= 1% divergence; novoalign was 3-4% lower instead, a result largely caused by its extensive use of 'soft clipping' to mask unaligned portion in a read. At an increased divergence of 5%, gsnap, NextGenMap and stampy still achieved ~99% mapping accuracy, versus up to 20% unmapped rate by bwa. At 10% and 15% divergence in particular, stampy represents the most effective mapper, followed by NextGenMap and gsnap. We next investigate the overall performance of five selected variant callers: GATK UnifiedGenotyper, GATK HaplotypeCaller, freebayes, platyus and SAMtools/mpileup. GATK UnifiedGenotyper showed the highest sensitivity for SNP calling across nearly all the divergent levels, from simulated reads mapped by gsnap (at >=1% divergence rates) or by bwa and stampy (at <1% divergence rates). More importantly, we observed similar trends in performance for these mappers and callers when applied to the CLL data, which were supported by comparing discovered variants to the calls made from our in-house Illumina iSelect genotype array data and to the known variants in dbSNP. Our findings highlight several key factors and combinations recommended to use in order to have a successful WES-based variant discovery in HDRs.

An in silico Post-GWAS Analysis of C-Reactive Protein Loci: a Pipeline of Sequential Bioinformatics-Based Approaches. *A. Vaez[1], R. Jansen[2,3], B. Prins[1], J. Hottenga[3,4,5], E. de Geus[4,5], D. Boomsma[3,4,5], B. Penninx[2,3,5], I. Nolte[1], H. Snieder[1], B. Alizadeh[1].* 1) Department of Epidemiology, University of Groningen, University Medical Center Groningen, Groningen, The Netherlands; 2) Department of Psychiatry, VU University Medical Center, Amsterdam, The Netherlands; 3) Neuroscience Campus Amsterdam, VU University and VU University Medical Center, Amsterdam, The Netherlands; 4) Department of Biological Psychology, VU University, Amsterdam, The Netherlands; 5) EMGO+ institute, VU University and VU University Medical Center, Amsterdam, The Netherlands.

Genome-wide association studies (GWASs) have successfully identified a number of Single Nucleotide Polymorphisms (SNPs) associated with serum levels of C-reactive protein (CRP). An important limitation of GWASs is that the identified variants merely flag the nearby genomic region and do not necessarily provide a direct link to the biological mechanisms or pathways underlying their corresponding phenotype. To this end we assembled an integrated pipeline of sequential bioinformatics-based approaches for post-GWAS analysis of human traits or diseases. In the first phase of 'in silico' sequencing it explores the nearby genomic region to identify all linked variants, with a focus on non-synonymous SNPs as potentially functional variants. In the second phase of eQTL analysis, it attempts to identify all nearby genes whose expression levels are associated with the corresponding GWAS SNPs. These two phases generate a number of relevant genes that serve as input to the next phase of functional network analysis. We applied this pipeline to the 18 SNPs that had previously been associated with CRP at a genome-wide significant level[1]. Our in silico sequencing analysis using 1000 Genomes Project data identified 3,801 linked variants, including 25 non-synonymous SNPs. Our eQTL analysis, based on one of the largest single datasets of genome-wide expression probes (n>5000) assessed in participants from the Netherlands twin Register (NTR) and the Netherlands study of Depression and Anxiety (NESDA)[2] identified 23 significantly associated expression probes belonging to 15 genes (FDR<0.01). The final phase of functional network analysis, which was based on 40 relevant genes identified in the previous two phases, revealed 93 significantly enriched biological processes (FDR<0.01). Our post-GWAS analysis of CRP GWAS SNPs confirmed the previously known overlap between CRP and lipids biology. Additionally, it suggested an important role for interferons in the metabolism of CRP.

The Variant Characterization of 211 Whole Genome Sequences: The Cache County Study on Memory Health and Aging. *M.E. Wadsworth[1], B.D. Pickett[1], J.B. Miller[1], J.D. Duce[1], R.G. Munger[2], C.D. Corcoran[2], J.T. Tschanz[2], M.C. Norton[2], J.S.K. Kauwe[1], K.V. Voelkerding[3,4], P.G. Ridge[1].* 1) Department of Biology, Brigham Young University, Provo, UT., USA; 2) The Cache County Study on Memory and Aging, Utah State University, Logan, UT., USA; 3) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT., USA; 4) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT., USA.

The 1000 Genomes Project is the current standard for population based variant profile analysis and accurately accounts for 95% of common variants in the human genome. Consequently, the 1000 Genomes dataset has been used to develop novel bioinformatics methods, design genetics studies, and evaluate the accuracy of new variant datasets. While the 1000 Genomes Project is an unparalleled resource for the study of human genetics, rare variants (<5%) were poorly characterized in the 1000 Genomes because of the low coverage of the majority of genomes in the dataset. This leaves an important gap in our understanding of population-level genetic variation since many important variants are rare. In this research we used 211 whole genomes sequenced to an average depth of 37 from The Cache County Study on Memory and Aging (Cache). Each of the genomes is from elderly (>65 years old), healthy individuals of European descent. Many of the CEU genomes in the International HapMap study were derived from individuals in the Cache study and are comparable to the European genomes from the 1000 Genomes Project. Due to the high coverage of these genomes it is possible to accurately characterize rare variants. We created a variant profile for each of the 211 individuals and the Cache dataset as a whole. In total, we observed ~16 million unique single nucleotide variants (SNV) in the dataset. Each individual had ~3.9 million SNVs and ~38,000 InDels. We further classified variants by type, and specifically analyzed variants located in the 57 genes the America College of Medical Genetics and Genomics defined as clinically relevant. Our analyses revealed that each individual had an average of 35 nonsynonymous SNVs, 13,180 SNVs, and 8,136 InDels located in 57 genes (exons and introns). Our research provides important insights into the type of genomic variation that can be expected in a healthy population of Caucasian individuals.

Genome-wide haplotype-based association study in Chinese Han population identified novel susceptibility locus for systemic lupus erythematosus. *Y. Wang[1], Y. Zhang[1], J. Yang[1,2], Y. Lau[1], W. Yang[1,2].* 1) Department of Paediatrics and Adolescent Medicine, LKS Faculty of Medicine and Queen Mary Hospital, The University of Hong Kong, Hong Kong, China; 2) Centre for Genomic Sciences, LKS Faculty of Medicine and Queen Mary Hospital, The University of Hong Kong, Hong Kong, China.

Systemic lupus erythematosus (SLE) is a heterogeneous and chronic autoimmune disease, resulting in recurrent inflammatory response and multiple-organ damage. Family and twin studies suggested that genetic factors are a crucial component contributing to the disease. The first wave of Genome-wide association studies have identified more than 40 susceptibility loci robustly associated with SLE. However, all of them together only explained a small fraction of disease heritability. In this study, we carried out a genome-wide haplotype-based association study, using the previously published GWA data from two Chinese Han cohorts, Hong Kong (Southern China) and Anhui (Northern China), respectively. Our analyses identified a novel region (meta haplotype-based p-value 6E-07) in chromosome 2q22.1 (upstream of CXCR4). The haplotype-based P value is smaller than any single-SNP P values within the region, suggesting haplotypes are more informative than single SNPs in this case. This strategy was demonstrated to be helpful to partially explain the missing inheritability of the complex diseases including SLE. Here we have provided a detailed account of the methodology (haplotype-based association analysis) and the association signals from this novel locus.

Next-Generation Sequencer Analysis: The Accurate Somatic SNV Detecting Workflow. *M. Yamaguchi.* Amelieff Corporation, Tokyo, Japan.

Next-generation sequencing technique has dramatically improved the efficiency and the speed of large scale sample analysis. As a result, picking out variations that have a significant impact on the disease of interest from a massive number of detected variations has become a difficult challenge. To overcome this problem, we established an analysis workflow to detect realistically verifiable number of somatic SNVs. In this workflow somatic SNVs are detected by SomaticSniper, the existing software designed to detect somatic SNVs. After detection, known variations, variations of low quality, and variations with low impacts are filtered out. We analyzed publically available NGS data of tumor-normal pair samples to verify the accuracy of our workflow.

1545S

Identification of recurrent drive gene fusions in melanoma using RNA-Seq data. *T. Zhang[1], M. Xu[1], P. Johansson[2], A. Pritchard[2], N.K. Hayward[2], K.M. Brown[1].* 1) National Cancer Institute, Bethesda, MD; 2) QIMR Berghofer Medical Research Institute, Brisbane, Australia.

Molecular targets for effective therapeutic intervention in melanoma have recently been identified within the RAS-RAF-MEK-ERK and, to a less extent, PI3K-AKT pathways. Despite the promise of approaches targeting these pathways, therapeutic resistance remains a significant problem, and the need to identify new molecular targets remains a critical need. Gene fusion events resulting from inversions, interstitial deletions, or translocations occur commonly in cancers, leading to the generation of novel fusion proteins with unique oncogenic properties. In order to identify fusions driving melanoma development and/or progression, we performed paired-end RNA-Seq of 72 melanoma cell lines using the Illumina HiSeq 2000. After filtering out low quality data, TopHat was used to align RNA-Seq reads to the human genome (hg19), and TopHat-Fusion was subsequently applied to identify potential fusions. In order to assess the potential of these fusions to act as driver events, we used a naïve Bayesian classifier Oncofuse to highlight fusions with common characteristics of known 'driver' events. In total, we observed 295 potential fusion events, 112 of which involved neighbor genes located within 1 Mbp on the same chromosome and 101 involving more distant same-chromosome partners. Only 82 of potential fusions were inter-chromosomal. In summary, we detected gene fusions involving PRKAR1A, RBMS3, CBX3, PTPRO, RERG, PTEN and BRAF recurrently occurring in at least 3 samples with the same partner genes. Notably, we identified multiple fusions involving known melanoma oncogenes or tumor suppressors, including BRAF, PTEN, GRIN2A and NF1. The Oncofuse pipeline identified the significant potential driver fusion genes such as BRAF, ATF2, PRKAR1A, MECP2 and IGF1R (FDR<0.01). In addition, we also identified and summarized fusion events in the TCGA Skin Cutaneous Melanoma dataset and found the recurrent/drive fusion genes in melanoma cell lines were also identified in TCGA samples. Particularly, PTEN, MAPKAPK5, RERG, PTPRO and BRAF fusions in melanoma cell lines were also observed in multiply TCGA samples with the same break point. There were a total of 9 BRAF fusions in our cell lines and TCGA samples, and 7 of them were BRAF wild type with the protein kinase domain retained. We are presently functionally characterizing several of these gene fusions, including BRAF, PTEN, ATF2, and PRKAR1A to establish their role in driving melanoma and as potential novel therapeutic targets.

1546M

Application of gene expression deconvolution to the translation of gene expression signatures from pre-clinical models to the clinic. *C. Campbell, A. Reddy, H. Huet, K. Venkatesan, W. Winckler, M. Morrissey, H. Bitter.* Novartis Institutes for BioMedical Research, Cambridge, MA.

Global gene expression profiling by microarray or RNA-seq has been used successfully to discover prognostic and predictive gene signature biomarkers in a number of cancer types and therapies. Translation from pre-clinical cell line models can be difficult because in primary tumors, the average expression is measured in a mixed population of cells, including not only the tumor cells themselves but non-cancerous cells from the surrounding stromal tissue, infiltrating immune cells, and others. Methods using cell-type frequencies in mixed cell populations have been developed to deconvolute cell-type specific gene expression to obtain average cell type expression levels across samples. We have performed *in silico* mixture experiments between cell line expression data from different lineages (pancreatic and myeloid (N=32)). Using these simulated data, we have developed a method to obtain deconvoluted expression values on the individual sample level that show high concordance to the true expression values prior to *in silico* mixing. We are using simulations to analyze the effect of non-uniformity and imprecision in the tumor purity estimates that would be inherent to primary tumor datasets. In addition, we have applied deconvolution to a gene expression signature that was predictive of sensitivity to death receptor 5 activation in cell lines and mouse xenograft models of pancreatic cancer. We examined TCGA pancreatic adenocarcinoma samples (N=39) for which RNA-seq as well as measurements of tumor purity were available. The sensitivity scores in the TCGA primary tumors (mean=0.21) were lower than in pancreatic cancer cell lines (mean=0.36) (p=0.003). When we deconvoluted these expression data (N=18,030 genes), most genes showed a similar level of expression in the tumor and non-tumor cells (96 % within an order of magnitude). We found that the average score in tumor cells (0.23) was higher than in the non-tumor cells (0.15). In addition, tumors with low scores tended to show high expression of genes associated with pancreatic acinar cells, which comprise the bulk of the pancreas, suggesting that contamination of these tumors with normal cells was leading to lower scores. The results point to the utility of this approach for accurately measuring gene expression signatures in the specific cell-type of interest. Such an approach may boost the clinical utility of signatures developed in cancer cell lines or xenograft models.

Whole Exome Sequencing in Two Siblings with Developmental Regression and Hypermetabolism. *S. Jougheh Doust[1], J. Clark[1], B. Robinson[2], J. Cameron[1], R. Cohn[1].* 1) Clinical and Metabolic Genetics, The Hospital For Sick Children, Toronto, Canada; 2) Mitochondrial Laboratory, DPLM, The Hospital for Sick Children, University of Toronto.

Hypermetabolism is physiological state of increased rate of metabolic activity. The patients have an abnormally high intake of calories followed by continuous weight loss. It is a common feature of metabolic and mitochondrial disorders. We report two sisters with developmental regression, hyperactivity and hypermetabolism confirmed with indirect calorimetry. Other symptoms include: seizures, aggressive behavior and oral intake of about 4000 kilo calories per day. The growth curves were at 25th and 50th percentile for their weights. The patients had coarse facial features with synophrys. The parents are consanguineous (half first-cousins) and Caucasian. They have one healthy son. The rest of the family history is non-contributory. Extensive investigations including brain imaging, electroretinography, genetic and metabolic work up were inconclusive. Mitochondrial assays showed an increase in mitochondrial lactate production, normal pyruvate production and a normal lactate to pyruvate ratio. Pyruvate dehydrogenase(PDH) enzyme activity was decreased. Sequencing of *PDH1* and *PDK3* (pyruvate dehydrogenase kinase 3) genes were negative. Whole exome sequencing performed on genomic DNA of one of the siblings at TCAG. In searching for candidate gene(s) responsible for these sisters' phenotype we looked for homozygous mutations in either mitochondrial genes or the genes that are expressed in the brain. No mitochondrial candidate genes identified. However, a homozygous frameshift mutation in *MAPK8IP2*(mitogen-activated protein kinase 8 interacting protein 2) gene, aka, *IB2* (Islet Brain 2), is reported in our patient. *IB2* is located on long arm of chromosome 22 and is one of the deleted genes in 22q13 microdeletion syndrome. The function of *IB2* is unknown in human. Recent studies showed that IB2 protein is expressed in brain and disruption of *IB2* gene can cause autism-like phenotype in knock-out mice (Gisa et al 2010). Sanger sequencing did not confirm the presence of the mutation in both siblings. Therefore we excluded *IB2* gene mutation as a cause for our patients' presentation. The next step is to look for other candidate gene(s) in our patient's exome library and explore more about the new candidate gene(s).

1548S

Genome-wide association study of serum metabolites using non-targeted metabolomics to identify new metabolic loci. *L. Lind[1], S. Gustafsson[2], S. Salihovic[1], A. Ganna[3], T. Fall[2], A.C. Syvänen[2], T. Axelsson[2], C.M. Lindgren[4], A.P. Morris[5], C.D. Broeckling[6], J. Prenni[6], E. Ingelsson[2].* 1) Dept of Medical Sciences, Uppsala University, Uppsala, Uppsala, Sweden; 2) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 5) Genetic and Genomic Epidemiology Unit, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 6) Proteomics and Metabolomics Facility, Colorado State University, Fort Collins, Colorado, USA.

Background: One way to understand human metabolism in more detail is to identify genes involved in metabolic pathways. The most recent efforts have linked around 150 genetic regions to different metabolites via genome-wide association studies (GWAS) of the metabolome. The present study aimed to extend this knowledge using three large independent cohorts in which multiple metabolic features were measured using non-targeted metabolomic profiling. Methods: In the ULSAM (n=1,028), PIVUS (n=970) and TwinGene studies (n=1,670), up to 10,000 metabolic features were measured in serum/plasma using the same technical platform across studies (UPLC and MS/MS). Genotyping was performed using the Illumina Human OmniExpress or Omni2.5M array and subsequently imputed using 1000 Genomes CEU data. A GWAS was performed for each metabolic feature using linear regression adjusting for age, sex and population-based principal components. We used TwinGene as the discovery dataset and attempted replication of genome- and metabolome-wide significant findings in the ULSAM and PIVUS cohorts. Results: We could confirm 42 of the previously reported associations between genetic regions and metabolites. Top findings included associations with the PYROXD2 locus (p-value=4.0×10-323) and the FADS gene cluster (P=4.6×10-111). In addition, we identified 8 novel associations between genetic variants and circulating metabolites (p-value range 1.1×10-11-9.6×10-93). Likely genes in those 8 regions were PNLIPRP1, LOXL4, FDX1, BCMO1, CYP2D6, UGT2B17, SLC22A1, and CYP3A43. Conclusion: In a GWAS of non-targeted metabolomics data, we could identify eight new genetic loci being related to metabolic traits, and replicate a large number of previously reported loci. Our findings will contribute towards an improved understanding of human metabolism.

A β-cell specific protein subnetwork significantly enriched for association with GLP-1 stimulated insulin secretion: A DIRECT study. *V. Gudmundsdottir[1], H.K. Pedersen[1], L.M. 't Hart[2], K. Banasik[3,4], D. Boomsma[5], E. de Geus[5], M. Eekhoff[6], M. Diamant[6], M. McCarthy[3,7], E. Pearson[8], C. Workman[1], R. Gupta[1], S. Brunak[1].* 1) Technical University of Denmark, Lyngby, Denmark; 2) Leiden University Medical Center, Leiden, The Netherlands; 3) University of Oxford, Oxford, UK; 4) University of Copenhagen, Copenhagen, Denmark; 5) VU University Amsterdam, The Netherlands; 6) VU University Medical Center, Amsterdam, The Netherlands; 7) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; 8) University of Dundee, Dundee, UK.

The heritability of insulin secretion response (ISR) during a modified hyperglycemic clamp with glucose, glucagon-like peptide 1 (GLP-1) and arginine stimulation has been shown to be considerable (h2=0.52 to 0.80) and it is of great interest to identify genetic variants influencing these responses. Evaluating ISR with a modified hyperglycemic clamp is not feasible in larger cohorts of sizes preferred for genome-wide association studies (GWAS). When sample sizes are small, GWAS may be complemented with systems biology approaches to aid the prioritization of genetic variants. Within the DIRECT consortium a GWAS was performed on GLP-1 stimulated ISR and data integration used to add biological context to the results and facilitate variant prioritization. GLP-1 stimulated ISR was measured with a modified hyperglycemic clamp in 130 twins and sibs from the Netherlands twin register. The cohort was genotyped using the Illumina HumanCore Exome BeadChip and association analysis was performed using the QTassoc software and adjusted for age, sex, familial relationships and insulin sensitivity index. Gene-based P-values were mapped onto a β-cell specific protein-protein interaction (PPI) network, which was created by pruning high confidence PPIs from InWeb 3.0 using published β-cell RNAseq data. Connected components in the network enriched for high scoring genes were identified with the Cytoscape plugin jActiveModules and their significance evaluated by comparing to 10,000 degree-preserved randomly sampled subnetworks from the β-cell PPI. None of the variants tested in the GWAS reached a genome-wide significance of $P \leq 5.0E-8$. However, the top scoring subnetwork (25 genes) had a significantly higher combined z-score than expected by random ($P \leq 1.0E-4$). It was most strongly enriched for the Gene Ontology terms “cell junction” (P = 3.6E-4), “plasma membrane part” (P = 2.2E-4) and “cell projection” (P = 4.9E-3) and contained a number of genes known to affect β-cell mass and function (FOXO1), insulin secretion (WFS1, RYR2) or be implicated in type 2 diabetes (MAGI2, CTNNA2 and PTPRD). We have identified a β-cell PPI network enriched for genes with nominal associations with GLP-1 stimulated ISR, demonstrating how data integration can highlight biological mechanisms underlying a phenotype where GWAS results on their own may be insufficient. Furthermore, the network can be used to prioritize genetic variants to take forward for replication in independent cohorts.

1550T

Analysis of Whole Exome Datasets to Test the Hypothesis of Digenic Inheritance in Stargardt Disease. *K. Lee[1], D.S. Marchuk[1], M.J. Friez[2], C. Bizon[3], D. Young[3], D. Gillis[3], P. Owen[3], K. Wilhelmsen[1], K.E. Weck[1,4], S. Garg[5], J.P. Evans[1], J.S. Berg[1].* 1) Dept Genetics, Univ North Carolina, Chapel Hill, NC; 2) Greenwood Genetic Center, Greenwood, SC; 3) Renaissance Computing Institute, Chapel Hill, NC; 4) Dept Pathology and Laboratory Medicine, Univ North Carolina, Chapel Hill, NC; 5) Dept Ophthalmology, Univ North Carolina, Chapel Hill, NC.

Whole exome sequencing (WES) is a valuable tool in determining the molecular etiology for retinal disorders given their genetic heterogeneity. We performed WES in 45 patients with various retinal disorders. Two patients with simplex Stargardt disease (SD; [MIM 248200]) harbored one pathogenic variant in ABCA4 and one pathogenic variant in a second retinal disease gene (CNGB3 or GUCA1A) suggesting the possibility of digenic inheritance. Digenic inheritance has been reported in other retinal disorders, but not in SD. Approximately one-third of simplex cases have only one identifiable mutation in ABCA4; digenic inheritance may explain a subset of these cases and would be supported by finding an excess of mutations in other retinal disease genes in such patients. We evaluated the frequency of double carrier status for ABCA4 and another retinal disease gene in the general population by searching for carriers of ABCA4 pathogenic variants in WES datasets not enriched for retinal disorders (1,189 individuals). ABCA4 variants previously reported as pathogenic, or rare (<1% minor allele frequency) and possibly damaging (missense, nonsense, frameshifting indels, canonical splice site), were selected for further analysis. Pathogenicity was assessed by allele frequency, conservation data, in silico modeling and cosegregation data. For the 40 (3%) ABCA4 carriers identified, we analyzed 448 variants within 213 genes associated with retinal disorders. No individual had two pathogenic ABCA4 variants. One of 8 variants of possible pathogenicity was identified in 9 ABCA4 carriers within PDE6A, EYS, ALMS1, USH2A, BBS9, BBS10, ABCC6 or NR2E3; two individuals harbored the same variant previously reported as a pathogenic mutation in the NR2E3 gene. However, no carrier had a known pathogenic variant in other genes associated with SD, including PROM1, PRPH2, ELOVL4 and CNGB3, or GUCA1A. The finding of 2 heterozygous variants associated with SD among 45 patients with retinal disorders is significantly enriched compared to population controls (Fisher’s exact test, P=0.0013). Our preliminary analysis suggests that double carrier status for ABCA4 and another SD disease gene is rare in the general population, supporting the possibility that double heterozygous mutations in two SD genes could be causative for SD. WES datasets are an effective method to evaluate heterogeneous disorders for the presence of double carrier status as a means to test the hypothesis of digenic inheritance.

Efficiency of exome sequencing for the molecular diagnosis of Pseudoxanthoma Elasticum. *M.j. Hosen[1], F. Van Nieuwerburgh[2], D. Deforce[2], L. Martin[3], G. Lefteriotis[4], A. De Paepe[1], P.J. Coucke[1], O.M. Vanakker[1].* 1) Centre for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Department of Pharmaceutics, Laboratory of Pharmaceutical Biotechnology, Ghent University, Ghent, Belgium; 3) Department of Dermatology, Angers University Hospital, Angers, France; 4) Department of Vascular Physiology and Sports Medicine, Angers University, Angers, France.

The molecular etiology of pseudoxanthoma elasticum (PXE), an autosomal recessive connective tissue disorder, has become increasingly complex as not only mutations in ABCC6 but also ENPP1 and GGCX can cause resembling phenotypes. Identification of modifier genes, such as VEGFA, has further contributed to the molecular heterogeneity of PXE. In such heterogeneous diseases, Next Generation Sequencing allows to perform mutation screening of several genes in a single reaction. We explored whole exome sequencing (WES) as an efficient diagnostic tool to identify the causal mutations in ABCC6, GGCX, ENPP1 and VKORC1, in 16 PXE patients. WES identified the causal mutation in 27 of 32 alleles (ABCC6 or GGCX, with no causal mutations in ENPP1 or VKORC1). Exomes with insufficient reads (≤20 depth) and patients with no or single mutations were further evaluated by Sanger sequencing (SS) and MLPA, but no additional mutations were found. The potential of WES is to explore multiple genes at a time, the ease to update target genes and the opportunity to search for novel genes when targeted analysis is negative. Together with low cost, rapid and less laborious workflow, we conclude that WES complemented with SS can provide a tiered approach to molecular diagnostics of PXE.

1552M

Unraveling Genetic Architectures Spanning Mendelian and Complex Phenotypes with Data Driven Electronic Medical Record Validation. *B.S. Glicksberg[1,2], L. Li[1], R.Z. Castellanos[1], J. Hakenberg[1], W. Cheng[1], S. Khader[1], M. Ma[1], L. Shi[1], H. Shah[1], J.T. Dudley[1,3], R. Chen[1].* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Health Evidence and Policy, Icahn School of Medicine at Mount Sinai, New York, NY.

While Mendelian and complex phenotypes are traditionally organized into distinct categories, emerging studies suggest there may be pervasive shared genetic connections within and across these categories. To further explore this intriguing relationship, we have compiled and analyzed a comprehensive, integrated knowledgebase comprised of known published mutation-gene-phenotype relationship representing over 2,500 Mendelian phenotypes with around 4,000 unique variant-associated genes collected from the Online Mendelian Inheritance in Man (OMIM) and Human Gene Mutation Database (HGMD) online sources. Additionally, we compiled genetic disease associations for >700 complex phenotypes and >3,500 variant-associated genes from the open Genome-Wide Association Studies (GWAS) Catalog as well as a proprietary database ActiVar which provided additional GWAS findings from manual curation of ~13,000 publications. We performed a statistical analysis based on the Term Frequency-Inverse Document Frequency (TF-IDF) and Cosine similarity method to test for enrichment between Mendelian and complex diseases based on shared genetic associations. This analysis identified 1,116 significantly enriched Mendelian-complex disease pairs at q-value < 0.05 and 609 enriched pairs at q-value < 0.01. We further evaluate these novel Mendelian-complex disease pair enrichments by analyzing disease co-morbidities across Electronic Medical Records (EMR) for 3.5 million unique patients comprising more than 2 billion clinical encounters in the Mount Sinai Electronic Medical Record Warehouse (MSDW). Of the genetically enriched pairs (q<0.01), we found 23 that were also significantly enriched in the MSDW using a Bonferroni corrected Fisher's Exact test (p<0.0001). There were 25 Mendelian phenotypes hubs and 44 complex disease hubs that had 10 or more significantly enriched connections. These results from our analyses have been incorporated into a comprehensive phenotype network for visualization and exploration. Furthermore, borrowing information from these phenomic cross connections, new insights can be extracted regarding inheritance patterns of complex diseases as well as candidate modifier genes in Mendelian phenotypes. Additionally, these connections can inform clinical aspects of these phenotypes utilizing data from the MSDW validation: phenotypes in a validated pair can be used as a diagnostic marker of risk, symptom alteration, and prediction.

1553T

Integration of GWAS signals, measures of polymorphic structure and linkage disequilibrium to discover clinically relevant biomarkers and improve identification of causal variants. *M.W. Lutz[1], R. Saul[2], O. Chiba-Falek[1], D.K. Burns[3], A.M. Saunders[1], A.D. Roses[1,3].* 1) Department of Neurology, Duke University School of Medicine, Durham, NC; 2) Polymorphic DNA Technologies, Alameda, CA; 3) Zinfandel Pharmaceuticals, Inc., Durham, NC.

Variants in non-coding RNA, epigenetic regulators, introns, promoters, and distal regulatory elements are associated with a variety of complex phenotypes including longevity and neurodegenerative diseases. We have also shown that small insertion/deletion polymorphisms within noncoding regions of the gene *TOMM40* are associated with tissue-specific modulation of *APOE* and *TOMM40* gene expression, a mechanism presumably underlying their contribution to genetic susceptibility to late-onset Alzheimer's disease (LOAD). These variants were identified through phylogenetic analysis and consideration of linkage disequilibrium (LD) for a 10 kb genomic region on chr 19 that consistently showed a strong genome-wide association (GWA) signal for LOAD. Here, we present a genome-scale implementation of an approach that integrates GWAS signals with measures evaluating the polymorphic potential of genetic variants (small insertion/deletion polymorphisms, structural variants). The approach utilizes bioinformatics methods, i.e., preferential LD (Zhu Q., 2012) and localization of a minimal region containing a causal variant (Bochdanovits Z., 2013), to identify potential causal regulatory variants. We employed this approach for examining the association of 20 contiguous genes on chr 19 (spanning 1.4 Mb) with longevity and LOAD using the AD Neuroimaging Initiative (ADNI) database and a dataset from a study on longevity (Sebastiani P., 2012). The two methods identified 88-Kb and 300-Kb regions likely to contain causal variants. In addition to the strong GWAS signal for this region, genomic structural features suggest possible inter-relatedness of genes and variants in this region. 209 variants were identified and scored with respect to their likelihood of being highly significant. An unusual strand alignment in this region, unlikely to occur by chance, involves 15 consecutive genes (PVR through CLASP) all located on the + strand. Our findings have a biological significance; co-regulation of APOE expression by variants located in the *TOMM40* gene has been reported and four neighboring genes in the cluster (*APOE*, *APOC1*, *APOC4* and *APOC2*) belong to a gene family and exhibit similar biological function. Application of the general approach has the potential to elucidate the biochemical basis for disease-gene associations, identify genetic biomarkers for clinical application, and enrich the analysis of biochemical pathways.

1554S

The Utah Genome Project is successfully discovering and diagnosing genetic disease using VAAST, pVAAST and Phevor. *M.V. Singleton[1], B. Kennedy[1], Z. Kronenberg[1], M.G. Reese[3], M. Yandell[1,2].* 1) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT 84112, USA; 2) Utah Science, Technology, and Research Center for Genetic Discovery, University of Utah, Salt Lake City, UT 84112, USA; 3) Omicia Inc., 1625 Clay Street, Oakland, CA 94612, USA.

The Utah Genome Project (UGP) is a large-scale, intramural genome-sequencing project, the aim of which is to discover new disease-causing genes and diagnose inherited diseases. What sets the UGP apart from similar projects is its variant interpretation and diagnostic pipeline that includes innovative bioinformatics tools, including VAAST, pVAAST and Phevor. VAAST and pVAAST are probabilistic disease-gene finders capable of prioritizing every variant and gene in the human genome. Single affected and case control cohorts are analyzed using VAAST while pVAAST adds linkage information for additional power in large pedigrees. Successful molecular diagnosis using an exome or genome sequence hinges on accurate association of damaging variants to the patient's phenotype. Unfortunately, many clinical scenarios (e.g. single affected or small nuclear families) have little power to confidently identify damaging alleles using sequence data alone. Today's variant interpretation tools are simply underpowered for accurate diagnosis in these situations, limiting successful diagnoses. Phevor alleviates this lack of power by dynamically incorporating the patient's phenotype into the disease-gene search. Phevor works by expanding known phenotype associations using knowledge resident in biomedical ontologies, like the Human Phenotype and Gene Ontologies, and combines those results with the VAAST/pVAAST outputs. Phevor accurately reprioritize candidates identified by VAAST/pVAAST in light of knowledge found in the ontologies. Phevor is not limited to a fixed set of genes or phenotypes. This enables Phevor to improve diagnostic accuracy for established diseases and previously un-described or atypical phenotypes. The UGP pipeline, including Phevor, has been successfully applied to several clinical cases. The UGP provides successful diagnosis of genetic disease for those with known and novel disease-alleles, novel disease-genes, atypical phenotype presentation and family specific mutations discovered in large pedigrees. Presented are several clinical cases where the UGP provided a molecular diagnosis where the common technique (filtering and querying disease databases) failed. Free from the limitations imposed by disease databases, the UGP analysis pipeline promises to improve diagnostic rates for inherited disease.

1555M

GWAS analysis of epigenetic age acceleration. *A. Lu[1], R. Ophoff[1,3,4], K. Eijk[4], J. Bell[5], I. Erte[5], P. Tsai[5], T. Spector[5], K. Hao[6], S. Dracheva[7], S. Horvath[1,2].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Biostatistics, UCLA, Los Angeles, CA; 3) Center for Neurobehavioral Genetics, Department of Psychiatry, UCLA, Los Angeles, CA; 4) Rudolf Magnus Institute of Neuroscience, Department of Genetics, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Department of Twin Research and Genetic Epidemiology, King's College London, United Kingdom; 6) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine; 7) Department of Psychiatry, Mount Sinai School of Medicine.

Recent articles describe methods for estimating the age of a tissue sample based on DNA methylation levels. By contrasting estimated age, referred to as DNAm age, with chronological age, one can arrive at a measure of age acceleration. Age acceleration is highly heritable (estimated to be around 40%). Age acceleration is a quantitative measure that can be used in a QTL analysis to identify SNPs. Here we report the findings of a large meta-analysis involving over a dozen data sets comprised of both DNA methylation and SNP data. Imputation was performed for each study using 1000 Genome reference panels newly released in December 2013. This yields ~7 M reliable markers with common variants, minor allele frequency (MAF) >0.05 in at least one study, available for association analysis. A genome-wide QTL analysis was performed in each dataset. We used a meta-analysis to aggregate the results from the different data sets identifying 34 SNPs (1 called and 33 imputed) in 8 genes. The imputed markers passed stringent quality controls (genotype information measure > 0.74 and mean MAF = 0.16). When we restricted the analysis to participants who are younger than 70, we found 5 more SNPs in two additional genes. Overall, our results demonstrate that epigenetic age acceleration is under strong genetic control.

Differentially Expressed Genes in Asthma Differ by Tissue-type. *T.B. Mersha[1], E. Geh[2], D. Ghosh[2], J.A. Bernstein[2], G.K.K. Hershey[1].* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Internal Medicine, University of Cincinnati, OH.

Several studies have identified differentially expressed genes (DEGs) between healthy versus asthmatic patients using microarray technology. This approach, however, have led to considerable variation in the lists of genes generated by various groups due to variation from random noise to biological samples. There are two objectives of this study a) conduct a comprehensive cell-type specific expression profiling analysis in order to identify the target genes, pathways and networks that are enriched in each cell or tissue-type, b) develop cell and tissue-type specific predictions models. Based on cell/tissue origin, a total of 400 samples and 22,590 DEGs were divided into bronchial epithelia (BEC), nasal epithelia (NEC), bronchial biopsy (BB), nasal biopsy (NB), alveolar macrophages (AM), lymphocytes (CD) and lung fibroblasts (FIB). Multivariate analysis of heatmaps of DEGs from similar cells shows a clear separation between asthmatics and controls. Moreover, DEGs from various tissue-specific datasets share more commonality at the pathway level than at the gene level as reflected by Jaccard similarity index of 0.65 between BEC and NEC. These results also highlight the importance of a cell-type based approach when analyzing multiple gene expression data. Our study identified novel asthma-related genes and pathways as future therapeutic targets and prediction models.

Smoking-related microRNAs and mRNAs in human peripheral blood mononuclear cells. *M.W. Su[1,3], K.Y. Tung[1], S.L. Yu[2], C.H. Tsai[1], Y.F. Wu[1], Y.J. Lai[3], C.H. Liu[3], Y.L. Lee[1,3].* 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Department of Clinical Laboratory Sciences and Medical Biotechnology, National Taiwan University College of Medicine, Taipei 100, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Teenager smoking is of great importance in public health which may increase the incidence of asthma and allergy. Tobacco smoke would be sensed by monocytes as an injurious stimulus and induced the expression change of genes associated with immune, and inflammatory. However, the regulatory mechanisms and the benefits of smoking reduction in alteration of immunotoxicological system remained poorly understood. In 2011, we conducted the Teenager Smoking Reduction Trial (TSRT), which was a community-based trial aiming to evaluate the effectiveness of smoking reduction in teenagers, to examine the causal relationship between smoking reduction and alterations in immunotoxicological system. A total of 100 teenagers with active smoking habits were recruited and 12 teenagers who reported a substantial reduction in smoke quantity and an decrease in cotinine/creatinine ratio were included in genomic analyses. We examined the whole genome mRNA expression in peripheral blood mononuclear cells (PBMC). A total of 292 genes with a false discovery rate adjusted p-value < 0.01 were deemed to be differentially expressed in TSRT. The Gene Ontology biological process annotations based on Gene Set Enrichment Analysis was conducted on the 292 differentially expressed genes. The smoking reduction induced expression changes mainly involved in the signal transduction. We found *BCL3*, *TNF*, *RHOB*, *BCL6*, and *NLRP3* were important genes in regulation of multiple biological processes after smoking reduction. We increased the gene expression fold changes cut-offs >1.5 to depict the regulatory pathways by Ingenuity Pathway Analysis. The primary regulatory pathways characterized to be differentially regulated in PBMC after smoking reduction were "Glucocorticoid Receptor Signaling", "Differential Regulation of Cytokine Production in Intestinal Epithelial Cells by IL-17A and IL-17F", "IL-6 Signaling", "TNFR2 Signaling", and "Communication between Innate and Adaptive Immune Cells". Integrated analyses of microRNA and mRNA expression further identified eleven differentially expressed microRNAs negatively correlated with their predicted target genes ($p<0.05$). Among the eleven microRNAs, CD83 molecule was regulated by mir-4498, which was critical for the communication between innate and adaptive immune cells and played an important role in regulation of immunotoxicological system of allergy. Real-time PCR confirmation and functional validation of miR-4498 and CD83 molecule were undergoing.

The mitochondrial mutational landscape of human cancer and its impact on tissue- and tumor-specific gene expression. *S. Grandhi, N. Dhami, C. Bosworth, T. Laframboise.* Department of Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH.

Unlike that of the nuclear genome, the regulatory landscape of the mitochondrial genome remains largely uncharacterized, particularly in the context of cancer. In contrast to normal cells, which rely primarily on mitochondrial oxidative phosphorylation for energy production, cancer cells instead rely heavily on aerobic glycolysis, even in the presence of oxygen. Although there is an accumulation of somatic mitochondrial DNA (mtDNA) mutations in cancer, the impact of these mutations on the role of mitochondria in reprogramming cancer cell bioenergetics is unclear. Even in the context of normal cells, mitochondria are highly sensitive to their cellular environment: heart, muscle, kidney, and liver cells have higher mitochondrial gene expression levels than lung, adrenal, and thyroid cells, likely in response to tissue-specific energy demands.

Here we investigate the role of the mitochondrial genome in tumor cell bioenergetics while addressing tissue specificity. To achieve this, we mine publicly-available next-generation sequencing (NGS) data across 15 cancer types from the Cancer Genome Atlas (TCGA), the Cancer Cell Line Encyclopedia (CCLE), and the Encyclopedia of DNA Elements (ENCODE). Using these datasets, we survey mitochondrial DNA mutational patterns, mRNA expression levels, and mtDNA transcription factor occupancy.

Our analysis of TCGA RNA-sequencing data from approximately 1,800 cancer patients suggests that mitochondrial-encoded gene expression is significantly dysregulated in cancer cells and also clusters distinctly based on the tumor's tissue of origin. Additionally, we observe that patterns of differential gene expression in tumor as compared to matched normal samples vary across tumor types. To interrogate potential mechanisms underlying these gene expression patterns, we integrate them with mtDNA copy number, mtDNA mutations, and mtDNA-binding transcription factors, while addressing the overall somatic mutation frequency in mtDNA across cancer types.

This pan-cancer query of the mitochondrial regulatory landscape distinguishes tumor- and tissue-specific mitochondrial aberrations on the DNA and RNA levels by integrating multiple NGS platforms from disparate sources and analyzing them in tandem.

Somatic Mutation Detection by Whole Exome Sequencing in Patients with Adult-onset Still's Disease. *Z. Deng, C. Jeon, A. Almeida de Jesus, M. Ombrello, R. Goldbach-Mansky.* Intramural Research Program, NIAMS, National Institute of Health, Bethesda, MD.

Adult-onset Still's disease (AOSD) is a severe, inflammatory disease that is characterized by high, spiking fever, arthritis, a characteristic skin rash and increased acute phase reactants. The molecular mechanism underlying AOSD is unknown, but given its apparent lack of heritability, we hypothesize that somatic mutations or mosaicism may contribute to its pathogenesis. To investigate whether somatic mutations play a role in AOSD, we have sequenced matched tissues (whole blood, fibroblasts and monocytes) from 5 patients. Using fibroblasts as the control tissue to determine germline variation, we test the hypothesis that monocytes or another cell population in whole blood might harbor somatic mutations that contribute to the disease. Whole exome sequencing was performed by a sequencing service provider (Otogenetics) using Agilent SureSelect V5 (51Mb) capture and Illumina HiSeq instruments. The average coverage of each sample is about 60X with greater than 95% of the exome having at least 10X coverage. Four different computational methods have been utilized for detection of somatic mutations: BWA-PICARD-GATK, MuTect, VarScan2 and Diamund. While the first three tools require BAM files generated by aligning sequence reads to the reference genome, Diamund directly compares the reads and thus doesn't require the reference genome for variant detection. The number of potential somatic mutations called by each method ranges from fewer than 100 to over 1,000 per matched pair. Among the methods used, Diamund reports the most candidate somatic mutations, while muTect identifies the least. The results generally don't overlap between the different methods and are comprised of mostly low quality variants, suggesting that most of the somatic calls are likely to be false positives. This observation is consistent with the 0.5% to 5% discordant rates observed between technical replicates and the assumed low mutation rates in the affected tissues. The few mutations called by more than one method are being evaluated and could provide important clues on the molecular etiology of AOSD.

1560S

Weighted gene co-expression network analysis suggests white matter might play a role in epilepsy and episodic motor disorders. *L. Silveira-Moriyama[1, 2,3,4], M. Ryten[4,5], P. Forabosco[6], C. Bettencourt[4], A.J. Lees[1,2], H. Houlden[4], J. Hardy[1,4], T. Warner[1,2,4], UK Brain Expression Consortium.* 1) Reta Lila Weston Institute, UCL Institute of Neurology, London, London, United Kingdom; 2) Queen Square Brain Bank for Neurological Studies, London, UK; 3) Neurology Department, University of Campinas, Campinas, Brazil; 4) Department of Molecular Neuroscience, UCL Institute of Neurology, London, UK; 5) Department of Medical and Molecular Genetics, King's College London, London, UK; 6) Istituto di Ricerca Genetica e Biomedica CNR, Cagliari, Italy.

PURPOSE: There is a significant phenotypic overlap of genes causing epilepsy and episodic motor phenomena (such as episodic dyskinesia, episodic ataxia and episodic hemiplegia). We used genome-wide gene expression (GWGE) data to study co-expression of these genes. METHODS: GWGE data generated from 788 samples of 101 adult control human brains (10 distinct brain regions each) was collected as part of the UK Human Brain Expression Consortium (UKBEC). Weighted gene co-expression network analysis was used to group all expressed genes into modules in an unsupervised manner. Target genes were: "episodic" genes (ATP1A2, SCN1A, SLC1A3, ATP1A3, KCNMA1, CACNB4, CACNA1A, KCNA1, GCH1, SLC2A1, PNKD and PRRT2) and "epilepsy" genes (PRRT2, ARX, CDKL5, CHRNA2, CHRNB2, GABRG2, GABRA1, KCNQ2, KCNQ3, LGI1, PCDH19, SCN1A, SCN1B, SCN2A, STXBP1, NDE1, TBC1D24, GOSR2, AFG3L2, GRN, KCNT1,CHRNA4, PLCB1, and SLC2A1). The overrepresentation of each group in modules was assessed using chi-squared tests with Yates correction. Gene ontology (GO) and KEGG pathway enrichment analysis (with Bonferroni correction) was performed. RESULTS: Episodic genes highlighted a single white matter gene co-expression module (blue module), which was enriched for such transcripts (8/12 genes, 13/17 transcripts, $p<0.0001$) and for epilepsy transcripts (18/23 genes, 20/26 transcripts, $p<0.0001$). This module was enriched for synaptic transmission (p-value = 4.02 x 10-44) and more specifically the glutamate signalling pathway (p-value = 4.89 x 10-6) and others. It was also enriched for a number of KEGG pathways including the long term potentiation (p-value = 7.47 x 10-8) and axon guidance (p-value = 1.17 x 10-7). Of the 60 top genes in this module (module membership 0.9 or higher) 12 are known to cause human disease. Of these, eight cause epilepsy (SCN8A, ARHGEF9, GABRB3, GRIN2B, SCN2A, SYN1, GLRB and GABRG2). CONCLUSION: Our data reinforces the link between epilepsy and episodic disorders, and the notion that PRRT2 and PNKD - relatively unknown genes - relate to synaptic transmission. It suggests that white matter might play a role in these disorders. The main caveat of the finding is that globally genes in the blue module have lower expression in the white matter than in other brain regions. Further studies are warranted to understand these findings at depth including replication of the clustering in an independent data set and in-situ studies of gene expression in the various white matter cell types.

Novel intergenic large non-coding RNAs (lincRNA) in Human Retina and RPE/Choroid. *L. Tian[1], A. Bowman[2], Y. Liu[1], C. Curcio[3], H. Hakonarson[1], M. Li[4], D. Stambolian[2].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pa. 19104. USA; 2) Department of Ophthalmology, University of Pennsylvania, Philadelphia, Pa. 19104. USA; 3) 4. Department of Ophthalmology, University of Alabama School of Medicine, Birmingham, Al. 35294. USA; 4) 3. Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, Pa. 19104. USA.

Large intergenic non-coding RNAs (lincRNAs) are emerging as key regulators of diverse cellular processes. Recent advances in RNA sequencing (RNA-Seq) and computational methods allow for a comprehensive analysis of lincRNAs. There have been no comprehensive studies involving the presence and role of lincRNA in the eye tissues and eye related pathologies till date. To build a comprehensive catalogue of novel lincRNAs expressed in eye, we performed RNA-Seq on eight human post-mortem eyes and generated a comprehensive set of data for both region-based (macular versus peripheral retina) and tissue-based (retina versus RPE/choroid) studies. We have processed RNA-seq data and identified ~2000 potential novel lincRNAs per sample which are not present in the catalog of the Human Body Map lincRNAs. Briefly, we first assemble the transcripts using Cufflinks and Scripture. To differentiate true lincRNA transcripts from assembly artifacts, we use the software Sebnif, which implements a series of filtering steps such as filters of transcript length, expression level and coding potential. Each lincRNA has been annotated with genomic features around its promoter and gene body, such as 36 of histone H3 (H3K4me3, and H3K36me3), Expressed Sequence Tag (EST) and Cap Analysis of Gene Expression (CAGE) tags. We also looked for colocalization and coexpression of the novel lincRNAs with known AMD GWAS hits to identify possible links between lincRNA and AMD genes.

Gene variant modification in keratinocyte cell samples irradiated by UV using RNA-seq. *V. Mijatovic[1], C. Patuzzo[1], G. Buson[2], A. Dal Molin[1], A. Mori[1], E. Caviola[3], M. Delledonne[2], P. Pertile[3], P.F. Pignatti[1], G. Malerba[1].* 1) Dep. of Life and Reproductions Sciences, University of Verona, Verona, Verona, Italy; 2) Department of Biotechnology, University of Verona, Verona, Italy; 3) Cutech Srl, Padova, Italy.

Currently the levels of gene expression can be estimated at the genomic level using the high throughput sequencing platforms. Therefore it is theoretically possible to identify genetic variants present in most expressed genes. Over-exposure to ultraviolet (UV) radiation is important environmental risk factor related to skin cancer development. We studied keratinocyte cell samples irradiated by 2 different dosages of UV rays (250 e 500 mJ/cm2) to investigate if UV irradiation might modify the sequence of some gene transcripts, reflecting changes on DNA sequence, and if such modifications might be detected in RNA-seq experiments. We started focusing our attention on heterozygous single-nucleotide polymorphisms (SNPs) and alternative-allele homozygous SNPs. This study was performed on two human keratinocyte cell samples. Both samples were divided into three plates. The first plate did not undergo UV treatment, while the other two plates were treated with 250 and 500 mJ/cm2, respectively. Afterwards they were sequenced with Illumina Hi-seq 1000, producing from 23 to 45 million reads (depending on the sample), and aligned to the reference genome GRCh37.74 with GSNAP software. The variant calls were performed with Samtools software. The analysis were performed on variants called by at least 10 reads. The preliminary results on heterozygous SNPs detected 3 loci with different variation calls at the following positions: chr12:52841320 (KRT6B gene, after the treatment with 250 mJ/cm2), chr12:52745931 (KRT6B gene, after the treatment with 500 mJ/cm2) and chr3:195694460 (SDHAP1 pseudogene, after the treatment with 250 mJ/cm2). The first two loci were detected in the first sample whereas the variant at chr3:195694460 was detected in the second sample. The nucleotide at chr12:52841320 is located in the splicing site of the KRT6B gene and it resulted to be conserved in vertebrates while nucleotide at chr12:52745931 is in a non coding, not conserved KRT6B region. The nucleotide at chr3:195694460 resulted to be not conserved across vertebrates. In conclusion we used very stringent conditions to call genotypes from mRNA transcripts and preliminary results suggest the possibility to employ successfully RNA-seq for variant call detection. We plan to study in more detail the effects of UV radiations on keratinocyte cell samples extending the analysis on the entire spectrum of detectable variations that might be then validated by independent technologies.

TRRUST: A reference database of human transcriptional regulatory network. *H. Han, H. Shim, D. Shin, J. Shim, Y. Ko, J. Shin, H. Kim, E. Kim, T. Lee, H. Kim, K. Kim, C. Kim, S. Shin, I. Lee.* Biotechnology, Yonsei University, Seoul, South Korea.

Transcriptional regulatory networks (TRNs) that represent regulatory relationship from transcriptional factors (TFs) to target genes are important resources to study genetic regulatory programs for complex phenotypes in higher organisms including human. While many human TRNs inferred from various large-scale experiments are publicly available, only few reference databases for human TRNs have been published. Here we present an extensive database of human reference transcriptional regulatory network, TRRUST (Transcriptional Regulatory Relationships Unraveled by Sentence-based Text-mining), which contains 5,460 regulatory relationships between 646 TFs and 1,823 target genes identified by manual curation of 18,446 relevant sentences extracted from more than 15,000 abstracts. To collect the relevant sentences, which might contain information about human transcriptional regulation, we scan more than 20 million Pubmed abstracts for a set of key words implying human transcriptional regulation. TRRUST is the largest reference database for TF-target links based on literature curation to date to our best knowledge. TRRUST provide disease & biological process ontology terms that are enriched with target gene sets of TFs. Also we constructed a network of TF cooperativity, which might be useful to study co-regulatory complex. TRRUST will provide a reference database of TF-target relationships for validation of large-scale mapping of TF-target links and learning new TF-target links from biological data mining. TRRUST data is freely available at http://www.inetbio.org/trrust.

1564M

MokaSeq: Initial validation of the sequence analysis module of an NGS software platform for clinical diagnostics. *J.W. Ahn[1], N. Chandler[2], N. Parkin[2], M.A. Simpson[3], S.C. Yau[2], C. Mackie Ogilvie[1], K.J.P. Ryan[2].* 1) Genetics, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; 2) Genetics, Viapath, London SE1 9RT, United Kingdom; 3) Division of Genetics and Molecular Medicine, Kings College London, London SE1 9RT, United Kingdom.

Guy's and St Thomas' NHS Foundation Trust and Viapath represent a centre of excellence in clinical genetics, servicing the South East Thames region population of ~6 million. We currently offer NGS-based testing for a number of heterogeneous genetic disorders. For each of these tests, DNA libraries are prepared targeting specific genes using custom Agilent SureSelect kits and sequenced on the Illumina MiSeq and HiSeq systems. As part of the newly formed bioinformatics core within Viapath, we are developing a bespoke NGS software platform (Moka) to perform high quality analysis within a robust and scalable framework that can be adapted in line with diagnostic demands. The Moka platform will provide an end-to-end system from patient test request to diagnostic report, and will include components for LIMS, sequence analysis, a variant database, variant interpretation, and cross-referencing/auditing our resulting data. Moka's sequence analysis module (MokaSeq) uses the Novoalign aligner alongside Picard Tools to carry out BAM file processing, and Samtools for variant calling of SNVs and small indels. Variants not relating to the regions of interest specified by our library panels are filtered out with Vcftools and the remaining variants are then annotated using Annovar, and a compendium of variant attribute repositories. CNV detection is performed using the R package ExomeDepth. Here we report findings from our initial validation of the sequence analysis module; this validation investigated the efficacy of detecting SNVs and CNVs previously identified by NGS and confirmed by Sanger sequencing/MLPA. To date, Moka has shown robust detection of all Sanger confirmed SNVs (n= 114) at a coverage of 30x or greater. Similarly all previously confirmed CNVs have also been detected, albeit from high coverage data (~6000x). Downsampling BAM files from CNV-containing samples by a factor of 5, 10, 50 and 100 to simulate coverage depths of 1200x, 600x, 120x and 60x respectively did not affect the capacity to detect any of the CNVs. However, reduction in coverage to 120x and 60x did result in the detection of a number of spurious false positives.

1565T

Combining callers across different sequence contexts improves somatic SNV detection. *K. Arora[1], E. Grabowska[1], R. Darnell[1,2,3], T. Bloom[1], V. Vacic[1].* 1) New York Genome Center, New York, NY; 2) Howard Hughes Medical Institute, New York, NY; 3) The Rockefeller University, New York, NY.

Somatic single nucleotide variants (SNVs) are the most frequent class of driver mutations in majority of common cancer types and consequently the most studied group of somatic alterations. Although SNVs are comparatively easy to detect using sequencing technologies, initial comparisons showed a poor overlap between callsets and necessitated development of ad hoc filters, extensive manual curation and validation of called variants, and motivated ongoing development of better methods for somatic variant calls. Despite considerable improvements over the initial algorithms, calling SNVs from whole genome tumor-normal pairs remains an open problem, aggravated by the issues of tumor purity and clonality, and difficulties in distinguishing between true low frequency mutations and sequencing errors. We conducted a systematic analysis of eight popular SNV callers using synthetic datasets as well as whole genome, exome and validation data from the TCGA glioblastoma, acute myeloid leukemia and thyroid carcinoma projects, with the goal of finding the best combination of callers to be included in our pipelines. Based on data from the Platinum Genomes resource that included a trio sequenced to 200x depth and exomes sequenced in house, we combined random lanes of a single sample into mock tumor and matched normal pairs and analyzed false positive calls. In our experiments different callers returned between 900 and 60,000 false calls per genome pair, indicating a lower bound of specificity in SNV calling. In order to estimate sensitivity, we followed the previously described "virtual tumor" approach where a synthetic tumor is generated by swapping reads between two germline samples at sites known to have discordant genotypes. Having a controlled ground truth dataset, built around a systematic grid of variant allele frequencies and read depths, allowed us examine type I and II errors across the genome as well as within local sequence and technical covariates contexts. Most somatic calls have poor calling rates on the extremes of the variant allele frequency spectrum; the same is true of the variant scores range. The analysis of local contexts of SNV calls points to differences in calling errors across different methods. This suggests a conditional combination method for calling SNVs, which in our preliminary experiments improved both sensitivity and specificity of calling SNVs, an important first step towards understanding the mechanisms leading to oncogenesis.

Functional interpretation of variant and non-variant positions in whole-exome sequencing data. *M. Delledonne[1,2], M. Garonzi[1], F. Griggio[1], C. Centomo[1], L. Xumerle[1], L. Venturini[1], A. Minio[1], A. Dal Molin[1], G. Martinelli[3], I. Iacobucci[3], B. Salisbury[4], M. Harvey[4], M. McManus[4], E. Zago[2], A. Ferrarini[1].* 1) Department of Biotechnology, University of Verona, Verona, Italy; 2) Personal Genomics s.r.l., Verona, Italy; 3) Department of Hematology and Oncological Sciences 'L. and A. Seragnoli', Institute of Hematology L. and A. Seragnoli', University of Bologna, Bologna, Italy; 4) Knome Inc., Cambridge, MA, USA.

Hematological diseases are malignancies with an high etiologic heterogeneity. These diseases may also encompass considerable heterogeneity in risk and in response to therapeutic treatments among subsets of patients. Within the project "Next Generation Sequencing platform for targeted Personalized Therapy of Leukemia" (NGS-PTL; FP7 european grant) we are involved in the setup of a bioinformatic pipeline for the identification of sequence variants as leukemia disease markers and therapy response markers from the analysis of Next Generation Sequencing (NGS) data. Methods for the analysis of whole-genome and -exome data are currently based on detection of variant sequences by comparison of sequencing reads with the reference human genome which are then stored in the Variant Call Format (VCF). However, the reference sequence contains both common and rare disease risk variants, including rare susceptibility variants for acute lymphoblastic leukemia and the Factor V Leiden allele associated with hereditary thrombophilia (Chen et al. 2011). In fact, out of 16,400 variant positions associated with disease, more than 4,000 variants are represented in the reference genome by the minor allele (Dewey et al. 2011). This poses a seriuos limitation to a comprehensive evaluation and detection of markers related for example to response to drugs and treatments. To overcome this problem we are developing, in collaboration with Knome Inc., an integrated hardware-software platform for the annotation and interpration of variation in genomes/exomes. The platform uses the emerging genome Variant Call Format (gVCF) which allows to store the information of both variant and non-variant positions in the genome/exome. Analysis of patients affected by disease with the pipeline based on knome system (knoSYS 100) identified about 500 variants represented in the genome by a minor allele (MAF < 5%) per patient. These variants will be correlated with clinical data as they may represent important candidates as molecular markers of predisposing factors of disease and of response to drugs. Chen R, Butte AJ (2011) The reference human genome demonstrates high risk of type 1 diabetes and other disorders. Pac Symp Biocomput. pp 231- 242. Dewey, F. E., Chen, R., Cordero, S. P., Ormond, K. E., Caleshu, C., Karczewski, K. J., ... Ashley, E. a. (2011). Phased whole-genome genetic risk in a family quartet using a major allele reference sequence. PLoS Genetics, 7(9), e1002280.

Reducing INDEL errors in whole-genome and exome sequencing. *H. Fang[1,2], G. Narzisi[3], J.A. O'Rawe[1,2], Y. Wu[1,2], M.C. Schatz[3], G.J. Lyon[1,2].* 1) Stanley Institute for Cognitive Genomics, One Bungtown Road, Cold Spring Harbor Laboratory, NY, USA; 2) Stony Brook University, 100 Nicolls Rd, Stony Brook, NY, USA; 3) Simons Center for Quantitative Biology, One Bungtown Road, Cold Spring Harbor Laboratory, NY, USA, 11724.

Background: INDELs, especially those disrupting protein-coding regions of the genome, have been associated with human diseases. However, there are still many errors with INDEL variant calling, with these errors being driven by library preparation, sequencing biases, and algorithm artifacts. We have recently developed and reported a new INDEL-calling algorithm, Scalpel, with substantially improved accuracy. Results: We have analyzed simulation, whole genome sequencing (WGS), whole exome sequencing (WES), and PCR-free sequencing data from the same samples to investigate the properties of false-positive and false-negative INDEL errors. Simulation data show that Scalpel can achieve sensitivity of 90% at 30X mean coverage, while maintaining a reasonable false discovery rate (0.06%) for large INDELs. We developed a classification scheme for INDELs utilizing extensive high-depth sequencing validation data, and we show that low-quality INDELs have ~2.7-fold higher error rates than high-quality INDELs (32% vs. 12%). The mean concordance of INDEL detection between our WGS and WES data is ~52%, while WGS data uniquely identifies ~10.8-fold more high-quality INDELs, and WES data uniquely identifies ~1.9-fold more low-quality INDELs. INDELs called within both datasets are designated as "high confidence INDELs". Low-quality homopolymer A/T (Poly-A/T) INDELs are enriched in the WES-specific call set (82.6%), relative to the high confidence (44.2%) and WGS-specific call sets (45.1%). Concordance of INDEL detection between with-PCR and PCR-free data is ~71%, while PCR-free data uniquely yields ~4.4-fold more high-quality INDELs and with-PCR data uniquely yields ~6.3-fold more low-quality INDELs. We demonstrate that these types of INDEL errors are significantly reduced with a PCR-free library protocol, implying that these errors are introduced with PCR amplification. We have also calculated that ~95% of INDELs can be detected with 60X mean coverage WGS data using 2*100 bp reads from the Illumina HiSeq 2000 platform. Accurate detection of heterozygous INDELs naturally requires ~1.2-fold higher coverage relative to that required for homozygous INDELs. Conclusions: Homopolymer A/T INDELs are a major source of low quality INDELs and multiple signature events, and these are highly enriched in the WES data. We recommend WGS for human genomes at 60X mean coverage with PCR-free protocols, which can substantially improve the quality of personal genomes.

1568T

Single-nucleotide mosaicisms in whole-genome sequences of clinically unremarkable individuals. *Y. Huang[1], X. Xu[2], Y. Ye[3], Q. Wu[3], L. Yan[1], B. Zhao[3,4], X. Yang[3], Y. He[3], S. Wang[3], B. Gu[3], H. Zhao[1], M. Wang[1], H. Gao[1], G. Gao[1], Z. Zhang[2], X. Yang[2], X. Wu[2], Y. Zhang[2], L. Wei[1,3].* 1) Center for Bioinformatics, State Key Laboratory of Protein and Plant Gene Research, School of Life Sciences, Peking University, Beijing 100871, People's Republic of China; 2) Peking University First Hospital, Peking University, Beijing 100034, People's Republic of China; 3) National Institute of Biological Sciences, Beijing 102206, People's Republic of China; 4) Graduate School of Peking Union Medical College, Beijing 100730, People's Republic of China.

Postzygotic single-nucleotide mosaicisms (SNMs) have been studied in cancer and a few other overgrowth human disorders at whole-genome scale and found to play critical roles. However, in clinically unremarkable individuals, SNMs have never been identified at whole-genome scale largely due to technical difficulties and lack of matched control tissue samples, and thus the genome-wide characteristics of SNMs remain unknown. We developed a new Bayesian mosaic genotyper and a series of error filters, using which we were able to identify 17 SNM sites from whole-genome sequencing of peripheral-blood DNAs from three clinically unremarkable adults. The SNMs were thoroughly validated using pyrosequencing, Sanger sequencing of individual cloned fragments, and multiplex ligation-dependent probe amplification. In addition to peripheral-blood samples, the identified SNMs were also detected in the majority of other samples non-invasively obtained from the same donors, implying the whole-body presence of SNMs.

A Next-Gen Sequencing Software Workflow for Gene Panel Validation Control. *M. Keyser[1], J. Carville[1], T. Schwei[1], T. Durfee PhD[1], A. Pollack-Berti PhD[1], D. Nash[1], J. Stieren[1], S. Baldwin[1], R. Nelson PhD[1], K. Dullea[1], J. Schroeder[1], P. Pinkas PhD[1], G. Plunkett III PhD[1,2], F. Blattner PhD[1,2,3].* 1) DNASTAR, Inc., Madison, WI; 2) University of Wisconsin, Department of Genetics, Madison, Wisconsin, USA; 3) Scarab Genomics LLC, Madison, Wisconsin, USA.

DNASTAR offers an integrated suite of software for assembling and analyzing sequence data from all major next-generation sequencing platforms. DNASTAR software supports a variety of key workflows on a desktop computer. A new Gene Panel Validation Control workflow supports several types of data sets, including Ion Torrent AmpliSeq™ Comprehensive Cancer Panel, Illumina TruSight Cancer Panel, as well as custom gene panels and evaluates the efficacy of gene panel targeting and the accuracy of variant calling. The accuracy of gene panel targeting is determined by multiple factors, including specificity of primers and probes used for gene panel design, efficiency of the sequencing technology, accuracy of assembly, accuracy of SNP calling, and the SNP filters applied. DNASTAR's SeqMan NGen and ArrayStar programs provide an accurate alignment algorithm and variant caller. They then utilize a validated SNP set in the form of a VCF file and a BED or Manifest file that specify targeted regions, to calculate SNP-calling sensitivity, specificity, and accuracy. By utilizing this workflow, users can ultimately validate their entire process to verify that their known variants are being identified.

Whole Genome Sequencing of 30 Admixed Brazilians. *M. Machado[1], R. Moreira[1], A. Pereira[5], M. Barreto[2], B. Horta[3], M.F Lima-Costa[4], A. Horimoto[5], N. Esteban[5], M. Scliar[1], G. Soares-Souza[1], R. Zamudio[1], M. Santolalla[1], C. Zolini[1], F. Kehdy[1], M.R. Rodrigues[1], W. Magalhães[1], E. Tarazona-Santos[1], The Brazilian EPIGEN Consortium.* 1) Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Universidade Federal da Bahia, Brazil; 3) Universidade Federal de Pelotas, Brazil; 4) Fundação Oswaldo Cruz, Centro de Pesquiça René Rachou, MG, Brazil; 5) Instituto do Coração, Universidade de São Paulo, Brazil.

As part of the Epigen-Brazil Initiative on population genomics and genetic epidemiology, we resequenced the complete genome of 30 Brazilian admixed individuals randomly selected from each of three Brazilian population-based cohorts with different histories of admixture: Salvador from North East (n= 10), Bambuí from the South East (n=10) and Pelotas from Southern Brazil (n=10). Salvador has predominant African ancestry (51%), 43% of European and 6% of Native American ancestry. Bambuí and Pelotas are predominantly European (>76%), with 16% of African and 7-8% of Native American ancestry. Sequences were obtained by paired-end reads strategy using Illumina technology. On average, each genome was sequenced 42.7X, with 128 Gbases that successfully passed filter and aligned to the reference HumanNCBI37_UCSC genome, 82% of bases that showed a quality QScore>=30, 96% of Non-N reference bases with a coverage >=10X. Agreement with Illumina HumanOmni2.5 genotyping was 99.26 % and with HumanOmni5 was 99.53%. We identified 15,033,510 SNVs and 1,479,746 of these are new (not present in dbSNP nor in 1000Genomes databases on May 2014). Importantly, 989 of these have a non-reference allele frequency >0.50 in our sample of 60 haploid genomes. Most of SNVs were classified as intergenic (58.03%) or intronic (34.88%) variants, the remaining variants were classified in other functional categories. Considering only exonic SNPs, similar proportions of non-synonymous and synonymous SNPs were identified: 49.91% and 47.88% respectively, a result that matches other studies. By comparing the allele frequency spectra obtained by WGS with those from the Illumina HumanOmni2.5 on the same cohorts, we observed that for this array, rare SNPs are under-represented in the population with higher African ancestry (Salvador). Thus even if this array was inspired in a multiethnic database (1000Genomes) and enriched for rare alleles, a population-based bias persists. Finally, we observed 9,143 deleterious variants (CONDEL score > 0.51) and we are now analyzing how admixture and the demographic history of these populations affected the additive and recessive genetic load in the Brazilian sample. Funding: Brazilian Ministry of Health/FINEP.

IntSplice: A tool to predict aberrant splicing of an SNV at intronic positions -50 to -3. *K. Ohno, A. Shibata, T. Okuno, M.A. Rahman, Y. Azuma, A. Masuda.* Division of Neurogenetics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan.

Precise spatiotemporal regulation of splicing is mediated by splicing cis-elements on pre-mRNA. Single nucleotide variations (SNVs) affecting intronic cis-elements potentially compromise splicing, but no efficient tool has been available. First, we analyzed the effect size of each intronic nucleotide on alternative splicing events annotated in the ENSEMBL database. We found that nucleotides at intron -13 to -5 (Int-13:Int-5), Int-3, exon +1 (Ex+1), and Ex+2 were critical splicing determinants. We further extracted a total of 111 parameters that possibly dictated the strength of splicing signals. Second, we calculated percent-splice-in (PSI) at all 3' splice sites of 14 RNA-seq data of normal human tissues and generated support vector regression (SVR) models with the 111 parameters. However, the correlation efficiencies between the calculated and predicted PSI's were less than 0.3. Third, we generated support vector machine (SVM) models to directly differentiate pathogenic SNVs in the human gene mutation database (HGMD) and normal SNVs in dbSNP using the 111 parameters as well as PSI's predicted by the SVR models above. HGMD had 1,162 SNVs (mutations) at Int-50:Int-3. We randomly chose 1,162 SNVs among 63,605 SNVs in dbSNP. A total of 2,324 SNVs were randomly divided into five groups, and four were employed to generate a SVM model and the remaining one was used to validate the efficiency. We repeated the modeling and validation five times. The generated SVM models yielded sensitivities of 0.800 ± 0.041 (mean and SD) and specificities of 0.849 ± 0.021. We compared efficiencies of our models with PSSM and MaxEnt, and found that sensitivity as well as the sum of sensitivity and specificity of our models were better than those of PSSM and MaxEnt. We serially introduced "A" nucleotide at Int-11:Int-3 in RAPSN minigene, and introduced them in cultured cells. RT-PCR analysis revealed that three out of the nine mutants caused aberrant splicing. We found that these mutants lost binding to U2AF65. We tested these nine mutants with our IntSplice model and found that splicing consequences were properly predicted in eight mutants. We created a web service program, IntSplice (http://www.med.nagoya-u.ac.jp/neurogenetics/IntSplice) to predict pathogenic SNVs at Int-50:Int-3. We hope that IntSplice will disclose yet unidentified splicing mutations and unveil pathomechanisms of human diseases.

Next generation sequencing approach to molecular diagnosis of auto-inflammatory diseases: from gene panel design to variant call. *M. Rusmini[1], F. Caroli[1], A. Grossi[1], L. Tattini[2], A. Magi[3], R. Ravazzolo[1, 4], A. Martini[4,5], M. Gattorno[5], I. Ceccherini[1].* 1) U.O.C. Genetica Medica;Istituto G Gaslini, Genova, Genova, Italy; 2) Dipartimento di Neuroscienze, Psicologia, Area del Farmaco e Salute del Bambino, Ospedale Pediatrico Meyer, Firenze, Italy; 3) Dipartimento medicina sperimentale e clinica, Università degli Studi di Firenze, Firenze, Italy; 4) Dipartimento di Neuroscienze, Oftalmologia, Genetica e Materno Infantile (DINOGMI), Università di Genova, Genova, Italy; 5) Pediatria II, Reumatologia, Istituto G Gaslini, Genova, Italy.

Auto-Inflammatory Disorders (AIDs) are a heterogeneous group of monogenic diseases caused by primary dysfunction of the innate immune system. Previous diagnosis by Sanger sequencing performed on a restricted number of genes has resulted time and cost consuming in addition to fail in detecting mutations in around 86% of patients recruited to our Unit. Clinical misdiagnosis, mutations in untested gene regions, genetic heterogeneity are possible explanations. We thought the Next Generation Sequencing approach could be the solution. By using the Ion AmpliseqTM Designer (LifeTech) online tool, 203 amplicons were included in the screening panel, for a total of 121 exons and 22 Kb of target DNA. The design has been performed on 11 genes mainly involved on AIDs, as reported in the database for these disorders, the Infevers database. Ion PGMTM has been used for runs and the mean coverage has turned out to be 347X, with 92.5% of amplicons at > 20X and 79.5% at > 35X. The analysis from FastQ to VCFs was carried out using 3 different workflows: i) Ion Torrent Alignment and Ion Reporter™ 4.0, specific for data generated by PGM ii) in-house pipeline based on open source tools like BWA and GATK, iii) CLC Bio software. We first focused on a set of 50 DNA samples already genotyped for the respective causative genes with the intention of comparing the three pipelines of analysis and assessing their sensitivity and specificity. Variants detected in genes which were not analyzed before have been validated by Sanger sequencing and differences in the variant calls from the three pipelines investigated. Through our analysis we found that the in-house pipeline has returned the most reliable results, missing only two of the 65 expected variants. However, this approach detected 34% of false positives, compared to the Ion Reporter™ and CLC Workbench which called only 2.5% of false positive variants. Moreover, only 2 of the 77 unexpected allelic variants detected with all the three pipelines and sequenced by Sanger have not been validated. Genetic diagnosis of patients affected by one of the Auto-Inflammatory Diseases will become more accurate by using these NGS approaches. Moreover, the complete analysis of all the genes present in the panel will allow us to correlate genotypes with the vast range of phenotypes, in addition to the assessment of allele frequencies of the variants detected and possibly involved in the pathologies.

From NGS back to Sanger Sequencing: Connecting and Synchronizing NGS and CE Variant Files with the Primer Designer Tool. *E. Schreiber, S. Berosik, M. Wenz, S. Chang, K. Gordeeva, S. Sharp.* Thermo Fisher Scientific, South San Francisco, CA.

Whole exome or panel sequencing projects performed by next generation sequencing (NGS) technologies typically reveal a large number of variants which may require verification by an orthogonal method. To that end, automated fluorescent Sanger sequencing is the method of choice since it is accurate, affordable and easy to perform. To facilitate the re-sequencing of any exon in the human genome we have recently made available to the scientific community a free to use tool called Primer Designer™ . The tool provides the designs for over 350.000 PCR primer pairs that cover 99% of all exons in the human genome. Amplicons generated with these primers can be readily sequenced using the BigDye® Direct, BigDye® Terminator v1.1 and v3.1 sequencing chemistries on the 3500xl Genetic Analyzer capillary electrophoresis platform. For variant identification the sequencing trace files are analyzed with Applied Biosystems Variant Reporter® Software which requires the import of a text file with a reference sequence for sequence alignment and comparison. Here we show the utility and workflow of a new on-line tool called VR Toolkit™ within the Primer Designer portal that generates a reference file from Primer Designer - derived PCR amplicons that contains the coordinates of the chromosomal location. Use of this annotated reference file in Variant Reporter® Software allows the generation of an output file that can be compared and matched to a variant call file (vcf) from an NGS instrument. The VR Toolkit enables the connection and synchronization between NGS data and traditional Sanger sequencing data analyzed with Variant Reporter® Software and should be of benefit for all researchers seeking to validate NGS data by Sanger sequencing.

1574T

A practical method to detect SNVs and indels from whole genome and exome sequencing data and an importance of in-house data for variant filtering. *D. Shigemizu, A. Fujimoto, S. Akiyama, T. Abe, K. Nakano, KA. Boroevich, Y. Yamamoto, M. Furuta, M. Kubo, H. Nakagawa, T. Tsunoda.* IMS, RIKEN, Yokohama, Kanagawa, Japan.

The recent development of massively parallel sequencing technology has allowed the creation of comprehensive catalogs of genetic variation. However, due to the relatively high sequencing error rate for short read sequence data, sophisticated analysis methods are required to obtain high-quality variant calls. Here, we developed a probabilistic multinomial method for the detection of single nucleotide variants (SNVs) as well as short insertions and deletions (indels) in whole genome sequencing (WGS) and whole exome sequencing (WES) data for single sample calling. Evaluation with DNA genotyping arrays revealed a concordance rate of 99.98% for WGS calls and 99.99% for WES calls. Sanger sequencing of the discordant calls determined the false positive and false negative rates for the WGS (0.0068% and 0.17%) and WES (0.0036% and 0.0084%) datasets. Short indels were also identified with high accuracy (WGS: 94.7%, WES: 97.3%). Currently we have applied this variant calling method to approximately 1,400 Japanese individuals and developed our own in-house database. Our own in-house database efficiently played a key roll in variant filtering for exome sequence analysis. We believe our variant method and own in-house database can contribute to the greater understanding of human diseases.

Group-based Variant Calling for a Large Cohort of Human Whole Genomes Leveraging Next-Generation Supercomputing. *K.A. Standish[1,2], T.M. Carland[2,3], G.K. Lockwood[4], W. Pfeiffer[4], M. Tatineni[4], C.C. Huang[5], S. Lamberth[5], Y. Cherkas[5], C. Brodmerkel[5], E. Jaeger[5], L. Smith[5], S. Szalma[5], G. Rajagopal[5], M. Curran[5], N.J. Schork[2].* 1) Biomedical Sciences Graduate Program, University of California, San Diego; 2) Department of Human Biology, J. Craig Venter Institute, La Jolla, CA; 3) The Scripps Research Institute, La Jolla, CA; 4) San Diego Supercomputer Center, University of California, San Diego; 5) Janssen R&D, LLC.

Recent advances in DNA sequencing technologies have increased the efficiency of sequencing, leading to an expanding deluge of high-quality data. However, DNA sequence reads have limited biological utility without relevant downstream processing and analysis, including read-quality assessment, alignment to a reference genome, variant identification, and individual genotyping. While the tools for performing these steps have improved, processing a whole genome from reads to variants remains an expensive and time-consuming aspect of sequencing studies. Furthermore, the accuracy of genotyping depends on accurate assessments of sequencing errors, which can be enhanced by processing large numbers of sequencing reads simultaneously. Here, we describe an efficient approach for obtaining high-quality variant calls from 438 whole genomes sequenced on an Illumina Hi-Seq 2500 platform. We exploited a group calling approach to minimize specific genotype assignment errors that arise from ignorance of sequencing error rates and inconsistent coverage. To accommodate the extraordinary computational and storage requirements associated with the scale and approach of this study, we used SDSC's Gordon supercomputer. It has 1,024 compute nodes, each with 16 cores, 64GB of DRAM, and 300GB of solid-state flash memory. To minimize cost, we optimized each step involved in genotyping to run as efficiently as possible on Gordon, parallelizing steps as appropriate during alignment and subsequent processing steps. To circumvent an I/O issue that arose while sorting the aligned reads, we used two "BigFlash" nodes with 4TB of SSD flash memory for temporary storage. Variants were then called with GATK's HaplotypeCaller in groups of 20-24 genomes. We found evidence that the ancestral makeup of a group influenced the accuracy of variant calls so groups were comprised of individuals with similar ancestral background. This approach provided increased power for variant detection while avoiding the prohibitively long computing time associated with large group variant calling. Our results suggest that this approach yields high-quality variant calls and genotype assignments in an efficient manner and highlights the need for sophisticated computational strategies in analyzing large numbers of human genomes.

Repeat-Aware Hidden Markov Models for the Comprehensive Joint Calling of SNPs, Indels, and Short Tandem Repeats. *A. Tan, H.M. Kang.* University of Michigan, Ann Arbor, MI.

Accurate detection of genetic variants in Next Generation Sequencing data has always been complicated by the presence of low complexity regions of the genome. While many indels located in regions with high sequence diversity are easy to assay, the challenge is in the large fraction (~50%) of indels that are located in low complexity regions of the genome, mostly in the form of short tandem repeats (STRs), often with inexact repeat units. In the vicinity of indels in low complexity regions, it is also difficult to classify nearby base mismatches as a SNP or as part of an inexact repeat within an STR.

To be an effective short variant caller, the calling algorithm must account for the inherent heterogeneous nature of indels. We thus developed a variant calling algorithm based on a set of novel repeat-aware Hidden Markov Models (raHMMs) that locally aligns a pair of sequences allowing for mismatches or indels, with an arbitrary number of repeat units.

For variant discovery, our approach first identifies the repeat unit in a candidate variant allele; using this candidate repeat unit, we then perform pairwise alignments using a pair of raHMMs to determine the most appropriate flanking sequences, even in the presence of inexact STRs. This procedure allows us to systematically define variants by their flanks and earmarks regions that a SNP should not be called indiscriminately.

For variant genotyping, we apply another raHMM that explicitly models both flanking sequences and the repeat unit. This model allows us to determine if a read contains the defining flanks of an indel, counts the number of repeats observed and keeps track of alternative alleles that are not explicitly modeled.

This calling algorithm not only allows us to better classify the variant types in repeat rich regions but also genotypes STRs with inexact repeat units. We demonstrate that our method comprehensively detects and genotypes SNPs, Indels and STRs using the deeply sequenced trios in the 1000 Genomes Project. This is implemented in vt and is available from http://genome.sph.umich.edu/wiki/Vt.

Describing complex rearrangements using HGVS sequence variation nomenclature, suggested extensions. *P.E. Taschner, J.T. den Dunnen.* Dept Human Genetics, Leiden Univ Medical Ctr, Leiden, Netherlands.

Breakpoints involved in translocation and chromothripsis are traditionally described using ISCN nomenclature based on chromosomal banding patterns (1). The sequence variation nomenclature guidelines of Human Genome Variation Society (HGVS, http://www.hgvs.org/mutnomen) traditionally focused on simple variants not requiring specific rules for detailed description of genetic rearrangements. This changed with the introduction of new technologies allowing rapid discovery of breakpoint sequences from complex structural rearrangements including translocations. The description of such complex variants challenges the existing guidelines. Previously, we suggested extensions for simple translocations (2). Here, we suggest extending the HGVS nomenclature guidelines to facilitate unambiguous description of more complex structural rearrangements including chromothripsis. A main requirement for the description is that precise chromosomal breakpoint sequences can be derived easily. The suggested format should provide sufficient flexibility and consistency limiting alternative interpretations and ambiguous descriptions. The new rules can be combined with those proposed previously for complex changes, which included: i) nesting to support description of changes within inversions and duplications, ii) composite changes to support concatenation of inserted sequences (3). We have applied the rules in practice by describing complex cases involving many breakpoints. The specifications should allow easy implementation in sequence variant nomenclature checkers (e.g. Mutalyzer, https://Mutalyzer.nl). We are planning to extend the functionality of Mutalyzer to incorporate the latest version of the HGVS sequence variation nomenclature guidelines as part of the development of curational tools for gene variant databases (Locus-Specific DataBases, LSDBs).

Comparing variant filters from transcriptome and exome sequencing data. *N. Thomson, C. Boysen, A. Arens, A. Heine, U. Appelt, A. Joecker, S. Monsted, B. Knudsen, R. Forsberg.* CLC division of QIAGEN, Fort Myers, FL.

Targeted gene panels, whole exome sequencing (WES), whole genome sequencing (WGS), and transcriptome sequencing (RNA-Seq), are revolutionizing cancer research. Many analyses, such as the comparison of tumor and normal cells, include the comparison of variant calls in the resulting VCF files. Here, we illustrate the benefits of leveraging read mappings in the comparison of WES and RNA-seq data using the CLC Cancer Research Workbench. WES and RNA-seq reads (paired-end, Illumina GA II, 100bp) from two patients (MM065 and MM089) are analyzed with built-in workflows in CLC Cancer Research Workbench. The sequences are available from SRA (bioproject 182345)1. When filtering the results for tumor-specific variants inducing an amino acid change 42 and 43 variants from WES and 827 and 1,497 variants from RNA-seq are identified in MM065 and MM089, respectively. A function in the Cancer Research Workbench, “Compare Shared Variants within a Group of Samples” identifies Variants from both WES and RNA-seq. Only two and five shared WES/RNA-seq variants, respectively, are identified for the two patients. “Identify Known Mutations from Sample Mappings”, searches RNA-seq read mappings for variants previously called from the exome data. This approach identifies 3 exome variants in the RNA-seq data from patient MM065 and 11 of the exome variants in the RNA-seq data of patient MM089. In contrast to comparing VCF files, the “Identify Known Mutations from Sample Mappings” tool provides a more reliable approach to recover previously detected variants in the WES data directly from the RNA-seq read mappings. Using this approach, 3 out of 42 variants for MM065 and 11 out of 43 variants for MM089 are confirmed by RNA-seq. 1Harbour JW et al., “Frequent mutation of BAP1 in metastasizing uveal melanomas”, Science, 2010 Nov 4;330(6009):1410-3.

Combining sets of indels with improved specificity and sensitivity using BAYSIC. *D. Weaver[1], B. Cantarel[1, 2], G. Benstead-Hume[1], V. Benstead-Hume[1], A. Mackey[3], J. Reese[1].* 1) Genformatic, Austin, TX; 2) Baylor, Scott & White Baylor Institute of Immunology, Dallas, TX; 3) University of Virginia. Charlottesville, VA.

Insertions and deletions ("Indels") comprise a source of human genome variation as significant as SNVs, and frequently cause clinically relevant phenotypes (Mulaney, et al., 2010). Moreover, the additional complexities of indel variation make their detection and accurate representation a more technically challenging problem than SNV detection. Many methods exist of the detection of indels, and as with SNVs, the concordance among sets of indels detected by different methods is poor. We previously described BAYSIC, a method of integrating variant calls using Bayesian statistics and latent class analysis to combine sets of SNVs with improved specificity and sensitivity. We extend this strategy here to combine sets of indels with increased sensitivity and specificity when compared to other currently popular methods for indel detection, e.g., GATK. BAYSIC provides the user with a posterior probability threshold that can be specified by the user to tune BAYSIC's performance according to the user's tolerance for false negative and false positive indel calls. Using genome data from the 1000 Genomes project, we evaluated the performance of BAYSIC and demonstrate BAYSIC's enhanced accuracy when compared to other popular indel detection methods.

CNV Detection Assessment. *J. White, X. Gai.* Mass. Eye & Ear Infirmary, Boston, MA.

Clinical assessment of patients at Mass. Eye and Ear includes diagnostic testing for pathogenic genetic variants. We assess both single nucleotide changes that result in missense or frameshift alterations, and structural/copy number changes that result from deletions or duplications. Our diagnostic rate based on SNP analysis alone is ~ 50%. In order to increase this rate we have used microarray chip based genotype analysis on the Illumina iScan platform. However, we wish to reduce costs by evaluating our exome sequence data to detect CNVs. To do so we compared CNV detection applications based on the following criteria: a) paired-end verses read-depth analysis, b) ease of installation and use, c) inclusion of baseline or matched-control samples, d) use of exome verses targeted exome sequence data, and e) detection of positive control samples. We have collected a number of data sets that have been found to include CNVs which have been confirmed to be associated with specific traits. We used these data sets as positive controls for detection of CNVs. We have so far compared XHMM, BreakDancer, and WaveCNV, with many more comparisons planned. We were unable to use WaveCNV due to its difficult installation and lack of documentation. We have evaluated whole exome sequence data in two ways: 1) comparison of family members against a group of "baseline" samples, and 2) comparison of family members against each other without baseline samples. •XHMM identified a deletion in samples known to have that particular deletion. However, XHMM was unable to identify the duplication in samples that had a known small duplications. •We evaluated the same family samples with BreakDancer. Neither the known deletion, nor the known duplication were identified by BreakDancer. BreakDancer generates a large amount of SV results that we filtered to search for known CNVs. •Inclusion of baseline samples did not improve CNV detection.

1581S

Cloud-based variation analysis using SRA sequencing data directly. *C. Xiao, E. Yaschenko, S. Sherry.* National Center for Biotechnology Information, National Library of Medicine, National Institute of Health, 45 Center Drive, Bethesda, MD 20892.

Variation analysis plays an important role in elucidating the causes of various human diseases. The drastically reduced costs of genome sequencing driven by next generation sequence technologies now make it possible to analyze genetic variations with hundreds or thousands of samples simultaneously, but currently with the cost of ever increasing local storage requirements. The tera- and peta-byte scale footprint for sequence data imposes significant technical challenges for data management and analysis, including the tasks of collection, storage, transfer, sharing, and privacy protection. Currently, each analysis group facing these analysis tasks must download all the relevant sequence data into a local file system before variation analysis is initiated. This heavy-weight transaction not only slows down the pace of the analysis, but also creates financial burdens for researchers due to the cost of hardware and time required to transfer the data over typical academic internet connections. To overcome such limitations, we here introduce a cloud-based analysis framework that facilitates variation analysis using direct access to the NCBI Sequence Read Archive. We demonstrate that it is cost and time effective to make variant calls using both public and control-accessed SRA sequence data without first transferring the raw or aligned sequence data into a cloud storage environment. Performance of this pipeline will be assessed against a comparable cloud analysis pipeline that first transfers all data into local storage, and a customized machine image (swift1.0 AMI) with preconfigured tools and resources essential for variant analysis, created for instantiation in an EC2 instance or instance cluster on Amazon cloud, will be introduced.

1582M

Low false-positive rate chromosomal structural variation detection procedure with statistical comparisons between case and control using paired-end reads. *K. Yamagata[1], A. Yamanishi[2], C. Kokubu[2], J. Takeda[2], J. Sese[1].* 1) Ochanomizu University, Bunkyo-ku, Tokyo, Japan; 2) Osaka University, Suita-shi, Osaka, Japan.

Recent high-throughput sequencing technology has uncovered the high frequency of both somatic and germinal chromosomal structural changes. To detect the changes, various software tools such as BreakDancer and GASV have been developed. However, most of those tools tend to yield a high rate of false-positives, which hampers the full understanding of the chromosomal changes in the cells. We here introduce a structural variation (SV) detection method with an extremely low false-positive rate by using the statistical comparison between case and control sequences. To detect SVs between two individuals, most existing tools need to perform the detection on each individual, and subsequently compare them with each other. However, this strategy may suffer from the problem of how to assess the differences in sequencing depth, quality and base biases between the samples. Our method first generates lists of candidate breakpoints using multiple sources of read information such as paired-end distances and the number of reads on each direction, and then makes statistical comparison of the candidate regions between samples. To evaluate our method's performance, we carried out SV analysis of mouse embryonic stem cell (ESC) lines by comparing gamma-ray irradiated (case) and unirradiated (control) cell populations. The frequency of irradiation-induced SVs was enhanced by increased genomic instability of the engineered ESCs in which the expression of the Blm helicase gene was transiently suppressed by doxycycline administration (Yamanishi A. et al, Genome Research 2013). We performed whole-genome sequencing (WGS) of both case and control samples using Illumina HiSeq-2000 at 30x coverage, and mapped the paired-end reads to the mouse reference genome using Bowtie2. Using the data, Breakdancer detected 3,177 deletions, 197 inversions and 125 translocations; GASV detected 12,563 deletions, 66 inversions and 138 translocations, most of which turned out to be false-positives by referring to the mapping results. In contrast, our method detected 21 deletions, 22 inversions, and 9 translocations. Among them, we examined 15 rearrangement breakpoints by direct PCR sequencing and confirmed them all as true-positives. This result indicates that our method largely contributes to the reduction of false-positive detection of chromosomal SVs in WGS data. In our presentation, we also show the result of SV analysis when our method is applied to human sequences in 1000 genomes database.

Multiplexing strategies for HLA genotyping using DNA barcoding methods for SMRT® sequencing. *S. Ranade[1], K. Eng[1], J. Harting[1], B. Bowman[1], E. Rozemuller[2], N. Westerink[2], M. Penning[2].* 1) Pacific Biosciences, Menlo Park, CA; 2) GenDx, Utrecht, The Netherlands.

Fully phased allele-level sequencing of highly polymorphic HLA genes is greatly facilitated by SMRT sequencing technology due to its long read lengths and ability to sequence an amplicon representing a gene allele in isolation. In the present work, we evaluate DNA barcoding strategies for efficient pooling of multiple samples and loci for simultaneous sequencing of these genes. Multiplex sequencing using symmetric and asymmetric barcode-tailed HLA amplification primers were tested. Full-length HLA class I genes HLA-A, -B, and -C were evaluated, using 8 different 16-bp barcode sequences in symmetric and asymmetric pairing. Eight barcodes generated 28 unique asymmetric pairings and allowed for simultaneous sequencing of 28 genomic reference DNA samples; symmetric barcodes could be used for unique tagging of 8 genomic reference DNA samples. Following amplification, the symmetric and asymmetric barcode-tagged libraries were pooled into two separate libraries for sequencing. The data was analyzed both separately and together to evaluate the ability of the barcode tags to uniquely de-convolute the samples. Consensus sequences were generated using LAA protocol in SMRT analysis 2.2. Allele sequences were typed using GenDx NGSengine HLA-typing software. We demonstrate the use of a DNA barcode strategy for multiplex full-length HLA gene sequencing to provide allele-level genotyping along with SNP phasing information.

Detection of Copy Number Variations in Cancer Genomes from High Throughput Sequencing Data. *G. Klambauer, S. Hochreiter.* Insitute of Bioinformatics, Johannes Kepler University Linz, Linz, Upper Austria, Austria.

"Copy Number estimation by a Mixture Of PoissonS" (cn.MOPS), is a well established and widely used method for detection of germline copy number variations (CNVs) in high-throughput sequencing data. cn.MOPS showed excellent performance at the detection of CNVs in HapMap samples, as well as in genomes of bacteria, fungi and plants. Since cn.MOPS constructs a model across samples for each genomic position, it is not affected by read count variations along chromosomes, and, therefore, geared to targeted sequencing. In a comparative study, cn.MOPS was the best performing method at the detection of CNVs in targeted sequencing data. However, the detection of somatic CNVs in cancer genomes is still challenging due to admixture of normal and tumor tissue, nondiploidy and very large copy number variations that affect normalization. Therefore, preprocessing, normalization, and the core algorithm of cn.MOPS have been optimized for CNV detection in cancer genomes. We demonstrate the improved performance of the enhanced cn.MOPS algorithm for cancer genomes on whole genome sequencing data from the International Cancer Genome Consortium (ICGC). cn.MOPS has been optimized for computation time and parallelized, which makes the method perfectly suited to analyze data sets of hundreds of cancer samples within a few hours.

Efficient variant pipeline for diagnosis of inherited cardiomyopathies associated genes using Ion Torrent PGM™ platform. *L. Cerdeira[1], T.G M. Oliveira[2], A. Pereira[2], M. Mitne-Neto[1].* 1) Research and Development, Fleury Group, São Paulo, SP, Brazil; 2) University of São Paulo - Heart Institute, São Paulo, SP, Brazil.

Hypertrophic cardiomyopathy (HC) is a primary cardiac disease characterized by hypertrophy of the left ventricle (LV) without dilation , usually asymmetrical and predominantly septal , in the absence of any other cardiac or systemic disease that can cause myocardial hypertrophy . Typically, CH is caused by mutations in genes encoding sarcomeric elements. Currently 19 genes have been discovered and linked to the CH spectrum, besides the filaments of the sarcomere, additional subgroups can be classified as related CH, as Z disc genes and calcium transport. Diagnosis is mainly clinical and usually only identified after the symptoms beginning. For that reason molecular genetic tests came up as a differential tool for the discovery of the mutations causing the phenotype. This study developed a bioinformatics pipeline for accurate molecular diagnosis of CH using Ion PGM data. The pipeline was developed using CLCBio Genomic Workbench 6.5 workflow and had as a first step a mapping assessment, with the 5 nucleotides at the 3'end trimmed and a Phred ≥ 20 used for quality control. Alignment against the human genome HG19 version was done using standard thresholds, followed by identification of variants by coverage and quality positioning. The identification of known variants was validated against the databases: dbSNP and clinicalvar and for further evaluation a prediction of splice site effect and amino acid change. The result were submitted to SIFT and Polyphen programs to obtain the values for protein damaging. To validate the pipeline we selected 15 DNA samples from previously analyzed patients, which had clinical and molecular diagnoses of HC from the Heart Institute (InCor - University of São Paulo, Brazil). The previous molecular diagnosis was performed by Sanger sequencing for the three most HC-associated genes: MYH7, MYBPC3 and TNNT2. All variants found were properly annotated for the three genes and were further used in the evaluation of NGS accuracy. The NGS pipeline presented here could identify > 97% of the Sanger sequencing identified mutations, showing its robustness and viability for HC and for other diseases with Mendelian heritability standard.

1586T

Assessing novel centromeric repeat sequence variation within individuals by long read sequencing. *K.H. Miga[1], J. Chin[2], A. Bashir[3,4].* 1) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA 95064, USA; 2) Pacific Biosciences, Inc, 1380 Willow Rd, Menlo Park, CA 94025, USA; 3) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, 1425 Madison Avenue, New York, NY 10029, USA; 4) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, 1425 Madison Avenue, New York, NY 10029, USA.

Centromeres and other heterochromatic regions are commonly enriched with long arrays of near-identical tandem repeats, known as satellite DNAs, that offer a limited number of variant sites to differentiate individual repeat copies across millions of bases. This substantial sequence homogeneity challenges available assembly strategies, and as a result, centromeric regions are vastly underrepresented in genomic studies. Further, as these sites are known to be variable among individuals in the population, it is necessary to not only characterize the sequence organization of these regions in a single genome, but to develop high-throughput methods to study this new source of human sequence variation among individual genomes. To advance characterization in these regions we have designed alphaCENTAURI (centromeric automated repeat identification for alpha satellite DNA) that takes advantage of Pacific Biosciences' long reads from whole-genome sequencing. Long reads allow direct determination of satellite higher-order repeat structure as opposed to using indirect inference methods, like assembly, with reads shorter than the underlying lengths of the high order repeat unit. Here we demonstrate a comprehensive assessment of higher-order repeat patterns for two human cell lines: NA12878 (diploid) and the hydatidiform mole (CHM1, haploid-like) genomes. First, we show the reliability of the method by validating consistency with existing centromere repeat references. Additionally, we are able to identify changes in repeat unit directionality that exist within arrays and between individuals, representing polymorphisms in the population or errors within existent assemblies. The analysis also represents a robust and straightforward methodology for characterization of higher-order repeat variants within the array that differ between individuals. Based on this analysis, resolution of higher-order repeats could be readily performed at low depth and reasonable cost across a population, or in genomes without high-quality references. This study demonstrates the methods to generate a sequence survey for regions enriched in satellite DNA that are typically omitted from genomic studies. We believe it establishes a foundation to extend and improve genomic characterization of any higher-order repeat structure using long reads.

1587S

Anchored Assembly: An algorithm for large structural variant detection using NGS data. *J. Bruestle, B. Drees.* Spiral Genetics, Seattle, WA.

Statement of purpose Characterizing large indels, inversions, and multi-nucleotide variants is important for understanding cancer, bacterial pathogens, and neurological disorders. Standard pipelines often miss these variants. Spiral Genetics has developed Anchored Assembly, a novel method using direct, *de novo* read overlap assembly to accurately detect variants from next-generation sequence reads. Anchored Assembly's range of detection and low false discovery rates may be useful for characterizing structural differences between tumor and normal samples.

Methods used Anchored Assembly was evaluated against Pindel and BWA + GATK using simulated read data. Datasets were generated by populating chromosome 22 of the human genome reference sequence with a set of SNPs, insertions, deletions, inversions, and tandem repeats.

Summary of results On human chromosome 22 data, Anchored Assembly detected over 90% of indels and structural variants up to 50 kbp and SNPs with false discovery rates well below 1%. In comparison, Pindel and BWA + GATK had overall false discovery rates of 10% and 9%, respectively. We detect, on average, over 90% of indels and structural variants up to 30 kbp in non-repetitive regions. The ability to detect deletions and structural variants is undiminished by variant size, and the ability to accurately detect and assemble insertions continues well into the 30 kbp range.

1588M

Short inversion detection by splitting and re-aligning poorly mapped next-generation sequencing reads. *R. Chen, W. Yang, Y. Lau.* Paediatrics & Adolescent medicine, The university of Hong Kong, Hong Kong, Hong Kong.

Rapid development of sequencing technology has enabled routinely discovery of deletions and insertions. Unlike these two kinds of structural variation, characterization of inversions is left behind. Summary of public databases and researches shows that little short inversions with length smaller than 500bp have been detected for now. Because in contrast to small insertions and deletions, which are considered by gap alignment and recorded in primary mapping files, inversions short enough to interrupt alignment probably cause poorly mapped reads, which are mostly left out of consideration for structural variation detection by existing methods. And as a result, signals of short inversions are lost. Here, we introduce SRinversion, which tries to reuse those poorly mapped reads by splitting and re-aligning them for inversion detection and in this way, improve the resolution of inversion detection to less than 10bp. Comparison with previous structural variation detection methods, i.e. Pindel, BreakDancer, and DELLY, using simulated data indicates that SRinversion performs much better when inversion size is smaller than 100bp. Testing on chromosome 21 of a high-coverage parent-child trio (NA12878, NA12891, and NA12892) from 1000 genomes project shows that SRinversion is the only method that is able to detect inversions smaller than 100bp. As for inversions with length from 100bp to 1000bp, besides SRinversion, Pindel is the only method that have output, which only include 7 regions, indicating relatively low power in detecting small inversions. PCR will be performed on randomly selected inversions detected by SRinversion on each individual of the trio for further validation. The method was also tested on a single African individual (NA18507) with both high-coverage and low-coverage whole genome data to check the effect of coverage, which will helps broader the spectrum of inversion at the same time.

1589T

Reproducible and repurposable toolkit of structural variant callers applied to 3,751 whole genomes and 10,940 whole exomes. *S. Ma[1], S. Ambreth[2], A. Carroll[1], A. Sabo[2], P. Mishra[2], W. Salerno[2], A. English[2], N. Veeraraghavan[2], E. Boerwinkle[2,3].* 1) DNAnexus, Mountain View, CA; 2) Baylor College of Medicine, Human Genome Sequencing Center, Houston, TX; 3) University of Texas Health Science Center, Human Genetics Center, Houston, TX.

Despite the significant influence human structural variation and copy number variation has on mendelian disease and cancer genomics, accurate calling of these variants remains a difficult problem. Great efforts have been made in understanding the concordance of SNP and small indel calls, allowing for groups to harden these pipelines for large scale research and clinical applications. A similar systematic approach to structural variant calls has until now remained lacking.

Baylor College of Medicine's Human Genome Sequencing Center (HGSC) has collaborated with DNAnexus to package together SVPipe which runs BreakDancer, CNVnator, CREST, DELLY, Genome STRiP, Pindel, and Tiresias for whole genome analysis, converting each output to a common format. A pair of CNV callers, CoNIFER and XHMM were also set up for exome analysis. The SVPipe multi-algorithmic approach was run on 3,751 low coverage whole genomes and the CNV callers were run on 10,940 exomes from the CHARGE project. These call sets provide a deeper understanding into the overlap between the tools and the amount of structural variation present in a large human population.

Thanks to HGSC's work, all of these callers are publicly available on the DNAnexus platform. Users can run any caller without the need to install or configure software and each has been optimized to improve the speed and cost of its execution. These tools are provided with a number of benchmarks sets to validate the results of pipelines which use them.

1590S

Orthogonal Resequencing Support of Structural Variation in a Personal Genome. *W.J. Salerno[1], A.C. English[1], C. Gonzaga-Jauregui[2], O.A. Hampton[1], S. Ambreth[1], D. Ritter[1], S. White[1], C. Davis[1], P. Mishra[1], Y. Liu[1], C.R. Beck[2], M. Dahdouli[1], N. Veerarraghavan[1], A. Hawes[1], D.A. Wheeler[1], J.G. Reid[1], D.M. Muzny[1], J. Rogers[1], K. Worley[1], A. Sabo[1], W.J. Salerno[1], J.R. Lupski[1], E. Boerwinkle[1], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX., USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX., USA.

Personal genome sequencing is becoming standard in research and clinical settings, and discovery of genetic disease etiologies increasingly requires genomic characterizations beyond single nucleotide variants and small insertions and deletions. The human genome is subject to large (>100 bp) deletions, insertions, inversions, translocations, and complex combinations of these events. While the number of such structural variant (SV) events is far fewer than the number of single nucleotide variants, SVs collectively affect a comparable or even larger fraction of the genome, directly impacting gene function and regulation. Any effort to robustly characterize structural variation must address the broad variation in SV size, type, and complexity. We have developed and implemented a novel approach for integrating whole-genome array comparative genomic hybridization (aCGH) and short-read next-generation sequencing (NGS) data with long-read (Pacific BioSciences RSII), long-insert (Illumina Nextera), and whole-genome architecture (BioNano Irys) data. These methods are illustrated via analysis of the genome of a phenotypically well-characterized individual with autosomal recessive Charcot-Marie-Tooth neuropathy. The integration of these orthogonal methods was performed with Parliament, a consensus SV-calling infrastructure that merges and evaluates the results from existing and novel SV-detection software and multiple input data sources. In this individual, Parliament identified 33,8862 loci (composing 2.65% of the genome) that are inconsistent with the hg19 reference assembly. Of these, 7,460 are supported as putative SVs by local hybrid assembly and 3,440 are supported by long-read force calling or multi-source heuristics. These 10,900 putative SVs have an aggregate length of approximately 20 Mbp (0.6% of the genome), including 4,427 deletions, 4,442 insertions, and multiple complex events such as a single 40 Kbp chimeric event on chromosome 11 (p15.5) that individual NGS methods classify as independent inversion, deletion, and insertion events. These data represent the most comprehensive characterization of SVs in a personal genome and provide a platform for SV validation efforts. We also update on de novo whole genome assembly, comparison of SVs in hg19 and hg38, and Parliament workflows for trio, cancer, and whole-exome samples. The complete Parliament infrastructure and a WGS NGS-specific workflow are available to the community on the DNAnexus platform.

Copy Number Variation Analysis using Single Cell Sequencing. *X. WANG.* Program in Public Health, Departments of Preventive Medicine, Biomedical Informatics, and Applied Mathematics & Statistics, Stony Brook University, Stony Brook, NY 11794.

Recently developed single cell sequencing (SCS) technology can amplify and sequence the genome of a single cell. It is a promising new tool to study tumor heterogeneity and evolution in cancer studies. In this study, we focus on methods for the copy number variation (CNV) detection using the low-coverage single cell sequencing data. Traditional methods for CNV analysis (based on CGH array or bulk-cell sequencing) are impractical for single cell, especially for the low-coverage sequencing. We proposed to use a two-step adaptive scheme for a more accurate CNV detection of the noisy data. In the initial step (after GC content correction and sample normalization steps), we apply a fast CNV calling algorithm based on the modified circular binary segmentation (CBS). To ensure better coverage and reliability, the data from cells with similar ploidy level are then pooled to create a bulk-sample data—with high purity. The preliminary ploidy estimates are validated by the lesser allele frequency (LAF) information from mapped reads. We propose two novel methods for more precise breakpoint detection in the second step: one method is based on mixture of Poissons and which can be used to model depths of coverage across samples at each position; the other is based on scan statistics which overcome the limitation of fixed window size in the first step. We tested our methods on simulated data and a prostate cancer dataset. All the scripts and pipelines are included in SinSat: a single-cell sequencing analysis toolkit.

1592T

A Convergent Clinical Exome Pipeline Specialised for Targeted Gene Analysis. *J. Plazzer[1], A. Oshlack[2], C. Gaff[3], N. Thorne[3], G. Taylor[4], H. Dashnow[5], A. Lonie[5], M. Bahlo[6], T. Bakker[3], D. Bauer[7], K. Siemering[8], P. James[1], S. Sadedin[2], Melbourne Genomics Health Alliance.* 1) The Royal Melbourne Hospital, Parkville, Victoria, Australia; 2) Murdoch Childrens Research Institute, Parkville, Australia; 3) Melbourne Genomics Health Alliance, The University of Melbourne; 4) Centre for Translational Pathology, The University of Melbourne, Parkville, Australia; 5) Victorian Life Sciences Computation Initiative, Carlton, Australia; 6) Walter and Eliza Hall Institute of Medical Research, Parkville, Australia; 7) Division of Computational Informatics, CSIRO, Sydney; 8) Australian Genome Research Facility, Parkville, Australia.

Efforts to move high throughput sequencing into the clinic must confront many challenges including meeting clinical standards for cost, reproducibility, quality, ethical and privacy considerations. The Melbourne Genomics Health Alliance was formed from a diverse group of institutions with the aim of sharing the burden of these challenges through a common sequencing and bioinformatics platform. Critical to this concept is that regardless of disease, all patients undergo full exome sequencing, and targeting to a specific disease is performed in silico. While this has many benefits, it also adds significant complexity to the analysis pipeline as it must meet the differing diagnostic needs of diverse disease cohorts. In this work we present the Melbourne Genomics Health Alliance bioinformatics analysis pipeline which has been specifically designed as a clinical grade exome sequencing pipeline with built in support for multiple sub-target regions. The pipeline is based on the Bpipe platform and includes support for customized sets of targeted regions, prioritized genes, regions blacklisted against incidental findings, automatic exclusion of sequencing artefacts and population variants, PDF provenance and quality reports. It allows genes to be prioritized at both a disease cohort and individual level and combines this with output from annotation tools to produce a clinically interpretable report that is available as an Excel spreadsheet or optionally can be imported into any LOVD (Leiden Open Variant Database) instance for curation. Being based on Bpipe, it offers powerful features for running many samples in parallel either on a cluster or dedicated computing resources as well as full traceability through auditable provenance of every file.

1593S

An ensemble variant calling approach to 10,000 low coverage whole genomes. *Z. Huang[1], N. Rustagi[1], L.A. Cupples[2], D. Muzny[1], R. Gibbs[1], E. Boerwinkle[1,3], F. Yu[1], CHARGE Consortium.* 1) Human Genome Sequencing Center and Molecular and Human Genetics Department, Baylor College of Medicine, Houston, TX 77030, USA; 2) Boston University School of Public Health, Boston, MA 02118, USA and the National Heart, Lung and Blood Institute (NHLBI) Framingham Heart Study, Framingham, MA, 01702, USA; 3) Human Genetic Center, University of Texas Health Science Center, Houston, TX 77030, USA.

Accurate calling of common and rare variants is critical for population genetic analyses and novel gene discovery, as is consideration of single nucleotide variants, indels and short tandem repeats (STRs). There is growing consensus of the practical utility of large sample sizes having both deep whole exome sequencing (WES) and low coverage whole genome sequence (WGS), made efficiently from the same library preparation. The Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium is aiming to identify novel genes (and other noncoding genomic motifs) influencing health and disease, and is accruing deep WES and low coverage WGS (6-7x) in ~10,000 deeply phenotyped individuals. In order to call and integrate variants across a large sample of low coverage genomes, multiple variant calling pipelines were used to avoid caller specific bias, and consensus filtering was adopted to select high quality variants. We utilized GATK UnifiedGenotyper (UG) and HaplotypeCaller (HC), GotCloud and SNPTools for SNP calling; GATK-UG, GATK-HC, Pindel for INDEL calling; and LobSTR for STR calling. We compared two consensus strategies: the 3-out-of-4 and a machine learning based consensus filtering. We built an automated pipeline including individual and consensus calling and quality assessment. This pipeline is computationally intensive, requiring a fully parallelizable design in a cloud environment (e.g. DNAnexus) to achieve high efficiency speed. We benchmarked the method using chromosome 20 data extracted from 3,751 whole genomes. With the 3-out-of-4 consensus strategy, we identified 1.37 million SNPs with a transition-transversion ratio of 2.83. Among them, 40.2% are novel compared to 1000Genomes phase3, and 91.2% of novel SNPs have MAF<0.1%. Compared to CHARGE WES from the same individuals, the WGS call set achieved a sensitivity of 61.1%, specificity of 99.8%, and 95.4% of the missed SNPs are singletons and doubletons. The SNP rediscovery rate in exome region is 38.3% for singletons and 62.2% for doubletons, which is higher than in 1000G phase1. We also identified 8,141 unique STR loci on chromosome 20, with a rediscovery rate of 97.8% compared to 1000G phase1 results. The entire process, including genotype/haplotype inference and WES integration, requires 3000 CPU-month for the Chromosome20 pilot. Deploying the pipeline in distributed computing environments (i.e. the Cloud) holds promise to make the ensemble method approachable to the community.

1594M

Likelihood-based filtering of indels and structural variants by leveraging Mendelian inheritance and transfer learning. *H. Kang[1], D. Absher[2], A. Tan[1], C. Quick[1], A. Locke[1], Z. Chen[1], G. Jun[1], J. Vincent[3], C. Pato[4], M. McInnis[5,6], S. Zoellner[5], G. Breen[7], S. Levy[2], R. Myers[2], W. Iacono[8], M. McGue[8], L. Scott[1], S. Vrieze[1], M. Boehnke[1], G. Abecasis[1], The BRIDGES Consortium.* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, Ann Arbor, MI; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 3) Center for Addiction and Mental Health, Department of Psychiatry, University of Toronto, ON, Canada; 4) Department of Psychiatry and Behavioral Sciences, University of California, Los Angeles, CA; 5) Department of Psychiatry, University of Michigan, Ann Arbor, MI; 6) University of Michigan Depression Center, Ann Arbor, MI; 7) Medical Research Council Social, Genetics and Developmental Psychiatry Center, Institute for Psychiatry, King's College London, UK; 8) Psychology Dept, University of Minnesota, Minneapolis, MN.

Accurate detection and filtering of short insertions and deletions (indels) and structural variants (SVs) is very challenging. Unlike SNPs, which can be validated using array-based genotyping, indels and SVs have fewer reliable resources to evaluate quality. Assessment of the pattern of genotype calls between members of the same family can provide an alternative way to evaluate variant quality, as the vast majority of variants should follow Mendelian inheritance (MI) patterns. However, even at truly variant sites, genotype calls contain errors and uncertainties due to variable read depth or quality, limiting the ability to distinguish between true and false variants. We develop a variant filtering method (MiFT) by quantifying the statistical support for a MI pattern of each variant in family sequence data. First, we compare the likelihood of sequence reads under models with and without family structure to obtain a Bayes' Factor that quantifies the degree of support for MI. Second, we train a support vector machine (SVM) classifier to differentiate between variants with very high or low Bayes' Factors, using the variant features annotated by each caller. Third, we can transfer the SVM classifier to predict the quality of variants produced from an independent sequencing dataset without related individuals. We used MiFT to filter SNP, indel, and SV calls produced by GotCloud, UnifiedGenotyper (UG), HaplotypeCaller (HC), GenomeSTRiP, Pindel, and CBS on whole genome sequences of 281 Minnesota Twins samples over 84 families. We then applied the prediction model to 2,833 unrelated subjects sequenced in BRIDGES. We observed that existing SNP filtering methods are highly concordant to results from MiFT (e.g. 97% for UG). For indels, concordance of MiFT prediction with standard filtering was substantially lower (e.g. 78% for UG). When the filters disagree, variants exclusive to MiFT were significantly more concordant to independent validation results from Affymetrix exome arrays (e.g. OR=8.3, p=7.6×10-8 for UG). For structural variants, we observed that GenomeSTRiP effectively filters out Mendelian inconsistent variants, but also filters out 30% of the Mendelian consistent variants preserved by MiFT. MiFT provides a general framework to robustly filter SNPs, Indels, and SVs. MiFT allows us to evaluate variant call sets against a single standard and will facilitate systematic integration of multiple call sets while achieving high sensitivity and specificity.

1595T

Strength in Numbers: Efficiency and Quality Improvements in Clinical Whole Genome Interpretation. *E. Ramos, C. Mead, J. Sardina, A. Khouzam, D. Mote, S. Pond, A. Crawford, S. Ajay, J. Silhavy, S. Chowdhury, T. Hambuch.* Illumina Clinical Services Laboratory, San Diego, CA.

As the cost of whole genome sequencing rapidly decreases and technical limitations are surmounted, one of the most significant remaining challenges of clinical human whole genome sequencing (WGS) is the interpretation of newly discovered variants. Since October 2012, the Illumina Clinical Services Laboratory has sequenced and interpreted the genomes from approximately 500 primarily healthy adults; with interpretation focusing on 1600 genes associated with 1221 of the most commonly tested monogenic conditions. All single nucleotide variants were assessed to determine clinical significance by a team of trained geneticists and genetic counselors, in accordance with the American College of Medical Genetics & Genomics guidelines. This process includes a manual review of the literature for all variants detected within that subset of 1600 genes. As the Illumina Variant Database has grown to greater than 60,000 variants, including more than 650 variants with potential clinical significance, the average number of variants per genome that are novel to our laboratory has decayed significantly. Currently, of the approximately 5000 single nucleotide variants detected within the subset of 1600 interpreted genes, an average of 65 novel variants is found per genome. This is a six-fold decrease from the 360 novel variants identified per genome in May 2013, resulting in a substantial concomitant reduction in manual effort. This reduction has been accelerated through custom software developed to facilitate the clinical process of classifying, interpreting and reporting on variant disease relationships. These two factors have contributed to an overall decrease in time required for a single WGS sample, from 35 hours in May 2013 to less than ten hours today. Continued growth in the total number of variants within the database, as well as improvements to the software that aids in the annotation and interpretation process, is anticipated to result in a continued diminution of interpretation effort, which will improve the quality of ongoing interpretation and mitigate the cost of offering WGS in the clinic. Although challenges involving the clinical interpretation of whole genome sequence data will persist, these advances are anticipated to facilitate the implementation of WGS in the clinical laboratory testing arena.

1596S

Effective filtering strategies to improve data quality from population-based whole exome sequencing studies. *E. Smith[1], A.R. Carson[1], T. Solomon[1], H. Matsui[1], S.K. Braekkan[2,3], K. Jepsen[1], J.B. Hansen[2,3], K.A. Frazer[1,4,5].* 1) Department of Pediatrics and Rady Children's Hospital, University of CA, San Diego, 92093, CA; 2) Department of Clinical Medicine, Hematological Research Group, University of Tromsø, Tromsø, Norway; 3) Division of Internal Medicine, University Hospital of North Norway, Tromsø, Norway; 4) Clinical and Translational Research Institute, University of California, San Diego, USA; 5) Department of Clinical Medicine, University of Tromsø, Tromsø, Norway.

Genotypes generated in next generation sequencing studies contain errors which can significantly impact the power to detect signals in common and rare variant association tests. These genotyping errors are not explicitly filtered by the standard GATK Variant Quality Score Recalibration (VQSR) tool and thus remain a source of errors in whole exome sequencing (WES) projects that follow GATK's recommended best practices. Therefore, additional data filtering methods are required to effectively remove these errors before performing association analyses with complex phenotypes. Here we empirically derive thresholds for genotype and variant filters that, when used in conjunction with the VQSR tool, achieve higher data quality than when using VQSR alone. The detailed filtering strategies improve the concordance of sequenced genotypes with array genotypes from 99.33% to 99.77%; improve the percent of discordant genotypes removed from 10.5% to 69.5%; and improve the Ti/Tv ratio from 2.63 to 2.75. We also demonstrate that managing batch effects by separating samples based on different target capture and sequencing chemistry protocols results in a final data set containing 40.9% more high-quality variants. In addition, imputation is an important component of WES studies and is used to estimate common variant genotypes to generate additional markers for association analyses. As such, we demonstrate filtering methods for imputed data that improve genotype concordance from 79.3% to 99.8% while removing 99.5% of discordant genotypes. The described filtering methods are advantageous for large population-based WES studies designed to identify common and rare variation associated with complex diseases. Compared to data processed through standard practices, these strategies result in substantially higher quality data for common and rare association analyses.

1597M

Computational validation of NGS variant calls using genotype data. *M.A. Taub[1], S. Shringarpure[2], R.A. Mathias[3], R.D. Hernandez[4], T.D. O'Connor[5], Z.A. Szpiech[4], R. Torres[4], F.M. De La Vega[2], C.D. Bustamante[2], K.C. Barnes[3].* 1) Biostatistics, Johns Hopkins, Baltimore, MD; 2) Genetics, Stanford University, Palo Alto, CA; 3) Medicine, Johns Hopkins, Baltimore, MD; 4) Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA; 5) Medicine, University of Maryland, College Park, MD.

Variant calling from next-generation sequencing (NGS) data is susceptible to false positive calls due to sequencing, mapping and other errors. We present a method that uses machine learning techniques, specifically Random Forests, for computationally validating variant calls obtained from a sample of individuals. While existing methods use site quality information from known samples such as HapMap and dbSNP for training classifiers to distinguish between true and false variant calls, our method uses genotype data from the same samples to learn a more accurate classifier. We demonstrate our method on a set of variant calls obtained from 643 high-coverage African-American genomes from the The Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA), sequenced to high depth (~30X). On variant calls obtained using Illumina's single-sample caller CASAVA, our method has a True Positive Rate of 97.5% (at a False Positive Rate of 5%). On variant calls obtained from Real Time Genomics' multisample variant caller, our method obtains a True Positive Rate of 95% (at a False Positive Rate of 5%). Since most NGS sequencing data is accompanied by genotype data for the same samples, our method can be trained on each dataset to provide a more accurate computational validation of site calls than using generic methods. In addition, our method can allow for adjustment based on allele frequency (e.g., allow a different set of criteria to determine quality for rare vs. common variants) and thereby provide insight into sequencing characteristics that most clearly indicate data quality for variants of different frequencies. We have also applied our classifier to compare call sets generated with different calling methods, including both single-sample and multi-sample callers, and we have found that allele frequency is an important determinant of which calling method makes the most accurate calls.

1598T

Blood vs Saliva: Analysis of the Effect of Sample Type on Variant Calling Confidence for Human Whole Genome Sequencing. *M. Tayeb[1], A. Mijalkovic[2], M. Kovacevic[2], M. Popovic[2], S. Wernicke[2], C. Dillane[1], A. Del Duca[1], R.M. Iwasiow[1].* 1) DNA Genotek Inc., Ottawa, Canada; 2) Seven Bridges Genomics Inc, Cambridge, Massachusetts.

Saliva, obtained using the Oragene self-collection kit, as a source of genomic DNA has grown in popularity due to participant compliance and the high quality and utility of the collected DNA. Although Oragene/saliva is supported by over 1000 peer-reviewed publications, to date few papers have been published on Whole Genome Sequencing (WGS) from saliva. Here we present a systematic, multi-sample analysis of the effect of sample type (blood vs. saliva) on variant calling confidence and the effect of bacterial DNA in saliva on sequence alignment.

Blood and saliva were collected from seven individuals (two families). The bacterial content in each saliva sample was determined by 16S qPCR. DNA was extracted and sequenced on the Illumina HiSeq2000 using standard protocols from Illumina. Variant calling and filtering was performed on the Seven Bridges Genomics platform for bioinformatics analysis using a standard BWA and GATK pipeline in accordance with the Broad Institute's best-practices guidelines.

The percentage of bacterial DNA was found to closely correlate with the number of reads that could not be mapped to the human genome. Those reads were aligned to bacterial and viral genomes obtained from the Human Microbiome Project (HMP). A significant portion of unaligned reads mapped to the HMP reference (72% in blood, 32% in saliva).

No significant difference in the total number of variants called in blood and saliva were observed. Only a slight difference in concordance between sample types was observed (<0.15% for SNPs and <1% for INDEL). Downsampling blood samples to equal coverage virtually eliminated these differences suggesting that the difference in concordance was primarily due to coverage effects. Additional analysis was performed to check for existence of ambiguous regions that act as baits for bacterial reads causing saliva samples to accumulate false positive mutations in those regions.

The overall coverage loss due to bacterial content in saliva is small (approx 3% for every 5% bacterial DNA in the sample) and does not result in a difference in the number of variants called. Concordance differences between blood and saliva are minor and can be eliminated by ensuring adequate sequencing coverage.

1599S

High resolution HLA genotyping software for exome and whole genome sequencing data. *K. Kryukov, S. Nakagawa, T. Imanishi.* Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

The MHC region on chromosome 6 contains human leukocyte antigen (HLA) genes, which are some of the most polymorphic genes in the human genome. Many HLA alleles are known to be associated with susceptibility to various infectious and autoimmune diseases. Genotyping HLA loci correctly is challenging due to abundant repeats, high sequence similarity among HLA genes, as well as the presence of highly similar pseudogenes. Normally, sequence-based genotyping is done by highly targeted sequencing of specific loci. Here we present a genotyping software that allows predicting HLA genotypes based on the whole exome or the whole genome sequencing data. Our method is based on sequence similarity searches of the raw reads to the database that combines HLA alleles from the IMGT/HLA database, the known MHC haplotype sequences from Sanger Center, and the entire reference human genome. This allows to accurately map reads to specific loci. We then focus on each locus and compare the mapped reads with the known allele sequences to determine the genotype. Our method has accuracy of 90% in 2-digit typing and 74% in 4-digit typing for Class-I and Class-II genes, on Ion Torrent sequence data targeted to specific HLA genes.

1600M

Using haploid human DNA to design and evaluate the HiSeq X data processing strategy. *M.O. Pollard, T.M. Keane, S.A. McCarthy, J.C. Randall, R.M. Durbin.* Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge CB10 1SA, UK.

The Illumina HiSeq X is a new sequencing platform that promises a reduction in sequencing cost to below $1000 per whole human genome. The dramatic increase in throughput that this platform will deliver has required changes to chemistry, software, and output. Of interest to dry lab scientists are several key changes in the data produced including an the increase in read length to 150 base pairs and the binning of base quality scores into eight distinct quality bins in order to reduce the quantity of data that is stored.

To take full advantage of this new platform, we have designed a series of systematic tests to evaluate the sequence data produced by the HiSeq X and determine the most appropriate subsequent processing protocols. We will test and compare different combinations of mapper, variant caller, and reference; using well characterised samples in order to examine the effects that this technology has on each and evaluating its utility for variant detection.

In this experiment, we plan to sequence the 1000 Genomes CEU Trio and two human haploid cell lines: CHM1hTERT and HAP1. We will evaluate the effects of various read alignment tools (BWA backtrack, BWA MEM, and SNAP), variant callers (samtools, GATK Unified Genotyper, and GATK Haplotype Caller), and choice of reference (GRCh37 vs GRCh38) on the sensitivity and specificity of SNP/InDel identification. The CEU Trio is a well-studied family, which has been used in many previous studies such as HapMap and 1000 Genomes providing a corpus of knowledge to compare against. Both the CHM1hTERT and HAP1 cell lines are effectively haploid, meaning that any heterozygous variants found are likely to be either a sequencing error or data processing artifact. In addition, when HAP1 is mixed with CHM1hTERT in equal proportions it should allow us to evaluate heterozygous calling and phasing performance. The findings of these experiments will be valuable for determining the optimal data processing strategy for the HiSeq X.

1601T

Genotyping Complex Markers for Drug Absorption, Distribution, Metabolism and Elimination with the Axiom® Genotyping Platform. *J. Gollub, C. Bruckner, M. Gallina, S. Malakshah, M. Mittmann, P. Roghani, A.H. Roter, F. Siddiqui, R. Varma, B. Wong, T. Webster, M.H. Shapero, J.P. Schmidt.* Affymetrix, Inc., Santa Clara, CA.

Many genomic markers (SNPs, indels, and copy number changes) relevant to drug absorption, distribution, metabolism and elimination (ADME) are difficult to genotype due to complex genomic contexts with high homology to other sites, and many nearby polymorphisms. Copy number (CN) changes in relevant genes such as GSTT1, GSTM1, UGT2B17, CYP2D6, and CYP2A6 can be difficult to assess because they are members of large gene families with highly homologous sequence, or because of the high prevalence of copy number states other than 2 in the population. We have developed algorithms for probe design and analysis on the Axiom® Genotyping Platform to assay these challenging regions. Copy number detection is based on signal response of SNP-genotyping probesets; considerations include probe selection for good dose response to changes in copy number state, and accurate summarization of signal values for classification. In the hybridization-based Axiom® assay, genotyping SNPs and indels in the presence of other, nearby polymorphisms requires probe design to account for alternative genomic contexts, as well as algorithmic identification of appropriate probes for each individual. Multiallelic markers pose a challenge as well, requiring the development of genotyping algorithms that allow for more than the usual three possible states per marker. Results indicate accurate copy number calls on the five key genes listed above, with good discrimination between homozygous copy loss (CN 0), hemizygous loss (CN 1), CN 2 and CN 3 where applicable. We likewise observe highly accurate genotype calls on many SNPs and indels in complex regions with multiple flanking variants. The ability to accurately identify pharmacogenomic polymorphisms in a highly multiplexed assay could dramatically impact future drug development processes. Here we show that advanced probe design strategies, and new algorithms, supported by the fundamental flexibility of the Affymetrix Axiom® technology, allow for successful genotyping of problematic ADME variants.

1602S

PHENOVAR: a phenotype-driven approach to facilitate routine utilization of clinical exome sequencing for the diagnosis of polymalformative syndromes. *C. Buote[1,4], F. Thuriot[1], M. Edmont[1], E. Gravel[1], Y. Trakadis[2], JF. Theriault[1,3], H. Larochelle[3], B. Maranda[1], S. Chénier[1], PE. Jacques[4], S. Lévesque[1].* 1) Dept. of Paediatrics, division of medical genetics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Canada; 2) Dept. of Medical Genetics, McGill University Health Center, Montréal, Canada; 3) Dept. of Informatics, Faculty of Science, Université de Sherbrooke, Sherbrooke, Canada; 4) Dept. of Biology, Faculty of Science, Université de Sherbrooke, Sherbrooke, Canada.

BACKGROUND: Polymalformation syndromes consist in a large group of heterogeneous genetic disorders, for which our ability to identify the causative gene using conventional investigations remains limited. Exome sequencing offers a solution and is now available either on a research basis or in few clinical laboratories across the US. Routine utilization of exome sequencing is still hindered by our capacity to predict effectively the causative change(s) out of several thousands of variants. To facilitate exome analysis and accelerate implementation of exome sequencing in clinical practice, we have developed and recently published a software, named PhenoVar. This software integrates the patient's phenotype to the genotype data and suggests to the physician-user a short list of prioritized potential diagnoses for review. Here, we present the preliminary results of PhenoVar validation in patients affected with an undetermined polymalformation syndrome, in comparison to standard bioinformatics analysis. METHODS: A total of 25 patients with polymalformative syndromes of likely genetic etiology were accepted for exome sequencing after genetic counselling. Each patient has a normal array CGH and remains without a clear diagnosis after Sanger sequencing-based gene tests. To date, we completed the sequencing of 14 patients. A medical geneticist performed the analysis on these patients using PhenoVar, in parallel of the standard analysis done by the bioinformatics team. RESULTS: On average, PhenoVar reduced the number of potential diagnoses for manual review to 20 per patient in comparison to 63, for standard bioinformatics analysis. In both cases, we obtained a diagnostic yield of nearly 50 % (6 /14). Each time, the correct diagnosis was found in the top ten diagnoses of the PhenoVar's list. In patients who provided consent, we searched for variants in cancer genes, which led to the identification of a pathological variants in *BRCA2* in one of them. Remaining patients' exomes are being sequenced and analyzed, and will be presented. CONCLUSION: Our preliminary results suggests that exome sequencing combined with PhenoVar, using a phenotype-driven approach, led to a similar diagnostic yield than standard bioinformatics analysis, reduced the human resources and time required for bioinformatics analysis. Since it can be used directly by medical geneticists, this software could facilitate routine utilization of exome sequencing in clinical practice.

Single molecule reconstruction and variant detection of less than 1 genome in 1000. *K.R. Covington, M. Wang, D.M. Muzny, H. Doddapaneni, R.A. Gibbs, D.A. Wheeler.* Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX., USA.

Genetic mosaicism contributes to phenotypic diversity both in physiology and disease including phenotypic diversity in monozygotic twins, brain development and disease, and cancer. Conventional sequencing approaches to variant discovery rely on repeated sampling of variants, from the population of genomes in a given sample. Standard sequencing methods fail to address rare, subclonal mutations due to confounding influence of sequencing errors, even at high sequence depth. We address this problem by adapting published proof-of-concept methodologies for deep sequencing using single molecule reconstruction. Single molecule reconstruction relies on repeatedly sequencing the PCR products of single molecules of DNA and using the sequence data to reconstruct the sequence of the initial molecule. With this strategy we turn PCR duplicates into an advantage to repeatedly sample fragments which can be traced to a single DNA molecule. We used a combination of 6 to 24 Illumina barcode adapters pooled to individually tag sheared DNA libraries. DNA libraries were then captured using custom cancer capture designs. Libraries were sequenced using either Illumina MiSeq (for initial testing) or HiSeq platforms. Sequencing data was aligned to the human genome hg19 build. We developed custom software to reassemble sequencing reads into their original single molecule DNA fragments and for further analysis. Over 90% of non-reference bases sequenced were observed only in one read of a duplex set, indicating that these non-reference bases are merely sequencing errors. Our ability to recreate the initial DNA molecule allowed us to detect variant genomes at less than 1:1000 variant allele fraction in a series of spike-in tests. Interestingly, over 50% of consensus variants were called in only one molecule, even in normal tissues. These data suggest the presence of an extensive reservoir of somatic variation in normal tissues, which may contribute to human disease.

1604T

Detection of common and low frequency variants in cancer samples with SNPPET using NGS target enrichment data. *A. LNU, D. Joshi, C. Lecocq, J. Ghosh.* Agilent Technologies, Santa Clara, CA.

Identification of variants from cancer samples using NGS target enrichment is becoming increasingly popular in clinical research. Cancer samples are challenging for variant detection due to tumor heterogeneity, low abundance of variant bases, mixed genotypes, multi-allelic loci, copy-number variations, variable background mutation rates and contamination from normal cells. After evaluating available methods it was imperative to develop an algorithm in-house. SNPPET was developed in Agilent SureCall software to detect cancer variants with high confidence. SNPPET has two basic steps - first an efficient search for variants and then a careful examination of the variant's neighborhood to confirm the call. In the first step, the reads and bases are filtered for quality and coverage criteria such as mapping qualities, base qualities and read depths. SNNPET's initial model evaluates each locus and all non-reference alleles are assigned to sequencing error. Then a second model considers each non-reference allele to be a true variant. The models allow presence of more than one allele at each locus. A log-odds score is calculated between the two models and if the score passes a specified threshold, it is considered as a variant indicating the allele is more likely to be a variant than a sequencing error. If multi-allelic option is chosen, all potentially variant alleles are retained. Otherwise only the one with maximum allele fraction is retained. In the second step, a local re-assembly is done to evaluate all potentials variant combinations as haplotypes. The haplotypes are scored by a Bayesian model and all variants passing the threshold are retained. SNPPET allows one to examine loci of interest irrespective of whether a "true" variant is present or not. This allows one to ascertain whether there is low significance event plausible at a locus which did not pass the statistical tests, but still may be indicative of potential variation in a site of interest. Dilution series experiments were performed to benchmark the sensitivity and specificity of SNPPET and to compare the variant calls with other state of the art methods. A cancer cell line(HCT116) was mixed with normal HapMap(NA10831) at various concentrations. At concentration of <= 5%; SNPPET detected expected variants that are missed by GATK unified genotyper and SAMTools. SNPPET demonstrated greater sensitivity than any other methods compared, keeping the specificity at par with these methods.

1605S

Identification of common non-synonymous SNPs in proteomic datasets and their use to obtain measures of individualization and biogeographic background. *G. Parker[1,2], D. Anex[2], T. Leppert[3], L. Baird[3], N. Matsunami[3], M. Leppert[3], B. Hart[2].* 1) Utah Valley University, Dept of Biology, Orem, UT; 2) Forensic Science Center, Lawrence Livermore National Laboratory, Livermore, CA; 3) Department of Human Genetics, University of Utah, Salt Lake City, UT.

We have developed methodology to extract identifying genetic information from proteomic datasets. DNA-typing has revolutionized forensic practice and jurisprudence, however DNA often is degraded due to biological, chemical or environmental factors. Protein is considerably more stable, more abundant than DNA, and persists in the environment for a longer period. Protein also contains genetic information in its primary structure, the result of non-synonymous SNPs (nsSNPs). These single amino-acid polymorphisms are accessible to shotgun tandem mass spectrometry. We have identified nsSNP-containing peptides from 35 alleles in 26 genes expressed in the forensically informative hair shaft proteome. We obtained complex proteomic datasets from trypsin digests of the hair shafts of 54 validated European American individuals. Peptides corresponding to nsSNPs expressed in this protein population were identified and collated for each individual. The combined probability of each individual nsSNP profile was calculated using genotypic frequencies of each allelic combination in the European population (1000 Genomes Project) and the "product-rule". The power of genetic discrimination ranged from 1 in 1.002 to 1 in 9,000. The average power of discrimination was 1 in 280. The power of discrimination increased as a function of proteomic dataset quality ($r^2 = 0.624$, $n = 58$, $p < 0.0001$). When the power of discrimination is calculated using genotypic frequencies from the African population, increased powers of discrimination are achieved. This is consistent with an increased likelihood that the samples originate from a European relative to African origin. Likelihood measurements range from 1 to 780 with an average of 50, a median of 18, and a standard deviation of 116. ($n = 64$). Direct validation of the imputed status of each nsSNP allele was achieved with Sanger sequencing. A total of 430 genotype determinations were made from the proteomic data and 426 assignments were confirmed (specificity = 99.1%, FPR = 0.93%). The average sensitivity was 31%. We have established a framework for the use of proteomic datasets as a source of identifying genetic information, allowing measures of identity and biogeographic background to be made from forensic or anthropological protein. This study also demonstrates that protections should be enacted to ensure the privacy and confidentiality of human subjects when providing tissue for proteomic studies.

1606M

SNP and CNV Detection in Trisomy 21 Individuals Using a First-Principles Approach. *Y.A. Jakubek, D.J. Cutler.* Human Genetics, Emory University, Atlanta,GA.

Genotyping arrays are used to simultaneously detect single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) across the genome. Current analysis methods use empirical data to call SNPs; therefore, they are not well suited for studies with a small number of samples and for SNPs with a low minor allele frequency. These methods drop 20% to 33% of the targeted SNPs and are susceptible to batch effects. We have developed a SNP and CNV detection algorithm for Affy 6.0 arrays that is based on a low-level model of hybridization on the array. In it we model binding between all probe-DNA duplexes that form on the array. Furthermore, we explicitly model batch effects through a set of parameters that describe binding for each array experiment: DNA concentration, probe errors, salt concentration, wash stringency, and scanner settings. This biochemical approach allows for the individual analysis of each chip. Since we directly model DNA concentration, our algorithm can type SNPs and CNVs on chromosomes of any ploidy. Our method assigns a posterior probability to each SNP; we refer to this value as the quality score (QS) for the call. We analyzed data from Down syndrome and normal samples. 13% of targeted SNPs show significant cross-hybridization. 84% of SNPs on diploid chromosomes and 57% of SNPs on trisomic chromosome 21 had QS > 0.99. Our algorithm directly estimates DNA concentration for each probe and then uses these values to detect CNVs. This approach is fundamentally different from current approaches that rely on probe intensity. We called an average of 50 CNVs per individual and 68% of the CNVs called were in the database of genomic variants (DGV). This data was previously analyzed; validation was attempted for 64 CNVs of which 59 were validated. Our method only called the 59 validated CNVs. This method can be easily adapted to call SNPs within CNVs and for aneuploid chromosomes in general. Using only first-principles our method detects genetic variants with high accuracy.

1607T

Variant Detection and Validation in RNA-Seq Data. *F. Schlesinger, I. Khrebtukova, L.C. Watson, S.M. Gross, S. Pathak, T. Singer, T. Hill, G.P. Schroth, R. Kelley.* Illumina Inc San Diego, CA.

Shotgun sequencing of cDNA (RNA-seq) has become a widely used tool to measure gene expression. One benefit of RNA-seq is that, due to the full sequencing read-out, it allows the detection of genomic sequence variation at the same time as expression levels; ranging from SNVs and small insertions or deletions, to large scale structural events, such as gene fusions. This can be used to create 'exome-like' variant call sets quickly and cheaply, without the need for sequence enrichment, especially in non-model organisms. Perhaps more importantly, it also allows researchers to confirm and extend results from matched DNA sequencing data and support variant interpretation. Especially in the context of cancer samples such collection of matched DNA and RNA is becoming common, for example by The Cancer Genome Atlas (TCGA) project. However, while a lot of progress has been made on variant calling software for DNA sequencing, these tools typically do not work well with RNA-seq data, and specialized RNA callers are still limited in reliability, accuracy and run-time. In addition systematic evaluation of accuracy on different RNA-seq datasets, as well as best practice guidelines are missing. Here we present a new analysis pipeline for RNA-seq that integrates gene expression analysis with high-accuracy variant calling, based on one single-pass alignment process, greatly reducing computational cost. We use a comprehensive set of known variants (including SNVs and Indels), validated by analysis of inheritance patterns across a large pedigree, for a systematic, unbiased evaluation of RNA variant calls. On this data we apply machine-learning techniques to train an RNA-specific variant scoring model and measure sensitivity and specificity as a function of expression levels, including the impact of allele-specific expression on sensitivity. We assess performance across a range of RNA-seq data-types, including different sample preparations techniques and sequencing depth, showing false positive rates ranging from 1% to 5%. Integrating matched DNA and RNA data, we demonstrate how RNA-seq can be used to improve accuracy of DNA variant call sets by rescuing up to 5% of marginal calls. We derive allele-specific expression and between-exon phasing information to guide variant interpretation.

1608S

An Evaluation of Splice Prediction Software Accuracy Using in vivo Data from Patients with Osteogenesis Imperfecta. *J. Schleit[1], S.S. Bailey[1], T.T. Tran[1], D. Chen[1], S. Stowers[1], U. Schwarze[1], P.H. Byers[1,2].* 1) Pathology, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA.

Approximately 20% of pathogenic mutations in COL1A1, which encodes the proα(I) chain of type I collagen, alter mRNA splicing. The Osteogenesis Imperfecta (OI) phenotypes that result depend on the sequence and stability of the resulting mRNA(s). Stable mRNA transcripts produce more severe OI, while unstable mRNAs are associated with milder OI. When molecular diagnostics relies on DNA sequence analysis alone, the need to predict splice outcomes has increased. Many diagnostic labs use prediction software to interpret splice site mutations. To test the accuracy of these tools we sequenced cDNAs from patient-derived fibroblasts, treated with cycloheximide to stabilize mRNAs, from 38 individuals with OI. Our sample set included 15 samples from individuals with OI type I, 4 with OI type IV, 7 with OI type III individuals, and 12 with OI type II. We found that IVS[X]-1G>A changes always resulted in frameshifts when the first nucleotide of the adjacent exon was G, that other mutations in consensus sites were not as predictable, and that there were often multiple outcomes. We compared our measured findings to outputs from three splice prediction software: Human Splice Finder (HSF), Spliceport (SP), and Automated Exon Definition and Splice Site Analysis (ASSEDA). All three programs predicted that the sequence changes examined were pathogenic with greater than 80% accuracy. However, the programs differed in their ability to predict the actual splice outcome (HSF correctly predicted splice outcome in 42% of cases, SP in 55%, and ASSEDA in 74%). Determination that a variant is pathogenic is the first step. If splice site mutations in the same gene result in a range of phenotypic severity, a clinical severity score would be a valuable adjunct to outcome prediction. Because for COL1A1 mutations, the relation between splice outcome and phenotype has been well studied, we asked if the incorrectly predicted splice outcomes could, nonetheless, result in appropriate phenotypic predictions. For splice outcomes incorrectly predicted by HSF 68% resulted in phenotype errors, by SP 76% resulted in phenotype errors, and by ASSEDA 60% still resulted in phenotype errors. The type of error differed among programs. At this point, there is no substitute for the measure of splice outcome in many instances and care must be taken in the use of splice prediction software for clinical purposes.

1609M

Higher power and efficiency of whole genome sequencing over whole exome sequencing to detect SNVs in exonic regions. *A. Belkadi[1], A. Bolze[2], J.L. Casanova[1,2,3], L. Abel[1,2].* 1) Laboratory of Human Genetics of Infectious Disease, INSERM U1163, University Paris Descartes. Imagine Institute, Paris, France; 2) St. Giles Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, the Rockefeller University, New York, NY, USA; 3) Howard Hughes Medical Institute, New York, NY, USA.

Whole exome sequencing (WES) is now a standard method to detect rare and common genetic variants. Whole genome sequencing (WGS) is becoming an attractive alternative approach with an affordable price. Here we compared WES and WGS in the detection of single nucleotide variants (SNVs) in the coding regions of the human genome using the most recent technologies. We performed WES (using the SureSelect Human All Exon Kit 71 Mb) and WGS (using the TruSeq DNA PCR-Free Sample Preparation Kit) in 7 European individuals. Both platforms sequence paired-end reads of ~100 base pairs. A total of 132,108 SNVs were detected by either WES or WGS within the regions targeted by the WES kit, 86.7% by both methods, 4.5% by WES, only and 8.8% by WGS only. While these variants were present in a total number of reads which were similar in WES (~5.8 millions) and in WGS (~4.7 millions), the distribution of the coverage depth was strikingly different between the two methods. In WES data, the distribution of depth was lognormal-like with a mode at 5x and a median at 26x, while the distribution was normal-like in WGS data with a mode/median at 38x, showing a much more homogeneous coverage by WGS. Among the 114,586 SNVs coded by both platforms, we noted discordant genotypes in 3,676 variants (3.2%) that were in all cases called as homozygous by WES and as heterozygous by WGS. We then filtered the variants on depth (> 8x), genotype quality (>20), and minor allele ratio in heterozygous genotypes (≥20%). Only 69.4% of WES variants passed the filter, while 97.1% of WGS variants did. After filtering, a total of 82,331 SNVs were called by both platforms (99.97% of those variants had the same genotype), 3,857 variants by WES only and 41,489 by WGS only. Refined analysis of variants exclusive to WES by the Integral Genomic Viewer tool showed that these variants are also present in WGS data but not called by Unified Genotyper. The utilization of an alternative/additional variant caller on WGS should call these variants. In contrast, variants exclusive to WGS were not present in WES data. These variants mapped to coding regions, UTRs, splice-sites and non-coding RNAs. We conclude that WGS is more powerful and more efficient than WES to detect SNVs even in exonic regions, as it calls about ~50% more high quality SNVs than WES. This work will have major impact to define the most cost-effective strategy to identify the genetic etiology of rare and common diseases.

1610T

Evaluation of the Illumina NextSeq500 for Rapid Whole Genome Sequencing. *S. Dames[1], J. Durtschi[1], R. Mao[1, 2], K.V. Voelkerding[1, 2].* 1) ARUP Labs, Salt Lake City, UT; 2) University of Utah Department of Pathology.

Introduction: Rapid sequencing of the whole genomes offers a new diagnostic tool in clinical settings, including newborns. A new next generation sequencing platform, the Illumina NextSeq500, generates 120 Gb of sequence in 29 hours using 2 X 150 base length reads. This represents 30-fold average coverage of the human genome. The current study evaluates the quality of whole genome sequencing data generated by the NextSeq500. **Methods**: HapMap sample NA12878 whole genome Illumina libraries were prepared using a Beckman Coulter SPRI-TE. The ARUP validated clinical pipeline comprised of BWA, SAMtools, GATK, and Annovar was employed. NextSeq500 NA12878 whole genome data was compared to NA12878 NIST and NA12878 exome data. For the gene structure variation and loss/gain analysis, alternate percentage and reference allele percentage reads per variant were plotted against chromosomal location to visualize CNVs that alter the expected allele read frequency. **Results**: Two independent runs of NA12878 yielded 68 Gb at 87.9 percent >Q30 and 134.5 Gb at 70.4 percent >Q30. Whole genome data filtered by exome bed file coordinates was intersected with NIST NA12878 data. 66,975 variants were detected in whole genome data, with 66,492 >4-fold (99.3 percent) and 65,232 >8-fold coverage (98.1 percent), average 21-fold coverage. The NIST high confidence data contains 55,176 variants in these regions, where 53,958 (97.8 percent) were concordant between whole genome data and NIST data, and 49,526 (89.8 percent) were concordant between the exome data and NIST data. The copy number gain/loss results were concordant with high density SNP array. **Conclusions**: Preliminary analysis demonstrates an approximate 98 percent concordance between variant calls derived from NextSeq500 whole genome sequencing of NA12878 and high confidence NIST NA12878 variant data More sophisticated analysis comparing different alignment and variant calling algorithms to improve alignment and variant call accuracy and speeds will be presented. Further analysis is underway to determine the cause of discordants between NA12878 NIST and whole genome data. Improvements in the speed of analysis and quality metrics will improve turn around time, and may preclude the requirement of Sanger verification for a subset of variants.

1611S

Benchmarking of DNA short read aligners on GCAT data sets. *R. Gupta, A. Kalbhor, P. Potla, S. Katragadda, V. Veeramachaneni, R. Hariharan.* Strand Life Sciences, Bangalore, Karnataka, India.

Background and Objectives: Next generation sequencing technology has led to the generation of millions of short reads at an affordable cost. Aligning these short reads to a reference genome is a crucial task for most of the downstream analysis. However aligning the short reads to a reference genome is a non-trivial task because of the large size of the data and many complex regions in the genome. These challenges necessitate the need for sophisticated algorithms that are both accurate and computationally efficient. In this work, we will briefly discuss Strand NGS (formerly Avadis NGS) alignment algorithm and present the benchmarking results on several simulated data sets and a real whole-genome data to compare it with other state-of-the-art algorithms. **Results:** Multiple aligners like Strand NGS, BWA, BWA-Mem, Bowtie2 and Novoalign3 are compared for accuracy and computational efficiency using 4 simulated data sets from the GCAT website and a real Illumina HiSeq 2500 whole-genome paired-end data of 1000 genomes CEU female sample, NA12878. Strand NGS and Novoalign3 showed comparable accuracy in terms of '% correctly mapped' reads and receiver operating curves (ROC). They also seem to outperform other algorithms especially on data sets with longer InDels. Our aligner, Strand NGS has been designed to detect longer indels by excluding the longest gap in a read match while computing the percent identity (alignment score) for the match. This makes it possible to give a higher cut-off for the percentage of gaps allowed, without reducing the percent match cut-off. For reads potentially originating from complex genomic locations like repeat regions, Strand NGS aligner produces a higher true positive rate compared to Novoalign3, when aligned reads are filtered based on the associated assigned mapping qualities. As for the performance comparison based on computational efficiency, other than minor differences, practically all the included algorithms showed comparable performance. **Conclusions:** Alignment of millions of short reads to a large reference genome with many complex regions is still a hard problem and almost all current algorithms adopt some form of strategy to trade-off accuracy and computational efficiency. The benchmarking results presented in this study suggest that Strand NGS aligner is a powerful approach for DNA short read alignment and either compares well or even outperforms other state-of-the-art algorithms.

1612M

A comparison of commonly used alignment algorithms using 15 whole genome sequences. *B.D. Pickett[1], M.E. Wadsworth[1], K.L. Hoyt[1], J.D. Duce[1], J.S.K. Kauwe[1], M.J. Clement[2], P.G. Ridge[1].* 1) Department of Biology, Brigham Young University, Provo, UT; 2) Computer Science Department, Brigham Young University, Provo, UT.

Due to the large amount of relatively small reads produced from next-generation sequencing (NGS), assembling a genome is a time-consuming and complex task. Aligning reads accurately and in a timely manner is critical for successful research. Many algorithms exist to align NGS reads and each claims to be the most accurate and has the data to "prove" it in publications describing the software. However, these comparisons are flawed for several reasons: (a) The developers of novel software packages most often are the researchers performing the comparison and report only the results demonstrating that their software is superior to existing software; however, these authors have an obvious conflict-of-interest, and indeed, their comparisons are frequently not repeatable by researchers. (b) Many of these comparisons have been performed using either very small data sets or simulated data that fails to capture the complexity of real biological data. (c) Each comparison uses different data and metrics to assess software performance. Until now, no comparison has been conducted to compare these software packages that overcomes these three challenges. We perform an unbiased comparison of various aligners for NGS to (a) identify overall effectiveness, strengths, and weaknesses of each software package and (b) make the data available as a standard efficacy test for newly created software. Our analysis provides other researchers with evidence suggesting which algorithm or series of algorithms will be best for their research with unique combinations of variations in their data. Our tests are run on 15 Illumina-sequenced whole genomes. Each genome has an average read depth of 37. For our research we test the following algorithms: Bowtie2, BWA, GSNAP, Mosaik, Novoalign, Soap2, and Stampy. Each of these is free for academic use and is currently maintained. Ultimately, this will lead to more accurate experimental and analytical results.

1613T

A comprehensive comparison of RNA-seq and microarray in transcriptome profiling of rat livers exposed to a broad range of agents. *C. Wang[1], B. Gong[2], P.R. Bushel[3], J. Thierry-Mieg[4], D. Thierry-Mieg[4], J. Xu[2], H. Fang[2], H. Hong[2], L.J. Lancashire[5], C. Furlanello[6], L. Shi[7], R.S. Paules[3], S. Auerbach[3], W. Tong[2].* 1) Center for Genomics, Loma Linda University, Loma Linda, CA; 2) National Center for Toxicological Research, Jefferson, AR; 3) National Institute of Environmental Health Sciences, RTP, NC; 4) NCBI, NLM, National Institutes of Health, Bethesda, MD; 5) Thomson Reuters, London, UK; 6) Fondazione Bruno Kessler, Trento, Italy; 7) Fudan University, Shanghai, China.

Next-generation sequencing technologies have revolutionized the genomic research and allow the genome and transcriptome of any organism to be explored without a priori assumption. Compared to microarrays, RNA-seq is able to provide single-nucleotide resolution, strand specificity, and short-range connectivity through paired-end sequencing. However, emerging transcriptomics technologies should be evaluated by ways in which they create opportunities to advance the understanding of complex biological systems. An extensive and systemic investigation based on a comprehensive study design was performed to investigate the strengths/weaknesses and comparability of the two platforms in biologic elucidation. RNA extracted from livers of rats exposed to 27 agents eliciting a broad range of transcriptional response, comprised of seven modes of action (MOAs) with varying degree of biological complexity, was used to profile gene expression using Illumina RNA-seq and Affymetrix microarrays and to assess concordance. We found that RNA-seq detected more differentially expressed genes (DEGs) than microarray and hence enriched more biological pathways. While RNA-seq was superior in detecting DEGs with low abundance and could also detect differential expression of transcripts, non-coding RNAs, and exon-exon junctions in a treatment-dependent manner, prediction performances of classifiers derived from both platforms were comparable. Overall, the cross-platform concordance in terms of DEGs, enriched pathways, or modes of action is highly correlated with treatment effect size, gene-expression abundance, and the biological complexity of the mode of action.

1614S

Implementing an NGS Bioinformatics Pipeline: Making the Transition from Research to Clinical. *L. Watkins, K. Hetrick, D. Snyder, H. Ling, S. Griffith, J. Goldstein, M. Mawhinney, J. Romm, E. Hsu, G. Lowe, K. Roberts, K. Doheny, B. Craig.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality sequencing and genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to disease. The CIDR NGS bioinformatics analysis pipeline, continually developed since 2009 to keep pace with the rapid changes in the predominant sequencing analysis tools, is designed and tuned for large-scale research projects with huge numbers of analyses that must be done in parallel and fault-tolerant fashion. In winter 2013-14 CIDR partnered with a molecular diagnostic lab at our institution to migrate a traditional genetic test panel to NGS, wherein CIDR would run the NGS bioinformatics analysis and they would handle everything else. Despite a limited budget and tight timeline the effort was successful, with the first clinical results reported out in March 2014. In some regards the requirements for a clinical bioinformatics pipeline are similar to that of production research (e.g., the need for reliability and strict quality control) while others can be quite different (e.g., the small numbers of samples, absolute need for quick turn-around time, strict adherence to well-defined regions of interest, an imperative to never report a false positive, the specific and limited relevant annotations), in particular the requirement to lock down all aspects of the pipeline after validation and to document it in detail and track any associated changes in accordance with new CAP guidelines for NGS bioinformatics analysis. This militates against sharing bioinformatics pipelines and infrastructure between research and clinical, so the decision was made to establish completely separate systems. This poster describes the practical aspects and related considerations of the subsequent effort, including getting separate equipment set up and tested/validated, the logistics of remote access and execution and data transfer (with integrity checks) between separate locations, the specifics of the software tools used in the final pipeline and relevant settings, filtering parameters and QC metrics chosen and how they're used, the informatics activities required to meet CAP requirements, the cumulative person-hours required for all these activities and how that effort was distributed, as well as plans for the future. The intent is to convey lessons learned and recommendations for labs pursuing similar efforts.

1615M

Amplicon based 16S ribosomal RNA Sequencing and Species Identification. *J. Dickman, J. Risinger, M. Toloue.* Bioo Scientific Corporation, Austin, TX., USA.

Next generation sequencing analysis of 16S ribosomal RNA is commonly used to identify bacterial species and perform taxonomic studies. Bacterial 16S rRNA genes contain nine hyper-variable regions with considerable sequence diversity among different bacterial species and can be used for species id. Rapid determination of highly complex bacterial populations through targeted amplification can provide an accurate gauge of diversity at taxonomic hierarchies as low as the genus level. A single 16s rRNA hyper-variable domain does not have enough sequence diversity to distinguish contain all bacterial. With increased read lengths of MiSeq chemistry, Bioo Scientific has expanded the common analysis of the fourth hypervariable domain (V4) of prokaryotic 16S rRNA to V1, V2 and V3 regions simultaneously. Optimized preparation through a streamlined standardized procedure allows for high-quality, reproducible libraries. This optimization can be applied to different windows of 16S rRNA as well as other relevant prokaryotic taxonomic markers.

1616T

Super-resolution imaging technique mbPAINT for DNA optical mapping. *J. Chen[1], L. Kisley[2], A. Bremauntz[2], C.F. Landes[2].* 1) Department of Chemistry & Biochemistry, Ohio University, Athens, OH; 2) Department of Chemistry, Rice University, Houston, TX.

Optical mapping has been used to assist the de novo assembly of whole genomes. This fluorescent imaging technique measures the restriction maps of very long DNA molecules that are stretched on a solid support. The resolutions of the traditional techniques are limited by the diffraction limit of light. Here I am reporting a new optical mapping strategy that allows sub-diffraction limit imaging of genome optical maps using a super-resolution optical nanoscopy based on single-molecule localization method, which has been named motion blur Point Accumulation for Imaging in Nanoscale Topography (mbPAINT). The strategy is demonstrated with model target and probe DNA sequences, and an optical map of a randomly chosen repeated 7-basepair sequence in the phage λ-DNA.

1617S

Greatly improved de novo assemblies of eukaryotic genomes using PacBio long read sequencing. *E. Antoniou[1], M.C. Schatz[1], P. Deshpande[1], J. Gurtowski[1], S.M. Eskipehlivan[1], M. Kramer[1], H. Lee[1], S. Goodwin[1], C. Heiner[2], G. Khitrov[2], W.R. McCombie[1].* 1) Genome Center, Cold Spring Harbor Laboratory, Woodbury, NY; 2) Pacific Biosciences, Menlo Park, CA 94025.

High-throughput short read sequencing has revolutionized re-sequencing applications. However, they have had a more limited impact on generating high-quality de novo assemblies of eukaryotic genomes, principally because the short reads are insufficient for disambiguating complex repeats in the genomes. However, in re-sequencing of human genomes with short reads, structural variations may be missed or be ambiguous because of the need to compare to a reference without the structural variants. A combination of rapid advances in Pacific Biosciences long-read sequencing chemistry and improved assembly methods are converging to make very high quality whole genome assemblies possible. We recently sequenced multiple strains of S. Cerevisiae and S. Pombe. By using the BluePippin (Sage Sciences) platform to produce long fragment libraries and the P5 enzyme / C3 chemistry combination, we obtained over 80x coverage of reads exceeding 10,000 bp, and maximum read lengths extending beyond 35,000bp.We are able to produce near-perfect assemblies of the genomes such that every chromosome was assembled into a single contig or a very small number of contigs. We also made an assembly of the IR64 strain of rice (430Mbases genome) using only Pacific Biosciences long read data. The N50 contig size of this assembly is 600kb, doubling our previous assembly N50 obtained with a mix of Illumina short read and PacBio long reads.

1618M

Naturally Hyperactive Transposase and its Application to High Coverage Whole Genome Sequencing With Low DNA Input. *A. Belyaev[1], C. Hansen[1], J. Fox[1], B. Arezi[1], B. Novak[2], F. Useche[2], C. Pabon[2], H. Hogrefe[1].* 1) Agilent Technologies, Inc., San Diego, CA; 2) Agilent Technologies, Inc., Santa Clara, CA.

Transposases are enzymes that facilitate movement (transposition) of mobile genetic elements (transposons) within and between genomes. High frequency transposition is believed to be detrimental to survival as transposases encoded in prokaryotic and eukaryotic genomes are notably inactive. For example, the best characterized transposase, hyperactive Tn5, required extensive engineering before it could be applied to *in vitro* DNA manipulations, such as cloning, mutagenesis and next generation sequencing library preparation. Based on our knowledge of Tn5, we were surprised to find that a transposase encoded in the genome of bioluminescent marine bacterium *Vibrio harveyi* is at least as active in vitro as hyperactive Tn5 transposase. Unlike Tn5, Vibrio harveyi transposase was expressed in *E.coli* to a high level of about 25% of soluble protein of total cell lysate. We purified the enzyme to homogeneity, proven it to be stable at -20°C for over 3 years and determined that it could be immobilized to a solid support. *Vibrio harveyi* transposase is included in the SureSelectQXT library prep kit. The method of this kit generates consistent fragmentation and uniform sequencing coverage from 50ng of genomic DNA compared to traditional time-consuming adapter-ligation methods that typically require 1-3µg input. In less than 1.5 hours (with only 30 minutes hands-on time) and using an automation-friendly workflow, one can prepare dual-indexed libraries for sequencing on the Illumina HiSeq or MiSeq instruments. Advantages of this transposase as a model for transposition studies and in applications for single-cell analysis, microfluidics and microarrays are discussed.

1619T

Exome Capture with Accelerated Hybridization Provides Same-Day Generation of High Performance Target-Enriched NGS Libraries. *M.C. Borns[1], B. Rogers[1], B. Arezi[1], M. Corioni[2], M. Visitacion[2], C. Pabon[2], D. Roberts[2], H. Hogrefe[1].* 1) Agilent Technologies, Diagnostics and Genomics Group La Jolla, CA; 2) Agilent Technologies, Diagnostics and Genomics Group Santa Clara, CA.

Assays of high sensitivity and minimal turn-around time that generate unambiguous results from minimal sample input are becoming essential. Coupled with the single-molecule resolution afforded by next-generation sequencing, target enrichment provides a cost-effective solution to enable confident analysis of various genomic targets by increasing assay sensitivity. In this study, we enable an accelerated workflow to generate exome-enriched libraries while providing uncompromised variant calling performance. Briefly, fragmented and adapter-tagged DNA libraries are produced in a single step with only 50ng genomic DNA using Agilent's transposase-based library prep technology. DNA libraries are then taken through a novel 1.5-hour fast hyb process, that provides accelerated capture of targets using Agilent's long 120-mer cRNA baits. Combining transposase-based library preparation with this novel in-solution capture technology enables the preparation of up to 16 dual-indexed (post-capture) libraries for sequencing on the Illumina HiSeq or MiSeq platforms in less than 8 hours. Optimized for transposase-generated libraries, SureSelect fast hybridization technology is fully automatable and can be used with bait libraries as small as 0.2Mb up to full exome + UTR libraries, achieving true "exome in a day" results. With this streamlined protocol, we routinely obtain high performance libraries with >60% on-target, >98% coverage at 1x depth, >75% at 20x depth, and <15% duplicates with the Human All Exon V5 and V5+UTR bait sets. Further performance metrics such as library complexity, SNP sensitivity and concordance will be presented for additional bait sets and competitor kits.

1620S

A comprehensive comparison of commercially available hybridization and amplification based exome enrichment methods. *T. Guettouche, K. Xu, L. Dong, L. Tian, C. Kim, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Whole exome sequencing (WES) has become a commonly used method for both research and clinical applications. The most widely used enrichment types are in-solution hybridization and amplification based methods for exome sequencing. WES allows the detection of causative genetic changes and candidate genes in Mendelian and complex disorders as well as germline genetic alterations in cancer. We report a comparison of solution based capture methods (Agilent SureSelect v4 and v5, NimbleGen SeqCap EZ 3.0, Illumina Nextera Rapid and Expanded Capture) as well as an amplification based method (Life Technologies Ion AmpliSeq Exome) and a restriction digest mediated capture method (Agilent Haloplex Exome). The kits included in this study are commonly used and up to date capture methods. All captured samples were sequenced on an Illumina HiSeq2000 except for the Ion Ampliseq exome samples which were sequenced on a Life Technologies Ion Proton system. We used a well characterized family trio from the Center for Applied Genomics Biorepository and the Genome in a bottle (NIST) human HapMap sample NA12878 available from Coriell to compare enrichment and genetic variant metrics of the different methods. We found significant differences in target coverage, on target bases, uniformity of coverage, detected SNVs and indels, and trio discordance. While generally all methods included in this study performed well, our results have important implications and should be considered especially for applications of clinical nature.

1621M

Korean Reference Genome Project: Design and Population Genome Variants. *K. Hong, K.S. Jung, H.Y. Jo, H. Choi, H.J. Ban, M. Chung, S. Cho, B.G. Han.* Center for Genome Science, KNIH, KCDC, Cheongwongun, Chungbuk, South Korea.

The Center for Genome Science (CGS) in Korea National Institute of Health (KNIH) drew up the Korean Reference Genome project (KRG) in 2012. Total 622 DNA samples of study subjects for the KRG were obtained from three different resources. The whole genome sequencing was conducted by Illumina Hiseq2000 sequencer. The sequencing reads trimmed by the Sickle trimming and mapped to human reference genome (hg19). The mapped sequences were analyzed by SAMtools to calling the variants. VCFtools were used to merged the population variant sites, and compute the variants stats. Annovar were used to understand the proportion of the Known variants in the dbSNP138 and 1000G and the variant positions of gene regions. Over 97% of the SNVs identified in each genome were found in dbSNP database or 1000 Genome Project variants. Over 55% of the indels in each genome were found in the 1000 Genome project. The insertion/deletion ratio was 0.75 and approximately 0.1% of the indels were located in the coding region. In this presentation, we will describe the sequencing subjects, raw sequencing stats, and variant calling results. The all variants presented in this paper can be found from our web-browser.

1622T

Resolving the 'Dark Matter' in Human Genomes through Long-Read Sequencing. *J. Korlach.* Pacific Biosciences, Menlo Park, CA.

Second-generation sequencing has brought about tremendous insights into the genetic underpinnings of biology. However, there are many functionally important and medically relevant regions of genomes that are currently difficult or impossible to sequence, resulting in incomplete and fragmented views of genomes. Two main causes are (i) limitations to read DNA of extreme sequence content (GC-rich or AT-rich regions, low complexity sequence contexts) and (ii) insufficient read lengths which leave various forms of structural variation unresolved and result in mapping ambiguities.

Long, unbiased sequence reads from single molecule, real-time (SMRT) sequencing overcome these limitations to provide a more comprehensive and contiguous view of genomes. The sequence data were used for the first long-read *de novo* assembly of a human genome, with over an order of magnitude greater contiguity than previous second-generation sequencing approaches, and a higher level of completeness. Base calls of uniform quality over the broadest DNA GC% and complexity spectrum, the majority of which are contained in reads greater than 11,000 bases, and exceeding 25,000 bases in many cases, provide the necessary performance to resolve many genomic regions previously considered 'difficult' or 'inaccessible.' The long reads also allow long-range phasing of allelic variation. I will highlight numerous examples demonstrating this capability, including the resolution of complex repeats, tandem duplications, insertions, deletions, palindromes, and repeat expansions in the human genome, as well as closing gaps in reference genomes and resolving complex splice isoforms.

1623S

A new method for low-input, PCR-free NGS libraries with exceptional evenness of coverage. *L. Kurihara, J. Laliberte, C. Couture, S. Sandhu, R. Spurbeck, L. Banks, S. Chupreta, V. Makarov.* Swift Biosciences, Inc., Ann Arbor, MI.

PCR-free NGS libraries demonstrate improved evenness of coverage relative to NGS libraries that have undergone PCR amplification. However, most PCR-free methods require 0.5-1 μg of input DNA which restricts such analysis when DNA sample quantity is insufficient. To expand the applicability of PCR-free sequencing, we developed a novel adapter attachment chemistry that is more efficient than existing methods. This new technology results in libraries that capture a higher complexity of each sample, enabling sequence-ready library preparation from 100 ng of input DNA with no PCR required. Another advantage of this technology is that it creates libraries with exceptional evenness of coverage over a broad range of base composition. This was demonstrated by Picard Collect GcBiasMetrics, by improved relative coverage of challenging human sequences such as the 1,000 bad promoters defined by the Broad Institute with 79%; GC content (Ross et al, Genome Biology 2013), as well as sequencing of Plasmodium falciparum (19%; GC) where coverage plots aligned to theoretical distribution. To further broaden the applicability of this method, libraries can be prepared from as little as 10 pg of input DNA by addition of limited PCR amplification. The broad dynamic range of this approach makes it possible to use one kit and one workflow for sample inputs over five orders of magnitude. Libraries prepared using this new method are compatible with both amplicons and hybridization capture and the improved library prep efficiency enables better recovery from FFPE and other samples with limiting input quality.

1624M

Understanding and adopting updates in the human reference genome assembly (GRCh38). *V.A. Schneider[1], T. Graves-Lindsay[2], P. Flicek[3], R. Durbin[4] for the Genome Reference Consortium.* 1) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 2) The Genome Institute at Washington University, St. Louis, MO; 3) European Molecular Biology Laboratory, European Bioinformatics Institute, Hinxton, Cambridge, UK; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

The availability of a high quality human reference genome assembly, coupled with advances in sequencing technology, has facilitated basic research leading to new insights into genetic variation and revealed a previously unrecognized level of diversity in the human population. Today, these findings are driving advances in the field of clinical genomics. They have also contributed to the identification of assembly errors and demonstrated that the initial linear representation of the human reference assembly insufficiently represents human genetic variation. Since 2009, the Genome Reference Consortium (GRC), the group responsible for updating the human, mouse and zebrafish reference genome assemblies, has used an assembly model that allows for representation of allelic variation in the human reference genome assembly. Linear chromosome models continue to provide haploid sequence representations, while scaffold sequences known as alternate loci provide alternate sequence representations for genomic regions too complex to represent by a single path or at which there are variants that have sequence not represented on the chromosome. The previous human reference assembly GRCh37 (hg19) contained just 9 alternate loci scaffold at 3 genomic regions. Released in December 2013, GRCh38 (hg38), the current reference assembly, now contains 261 alternate loci scaffolds at 178 distinct genomic regions. These alternate loci provide the only reference assembly representation for more than 3 Mb of sequence, including more than 100 genes. We will present analyses showing how use of alternate loci in alignment target sets can reduce off-target alignments, which may improve variant calling and reveal a need for the development of alignment and variant calling tool chains that make use of the full reference assembly. We will highlight other key improvements in GRCh38, including base updates, sequence additions and the use of single haplotype resources to retile complex regions, which corrected errors and improved annotation. We will describe modeled centromere sequences that have been added to the chromosomes and are expected to serve as mapping targets for α-satellite DNA and benefit studies of human variation, epigenomic regulation and centromere biology. We will present tools and resources developed at NCBI for migrating data to and utilizing GRCh38 and discuss the evolution of the human reference genome assembly as we enter the era of personal genomics.

1625T

The Ion PGM™ Hi-Q™ Sequencing Polymerase: Reducing Systematic Error, Increasing Accuracy, and Improving Read-length. *P.B. Vander Horn, A. Kraltcheva, G. Luo, M. Landes, S. Chen, K. Heinemann, T. Nikiforov, J. Shirley, E. Tozer, D. Mazur.* Ion Torrent, Thermo Fisher Scientific, Life Sciences Solutions Group, Carlsbad, CA., USA.

High accuracy and sequencing uniformity are the hallmarks of a successful DNA sequencing platform. These qualities benefit greatly various scientific and medical research applications. Here we show that the new Ion Torrent™ Hi-Q™ sequencing chemistry provides substantial improvements in overall accuracy, read-length, and systematic error relative to the previous sequencing chemistry. Using the Hi-Q system we see a 50% decrease in overall error, mainly by reducing InDels, and up to a 10-fold reduction in systematic error. In addition, we show that with optimized emulsion PCR cycling conditions, we have increased coverage uniformity of the *Rhodobacter sphaeroides* genome from 88% to 95%. We also observed improvement in uniformity and representation of GC-rich amplicons from various human libraries. By incorporating these improvements, the Ion PGM system is now poised to enable a broader range of research applications, such as enhanced de novo genome assemblies, Human Leukocyte Antigen (HLA) sequencing, bacterial identification, and meta-genomic analysis.

*For Research Use Only. Not for use in diagnostic procedures.

1626S

Third generation sequencing and analysis of complete mitochondrial genomes. *E.P. Hoffman[1], K.B. Gettings[2], K. Kiesler[2], P.M. Vallone[2], L.B. Davenport[1], S. Dadgar[1], K. Panchapakesan[1], S. Knoblach[1], J.M. Devaney[1].* 1) Research Ctr Genetic Medicine, Children's Natl Medical Ctr, Washington, DC; 2) National Institute of Standards and Technology, Gaithersburg, MD.

Next-generation sequencing (NGS) has enhanced investigators' ability to conduct biomedical research examining genetics. Mitochondrial genetics has benefitted from NGS because technology now allows for screening of all 16,569 base pairs of the mitochondrial genome simultaneously for single nucleotide polymorphisms and low-level heteroplasmy. We utilized Single-Molecule Real Time (SMRT) sequencing on a PacBio RS II (Pacific Biosciences) to sequence NIST Standard Reference Material (SRM) 2392 component A (lymphoblastoid cell culture line CHR) and component B (lymphoblastoid cell culture line 9947A), and SRM 2392-I (promyelocytic cell line HL-60). These SRMs are intended to provide quality control when sequencing of human mitochondrial DNA (mtDNA) for forensic identification, medical diagnosis, phylogenetics, and anthropology. We amplified with three overlapping PCR primers sets (6kb PCR products) the entire mtDNA sequence. Then we processed the three mtDNA SRMs using a DNA Template Prep Kit 2.0 (3Kb to 10Kb), Polymerase Binding Kit P4, and DNA Sequencing Kit 2.0. SMRTbell libraries were constructed from pooled, full-length 6kb PCR amplicons tiling the entire 16.6kb mtDNA genome. Each pooled sample was placed on SMRT cell V3 and a 180-minute movie was performed. The data was processed using SMRT Portal with the revised Cambridge Reference Sequence (rCRS). Average read lengths for each SRM were around 3,300 bp with an average coverage of 6,673X. For 2392 component A, we discovered 36 variations from the rCRS including three insertions of C's at positions 309.1, 315.1, and 16193.1. For 2392 component B and 2392-I, we were able to detect 20 variations and 33 variations, respectively, in each SRM from the rCRS including insertions of C's at mtDNA positions 309.1 and 315.1. The number of variants discovered in the three SRMs using the PacBio RS II matched previously published data. We are now investigating methods of analysis to detect heteroplasmy that is occurring in these mtDNA SRMs. This study shows that a third-generation sequencing system can be used to generate entire mtDNA sequences using a three-primer system for amplification. The current NGS approach used in this abstract has the potential to be beneficial in a forensic setting or for medical diagnostics.

1627M

Full-length, single molecule whole transcriptome sequencing reveals alternative 5'- start sites, splicoforms, and poly(A) addition signal sequences. *D.J. Munroe, T. Skelly, C. Raley, R. Stephens, Y. Zhao, S. Gowda, C. Xiongfong, K. Talsania, S. Ratnayake, D. Soppet, X. Wu, B. Tran.* Frederick National Laboratory, Frederick, MD.

Transcriptome analysis has illustrated that the splicing of individual mRNAs can be highly divergent, often resulting in different protein isoforms. Further, mRNA 5' and 3' untranslated regions (UTR), which can be variable, have been demonstrated to play an important role in post-translational gene regulation. The Pacific Biosciences SMRT DNA sequencing platform (PacBio) with its long-read length and single molecule sequencing characteristics is an ideal system for the analysis of these transcript variations. We have utilized this platform to examine divergent splice-forms, 5'-UTRs, and 3'-UTRs in a full-length whole transcriptome analysis of a variety of human samples. As expected, we have observed a plethora of splice-form variations. Somewhat un-expectedly, we also see significant 5'-UTR variation and differential poly(A) addition variation which results in alternative 3'-UTR sequences. Here we report and catalog these variations including alternative splicing, 5' start sites, and poly(A) signal sequences (both AAUAAA and non- AAUAAA). In addition, we have compared our PacBio sequencing results with those observed with the Illumina sequencing platform.

1628T

Preliminary analysis for the evaluation of risk prediction methods using SNP-based genomic profiles data. *R. Arguello[1, 2], F. Hernandez[3], E. Ramirez[1], F. Gonzalez[2], M. Duarte[2], H. Arredondo[1], A. Sanchez[2], Y. García[2], D. Arellano[1], F. Gonzalez[1].* 1) Faculty of Medicine, Autonomous University of Coahuila, Torreon, Mexico; 2) Institute of Science and Genomic Medicine, Torreon, Mexico; 3) School for Biological Sciences, Autonomous University of Coahuila, Torreon, Mexico.

Different methods for predicting genetic risk factors in human diseases have been developed in the last decade. However, many of these techniques have been primarily applied to individuals from Caucasian ancestry. Thus, there is a lack of analysis carried out in populations from other ethnic groups. In this study, we analyzed fifty randomly-selected individuals from the North Area of Mexico that were SNP genotyped using the Illumina array technology with more than 600,000 SNPs. Additionally, 1934 SNPs associated to 139 diseases extracted from the National Human Genome Research Institute GWAS Catalog were used to evaluate existing methods described in the literature for estimating genetic risk factors in human diseases. To do this, we implemented some of these algorithms in an in-house software package. As expected, these methods appear to be less precise when a large number of SNPs is associated to be linked to that particular disease but these can be used as an indicator in the assessment of human diseases by the medical and scientific community.

1629S

Development of a comprehensive, ontology-driven phenotyping system and web-based patient registry for Fanconi anemia. *A.D. Auerbach, S. Balakrishnan, S. Mollah, F.P. Lach, E. Sanborn, A. Smogorzewska, E. Barbour.* The Rockefeller Univ, New York, NY.

The International Fanconi Anemia Registry (IFAR) was established at The Rockefeller University in 1982 to serve as a longitudinal phenotyping system, source of DNA for genotyping studies, and a biorepository. In 1998, a separate public database was created to curate variants in all known FA genes, now in LOVD v.2.0 (www.rockefeller.edu/fanconi/mutate/). Here we describe our newest web-based application whereby clinical and molecular data for all 16 currently identified FA genes will be able to be queried via the internet. The ultimate goal of this new IFAR application is to help move FA research forward by collecting as much genotypic and phenotypic data as possible, displaying these data in a comprehensible, user-friendly manner, and making the data set available to other FA clinicians and researchers. The enhanced IFAR application uses Java for the Application Server programming, chosen because it is fast, secure and reliable. We are using Oracle as the database to store and retrieve related information. The web interface for the client was developed using JSP, HTML and JavaScript, allowing for multiple users to access the system concurrently. The special FA ontology was developed using Protégé for data modeling with the files in OWL format. The “Fanconi Anemia Ontology” is publically available in the NCBO BioPortal (http://bioportal.bioontology.org/ontologies/IFAR?p=summary). This Ontology was created using an OWL file provided by Dr. Ada Hamish and Francois Schiettecatte at the Centers for Mendelian Genetics, with their permission. Novel classes pertaining to FA were added and modifications were made using HPO, OMIM, NCI, and SNOMED. The ontology, while intended for the IFAR specifically, can be easily modified for other disease systems. We are currently migrating all of the clinical and molecular data from the original IFAR database created in FileMaker Pro, to this new ontology-based application. After this is accomplished, access to the de-identified data will be available to others, following rules set by the Rockefeller University Hospital regarding patient privacy. There are currently more than 1300 FA patients with this rare disease enrolled in the IFAR. The new display screens and navigational tools make the application easy to use, and should eventually enable researchers and physicians worldwide to learn more about genotype/phenotype correlations in FA and related diseases, and the role of the FA proteins in DNA damage repair and cancer.

Brudno[11], V. Straub[7], H. Lochmüller[7], M. Bellgard[12], J.L. Oliveira[10], P.A.C. 't Hoen[9], A. Valencia[5], C. Béroud[2,3,13], I. Gut[1].* 1) Centro Nacional de Análisis Genómico (CNAG), Barcelona, Catalonia, Spain; 2) Aix-Marseille Université, Marseille, France; 3) Inserm, UMR_S 910, Marseille, France; 4) EMBL Australia, Australian Regenerative Medicine Institute (ARMI), Monash University, Clayton, Victoria, Australia; 5) Centro Nacional de Investigaciones Oncológicas , Madrid, Spain; 6) European Molecular Biology Laboratory , European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Cambridge, United Kingdom; 7) Institute of Genetic Medicine, MRC Centre for Neuromuscular Diseases, Newcastle University, UK; 8) Dubowitz Neuromuscular Centre, UCL Institute of Child Health and Great Ormond Street Hospital for Children, London, United Kingdom; 9) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 10) DETI/IEETA, University of Aveiro, Portugal; 11) Centre for Computational Medicine, Hospital for Sick Children and University of Toronto, Toronto, ON, Canada; 12) Centre for Comparative Genomics, Murdoch University, Perth, Western Australia; 13) APHM, Hôpital TIMONE Enfants , Laboratoire de Génétique Moléculaire, Marseille, France.

Around 300 million people worldwide are estimated to suffer from one of the 6000+ known rare diseases. Rare disease research faces particular challenges because patient populations, clinical expertise, and research communities are small in number and highly fragmented both geographically and in terms of medical specialty. Therefore, discovery is slowed down due to limited access to sufficient patients, high quality information and results and would benefit from greater coordination of patient registries, biobanks, data repositories, and best practices in deployment of new -omics technologies and analysis methods. The EU FP7-funded RD-Connect project is building a platform to harmonize and securely integrate databases, registries, biobanks, clinical bioinformatics and -omics data generated with standardized pipelines. Platform design has consisted of a formal use-case evaluation process performed in collaboration with potential clinical research users and the two main associated EU FP7-funded projects Neuromics (rare neuromuscular and neurodegenerative diseases) and EURenOmics (rare kidney diseases). These projects have adopted the Human Phenotype Ontology to describe their patients and are generating genomic, proteomic and metabolomic data that is being deposited at the European Genome-phenome Archive (EGA). The data is then accessed and processed by RD-Connect's standard analysis pipelines to generate comparable results that are integrated in the platform. We present here the first version of the RD-Connect exome sequencing analysis, annotation and prioritization pipeline, which includes widely used prediction tools such as SIFT, PolyPhen, phyloP or MutationTaster together with novel ones such as Human Splicing Finder and UMD predictor. Tools that use phenotypic, expression and regulatory information have also been used for variant and gene prioritization. We report here the outcome of applying the pipeline to an initial set of 20 use cases and the preliminary version of the platform back-end and front-end that allows storage, access and filtering of the genomic and phenotypic information. The integration of resources being conducted by RD-Connect is a working example of the emerging global rare disease bioinformatics ecosystem.

PATHWAY APPROACHES TO STRENGTHEN GENETIC VARIATION ANALYSIS. *E. Cirillo, M. Kutmon, C. Evelo.* Department of Bioinformatics - BiGCaT, Maastricht University, The Netherlands.

Introduction. Pathway and network analysis is used to understand genomics data from transcriptomics, proteomics and metabolomics experiments. It uses prior knowledge of biological relationships and can evaluate related effects that strengthen each other. Genetic variants analysis (such as SNPs, indels..) would also benefit from this approach because of the evaluation of related variations in different genes, and integration of variant data with other omics results. Currently, genetic variations cannot easily be combined in pathway representations. It is also not clear how to better visualize and interpret variation data once we connected it to pathway content programmatically. In this project we take up the challenge to integrate genetic information in the open source pathway analysis program PathVisio (pathvisio.org). Design and analysis ideas. We connected variants with related genes, using bioinformatic mapping approaches (see bridgedb.org). With this we can visualize variants on a pathway. We now aim for meaningful presentations showing some design studies: - Variants information for selected genes is shown in a separate panel of PathVisio page. - Genetic variations with statistical values from large genetic datasets (e.g. GWAS) can be highlighted for the annotated variants (colors in the panel and clickable values). - Specific information about variants like HapMap environment or function predictions can be shown as popups or via linkouts to genome browsers. We will also map variants and genes for statistical approaches using larger sets of biological pathways (e.g. from WikiPathways), to find those where many variants occur in specific phenotypes. This is comparable to the over representation and gene set enrichment analyses. Finally, we will investigate the use of existing advanced tools (like sift and polyphen) to integrate predictions of biological functional changes. Pathways as a bridge to networks. Pathway and network biology can be easily combined: our tools convert one into the other and we can use the same mappings between database identifies in both. Variations are evaluated in pathways as networks, increasing network extensions (e.g. with miRNA or drugs) and topology studies. This will combine network connectivity, betweenness and shortest path analysis with the occurrence of deleterious variants in disease phenotypes.

Mutiple-trait genomic selection and phenotype prediction. *A. Dahl[1,2], J. Marchini[1,2].* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Random effect models have been used in genetics to control for aggregate genetic structure in association studies, estimate heritability and predict the latent genetic contribution to phenotypic variation. Unfortunately, the ordinary random effect model does not generalize well to multivariate phenotypes; the resulting high-dimensional parameter estimates are both statistically unstable and computationally intractable. Moreover, missing observations plague mulitvariate data, as typical methods must throw away all samples with even one missing phenotype. Motivated by these concerns, we propose a new random effect model to decompose genetic and environmental contributions to multivariate phenotypic variance. The method naturally incorporates missing data and, in particular, can be used to impute unobserved phenotypes for subsequent analyses. In terms of imputation, this new method outperforms all tested competitors, including standard univariate methods from genetics and state-of-the-art imputation tools from mainstream statistics, on both simulated data and real human glycomics data. A second application is to estimate the latent genetic contribution to phenotypes, or breeding value of study individuals. On simulated data and real data from chicken breeding, the proposed method produces the best estimates of the future breeding values. The model is fit with variational Bayes, enabling this method to be run on thousands of individuals and tens of phenotypes.

1633M

Scaling up genomic data management, indexing, and analysis for a million genomes. *F. De La Vega[1], S. Young[2], J. Wiley[2], A. Patel[2], M. Pae[2], R. Hayek[2].* 1) Annai Systems, Inc., Burlingame, CA; 2) Annai Systems, Inc. Carlsbad, CA.

As sequencing technologies continue to evolve and the cost of genome sequencing drops, several large-scale population sequencing projects with sizes ranging from tens to hundreds of thousand samples are now being started. This sample size imposes difficult demands in data management, metadata indexing, and analysis to which current paradigms of data distribution and access are inadequate. Cloud computing technology is enabling sharing of high-performance computational resources and inspiring new models for data analysis, but still suffer by lack of interoperability and data transport latency. Additional requirement include maintaining secure access to meet informed consent obligations and metadata storage and indexing to facilitate meta-analyzes. Here we present a cloud storage and analysis architecture that satisfies the above requirements. In this architecture we integrate technology we deployed as part of the Cancer Genomics Hub (CGHub) and which currently supports the TCGA, TARGET, and the CGCI programs, and hosts more than 44,000 data files totaling more than 500 Terabytes with capacity to grow to 5 Petabytes. For identity management we use the NIH InCommon identity provider (IdP) via the Shibboleth middleware and for metadata indexing the SRA Metadata XML Schema 1.5. The GeneTorrent (GT) protocol allows data migration supporting preauthentication and authorization keys, SSL encrypted data channels, and genomic metadata integration. GT provides inherent parallelization, and its provision for relatively painless horizontal scaling, allowing federation. We further integrated SeqWare, an open source computational scheduling infrastructure which facilitates automation of pipelines based on metadata, and Sage Synapse, a workspace that aggregates, describes, and allows sharing of analytical pipelines enabling reproducible bioinformatics. We are implementing a pilot of this architecture in support of the ICGC PanCancer project, which will analyze whole genome data from 2,000 tumor-normal pairs federated across six data centers, and for the ICGC-TCGA DREAM somatic mutation calling challenge.

1634T

ClinGen database for curation of clinically relevant genomic variants. *X. Feng[1], T.P. Sneddon[2], H. Chen[1], A.R. Jackson[1], S. Paithankar[1], L.J. Babb[3], C. Bizon[4], D. Maglott[5], E.M. Ramos[6], H.L. Rehm[3,7,8], J.M. Cherry[2], C. Bustamante[2], S.E. Plon[1], A. Milosavljevic[1].* 1) Baylor College of Medicine, Houston, TX; 2) Stanford University School of Medicine, Stanford, CA; 3) Partners Healthcare Personalized Medicine, Cambridge, MA; 4) Renaissance Computing Institute, Chapel Hill, NC; 5) National Center for Biotechnology Information, Bethesda, MD; 6) National Human Genome Research Institute, Bethesda, MD; 7) Harvard Medical School, Boston, MA; 8) Brigham and Women's Hospital, Boston, MA.

The Clinical Genome Resource (ClinGen) is an NIH-funded program dedicated to creating a database of clinically relevant genomic variants to inform genome interpretation in a variety of clinical contexts. ClinGen is collaborating closely with the NCBI ClinVar database and is supporting algorithmic and expert curation of data from a variety of sources, including hundreds of thousands of test results shared by clinical genetics laboratories through ClinVar and other research data and bioinformatic predictions. A core component of ClinGen is the development of ClinGenDB, a workspace with a dedicated user interface (UI) for curators to collect and track additional data on variants in ClinVar. It will draw data from a variety of clinical and research databases, including several genomics initiatives, and enable expert review of variants as well as resolution of discrepant classifications in ClinVar. ClinGenDB will support ongoing data updates and versioning and will be accessible through REST Application Programming Interfaces (REST APIs) for algorithmic processing. In ClinGenDB, the data model driven UI presents curators with aggregated and computationally derived variant information. The data is structured to support variant evaluation according to configurable guidelines such as the new American College of Medical Genetics and Genomics (ACMG) Interpretation of Sequence Variants (ISV) guidelines. Expert curation is supported by a semi-automated decision-making system. The system will apply the configurable guidelines to infer provisional conclusions about variants. The conclusions and justifications provided by the system will then be reviewed by curators with ongoing versioning of assertions. We anticipate that implementation of the data model and decision-making system in ClinGenDB will greatly assist curation of clinically relevant genomic variants. Toward this goal, we will provide several case studies of variant curation using a working prototype of ClinGenDB and the variant curation UI, focusing on the subset of 56 genes identified in a recent report by the ACMG on the return of incidental findings (Green et al., 2013).

1635S

Efficient sharing of exome/genome variant and phenotype data between diagnostic labs. *I.F.A.C. Fokkema, J.T. den Dunnen, P.E. Taschner.* Dept Human Genetics S-4-P, Leiden Univ Medical Ctr , Leiden, Netherlands.

Gene variant databases (LSDBs) using the LOVD platform (Leiden Open-source Variation Database, http://www.LOVD.nl) collect and share information about genes, variants and phenotypes (diseases) from research and diagnostic labs. LOVD version 3 also facilitates exome and genome sequence data analysis. LOVD can be queried and adapted for many different purposes. The Dutch and Belgian working group for Breast Cancer DNA Diagnostics (LOB) has decided to share >7500 variants detected in the BRCA1/2 genes in breast cancer families since 1997. For this, the data, almost evenly split among both genes, have been submitted to the LOVD 3 shared gene variant database installation (1,2). Others include: world-wide BRCA variant data sharing (Human Variome Project and Global Alliance for Genomics and Health); Insight Consortium colon cancer variant database; country-specific data views (Finnish Disease (FinDis) portal). LOVD system advantages: simple standardized submission of new data, instant updates after curation, easy maintenance and automatic backups. Although most data are publicly accessible online, some data (detailed phenotype information) are shared by consortium members only using the new LOVD3 access level, designated “collaborator”. Others can see whether such information is available (password protected file links), giving them the option to contact the submitter for further details. Members can contribute their opinions about variant classification, increasing its consistency, but being aware of potential misinterpretation they have reservations sharing this information. Data are stored variant-by-variant and connected to each individual patient and submitting diagnostic lab. Users can perform queries per gene or individual, use other linked resources of interest, view data tracks in genome browsers and use web services to access variants stored in other gene variant databases. For databases curated by us both phenotype descriptions and/or gene variants can be submitted with the request to assign the so-called VIP-status for both variants and phenotypes demanding specific attention. Within 3 weeks, this match-making feature successfully brought researchers into contact, cracking rare disease cases and resulting in a high-impact publication. 1) http://databases.lovd.nl/shared/genes/BRCA1 2) http://databases.lovd.nl/shared/genes/BRCA2 The Human Variome Project has granted LOVD the recommended system status for variant collection.

Design and Implementation of an Informatics Infrastructure for Clinical Genomics Analysis and Reporting. *J. Hirsch, A. Hsu, T. Loeser.* Syapse, Palo Alto, Ca.

This talk will discuss challenges and recent developments in implementing informatics infrastructure to support clinical use of genomics, specifically in the area of oncology. While much focus has been placed on the ability to properly call variants, the “last mile” in taking processed variant calls and producing a useful, annotated clinical report with therapeutic recommendations is critical for enabling the clinical use of genomics data. Generating, delivering, and updating a clinical genomic sequencing report that a physician can use in routine care has proven to be a challenge, driven by reliance on outdated software tools. To bring genomics data to point of care, labs and clinics must be able to handle three types of data with very different properties and requirements: evolving biomedical knowledge, complex medical data, and high-volume genomics data. This talk will present a software solution, based on semantic computing principles, that enables the integration of all three data types for the purposes of clinical reporting. We will present the results of clinical pilots focused on maintenance of an evolving variant interpretation knowledge base, sharing of variant interpretation across institutions, and the use of this knowledge base to automate clinical genomic report generation and updating, as knowledge changes. We will describe the interpretation of identified variants through a shared knowledge base, automated assembly of annotated clinical reports, and delivery of reports to clinicians at point of care. Results of a pilot program to integrate these technologies into practice within an integrated community health care system will be presented. We will also present the results of physician adoption of a web-based, interactive clinical genome report format that incorporates clinical care guidelines with genomic report data.

1637T

Functional interpretation of noncoding somatic variants from cancer genomes. *E. Khurana, Y. Fu, M. Gerstein.* Yale University, New Haven, CT.

Whole-genome sequencing generally reveals thousands of somatic variants in individual tumors. Identification of key variants responsible for tumor growth and progression is a major challenge. This is especially the case for noncoding variants that are less well understood than coding variants. Discovery of somatic mutations in telomerase reverse transcriptase (TERT) promoter across many different cancer types has shown that regulatory variants may constitute driver events. However, most current methods for identification of cancer driver mutations focus primarily on protein-coding genes. We previously developed a method for identification of candidate noncoding drivers by integrating patterns of selection from 1000 Genomes data with functional annotations from ENCODE (FunSeq). Besides analyzing loss of transcription factor binding sites, our method now identifies creation of new binding sites by somatic mutations in promoters and enhancers of coding genes. We have also integrated function-based FunSeq scoring scheme with patterns of recurrence of somatic variants across hundreds of patients from multiple studies. Tumors exhibit differential expression signatures of thousands of genes. Our unified approach allowed us to explore the fraction of gene expression changes that may be explained by regulatory mutations vs. mutations in coding genes across many different cancer types.

Update and expansion of Human Variation Database in Japanese Database Integration Program. *A. Koike[1], H. Sawai[2], I. Inoue[3], S. Tsuji[4], K. Tokunaga[2].* 1) CRL, Hitachi, Ltd., Kokubunji, Japan; 2) Dept. Hum. Genet, Univ. Tokyo; 3) Nat. Inst. Genet; 4) Dept. Neurology, Univ. Tokyo.

The Human Variation Database (http://gwas.biosciencedbc.jp/cgi-bin/hvdb/hv_top.cgi) is a repository database set up to achieve continuous and intensive management of Japanese GWAS data and variations identified by NGS and other experimental methods. We have widely called for data submission to aim for data-sharing among researchers. Variations include short/long insertions and deletion and structural variations as well as SNPs/SNVs. Since vast amount of knowledge about disease-variation relationships are varied in the scientific literature, these data have been extracted by manual curation to organize the disease-related variations and improve our understanding of disease mechanisms and disease-disease relationships. More than 30,000 disease-related variation entries are currently registered with allele/genotype frequencies and statistical data. Pathway data are also provided to facilitate the understanding of epistasis and relationships between similar diseases. Since some disease-related variations are recognized to be different among populations, the reference genomes are built in each population and are registered.

The recent improvements of the database are as follows. 1) The scope of the registry was extended to include drug response-related variations and virus resistance-related variations. 2) HLA-DB was constructed because of the characteristics of the HLA region. 3) Links to driver mutations archived in widely used cancer somatic mutation databases were added in order to clarify the relationships between the driver mutations in various cancers and germ-line mutations, although only variations in germ-line cells are targeted in the database. In this presentation, we overview the database structure and discuss the differences of deleterious variations between germ-line cells and somatic cells from the view points of physicochemical properties, functional properties, and evolutionary conservation properties.

Acknowledgement: This work was supported by the contract research fund 'Database Integration Program' from the Japan Science and Technology Agency.

Exploring the genome-wide roles of transcription factors and their complexes in chromosome interaction. *MJ. Li[1,2], LY. Wang[1], PC. Sham[3], MQ. Zhang[4], JS. Liu[2], JW. Wang[1].* 1) Biochemistry, The University of Hong Kong, Hong Kong; 2) Statistics Dept, Harvard University, Boston, MA, USA; 3) Psychiatry Dept, The University of Hong Kong, Hong Kong; 4) Molecular and Cell Biology Dept,, The University of Texas at Dallas, Dallas, TX, USA.

The tight regulation of genes in different cells is governed by temporal and spatial biological signals. It is very important to pinpoint the pattern of transcription factors (TFs) and their complexes in looping interactions and to detect TF complexes as well as the underlying cis-regulatory modules (CRMs) in different human cell types. Existing studies on analysis of TFs and their complexes were only performed at one dimension and not at genome-wide scale. Recently, the unbiased chromosome conformation capture, Hi-C, can detect the genome-wide chromatin interactions, but has restrictions on its resolution due to the variable cell-to-cell chromosome structures and inadequate sequencing depth. In this study, we provide a comprehensive analysis on TFs regulatory pattern within chromosome looping by combining Hi-C and ENCODE ChIP-Seq data from three human cell types (GM12878, H1-hESC and K562). We first devised a strategy to map ChIP-Seq peaks of each TF to a normalized 10kb Hi-C contact matrix and construct an interaction matrix for each participant TF. We observed tight correlation for TFs participant activities in high resolution chromosome looping between biological replicates, which indicate the TF activities is more stable than local DNA interactions. To check the enrichment of different chromatin marks and genomic features in the interaction region of each participant TF, we performed enrichment test on several histone modifications marks (H3K4me1, H3K4me2, H3K4me3, H3K27me3, H3K36me3, H3K9ac, H3K27ac), CAGE, DHSs, DNA methylation (RRBS) and conservation signals. We found chromatin markers and genomic features of each TF is highly correlated between replications. We also observed that grouped TFs shared consistent patterns of chromatin marks and genomic features, which indicate their similar roles in gene regulation. Furthermore, we developed a method to detect the candidate TF complexes by reducing the dimension of huge sparse interaction matrix for each participant TF followed by community clustering. We successfully detected several known complexes mediating long range enhancer-promoter interaction in different cell types. Using the combinatory motifs scanning, we can predict the genome-wide CRMs for specific TF complex with known motifs. Finally, by correlating gene expression profiles of TF and its targets , we can pinpoint the role of detected TF complexes (active or repressive) in controlling cell type specific gene regulation.

1640T

Comparing blood and brain gene expression networks in Huntington's Disease by semantic analysis. *E. Mina, P.A.C. 't Hoen, W. van Roon-Mom, M. Roos.* Department of Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Huntington's Disease (HD) is a neurodegenerative disease with the most prominent pathology in the brain. However, human brain tissue is not easily accessible for molecular biology studies and it cannot be isolated from living patients. The widespread pathology of HD indicates that the phenotype is not limited to brain dysfunction. Several studies have shown that understanding alterations in peripheral tissues could be valuable for monitoring disease progression. Considering that transcriptome technologies have successfully been used for biomarker discovery and the study of physiological and pathophysiological mechanisms, it is evident that studying transcriptional changes in peripheral tissue can provide new insights that can lead to the development of new therapies and markers to monitor disease progression. In addition, novel sequencing technologies and the wide availability of data and published articles, create opportunities for novel, more effective ways of data exploitation. Our methodology identifies and prioritizes disease signatures from blood that are also associated with abnormalities in brain, in a robust way by a combination of large scale network analysis, integration of heterogeneous datasets, and incorporation of prior knowledge mined from literature. Our preliminary data show that modules in gene co-expression networks are significantly more reproducible than individual gene markers between blood and brain. We additionally link significant HD signatures to biological and pharmacological knowledge sources to prioritize biomarkers based on their potential as drug targets using a 'Linked Data' approach. This allowed us to identify drug targets by querying across four different data sources, including drugbank and pathway data to target pathways that are impaired in HD. For instance, we found Imatinib, associated with the gene ABL1 that targets autophagy and is known to delay production of beta-amyloid. Moreover, in the HD context, we prioritize drug targets according to their structural or functional similarity to known targets that can pass the blood-brain barrier. In conclusion, our approach is a powerful method to identify genes that are potentially involved in physiological and pathophysiological processes in HD. Using the 'Linked Data' approach, our results can be easily extended and will become available to the scientific community as a resource for further investigation for understanding disease pathology in HD.

We have used a translational convergent functional genomics (CFG) approach to discover genes involved in alcoholism, by gene-level integration of genome-wide association study (GWAS) data from a German alcohol dependence cohort with other genetic and gene expression data, from human and animal model studies, similar to our previous work in bipolar disorder and schizophrenia. A panel of all the nominally significant p-value SNPs in the top candidate genes discovered by CFG (n=135 genes, 713 SNPs) was used to generate a genetic risk prediction score (GRPS), which showed a trend towards significance (p=0.053) in separating alcohol dependent individuals from controls in an independent German test cohort. We then validated and prioritized our top findings from this discovery work, and subsequently tested them in three independent cohorts, from two continents. In order to validate and prioritize the key genes that drive behavior without some of the pleiotropic environmental confounds present in humans, we used a stress-reactive animal model of alcoholism developed by our group, the DBP knock-out mouse. A much smaller panel (n=11 genes, 66 SNPs) of the top CFG-discovered genes for alcoholism, cross-validated and prioritized by this animal model, showed better predictive ability in the independent German test cohort (p= 0.041). The top CFG scoring gene for alcoholism from the initial discovery step, synuclein alpha (SNCA), remained the top gene after the stress-reactive animal model cross-validation. We also tested this small panel of genes in two other independent test cohorts from the United States, one with alcohol dependence (p=0.00012), and one with alcohol abuse (a less severe form of alcoholism) (p=0.0094). SNCA by itself was able to separate alcoholics from controls in the alcohol dependent cohort (p= 0.000013) and the alcohol abuse cohort (p= 0.023). So did 8 other genes from the panel of 11 genes taken individually, albeit to a lesser extent and/or less broadly across cohorts. SNCA, GRM3 and MBP survived strict Bonferroni correction for multiple comparisons. Taken together, these results suggest that our stress-reactive DBP animal model helped to validate and prioritize from the CFG-discovered genes some of the key behaviorally relevant genes for alcoholism. These genes fall into a series of biological pathways involved in signal transduction, transmission of nerve impulse (including myelination), and cocaine addiction.

Analyst Portal - a real-time, distributed web query tool that streamlines data search at a genomics center. *H. Qiu, C. Kim, F. Mentch, L. Hermannsson, H. Hakonarson.* Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

In the setting of a large genomics research center, we constantly have requirements to have up-to-date detailed workflow information as well as efficiency in querying available data in seamless and integrated way to help scientific discoveries. Instead of taking the conventional data warehouse approach to extract data from various sources into a centralized data store, which is both time consuming and hard to co-ordinate with the real-time workflow status, we use distributed database query facility to dynamically query different source databases. The resulting suite of web applications on top of the distributed real-time query layer is being referenced as Analyst Portal. Data modalities searched by Analyst Portal include service order intake, biorepository sample management, SNP-array genotyping, gene array expression data, next generation sequencing, DICOM neuroimaging, phenotype data from hospital EMR system and from collaborators, catalog of genetic variants (SNP, CNV, indel) . For individual modality, Analyst Portal supports three levels of detailed data queries: single subject information lookup, all records in the modality, and a search limited to an uploaded subject list. In case of multiple domains search, Analyst Portal supports cohort selection by combining user defined search terms from different modalities and generating complex distributed SQL query. For example, a query like “get a list of Caucasians, males only, 6-10 years old subjects who have at least 2 ADHD diagnoses over the past 3 years, and on at least one medication such as Adderal, Concerta or Ritalin, and have blood DNA samples in our biorepostiory, and already genotyped on Illumina or Affymetrix SNP chips, and not NGS exome sequenced yet” can be done real-time easily in Analyst Portal. Among 50 typical data queries scientists and researchers have used during previous research studies, the Analyst Portal has ability to address 70-80% of them instantly. Here, we review the software architecture, performance tuning, user experience and areas for future optimization.

1643T

Phenotype terminologies in use for genotype-phenotype databases: A common core for standardisation and interoperability. *P.N. Robinson[1], S. Aymé[2], L. Chanas[2], A. Hamosh[3], A. Rath[2], International Consortium for Human Phenotype Terminologies.* 1) Institute for Medical Genetics, Charite-Universitätsmedizin, Berlin, Germany; 2) INSERM, US14, Paris, France; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

The community needs to be provided with terminology standards in order to achieve interoperability between databases intended for clinical research. Phenotypic information is crucial to interpret genomic rearrangements as well as high-throughput sequence data including whole exome and whole genome sequencing. The aim of our work was to develop a core terminology of phenotypes interoperable with all terminologies in current use. Relevant terminologies in use by different communities to describe phenomes were cross-referenced: PhenoDB (2846 terms), London Dysmorphology Database (LDDB; 1318 terms), Orphanet (1243 terms), Human Phenotype Ontology (9895 terms, 22/08/2102), Elements of Morphology (AJMG; 423 terms), ICD10 (1230 terms), as well as medical terminologies in use: UMLS (7,957,179 distinct concept terms), SNOMED CT (>311,000 concepts), MeSH (26,853 concepts) and MedDRA (69,389 concepts). We established a strategy to compare the terminologies to find commonalities and differences, using ONAGUI as a tool to identify exact matches. The non-exact matches were verified manually by an expert. A core-terminology of 2,300 terms was derived and analyzed by a panel of experts (International Consortium for Human Phenotype Terminologies - ICHPT). The resulting consensual terminology will be freely available in a dedicated website (www.ichpt.org) and at the International Rare Disease Research Consortium (IRDiRC) website. Mappings from ICHPT to other terminologies will be given in order to enable interoperability between databases that use the various terminologies to annotate phenotypic data, with the goal of enabling data exchange between all major genetic databases.

1644S

Data exploration through stark visualizations in gene expression profile of down syndrome. *J. Rualo[1], P. Skinner[1], D. Weaver[1], N. Economou[1], DG. Knowles[2], E.G. Couto[2].* 1) Translational Medicine, PerkinElmer, Inc., Waltham, MA; 2) Bioinformatics, Integromics, Waunakee, WI.

Life Scientists are increasingly challenged by huge datasets resulting from High-Throughput Experiments that contain an enormity of information. Making sense of the big data produced is essential to understanding complex biological systems and doing so without wasting unnecessary resources is key. Frequently this problem is addressed using different software solutions for each technology and handling many steps manually or with ad-hoc scripting. This generates problems when comparing results from different technologies in a reliable way and makes it difficult to represent the data for analysis when attempting to answer biological questions of interest. In this work we evaluate if the use of interactive visual exploration of the data can provide the researcher with the ability to better evaluate their data and extract relevant biological conclusions. By taking advantage of visual data representations and the human capacity to immediately recognize patterns in visual data, we demonstrate how this approach accelerates data exploration and helps to reveal information easily missed using the traditional data analysis paradigm. In the traditional approach the data visualization is only used as the end product of the analysis. The initial steps and the exploratory analysis use limited visual aids that are frequently highly summarized visualizations focused on a specific question; thus, important trends are easily missed when not specifically searched. In order to demonstrate how visualizations can help not only in the representation of the final results but also during the entire analysis process we have reanalyzed the expression data from a recent study published in Nature (Letourneau A. et al. Domains of genome-wide gene expression dysregulation in Down's syndrome. Nature 2014 Apr 17;508(7496):345-50) together with other expression datasets related to Down Syndrome deposited in the GEO database. We show how by using interactive and visual exploration at the different steps of the analysis in combination with the standard tools used during the traditional data analysis we can reveal several interesting features of the data that can be easily missed and ignored when using only the conventional analysis & reporting.

1645M

Evaluating global enrichment of trait-associated variants in epigenomic features. *E. Schmidt[1], J. Chen[2], W. Zhou[2], J. Zhang[2], E. Chen[2], C. Willer[1,2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, MI.

Genome wide association studies have identified hundreds of non-protein-coding variants with modest effect sizes, making alterations in transcript levels difficult to detect. This trait-associated genetic variation likely plays a role in transcriptional regulation via epigenomic regulatory features, a diverse set of which have been experimentally defined by ENCODE in various cell types. We develop GREGOR (**G**enomic **R**egulatory **E**lements and **G**was **O**verlap algo**R**ithm) to address 3 aims: 1) elucidate the important tissue types in which genetic variation impacts transcription for a particular trait, 2) narrow our focus of the regulatory features underlying transcription disrupted by trait-associated variants, and 3) use positional overlap with selected regulatory domains to identify potential functional candidate variants at trait-associated loci.

Taking into account linkage disequilibrium, we evaluate enrichment of 5 sets of metabolic-related trait-associated variants in a range of regulatory features by comparison to control variants from 1000 Genomes. We match each GWAS SNP with control SNPs based on 3 properties: i) number of variants in high LD, ii) minor allele frequency, and iii) distance to nearest gene. We find enrichment of aggregated sets of trait-specific variants in DNase hypersensitive sites in biologically relevant tissue types. Examples include significant enrichment *P*-values and fold change of variants associated with blood pressure in blood vessel ($P=1\times10^{-9}$; 1.5), body mass index in olfactory neurosphere-derived cells ($P=4\times10^{-5}$; 1.7), coronary artery disease in heart ($P=2\times10^{-5}$; 1.7), lipids in liver ($P=2\times10^{-14}$; 1.6), and unexpectedly, type 2 diabetes in heart ($P=1.4\times10^{-6}$; 1.7). We further evaluate the position of index SNPs and their LD proxies relative to histone marks and ChIP-seq TF binding sites, as well as functional chromatin states.

We prioritize individual non-coding variants at GWAS loci and experimentally test candidate SNPs at ≥ 5 GWAS lipid loci using a luciferase reporter to measure transcript activity in human HepG2 cells. In all, our tool systematically employs the wealth of regulatory data available from ENCODE to establish known biological connections with trait-associated variation, find potentially novel biological mechanisms, and guide experimental follow-up to identify functional variants at GWAS loci.

A bioinformatic protocol for the study of rare diseases. *F. Tobar Tosse, E. Ocampo Toro, P. Hurtado Villa.* Department of basic Science for Health, Pontificia Universidad Javeriana Cali, Cali, Valle del Cauca, Colombia.

Introduction: Rare diseases (RDs) involve several genetics and molecular mechanisms, which describe diverse and specific phenotypes and conditions; which difficult the concentration of efforts to research and propose new therapies for the patients. However, there is a relevant feature in these kind of diseases; that is the genetic context, where a single variant in a gene could define the whole context of the disease, for example, in the lysosomal storage diseases. Additionally, there is a very important fact, that is the consequences in the genome; these mean, although several mechanisms are associated to each RDs, these can be generally described as aberrations of the human genome, whose organization is disrupted and therefore the dynamic is changing too. Results and discussion: Accordingly, at the present work we present a bioinformatics workflow for the association of genomic information related with RDs. We improved and applied methods of data mining and nodes theory, considering the phenotypic and genetics descriptions for several RDs. This approach allow us to identify, molecular and genomics associations among several rare diseases. Interestingly, physiological and phenotypic descriptions could be associated to the combination of genomic patterns, and could describe focused of genomic susceptibility. Additionally, it was associated to affectation of critical metabolic or physiological processes. For example, we identify several syndromes related to adrenal Insufficiency with genomics patterns (Based on density of repetitive elements), that phenotypically are related to hydroxylase deficiency, and the consequences in the lipid metabolisms. The relational network shows this metabolic process as critic node in the genomics associations identified in Rare diseases, therefore genomics context could define unknown related factors important for the exploration of new genetics, or new targets for disease exploration. Conclusion: Although Rare Disease are described as diverse molecular and genetics anomalies, by bioinformatics approaches could be possible the identification of genomics and metabolic connections, that allows the definition and implementation of new methods for specific target in several RDs.

1647S

EnhancerDB: a database of human enhancers and their putative targets. *P. Wang, L.Y. Wang, M.Q. Zhang, Q. Lian, J. Wang.* The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong.

As a major class of distal cis-regulatory elements, enhancers are crucial to the regulatory system orchestrating gene transcription. Thereby detection of enhancers has been extensively studied and numerous enhancers have been detected by experiments and predicted by computational models. Here we present a database containing ~3,000,000 human enhancers. 3,598 enhancers are experimentally detected and collected from 190 publications, and the rest are predicted based on transcription factor binding motifs, high conservation, histone modification marks or eRNA expression. Meanwhile, we incorporated data of transcription factor binding motifs and ChIP-Seq peaks to annotate the enhancers. In addition, we used available long-range chromatin interaction data, including ChIA-PET and Hi-C in 10 human cell lines to present putative target genes of the enhancers.

1648M

A highly efficient and scalable compute platform for massive variant annotation and rapid genome interpretation. *J. Warren[1], E. Colak[1], A. Kiani[1], J. Li[2], S. Bhattacharya[3], N. Bani Asadi[1,2], S. Barr[1], A. Butte[3], G. Nolan[4], R. Chen[5], W.H. Wong[6,7], H.Y.K. Lam[2].* 1) Department of Engineering, Bina Technologies, Redwood City, CA; 2) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 3) Division of Systems Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford CA; 4) Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford California 94305; 5) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 6) Department of Statistics, Stanford University, Stanford, CA; 7) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

After obtaining the variants from next generation sequencing data, researchers and clinicians still face the undertaking of interpreting the results. Despite the availability of numerous public databases, using this collective information is an arduous task due to inconsistent data, multiple versions and nonstandard formats. Even after aggregating the data and annotating the variants, it remains a laborious exercise to identify the causative variants associated with the disease in question.

To address this challenge we present a highly efficient data pipeline that leverages big data technologies to integrate annotations from a large range of biological databases. The pipeline takes variant callsets, annotates all samples, and indexes the variants to support real-time queries and analytics. Specifically, it uses Hadoop MapReduce to perform extensive precomputation on the annotation data; builds indexes of the annotated variants; versions and manages data in both relational and NoSQL databases; and horizontally scales to increase throughput. With this approach, a 5-node cluster can annotate a typical whole exome sequencing (WES) sample with ~300 million annotation records (>200GB) in under 30 minutes or a whole genome sequencing (WGS) sample under an hour. Annotating a sample and indexing its variants are computationally demanding steps, but these are one-time costs. After the indices are generated, users can concurrently and repeatedly perform ad-hoc queries to identify the variants that meet given criteria. On average, it takes less than one second for any complex query to return the results on a single sample.

Researchers can easily query the samples in a database-centric view or a genome-centric view. In one application we analyzed the WGS data from the DNA of *Ata*, the skeletal remains of a 6-inch human found in the Atacama Desert, Chile. The annotation and analysis took less than an hour for >3M total variants and identified 37 functional changing variants located in genes highly associated with dwarfism and skeletal dysplasia. Four of these variants were not found in dbSNP and may be of interest for further investigation. Such filtration greatly reduces the search time and space for researchers. With predefined statistical workflows, researchers can also carry out genetic studies for case-control, trio, cohort, and tumor-normal studies.

1649T

Investigating the genetic architecture of pulmonary arterial hypertension shared with other diseases. *L.A. Yancy[1,2], V.A. de Jesus Perez[3,4], R.T. Zamanian[3,4], A.J. Butte[1,2].* 1) Biomedical Informatics Training Program, Stanford University School of Medicine, Stanford, CA; 2) Division of Systems Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA; 3) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Stanford University School of Medicine, Stanford, CA; 4) Vera Moulton Wall Center for Pulmonary Vascular Disease, Stanford University School of Medicine, Stanford, CA.

Pulmonary arterial hypertension (PAH) is a rare and fatal disease with a median survival of approximately 4 years for those afflicted. Many genome-wide association studies (GWASs) have attempted to determine the variants predictive of PAH, but often due to small sample sizes, studies have not led to highly predictive markers. However, GWASs have been successful in determining variants associated with many other diseases. We have an ongoing effort to curate these variants into a database called VARiants Informing MEDicine (VARIMED). VARIMED contains results from over 17,000 peer-reviewed genetic epidemiology studies (e.g. GWAS), covering over 460,000 variants (in over 18,000 genes) associated with over 6,500 phenotypes. In this study, we leverage VARIMED to determine if PAH exhibits a shared genetic mechanism with other diseases. Finding other diseases that have a significant enrichment of PAH associated variants may provide insight into (novel) variants or genes that play a significant role in PAH (and are otherwise not detectable in a PAH GWAS due to small sample size) or even novel therapies for PAH that can be "borrowed" from diseases with similar genetic architecture. Here, we perform a GWAS on exomes (~88,000 variants) from PAH subjects, rank those variants based on p-values and odds ratios (leaving ~350 "priority" variants), and identify genes associated with those prioritized variants (~300 genes). Using those "prioritized" genes, we then query VARIMED and identify diseases with a similar genetic architecture (i.e. identify those diseases with a significant enrichment of top-ranked genes from our PAH GWAS). Through this, we found significant similarities between PAH and a number of immune-related diseases, with the most significant finding being an unusual acquired kidney disease. This work can be extended to investigate the shared genetic architecture of other diseases (rare or otherwise understudied) by taking advantage of the large spectrum of diseases now with characterized genetic architecture.

1650S

Integrative genomic analysis of exome and RNA-seq data from multiple tissue sources obtained from a single breast cancer patient. *A. Vladimirova, R. Goold, S. Sanga, T. Klingler.* Station X Inc., San Francisco, CA.

The ability to analyze genomic data from differing sequencing methodologies and multiple tissue types in a single cancer patient provides a tantalizing opportunity to explore the capabilities of an integrative genomic study to elucidate potential tumor drivers and mechanisms. Simply because of sample availability, researchers are typically limited to analyses of primary tumor data. Access to data from both RNA-Seq and DNA-Seq datasets from adjacent normal tissue, blood and metastatic tissue samples in a single patient is rare, yet could greatly increase signal and reduce noise in these analyses. Technological advances and cost reductions mean truly integrative genomic analyses, in which mutational signatures can be reviewed in concert with transcriptional profiles across relevant samples from multiple tissues, could be used to understand tumorigenesis and potentially guide intervention. We present here a proof of concept study of a single breast cancer patient where we integratively analyze exome and RNA-Seq data obtained from four sample types - primary tumor, blood, adjacent normal tissue and metastasis. We use GenePool™, a commercial software application for biomarker discovery and validation in large patient cohorts (Station X, San Francisco, CA) to quickly prioritize variants and genes found in the tumor and metastasis by comparison to the blood and the adjacent normal breast tissue. Similarly, we analyze the primary tumor relative to the metastasis to identify differences in mutational signatures and transcriptional profiles. We present the results of this single patient integrative analysis and show how GenePool can extend these types of analyses to cohorts of patients, becoming a useful tool in the understanding and treatment of tumors.

Limitation of multiple testing through the integration of TCF7L2 DNA occupancy and SNP association data reveals *GIP* and *CPPED1* as novel type 2 diabetes loci. *M.E. Johnson[1], J. Zhao[1], J. Schug[2], S. Deliard[1], Q. Xia[1], V. Guy[1], J. Sainz[3], K.H. Kaestner[2], A.D. Wells[4], S.F.A. Grant[1,2,5].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Genetics and Institute of Diabetes, Obesity and Metabolism, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Institute of Biomedicine and Biotechnology of Cantabria (IBBTEC), Spanish National Research Council (CSIC), Santander, Spain; 4) Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

The *TCF7L2* locus is strongly implicated in the pathogenesis of type 2 diabetes (T2D). We previously mapped the genomic regions bound by TCF7L2 using ChIP-seq in the HCT116 cell line, revealing an unexpected highly significant over-representation of specific GWAS loci categories. Given that only a minority of the predicted genetic component to most complex traits has been identified to date, plus the fact that a number of GWAS-implicated transcription factors have now been shown to exhibit statistically significant preferential binding to loci associated with complex traits, we investigated if restricting association analyses to just the genes uncovered from our ChIP-seq approach in order to substantially reduce multiple testing could yield novel T2D loci. When investigating all the known GWAS loci bound within 5kb by TCF7L2 (most likely to be functional), derived from HCT116, apart from the known *TCF7L2* locus itself (rs7901695), the coronary artery disease associated T allele of rs46522 within the *UBE2Z-GIP-ATP5G1-SNF8* locus yielded significant and novel DIAGRAM-derived association with T2D risk (OR=1.07; $P=3.20\times10^{-4}$); indeed, the occupancy site was approximately 4kb from the transcription start site for GIP in an intergenic region known to be a hub for binding proteins, H3K27Ac histone marks and open chromatin via a DNAse I hypersensitive site. Indeed the locus encoding the receptor for GIP (*GIPR*) has already been reported in relevant GWAS settings to be associated with BMI and glucose and insulin response metrics. Furthermore, when we analyzed tag-SNPs within genes not previously implicated by GWAS but bound within 5kb by TCF7L2 in HCT116, we observed significant association within the same dataset of the A allele of rs4780476 within *CPPED1* with T2D risk (OR=1.1, $P=4.10\times10^{-5}$). Furthermore, the TCF7L2 occupancy site was in the immediate *CPPED1* promoter region. This is an equally notable observation, as only one paper has been published to date on this gene product and shows that down-regulation of *CPPED1* expression improves glucose metabolism in vitro in adipocytes. Our limitation of multiple testing is based on biological plausibility, where a GWAS-implicated transcription factor is clearly pointing us to genes that are genetically associated with complex disease more often than expected by chance and thus may also be pointing us to novel genes where their strength of the association was at the level of noise at the genome wide scale.

1652T

Metadata-driven tools to access data from the ENCODE project. *E.T. Chan[1], C.A. Sloan[1], V.S. Malladi[1], J.S. Strattan[1], L.D. Rowe[1], B.C. Hitz[1], N.R. Podduturi[1], F. Tanaka[1], B.T. Lee[2], K. Learned[2], M. Maddren[2], S. Miyasato[1], M. Simison[1], E.L. Hong[1], W.J. Kent[2], J.M. Cherry[1].* 1) Genetics, Stanford University, Palo Alto, CA; 2) Center for Biomolecular Science and Engineering, University of California at Santa Cruz, Santa Cruz, CA.

The Encyclopedia of DNA Elements (ENCODE) project is an ongoing collaborative effort to create a comprehensive catalog of functional elements in the human and mouse genomes. Its current data corpus exceeds 4000 experiments across more than 400 cell lines and tissues using a wide array of experimental techniques to survey the chromatin structure, regulatory and transcriptional landscape in human and mouse genomes. All ENCODE experimental data, metadata and associated computational analyses are submitted to the ENCODE Data Coordination Center (DCC) for validation, tracking, storage, and distribution to community resources and the scientific community.

As the volume of data increases, the identification and organization of data sets becomes challenging to present to users. Here, we describe the web interface, search tools and underlying database the DCC have built for simple and intuitive access to ENCODE data and metadata. Extensive and structured metadata describing experimental variables, such as the biological samples, specific reagents, and protocols necessary to replicate the assays and their subsequent analysis collected from ENCODE data producers drive a powerful faceted browsing interface, allowing users to filter and retrieve particular slices of the large data corpus. Elasticsearch-driven real-time indexing also allows users to perform full-text searches to directly access specific data of interest. Upcoming features planned include access to data standards, quality metrics for data files, data visualization tools, uniform processing and analysis pipelines as part of the revamped ENCODE public portal. Data and metadata from the ENCODE project can currently be accessed at https://www.encodedcc.org.

1653S

Accessing ENCODE project data using a REST API and JSON. *C.A. Sloan[1], E.T. Chan[1], V.S. Malladi[1], L.D. Rowe[1], J.S. Strattan[1], B.C. Hitz[1], N.R. Podduturi[1], F. Tanaka[1], K. Learned[2], B.T. Lee[2], S. Miyasato[1], M. Simison[1], E.L. Hong[1], W.J. Kent[2], J.M. Cherry[2].* 1) Genetics Department, Stanford University, Palo Alto, CA; 2) School of Engineering, UC Santa Cruz, Santa Cruz, CA.

The Encyclopedia of DNA Elements project (ENCODE) has been producing data for over eight years to investigate DNA and RNA binding proteins, chromatin structure, transcriptional activity and DNA methylation on a variety of human and mouse tissues and cell lines primarily. As the complexity and diversity of the data grows, the tools required to organize, search and access the data in meaningful ways need to be more sophisticated. The ENCODE Data Coordination Center (DCC) has incorporated a representational state transfer application programming interface (REST API) with JSON objects to facilitate the access of ENCODE experimental metadata using a web portal. Meta-data can be accessed and data can be searched for at http://www.encodedcc.org/ using the HTTP access commands of get and post. We further expand on the access capability by allowing filtering of the meta-data with the use of search urls. This system allows external researchers to write their own interfaces to access, analyze and visualize the ENCODE data. It also facilitates the integration of the ENCODE data with other similar large-scale data sets like Epigentics Roadmap and modENCODE. Here we will present our JSON schemas, examples of the REST API and use-cases for the search functions. Our goal is for the genomics community to use the released ENCODE data available through these methods for data mining and integration.

1654M

Beyond Flat Files: Creating a web-based data API to simplify parsing and distribution of GTEx data. *T. Sullivan, D. DeLuca, K. Hadley, K. Huang, J. Nedzel, A. Segre, E. Gelfand, T. Young, G. Getz, K. Ardlie, the GTEx Consortium.* The Broad Institute, Cambridge, MA.

Large-scale genomics projects such as GTEx produce vast amounts of data, and the goals of many of these projects include creating publicly-accessible databases of genetic information. Often, to perform meaningful analysis, one must download very large text files, which must then be merged, integrated, and queried. The programming overhead the user faces during these integration and querying steps can be disproportionate to the amount of information sought by the analyst. While web pages can provide some querying capability, we argue that the heart of the solution to this problem lies in providing a web-based API. We outline here the major ways in which the GTEx API development has contributed to the ultimate goals of GTEx data distribution. These benefits fall into three categories: querying, software integration, and insulation. **Data querying:** The GTEx API provides the user with the ability to ask specific questions. For example, querying with an isoform instantly provides isoform specific expression levels across all GTEx tissues. **Integration in any software:** A major advantage that a data API has over a website is that the queries can be programmatically integrated into client systems. GTEx data can be accessed within scripts on demand. Non-GTEx web portals can query GTEx data at any time for integration and display within their webpages. **Insulation of data storage from data access:** The question of which technologies to use to store and query large datasets is non-trivial and often evolving. The API insulates the end user from these issues by providing a domain specific outward face to the data that is intuitive to use. As a result, database technologies could be modified or completely replaced without the API user having to modify existing code.

Thus far the major beneficiary of the GTEx API has been the GTEx Portal itself. Efforts to develop GTEx data visualization tools rely heavily on the GTEx API. The API delivers data efficiently for multi-tissue eQTL data, gene and isoform expression data, and sample metadata. In the future, the availability of public data APIs across large-scale genomics projects will allow researchers to easily integrate data from multiple types of studies and quickly find what measurements have been made about their genes of interest, be it in the context of a variety of normal tissues, cancer types, or disease states.

Association data in dbGaP and Minimum-Required Information for Data Sharing. *Z. Wang, M. Feolo, Y. Jin, N. Popova, M. Xu, S. Sherry.* Information Engineering Branch, National Center for Biotechnology Information, NIH, Bethesda, MD 20892.

Association statistics for each locus are important end products from studies that investigate the genomic contribution to disease/trait manifestation. Therefore since its inception, the dbGaP has been a central repository for archive and dissemination of these data. dbGaP currently provides over 3800 data sets for tests of association, linkage and somatic mutation analyses. Over 90 percent of these data sets are constructed with SNP markers, the rest are results for specific genes or whole genome copy number variations. Although these association data cover a variety of phenotypic traits, diseases and pharmacological responses, they have been provided by only a small portion of the studies in dbGaP. The dbGaP team is renewing its call to encourage researchers to upload their association results, including those that do not reach genome wide significance, to dbGaP. These results will be permanently archived and made fully accessible to authorized researchers. After potentially participant-identifiable information being removed, these data are also included to the open-access dbGaP browser and PheGenI web resource (http://www.ncbi.nlm.nih.gov/gap/phegeni) , where they are linked to NCBI resources and updated with subsequent genome builds and dbSNP annotations. To facilitate the sharing of these data, we propose a guideline for Minimum Info Required for Association Data (MIRAD). The MIRAD is composed of following data elements: 1) locus identifier (rs#, geneID, dbVarID); 2) variation summary (sample size, genotype quality and variant counts of each group) within the locus; 3) Statistics (p-value, FDR); and 4) Coding (risk) allele, and effect size. Collection of these minimal elements will aid other researchers to evaluate supporting evidence and independently verify discoveries from other research efforts in a consistent fashion. Association results are strongly encouraged for submission, even in cases where individual level data is not suitably consented for broad data sharing, as these data will allow the research community to directly use analysis results for meta-analyses, to increase statistical power, or for the development of hypotheses. This presentation will describe the current association analysis results data archived at dbGaP, and outline and discuss MIRAD.

1656S

Genome in a Bottle: So you've sequenced a genome, how well did you do? *J.M. Zook, H. Parikh, M. Salit, Genome in a Bottle Consortium.* Biosystems and Biomaterials Division, National Institute of Standards and Technology, Gaithersburg, MD.

To help clinical and research labs understand the trustworthiness of variant calls from Next Generation Sequencing, the Genome in a Bottle Consortium (www.genomeinabottle.org) is developing well-characterized whole human genomes. We recently published our methods to integrate and arbitrate between datasets from multiple sequencing technologies to develop high-confidence SNP, indel, and homozygous reference genotypes for our pilot NIST human genome Reference Material based on Coriell DNA NA12878 (Zook et al, Nat. Biotech. 2014). Since then, we compared our arbitrated multi-dataset calls to orthogonal methods developed by Illumina Platinum Genomes and Real Time Genomics using phased pedigree information to develop high-confidence calls. We found that our arbitrated calls are conservative but have exceptionally few errors and high quality homozygous reference calls, and that phased pedigree methods do particularly well in finding systematic sequencing errors such as homopolymer errors but have some systematic alignment errors that inherit properly. We combine the strengths of each of these datasets to develop the most comprehensive highly accurate benchmark set of SNP, indel, and homozygous reference calls. Genome in a Bottle is also developing similar multi-dataset arbitration and pedigree methods for structural variants. In addition, to enable users of our benchmark to assess sequencing and bioinformatics performance in a uniform manner, the Genome in a Bottle Consortium has developed a specification for performance metrics to be output by benchmarking algorithms using our Reference Materials. Finally, we will describe how labs are assessing their performance using our high-confidence SNP, indel, and homozygous reference genotypes for our pilot NIST human genome Reference Material, and our progress developing future Reference Materials.

1657M

Quantity or quality that is the question: integrative genome-wide association. *A.M. Mezlini[1,2], C. Baciu[1], S. Morrissy[1], M. Taylor[1], D. Malkin[1], A. Goldenberg[1,2].* 1) SickKids Research Institute, Toronto; Canada; 2) Computer Science, University of Toronto, Toronto, Ontario, Canada.

The causal factors behind complex genetic diseases are numerous and heterogeneous. Many studies have identified and functionally validated associated protein-coding variants. Recently, variants modulating gene expression levels and their relation to disease have attracted a lot of attention.This raises the question of how often gene products (proteins) quality versus quantity abnormalities are causing disruption in biological processes in relation to disease? Both gene products' quantity and quality might be important for any given disease thus, analyzing both data types simultaneously can provide better models of disease and characterize larger sets of patients. To address this issue we present an integrative method for combining two complementary data types: exome sequencing data as an indicator of protein quality and gene expression data which is indicative of protein quantity. Note that our approach is very different from eQTL analysis, since we are treating expression data as a predictor of a disease, rather than an outcome. Using variant harmfulness as a prior, we obtain a score per gene per patient and by exploiting gene interaction information such as protein-protein and/or regulatory networks, our method identifies sets of genes whose aberrant states potentially contribute to the disease in a large proportion of the patients. The significance of the gene set is assessed via permutations. Our analysis allows 1) identify a small set of relevant rare and common coding variants; 2) zero-in on potential regulatory aberrations. In the regulatory case, the “drivers” can be retrieved in a subsequent targeted analysis of regulatory SNVs, CNVs and epigenetic regions in a cost-effective manner for the candidate patients. Varying the proportion of the regulation-attributed vs coding variant-attributed genome aberration in a simulated setting we show that gene-based variant aggregation methods such as CAST, Calpha, RWAS fail in scenarios where less than 60% of the causal variants are coding and that our method is able to retrieve the disease mechanisms even in scenarios where as few as 20% of causes are coding variants. Our method is on par or outperforms all others in terms of precision and recall in all considered scenarios. We applied our methodology to a cohort of medulloblastoma patients and uncovered significant gene sets for different subtypes of medulloblastoma. Our results confirm and extend previously reported gene-disease associations.

1658T

Cross-species genome and epigenome visualization on WashU EpiGenome Browser. *X. Zhou[1], R.F. Lowdon[1], D. Li[1], I. Smirnov[2], Y. Cheng[3], P.A.F. Madden[4], R. Hardison[5], J. Costello[2], T. Wang[1].* 1) Department of Genetics, Center for Genome Sciences and Systems Biology, Washington University School of Medicine, St. Louis, MO; 2) Brain Tumor Research Center, Department of Neurosurgery, Helen Diller Family Comprehensive Cancer Center, University of California San Francisco, CA; 3) Department of Genetics, School of Medicine, Stanford University, Stanford, CA; 4) Department of Psychiatry, Washington University in St. Louis, St. Louis, MO; 5) Department of Biochemistry & Molecular Biology, Pennsylvania State University, University Park, PA.

Integrative comparison of genomes and epigenomes across mammalian species is of critical importance to human genetics research. While genome sequence comparison has pinpointed conserved elements in the human genome, patterns and rules of epigenomic conservation are not yet well defined. The same genome encodes multiple epigenomes. Epigenomes are cell type-specific, change with age, and respond to environment. Epigenetic variation and dynamics may be the foundations of great biological complexity across species and between individuals. For instance, human-mouse conserved genomic regions may have different epigenetic modification patterns, which may explain human-specific traits that are otherwise difficult to explain using the genome alone. Such an analysis requires representing each species’ epigenomic information in the context of genome sequence comparison. It thus poses a great challenge to data access and visualization. We address this challenge through a major innovation in the WashU EpiGenome Browser (http://epigenomegateway.wustl.edu/browser/). We developed a new mechanism that allows investigators to compare genomes of two species by visualizing their genome alignments at different resolution, smoothly transiting from gapped-alignment at single-base resolution, to syntenic blocks and rearranged genomes at megabase-scale. In the context of this alignment, vast epigenomic data from both species can be displayed and directly compared. Our Browser breaks the “one-reference-genome-only” status quo of genome browser tools, and contributes a powerful tool for the research community to access the cross-species genomic resources (i.e., Roadmap Epigenomics, ENCODE, modENCODE) in comparative genomics and epigenomics framework.

1659S

The Bio-LarK Patient Archive - Systematic phenotype data collection for Rare Disease Genomics. *A. Zankl[1,2], C. McNamara[3], T. Groza[3].* 1) Academic Department of Medical Genetics, Sydney Children's Hospitals Network (Westmead), Sydney, NSW, Australia; 2) Genetic Medicine, Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 3) School of Information Technology and Electrical Engineering, The University of Queensland, Brisbane, QLD, Australia.

Many applications in Clinical Genomics are hindered by a lack of good phenotype data. This is particular true for rare diseases, where patients to phenotype are hard to find. Only global consortia can assemble sufficiently large patient cohorts to collect high quality phenotype data. However, a number of practical issues stymy current phenotyping efforts: 1. Phenotype data collection relies mainly on busy clinicians who are not specifically paid for the task. Phenotype data collection therefore has to be as user friendly as possible and needs to be incentivised to achieve high participation rates. 2. Medical terminology is very complex and poorly standardised. This makes combining phenotype descriptions from different sources very difficult. 3. Aggregating phenotype data from multiple institutions raises concerns regarding patient privacy, but also regarding data ownership. The Bio-LarK Patient Archive (Bio-LarK PA) was specifically built to address all these issues. Bio-LarK PA is a web-accessible database that allows clinicians to store rich phenotype data on their patients, including clinical summaries and images (photos, xrays etc.). Clinical summaries and image descriptions (e.g. xray reports) can be entered as free text or even pasted in from other sources, thus reducing the data entry burden. Clinical summaries and image descriptions are automatically annotated with suitable terms from the Human Phenotype Ontology (HPO), thus standardising the entered information and making it easily retrievable. Patient data can be kept private, shared with one or more individuals or shared with one or more groups. Sharing can be limited to the HPO annotation only or can include the full text and/or images. Shared cases can be discussed via a built-in discussion forum, for example to review a case with a group of colleagues or to obtain expert advice from a specialist overseas, a powerful incentive for clinicians to enter data into the database. Bio-LarK PA is built on Semantic Web technologies and integrates with other Bio-LarK projects such as the Bio-LarK Knowledge Base. All data is stored in RDF format and made available through a SPARQL endpoint. Other ontologies such as the Orphanet Rare Disease Ontology can be easily integrated. All Bio-LarK software is Open Source and distributed free of charge. We believe adoption of the Bio-LarK Patient Archive could leapfrog phenotype data collection for many rare diseases initiatives.

1660M

Genetic predictive modeling of diabetes based on circulating glycemic measures. The Long Life Family Study (LLFS). *A.T. Kraja[1], M.K. Wojczynski[1], J.H. Lee[2], I. Miljkovic[3], B. Thyagarajan[4], S.J. Lin[1], I.B. Borecki[1], T.T. Perls[5], K. Christensen[6,7], A. Newman[3], P. An[1], M.A. Province[1].* 1) Division of Statistical Genomics, Department Of Genetics, Center for Genome Sciences & Systems Biology, Washington University School of Medicine, St. Louis, MO, USA; 2) Department of Epidemiology, the Sergievsky Center, Columbia University Medical Center, New York, NY, USA; 3) Graduate School of Public Health, Department of Epidemiology, Center for Aging and Population Health, University of Pittsburgh, Pittsburgh, PA, USA; 4) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN, USA; 5) Division of Geriatrics, Department of Medicine, Boston University Medical Center, Boston, MA, USA; 6) Danish Aging Research Center, Epidemiology, University of Southern Denmark, Odense, Denmark; 7) Department of Clinical Biochemistry and Pharmacology and Department of Clinical Genetics, Odense University Hospital, Odense, Denmark.

The LLFS is a cohort study of longevous families recruited from 4 centers Boston, New York, Pittsburg and Odense, Denmark. The LLFS family members have lower prevalence (7.1%) of type 2 diabetes (T2D) than the US European-ancestry population (10.2%) 20 years and older. We compare genetic associations of literature validated loci for glucose, insulin, insulin resistance and diabetes in LLFS versus top ranked results of LLFS. We hypothesize that this approach may identify genes that associate with insulin and glucose metabolism that do not operate under disease conditions. We conducted an additive genetic model genome-wide association scan (GWAS) for fasting glucose (FG), insulin (FI), HOMA-IR, HOMA-B, and glycated hemoglobin HbA1c (N=4,550). The Illumina Omni 2.5 chip was used and ~9.2M (MAF > 0.01, r^2>0.3) variants were imputed. From public databases, GWAS variants unique per gene with p-values at $p \leq 10^{-7}$ were selected (n=279). Predictive models via Graphical Trees and Support Vector Machine for T2D/pre-diabetes were constructed. Analysis of this list of candidate genes using GeneGO software revealed involvement in "Protein folding and maturation insulin processing" pathway ($-\log_{10}$(p)-FDR=10.4) and "Diabetes" ($-\log_{10}$(p)-FDR=77.9). The best LLFS SNPs of the 279 candidate genes performed poorly in LLFS in associations with five features compared with other top ranked variants present in LLFS. Best LLFS SNPs of 279 candidate genes showed respectively a Range, Mean, Median and SD $-\log_{10}$(p) for FG 0.3-6.7, 2.2, 2.2, 1.0; FI 0.3-5.6, 2.0, 2.0, 0.8; HOMA-IR 0.4-5.0, 2.0, 2.0, 0.8; HOMA-B 0.2-5.0, 2.0, 2.0, 0.9; and HbA1c 0.4-5.0, 2.0, 2.0, 0.8; compared to LLFS best SNPs (p<0.00001) for FG 5.0-7.8, 5.4, 5.2, 0.5; FI 5.0-7.7, 5.6, 5.4, 0.6; HOMA-IR 5.0-7.6, 5.5, 5.3, 0.5; HOMA-B 5.0-6.3, 5.4, 5.3, 0.3; and HbA1c 5.0-6.6, 5.5, 5.4, 0.5. Between LLFS own top ranked candidates and literature's top candidate gene list, a few overlap (LLFS own Genes/New, FG 43/37, FI 35/34, HOMA-IR 41/40, HOMA-B 33/33 and HbA1c 35/34). The new LLFS findings may point to loci important for normal glycemic metabolism conditional on age. Among new findings rs78375027 (chr6:19304147, $-\log_{10}$(p) =7.7, MAF=3.5%, n= 3,943) near *LOC100506885* associates significantly with FI. This locus has been previously associated with myocardial infarction (rs9460319, $-\log_{10}$(p) =3.5), hypertension (rs11755216, $-\log_{10}$(p) =5.1), LV mass (rs10498696, $-\log_{10}$(p) =5.7) and stroke (rs9295438, $-\log_{10}$(p) =3.8).

1661T

Changing patient behavior through comprehensive risk analysis with genomic and health data. *H. Fakhrai-Rad, P. Menon.* BaseHealth, Redwood City, CA., Select a Country.

70% of diseases are preventable, and common complex diseases and conditions like Heart Disease, Cancer, Stroke, Diabetes, Arthritis, and Obesity account for 7 in 10 deaths each year in the US. Changes in behavior can dramatically lower patient risk of developing diseases, even if one has a genetic predisposition. The first wave of consumer-focused genomics took fragmented approaches that focused strictly on genomic data, or health assessment data, and didn't provide the full view of a person's health, and ultimately did not lead to patient behavior change at high rates. We've since learned that genomic data for common complex diseases is only part of the puzzle, and should be used in concert with all of a patient's risk factors to get the most personalized and complete view of a patient's health available. How then, with the care of a physician, can genomic data best be delivered to an individual, alongside comprehensive health data, with clear ways to turn insights into enduring action? At BaseHealth, we have created a platform that leverages big data analysis to synthesize many data sets (genomic data, lab tests, lifestyle factors, family history, and other medical information) to output a comprehensive health assessment unique to each patient. Through multidimensional data modeling and meta-data analysis driven by published and curated genetic data and scientific data, health databases, and metadata analysis, we can capture complex relationships between diseases and risk factors and give physicians a better understanding of their patients' unique risks for keycommon complex diseases. The platform covers more than 40 common complex diseases that combine both modifiable and nonmodifiable risk factors and engages patients and their physicians in a highly collaborative way. With analysis provided by our platform, physicians can make meaningful recommendations that lead to patient behavior change. In this presentation, we will show how statistical modeling can meaningfully increasing a patient's chance to prevent a high-risk disease. Furthermore, we'll examine what happens when physicians use a comprehensive approach that combines all data types that have an effect on health to engage their patients to improve health and lower disease risk over time. In addition, we will share results some of the pilot programs from among the 50 physicians and 250 patients that are currently using Genophen.

Discover and access human genome sequence with new NCBI services. *S. Sherry, C. Xiao, D. Slotta, K. Rodarmer, M. Feolo, M. Kimelman, G. Godynskiy, C. O'Sullivan, E. Yaschenko.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

Next Generation Sequencing (NGS) activities currently generate a massive amount of data for use in human disease research, population genetics, and methods development. Most of this data is currently generated on research subjects who, through their informed consent, have placed restrictions on the use and redistribution of their data. This presentation will introduce new NCBI services that facilitate the discovery and computational access these data for dbGaP's current collection of 750,000 individuals.

Discovery is facilitated by "Beacons" developed in collaboration with the Global Alliance for Genomic Health (GA4GH) that identify if a specific allele is observed in any of the repository's data. NCBI has developed a public beacon at www.ncbi.nlm.nih.gov/projects/genome/beacon/ and a dbGaP beacon at https://dbgap.ncbi.nlm.nih.gov/aa/wga.cgi?page=beacon. The public beacon returns a true/false reply, and the dbGaP beacon provides individual level details of SRA allele coverage and limited phenotypes for study approved users.

Improved methods for access have been introduced into the SRA toolkit that support encryption during delivery and at rest for secure transport and local management of dbGaP data. This is an appropriate technology for NIH-approved cloud-based computational environments that conform to the revised dbGaP data security policy. A demonstration API of these new iterator classes in Java and C++ illustrates easy programatic access to NGS data. It is available at http://ftp-trace.ncbi.nlm.nih.gov/sra/sdk/ngs/package/ and uses example queries to 1000 genomes data stored in public SRA and dbGaP to help developers create analysis pipelines that are interactive with NCBI services using an easily configured encryption environment that is transparent to the user. These methods can significantly reduce the local storage footprint for NGS data when hardware costs are a consideration.

1663M

GenomeBrowse: A Comprehensive Community-Driven Visualization Platform for NGS data and Public Annotations. *G. Rudy, S. Gardner, G. Christensen.* Golden Helix, Bozeman, MT.

Next generation sequencing data has become a prolific tool in genetic research. As such, tools supporting that interpretation must provide an intuitive and powerful user experience that integrates research data with public resources. Current tools such as IGV focus on only local data, while web-based browsers that have public annotations are cumbersome to use with private data. We introduce Golden Helix GenomeBrowse 2, a free visualization tool for all common NGS file formats such as BAM, VCF, BED, WIG, FASTA, BigBed and BigWig while also hosting an instantly streamable public repository of annotations for 43+ species and 250 tracks. With over 3,000 registered users, GenomeBrowse has a healthy community contributing their own reference genomes and annotations to the repository. Annotations can be imported from any binary or text format into a columnar store database like format we created called Tabular Storage Format (TSF). It embeds both a genomic index for quickly visualizing genomic features at a given interval as well as different levels of aggregate binned data to enable views of large sources at genomic scale. While these features are shared with the BigBed/BigWig format, TSF also includes column-based per-field compression and lexicographical indexing to enable searching large sources like dbSNP for an RSID. Locating a RSID on the TSF converted dbSNP file (1.2GB TSF with 61 million records) takes 70ms in GenomeBrowse versus 48 seconds to locate the record with grep on the 10GB VCF or 1.6 seconds to start loading the RSID on NCBI's dbSNP website. GenomeBrowse enabled collaboration on projects by integrating with the Evernote cloud-based notebook store. You can link GenomeBrowse to your free Evernote account, open, create and edit notes on your project, and copy into your notes contextual data from your samples or public annotations. Notes can contain hyperlinks to jump back to a given genomic context, as well as custom formatted screenshots. Notes can be shared through Evernotes built-in notebook sharing, as well as through a single-button publish feature that provides a cloud-hosted hyperlink of a note. We demonstrate how GenomeBrowse can integrate public data sources such as ClinVar, COSMIC, dbNSFP 2.4 and ESP6500 to aid in the validation and interpretation of putative causal variants in a Mendelian study and document the findings in Evernote.

1664T

A mutation in TBC/LysM associated domain containing 1 (Tldc1) causes craniofacial abnormalities in mice. *R. Zeng[1], V.W Keener[2], B. Dawson[2], B. Lee[2], C.A Bacino[2], J. Shendure[3], M.J Justice[1,2].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Molecular Physiology and Biophysics Houston, Baylor College of Medicine, Texas, US; 3) Department of Genome Sciences, University of Washington, Seattle, Washington, US.

Craniofacial 3 (Crf3; MGI: 2671818) is a highly penetrant recessive trait that was previously isolated in a series of large-scale mouse N-ethyl-N-nitrosourea (ENU) mutagenesis screens on a mixed strain background consisting of C57BL/6J and 129S6/SvEvTAC. Crf3 homozygotes are small in size with visible craniofacial phenotypes including short snout, microcephaly and upright standing ears. We used a novel soft-tissue scanning technique to provide a non-invasive, reliable and quick method to accurately distinguish, quantify and classify the craniofacial abnormalities in mutant mice, and link them to craniofacial defects of human syndromes. The Crf3 locus has been mapped to mouse chromosome 8, linked to D8Mit92 (Z=5.7). To identify causal DNA variants, we sequenced one homozygous Crf3 sample by using whole-exome capture and massively parallel DNA sequencing. Sequencing of paired-end libraries was performed on an Illumina Hiseq 2000 system (100bp reads). Sequence reads were mapped to the mm10 (GRCm38) mouse reference genome by BWA and variants were called by GATK. Hard-filtering for the variants was based on a minimum SNP quality of 20, read depth of 5 and variant confidence of 1.5. Annotation of variants and prediction of impact of protein sequence were performed by Annovar. Variants were filtered by removing common polymorphisms, which were present in sequence from 14 mouse lines that had been isolated in our lab on the same strain background and in sequence from 18 different mouse strains from the Wellcome Trust Sanger Institute mouse SNP database. After filtering, only one homozygous variant remained that was located on mouse chromosome 8: a T to C nucleotide change in a splice donor site of Tldc1 (NM_028883: exon4: c.378+2T>C). Eight DNA samples presumed to be Crf3/Crf3 homozygotes based on phenotype were homozygous for this mutation, whereas none of seven DNA samples from unaffected, presumed heterozygous or wild type littermates were homozygous for this allele. To date, the function of human TLDC1 on HSA 16q24.1 is unknown. TLDC1 lies near the FOXF1 cluster, and is deleted in some cases of the 16q24.1 microdeletion syndrome, and lies within human duplications associated with disease. Mice with mutations in Tldc1 may prove useful as models to determine if craniofacial defects are a part of the syndrome in such patients.

1665S

Completing CpG methylation statuses in human and vertebrate genomes by integrating SMRT sequencing kinetic data. *S. Morishita[1], Y. Suzuki[1], J. Korlach[2], S. Turner[2], W. Qu[1], T. Tsukahara[3], H. Yurino[1], J. Yoshimura[1], Y. Takahashi[4], J. Mitsui[4], S. Tsuji[4], H. Takeda[3].* 1) Department of Computational Biology, Graduate School of Frontier Sciences, The University of Tokyo, Japan; 2) Pacific Biosciences, Menlo Park, CA, USA; 3) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan; 4) Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

Determining the methylation information for regions with low or high copy numbers using second-generation sequencing is challenging because the read length is insufficient, especially when the repetitive regions are long and nearly identical to each other. To resolve these problems, single-molecule real time (SMRT) sequencing shows promise because it is not vulnerable to GC bias, it has long read lengths, and its kinetic information is sensitive to DNA modifications. However, raw kinetic information at a single CpG site contains some noise, and characterizing the DNA methylation for large size genomes demands prohibiting coverage of SMRT reads. Since hypo-/hypermethylated CpG dinucleotides are often contiguous over a long span in vertebrate genomes, we propose a novel algorithm that combines the kinetic information for neighboring CpG sites and increases the confidence in identifying the methylation statuses of those sites when they are correlated. The sensitivity and specificity of our algorithm were both of >90% for the genome of an inbred medaka (*Oryzias latipes*) strain within a practical read coverage of <30-fold. With this method, we newly characterized the methylation status of repetitive elements (*e.g.,* the occurrences of ~6-kb-long interspersed nuclear elements (LINEs)), regions of duplicated genes (*e.g.,* HIST2 cluster) in the human genome, and nearly identical living transposons of length 4682 bp in the medaka genome, which were difficult to observe using bisulfite-treated short reads.

1666M

Sequencing of 50 rhesus macaques facilitates identification of new genetic models of human disease. *G. Fawcett[1], D. Rio Deiros[1], R.A. Harris[2], M. Raveendran[1], B. Ferguson[3], Z. Johnson[4], S. Kanthaswamy[5,6,7], E.J. Vallender[8], N.H. Kalin[9,10,11], R.W. Wiseman[12,13], D.M. Muzny[1], R.A. Gibbs[1], J. Rogers[1].* 1) Dept Mol & Human Gen, Baylor College Med- HGSC, Houston, TX; 2) Dept. Mol. & human Gen, Baylor College Med, Houston, TX; 3) Division of Neurosciences, Oregon National Primate Research Center, Oregon Health & Science University, Beaverton, OR; 4) Yerkes National Primate Research Center, Emory University, Atlanta, GA; 5) Molecular Anthropology Lab, Department of Anthropology, UC Davis, Davis,CA; 6) California National Primate Research Center, UC Davis, Davis, CA; 7) Department of Environmental Toxicology, UC Davis, Davis, CA; 8) New England Primate Research Center, Harvard Medical School, Southborough, MA; 9) Depts. of Psychology and Psychiatry, Univ. of Wisconsin-Madison, Madison, WI; 10) Waisman Laboratory for Brain Imaging and Behavior, Univ. of Wisconsin- Madison, Madison, WI; 11) HealthEmotions Research Institute, University of Wisconsin-Madison, Madison, WI; 12) Wisconsin National Primate Research Center, University of Wisconsin-Madison, Madison, WI; 13) Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison, Madison, WI.

Rhesus macaques (*Macaca mulatta*) are the most commonly used non-human primate model of disease, and are particularly important as models of psychiatric, neurological and infectious diseases. Therefore, characterizing genetic variation within research colonies of rhesus monkeys will advance the study of a variety of different diseases. We sequenced the exomes of 50 unrelated rhesus macaques from 5 NIH-funded primate research centers. Single nucleotide variants (SNVs) are defined as variants with a minimum of 4 reads covering each position with a minimum quality score of 30, whereas validated SNPs also have both alleles observed in at least two animals. Prior studies suggest rhesus macaques have greater genetic diversity overall than humans. Yuan, et al (2012) reported that while rhesus macaques exhibited ~3 SNPs/Kb, the majority of these variants were in intergenic regions, and that coding regions were similarly polymorphic in rhesus macaques and in humans. Estimates of human SNP density in predicted exonic regions (Bainbridge, et al 2011) show 1.45 SNPs/Kb in exons. Our data is similar to the human data with an exonic SNP density of 1.15 SNPs/Kb. However, our SNP density in off-target intronic regions is significantly greater in macaques (4.8 SNPs/Kb). Our results are consistent with Yuan et al's expectation of greater non-coding but similar coding variation density in macaques relative to humans. This result is unsurprising since coding variants are likely to be under strict negative selective pressure. We also sought to identify specific new potential models of disease. Among the 50 exomes, we identified: 133 transcription stops gained, 17 transcription starts lost, 225 splice sites changed, and 11,768 non-synonymous SNPs. We observed variants in genes from many different ontological categories (DAVID analysis) including neurologically relevant and immune system genes. For example, there was one non-synonymous variant in *CR2*, four in *DNAH11*, one in *ATP6AP2* and two in *FGFR3. CR2* is important for immune system function, and *DNAH11* and *ATP6AP2* are neurologically functional genes, while *FGFR3* is associated with a variety of morphological disorders and cancer. Our results indicate that this species carries functionally significant mutations in many genes relevant to human disease risk.

1667T

Identifying mouse models related to human disease. *S. Rockwood[1], S.M. Bello[2], J.T. Eppig[2], J.E. Richardson[2], M. Sasner[1], C.L. Smith[2], L. Donahue[1].* 1) Genetic Resource Science, The Jackson Laboratory, Bar Harbor, ME; 2) Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

Access to model organisms is of paramount importance to advancing the research objectives of the bio-medical research community. To facilitate this access, the Mouse Repository at The Jackson Laboratory (JAX) has served as a centralized resource for the distribution, cryopreservation and development of high health status mouse models for over 50 years. Hundreds of new strains are added each year to one of the largest collections of characterized mouse strains available. The increasing magnitude and diversity of current day mouse resources present a challenge to researchers who attempt to identify and obtain mouse models most appropriate for their work. In addition to newly designed search interfaces at the JAX website (www.jax.org), other web-based search resources are available to assist with this task. The Mouse Genome Informatics group at JAX maintains two of the most useful: the International Mouse Strain Registry (IMSR) and the Human/Mouse: Disease Connection site (HMDC). The IMSR (www.findmice.org) is a searchable online database of mouse strains and mutant ES cell lines available worldwide. The HMDC (www.diseasemodel.org) provides a seamless human-to-mouse data traversal, enabling clinical and translational researchers to take advantage of the wealth of data and annotations from mouse models; as well as allowing mouse researchers to connect their findings directly to genetic associations reported in human disease. This poster provides several examples illustrating how these resources can be used to quickly identify and obtain mouse models related to human disease research applications. (also see related posters by Smith CL et al and Eppig JT et al). Donating a strain to the Jax Mouse Repository is an easy way to fulfill the NIH's requirements for sharing mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains at: www.jax.org/donate-a-mouse The JAX Mouse Repository is supported by NIH, The Howard Hughes Medical Institute, The Ellison Medical Foundation and several private charitable foundations.

1668S

FlyNet: a genome-wide functional gene network for Drosophila melanogaster as a platform to explicate human GWAS gene candidates. *J. Shin, C. Kim, H. Shim, H. Kim, S. Hwang, T. Lee, I. Lee.* Dept. of Biotechnology, Yonsei University, Seoul, South Korea.

Drosophila melanogaster (fruit fly) is a historically long-established model organism and its availability encompasses almost every field in modern biology, such as genetics, development and neurobiology. Moreover, D. melanogaster can provide many human disease models including diabetes and neurological disorders. Recent progress of genome-wide association study (GWAS) in humans has elucidated thousandish disease-associated genetic elements. Nevertheless, model organisms are still indispensable for functional validation and characterization of those candidate disease genes. In this study, we present a genome-wide functional gene network for D. melanogaster, FlyNet, and demonstrate its utility in pathway interpretation and functional characterization of the candidate genes from human GWAS, facilitating genetic dissection of human diseases in D. melanogaster.

1669M

Benchmarking of isoform quantification tools for GTEx using long read technologies. *D.S. DeLuca[1], A. Battle[2], T. Sullivan[1], T. Lappalainen[3], M. Sammeth[4], S. Montgomery[2], F. Reverter[4], T. Nance[2], E. Tsang[2], E. Pantaleo[5], J. Maller[1], C. Brown[6], B. Engelhardt[7], G. Getz[1], K. Ardlie[1], The GTEx Consortium.* 1) The Broad Institute, Cambridge, MA; 2) Stanford University, Stanford, CA; 3) New York Genome Center, and Department of Systems Biology, Columbia University, NY; 4) Center for Genomic Regulation, Barcelona, Spain; 5) University of Chicago, IL; 6) University of Pennsylvania, PA; 7) Duke University, NC.

One of the hallmark benefits of RNA-seq over traditional gene expression quantification methods is the ability to capture the sequences of exon-exon junctions, which are indicative of the transcript isoform structure present in the samples. Beyond qualitatively measuring the presence of alternative isoforms, methods exist to infer isoform abundance. However, assessing the accuracy of isoform quantification methods remains extremely challenging due to a lack of ground truth. Orthogonal technologies such as qtPCR or NanoString have been used for validation but any approach that targets only portions of each isoform is limited in its applicability to validate the range of alternative isoforms produced by RNA-seq. Here we evaluate a panel of algorithms for the quantification of isoforms, including Flux, Cufflinks, eXpress, RSEM and Sailfish in combination with multi-tissue validation experiments from the Genotype Tissue Expression (GTEx) project. As orthogonal technologies we are employing long fragment, long read Illumina RNA-seq as well as deep 1-2 kb read PacBio sequencing. We have generated 66 TruSeq libraries from a panel of 13 different GTEx tissues with an average fragment length of 400 base pairs. These libraries were sequenced to 100 million 250bp paired-end reads. The tissue panel consists of adipose, artery, cerebellum, frontal cortex, lymphocytes, heart, lung, muscle, pancreas, testis, thyroid and whole blood. The dataset to be evaluated consists of the standard GTEx sequencing runs (2x76bp short fragment TruSeq) derived from the same samples, as well as a subsampled version of the evaluation set in which the read lengths have been truncated to 76bp to simulate standard runs. The opportunity provided by the multi-tissue GTEx sample bank is critical to this evaluation considering that many isoforms are expressed in a tissue specific manner. These data will provide insight into the strengths and limitations of current algorithms as well as into the process of isoform specific expression in general.

1670T

Droplet Digital PCR: A new tool for quantitative analysis of alternatively spliced mRNAs and pre-mRNA processing. *G. Karlin-Neumann, C. Litterst, D. Maar, S. Marrs, S. Tzonev, G. McDermott.* Digital Biology Center, Bio-Rad Laboratories, 5731 W. Las Positas, Pleasanton, CA.

Understanding the transcriptome's regulatory complexities including co- and post-transcriptional modifications such as splicing (Bentley, 2014), can be of key importance. Examples range from defining the post-transcriptional regulatory role of Cytoplasmic Intron-Sequence Retaining Transcripts (CIRTs) in the firing of hippocampal neurons and in platelet activation (Khaladkar et al, 2013), to assessing the effects of exon-skipping drugs in mitigating disease in Duchenne muscular dystrophy (Arechavala-Gomeza et al, 2012). Here we demonstrate the ability of droplet digital PCR's (ddPCR's) EvaGreen detection capability to distinguish and quantify intron-containing RNA intermediates and splice variants. As an example of differences in pre-mRNA processing, spliced and unspliced *GUSB* transcripts were quantified in total RNA from 20 human tissues. Among these tissues, testes showed the greatest fraction of unspliced transcript (~32%) whereas skeletal muscle showed the lowest (~1.3%), with testes having ~3X the concentration of spliced RNA (~1900 copies/ 4 ng total RNA) as skeletal muscle (660 copies/ 4 ng total RNA). Similar results were seen for other genes, e.g. *GAPDH* and *ACTB*. Simultaneous detection and quantification of exon-skipping was demonstrated in a similar fashion for three genes with numerous brain isoforms: *CAMTA1*, *TPM3* and *ABLIM1*. Most tissues tested showed one log (e.g. *ABLIM1*) to two logs (e.g. *TPM3*) more of the unskipped variant (containing the intervening exon) than the skipped; however, some tissues such as brain, heart and thyroid showed nearly a log-fold greater abundance of the skipped variant than in most other tissues. Both of these study results were confirmed with Taqman 5' nuclease probe assays using the same gene primer pairs as in the EvaGreen analyses. Thus, we demonstrate that ddPCR enables rapid and sensitive, multiplexed quantification of RNA processing intermediates and splicing isoforms with or without probe-based assays.

1671S

Approach for limited cell ChIP-Seq on a semiconductor-based sequencing platform. *S. Ghosh[1], K. Giorda[1], R. Marcus[2], M. Taylor[1], E. Farias-Hesson[1,2], D. Bluestein[2], G. Meredith[1], S. Leach[2], B. O'Conner[2].* 1) Thermo Fisher Scientific, South San Francisco, CA 94080; 2) National Jewish Health, Center for Genes, Environment & Health, 1400 Jackson St., Denver, CO 80206.

Dendritic cell (DC) lineages coordinate immune system activity through functional specialization. Irf4, a transcription factor, is required for CD11b+ DC lineage development from bone marrow stem cells and has been implicated in multiple inflammatory diseases such as asthma. The epigenetic consequences of immune specialization in CD11b+ DCs and relation to inflammatory diseases remain largely unexplored partly due to the difficulty of using highly purified, and typically, limited populations of cells in ChIP-seq (chromatin immunoprecipitation followed by sequencing) assays.

A robust ChIP protocol - using an input control - was developed using limited amounts of K562 cells. ChIP-seq* on the Ion Proton™ - followed by analysis using MACS2 - of the transcription factor CTCF and histone modification marks (H3K9me3-methylation, H3K27ac-acetylation) strongly correlate with ENCODE datasets - with confirmation rates of 69%(CTCF), 73%(H3K27ac), 89%(H3K9me3). Furthermore, CTCF Proton™ data show significant enrichment for insulator domains at 41%; the moderate presence of DNA methylation concomitantly with H3K27me3 - a signature for polycomb repression - is attested to by the ENCODE-Broad ChromHMM. Also, 55% and 35% of the acetylation marks enrich for the enhancers and promoters respectively. These results are based on chromatin derived from 1 million(M) cells, making it viable for generating data from limited number of primary cells. This is in contrast to the 10M cells recommended by the ENCODE consortium.

This methodology was used to compare Irf4 genomic binding sites generated from flow-sorted population of 1, 3, 5, and 25M CD11b+ lineage murine DCs. We observed comparable Irf4 ChIP-seq results from 5 versus 25M cells. Moreover, results indicate that as low as 5M flow-sorted cells can be used to acquire high quality(FDR: 10^{-19}) ChIP-seq data. We identified genomic Irf4 binding sites proximal to genes, whose activity is consistent with CD11b+ DC lineage activity and/or known to contribute to inflammatory disease. To examine Irf4 functional regulation of the identified gene targets, we performed RNA-seq analysis with CD11b+ DCs and a related lineage, CD103+ DCs. Integrating expression analysis with ChIP-seq indicates a unique CD11b+ DC gene expression program concordant with Irf4 loci association in comparison to CD103+ DC. **For Research Use Only*..

GEM.app: using hadoop to empower the revolution of large-scale collaborative analysis and data-sharing in the genomic age. *M. Gonzalez, R. Acosta, R. Schule, S. Zuchner.* Human Genetics and Genomics, Unviersity of Miami Miller School of Medicine, Miami, FL.

Next-generation sequencing technologies have revolutionized how the human genetics research community explores genetic variation. The use of NGS has led to the identification of numerous genes, that when mutated, can give rise to disease phenotypes. However, due to high rates of genetic/clinical heterogeneity and the abundance of rare variation, it is now evident that large cohorts will be necessary in order to achieve enough power to detect biological/genetic pathways that are enriched in disease processes. The management and interpretation of such data is vital to continue the progress of human genomics research. To this end, we have developed, GEnomes Management Application (GEM.app), in order to make large-scale genomic analysis and data sharing accessible to users of all technical backgrounds. GEM.app uses the combination of a highly distributed computing cluster and a user friendly graphical web interface to provide users the capabilities to run real time analyses of the ~6,000 exomes and ~900 genomes currently uploaded in GEM.app. In addition, we have developed tools within GEM.app to facilitate the creation of collaborative data-sharing groups, where researchers are in full control to share data-sets instantly. Within these collaborative data-sharing groups, researchers from around the world can contribute data that can be concurrently analyzed by all users in the data-sharing network. GEM.app utilizes the latest variant annotations (conservation, amino acid substitution predictions, ClinVar, EVS, etc.) to allow flexible and powerful analysis options. We provide five major analysis modules: 1) Variants within Families - basic filtering of variants, 2) Genes Across Families - filtering for genes that are recurrently mutated, 3) Allele Sharing - filtering for alleles that are enriched, 4) Cancer Analysis - quickly analyze tumor/normal pairs, and 5) PathFinder - hypothesis driven analyses using Gene Ontology and various pathway databases to identify pathways enriched for mutations. Over 60 genes have been identified by GEM.app users, including DDHD1, DDHD2, GBA2, CYP2U1, RTN2, B4GALNT1, BICD2, FBXO38, ANKRD11, PNPLA6, SARM1, DNAJC5, etc. Combining powerful distributed IT technologies with bioinformatics will lead to efficient tools to explore the complexities of human disease. As we see consortia and collaborative networks adopting GEM.app for analysis, we observe a radical reduction in time to discovery and increasingly complex questions resolved.

A Data Driven Approach to Precision Medicine. *P. Lum.* Ayasdi, Menlo Park, CA.

The pharmaceutical industry is currently in the midst of a large data problem: there is far too much data to be analyzed in order to promote a viable compound, and there are too many different types of data to fuse in order to get started. There is an urgent need for software that can analyze clinical and genomic data and derive valuable insights in one place. Ayasdi's application, Ayasdi Cure makes it easy for biologists, chemists, and physicians to consume and derive value from complex data by revealing patterns and subgroups in a visualization-based user interface. This product is built on the Ayasdi Platform which leverages hundreds of machine learning algorithms through the framework of Topological Data Analysis (TDA) to deliver operational insights from data in minutes. The product contains specific features that are best suited to pharmaceutical discovery in research including biological pathways, a gene variant viewer, and a compound visualization tool. However, this application represents a larger theme in the pharmaceutical industry: the movement towards data-driven approaches to precision medicine. With Ayasdi Cure, it is easy to incorporate patient information with chemical information to create more effective and targeted treatments, truly turning data into therapies. For example,a top 5 pharma company used Ayasdi Cure to salvage a chemical compound during clinical trials which was proven to be effective for a specific sub-population. This talk will focus on the trends in data-driven approaches to drug discovery, the types of data ecosystems that need to exist for effective analyses, and a few case studies that illustrate how Ayasdi Cure has helped pharmaceutical companies derive insights from complex data.

1674S

Improved Small RNA Library Preparation Workflows for Next-Generation Sequencing. *S. Shore[1], N. Paul[1], M. Salcedo[1], G. Zon[1], C. Olsen[2], K. Qaadri[2].* 1) TriLink BioTechnologies, San Diego, CA; 2) Biomatters, Inc. Newark, NJ.

MicroRNAs (miRNAs) are a group of small noncoding RNAs that regulate transcriptional and post-transcriptional gene expression. They regulate gene expression by binding to the 3'-untranslated region (3'UTR) of mRNAs, which leads to mRNA degradation or destabilization. Studies have demonstrated the effect of miRNAs on methylation machinery and protein expression in disease progression via epigenetic mechanisms. With the improvement of sequencing technologies, miRNAs are increasingly being characterized using deep sequencing. One of the challenges of deep sequencing small RNAs (small RNA-Seq) is in the sample preparation workflow. This workflow involves the ligation of fixed sequences (adaptors) onto the 5' and 3' ends of the starting RNA library. These adapters are prone to mispairing with one another without a segment of the library in between, resulting in adapter-dimer formation. Most library workflows use affinity capture to remove these adapter dimers, which is inefficient due to the close size similarity between adapter dimers and adapter-tagged small RNA libraries. Alternatively, a gel purification step can be used, which in consequence, can deplete low abundance sequences from the starting library. Furthermore, adapter-dimers can predominate when input library concentrations are low, thus suppressing formation of the adapter-tagged library. In this poster, we present a novel approach to small RNA library sample preparation using chemically modified adapters to disfavor adapter-adapter ligation while allowing for efficient joining of adapters onto the 5' and 3' ends of the library. Using this technology, we demonstrate improvements in specificity and yield for small RNA library preparation.

Enhanced fetal aneuploidy detection using hardware accelerated alignment. *M. Sykes[1], C. Roddey[2], M. Ruehle[2], R. McMillen[2], P. Whitley[1].* 1) Sequenom Inc., San Diego, CA; 2) Edico Genome Inc., La Jolla, CA.

Noninvasive prenatal testing can be performed by massively parallel sequencing of DNA from maternal plasma. This method has been shown effective in the detection of fetal aneuploidies of chromosomes 13, 18, 21 and the sex chromosomes. Accurate classification of these aneuploidies requires, in part, alignment of sequencing reads to the human genome, calculation of chromosome fractions based on these alignments and calculation of z-scores for each chromosome based on these fractions. The success of these steps relies upon the choice of aligner and algorithm used to determine the chromosome fractions.

Here we present reclassification of a dataset of 1269 samples previously analyzed using bowtie 2 as the aligner. In this study alignments are generated by the DRAGEN processor, a hardware-accelerated sequencing analysis system developed by Edico Genome. We report systematic differences between the two aligners but equivalent performance in terms of chromosome fraction variability and thus chromosome quantification.

Both the bowtie 2 and DRAGEN based analyses successfully identified all known T13, T18 and T21 cases in the dataset. The sensitivity and specificity were both > 99.9% in each classification. At the same time the DRAGEN system provides speed increases of greater than thirty-fold relative to bowtie 2 running with 6 threads on a 3.5 GHz Xeon CPU, allowing a single computer to replace the efforts of a small cluster.

These results demonstrate that the classification algorithm for fetal aneuploidy is robust and resistant to localized changes in the alignment profile. Furthermore the DRAGEN system provides equivalent performance to bowtie 2 with a significant increase in speed.

1676T

Platform comparison between Ion Proton and Illumina HiSeq 2500 on a 759-gene disease panel across 248 samples. *A.V. Uzilov[1,2], H. Shah[1,2], M. Mahajan[1,2], D. Starcevic[1,2], R. Sebra[1,2], R. Chen[1,2], E. Schadt[1,2].* 1) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Targeted panels allow making next-generation sequencing libraries enriched for genomic regions of interest, providing more cost-effective sequencing for the needed depth. Commercial panels and custom panel design services exist for both Ion Proton and Illumina HiSeq instruments. However, little publically available comparative data exists to guide choice of appropriate platform for large sequencing projects. We sequenced blood-extracted DNA from 248 individuals on Ion Proton and Illumina HiSeq 2500 using a custom targeted panel covering 4413 genomic regions and full exons from 759 genes selected for their genetic disease relevance. Agilent's SureSelect hybridization-capture chemistry (covering 2.8 Mb) was used for Illumina and amplicon-based AmpliSeq (covering 4.4 Mb) was used for Proton. We look at coverage uniformity and variant concordance to compare the two panel versions in their 2.6 Mb overlap. This is the largest comparative analysis between the two chemistry/platform combinations both in terms of sample volume and panel size. 18.1% of variant calls are unique to the Illumina panel, 6.6% are unique to the Proton panel, 1.0% are conflicting calls at the same site, and 74.5% are concordant (median percent across all samples). We observe that Proton concordance depends on sequencing depth at depths seen in our study (median 118X for Illumina and 100X for Proton). As Proton depth increases, concordance increases and "unique in Illumina" calls decrease, suggesting that raising Proton depth leads it to make more calls found by Illumina. However, there is no improved concordance at higher Illumina coverage, suggesting we are operating at or above optimal depth there. To find optimal depth for Proton, we sequenced NA12878 on two Proton instruments to high depth (one barcode per 318-type chip, 972X and 766X median coverage). We show how subsampling reads impacts variant calling accuracy versus similar high-depth replicate runs on Illumina (323X and 289X median coverage). At highest depths, sensitivity for GIAB gold-standard set of known variants was 96.6% for both Illumina replicates and 89.0% and 89.4% for the two Ion replicates. We describe factors influencing accuracy, concordance, and callability and discuss if they can be controlled by adjusting depth or variant caller settings or whether they are a property of the panel or sequencer. Our findings will be useful to investigators when selecting technology appropriate for their NGS study.

1677S

Sparse sufficient dimension reduction and matrix subset selection methods for big image data analysis in cancer. *N. Lin, J. Jiang, S. Guo, M. Xiong.* University of Texas School of Public Health, Houston, TX.

With the advancements in modern biomedical engineering, biomedical imaging has become one of the most reliable tools for disease diagnostics and the evaluations of the progress of different treatments. A Key issue for image analysis is high dimension data reduction and feature selection. The most widely used dimension reduction and feature selection methods have two serious limitations. One limitation is that these methods often use unsupervised dimension reduction method, which selects dimensions without taking information on class labels or disease status into account. The reduced data will then lose important class information that is hidden in the original data. The second limitation is that the algorithms for searching features are unable to deal with large number of features. To overcome these limitations, we introduce concepts of sufficient dimension reduction (SDR) and coordinate hypothesis which project the original high dimensional data to very low dimensional space while preserving all information on clinical outcome information, and formulate feature selection problem as a subset selection problem for matrices. We develop matrix approximation theories and error estimation methods as powerful tools for optimal image feature matrix column selection. We develop a randomized algorithm that is designed to select image features with provable guarantees that image reconstruction by selected image features can reach prespecified high accuracy. To further reduce dimensions, we extend one dimensional principle component analysis to two dimensional principle component analysis (2DFPCA) and use 2DFPCA scores to represent image data. The proposed method is applied to 188 kidney cancer histology images from different individuals. Of these 188 images, 121 of them are confirmed to have kidney cancer and the rest of them are served as the control in our study. The randomized based sparse SDR method was applied to 2DFPCA score to select features. We used support vector machine (SVM) as classifier which took selected features as input. By 5-fold cross validation, the average classification accuracy in the test dataset was 89.3% and in the training dataset was 96.4%. If we use only 2DFPCA score of the original image data as features and the same SVM as the classifier, we only can reach average accuracy 65% in the test dataset and 67.2% in the training dataset. This strongly demonstrates that the proposed method substantially outperforms other methods.

1678M

A Genomics Analysis Pipeline for Cloud Computing. *R.J. Mashl[1], K. Ye[1], N. Nutter[1], D.C. Koboldt[1], D.E. Larson[1], K. Chen[2], L. Ding[1].* 1) The Genome Institute, School of Medicine, Washington University, St. Louis, MO; 2) Department of Bioinformatics and Computational Biology, The University of Texas MD Anderson Cancer Center, Houston, TX.

As medicine continues to enter the era of personalized medicine, the amount of raw genomics data is expected to increase substantially. The traditional analysis model, wherein data is downloaded from secured internet sites, e.g., data coordination centers, to local storage for processing, is likely to result in an accumuation of unprocessed data if data transfer rates, storage capacities, and computing rates cannot keep apace. Individual investigators or those working in small collaborative groups may face additional logistical challenges in terms of cost, compute resources, data storage and security, and computer management expertise. One possibility for addressing these problems is to use cloud computing, which provides access to large amounts of storage and computation as a service. Technologies that enable data analysis to be performed at the data storage site, i.e., those that "bring the tools to the cloud," are therefore beneficial. In this study, we describe an easy-to-use web interface for configuring a genomics analysis pipeline featuring software packages that are among the state-of-the-art in variant calling tools for next-generation sequencing methods, namely, VarScan, BreakDancer, and Pindel. This combination of tools allows users to analyze for germline and somatic single-nucleotide polymorphisms (SNPs) and insertions and deletions (indels), copy-number variations, and structural variations that include translocations and inversions. The configured computations can be deployed either on a physical compute cluster or on cloud/virtual compute clusters. The interface utilizes the StarCluster cluster-computing toolkit for interacting with Amazon's Elastic Compute Cloud. The software is available through the Turnkey Variant Analysis Project (TVAP) web site at http://tvap.genome.wustl.edu. Additional information is available at the ASHG 2014 Annual Meeting workshop "iSeqTools to Demistify the Cloud and Genomics Analysis for Researchers Seeking Ways to Analyze High-Throughput DNA Sequencing Data." This work is supported by the National Human Genome Research Institute grant U01HG006517 (to L.D.).

1679T

A Comprehensive Bioinformatics and Data Management Platform to Enable High Powered Genomic Discovery. *J. Kaufman[1], F.M. De La Vega[1], T. Schlumpberger[1], S. Young[2], J. Wiley[2], A. Patel[2], M. Pae[2], R. Hayek[2].* 1) Annai Systems Inc., Burlingame, CA; 2) Annai Systems Inc., Carlsbad, CA.

As the amount of sequencing data that is available in the public domain continues to increase, and the cost of a whole human genome sequence declines, the desire to perform large-scale analyses has grown considerably. By combining large public data sets with one's own data, the statistical power of a study can be increased in a cost effective, streamlined manner. However, the availability of a compute, storage and data-sharing platform that can facilitate these types of "big data" analyses is relatively limited. The options that are available for these studies are typically lacking in one key aspect or another such that identifying an optimal solution often involves some level of pulling together disparate, sub-optimal components. Here we describe a singular environment that includes high performance computing, data storage, data sharing and access to high value public data sets. Annai ShareSeq™ Genomic Resource is a bioinformatics and data management platform that provides a highly scalable, secure and computationally powerful solution for genomic researchers, in particular, those interested in cancer related data. We will describe the various aspects of ShareSeq as well as present examples of how this resource can be used for data analysis. A workflow manager can be used to configure an analysis pipeline by taking advantage of a variety of analysis tools that are resident in ShareSeq. Computing resources can be accessed in an on-demand manner by initiating a virtual machine that can be scaled appropriately, depending on the analysis job size. Other robust tools can be used to transfer sequencing files, create a storage repository to house them, and later, leverage metadata that has been automatically indexed, for flexible querying of the collection of files. These capabilities, in combination with easy access to large data sets, create an invaluable resource for researchers and clinicians that are using genomic data.

Validation of a Series of Genomic StripAssays® to Salivary DNA Collection Using the DNA•SAL™ Device. *P.D. Slowey[1], C. Oberkanins[2], A. Berndt[2], G.A. Thomas[1].* 1) Oasis Diagnostics Corporation, Vancouver, WA US; 2) ViennaLab Diagnostics Vienna, Austria.

PCR hybridization based StripAssays® [ViennaLab Diagnostics] provide a rapid convenient method for research and diagnostic detection of mutations associated with cancer, genetic disorders, genetic predispositions and pharmacogenomics. The assays consist of four steps: gDNA isolation, multiplex PCR, hybridization, and detection. Using DNA isolated from blood, conventional StripAssays® detect a combination of wild type and mutant probes for the identification of a variety of genetic disorders and predispositions including Gaucher disease, thalassemias, CVD and others. While blood is a common specimen matrix, invasive collection limits participant compliance particularly with small children and its utility for remote point of care applications. Due to a number of factors including the non-invasive nature of collection, ease of use and subject compliance, saliva has become an increasingly important alternative to blood for nucleic acid based research and diagnostics. While saliva is simple to collect, the proportion of epithelial cells (buccal,) leukocytes and non-human nucleic acid from microbial sources varies between individuals and can confound analysis and restrict adoption of saliva based testing. In the present study, the performance of gDNA extracted from saliva collected using the DNA•SAL™ Salivary DNA Collection Device [Oasis Diagnostics®, Vancouver WA US] and isolated using the Mini•SAL™ DNA Isolation Kit [Oasis] was evaluated in 5 different commercially available PCR assays from ViennaLab: α and β thalassemia (4-130, 4-160), Gaucher disease (4-260), CVD T (4-360) and CVD A (4-370) chosen from the ViennaLab portfolio as tests with the highest level of complexity and sensitivity to DNA quality and quantity. For each test, 5 μl of DNA isolated at a concentration from 2-19 ng/μL using the Mini•SAL™ protocol was used in the StripAssay®. Bands on the StripAssay® test strips were inspected visually and using ViennaLab's own proprietary software package [Evaluator™]. All tests yielded results directly comparable to results obtained using DNA isolated from blood samples. The data indicate that gDNA extracted from saliva via the Mini•SAL™ DNA Isolation Kit following collection using the DNA•SAL™ device is a robust alternative to blood DNA when used with the ViennaLab StripAssays.® Together they provide a simple-to-use system with the potential for truly realizing point of care genetic testing.

1681M

Direct to PCR Genomic Analysis Using Saliva Derived Samples. *G.A. Thomas[1], C. Oberkanins[2], A. Berndt[2], P.D. Slowey[1].* 1) Oasis Diagnostics Corporation, Vancouver, WA; 2) ViennaLab Diagnostics, Vienna, Austria.

Saliva has become an increasingly important sample matrix as an alternative to blood for nucleic acid based research and diagnostics utilizing PCR, hybridization, microarrays and next-gen sequencing due to the non-invasive nature of the collection, ease of use and participant compliance. While saliva may be readily collected, the proportion of epithelial cells (buccal,) leukocytes and non-human nucleic acid from microbial sources varies between individuals and can confound analysis. Recently, the utility of DNA extracted from saliva has been validated as a robust alternative to blood for use in PCR based strip assays. The StripAssay® technology [ViennaLab] consisting of four steps: gDNA isolation, multiplex PCR, hybridization and detection provides a rapid convenient method for research and diagnostic detection of mutations associated with cancer, genetic disorders and pharmacogenomics. In the study, DNA extracted from saliva using the DNA•SAL™ Salivary DNA Collection Device [Oasis Diagnostics®] and isolated using the companion Mini•SAL™ isolation kit [Oasis] performed identically to blood DNA in 5 different multi-probe StripAssays®. To test the suitability of DNA•SAL™ collected saliva samples for direct PCR analysis without DNA isolation, the performance of independently collected saliva samples in two genetic disorder tests from ViennaLab [FV-PTH-MTHFR (4-260) and Hemochromatosis (4-210)], was evaluated as a function of input sample dilution. Both StripAssays® examine multiple wildtype and mutant probes (4-260: factor V G1691A, prothrombin G20210A and MTHFR C677T. 4-210: HFE H63D, S65C and C282Y). Normal test results were obtained for all samples when simply diluted with water within the range of 1:5 to 1:100. Half of undiluted samples failed presumably due to inhibition of PCR activity, while all samples failed at a dilution of 1:500 presumably due to excessive dilution of the target. The data demonstrates that saliva collected using the DNA•SAL™ Device when diluted within the range of 1:5 to 1:100 can be used directly in PCR assays without substantial signal loss. The elimination of the requirement for DNA isolation when using the DNA•SAL™ collection tool in tandem with PCR hybridization StripAssays® greatly facilitates the potential for truly realizing remote point of care genetic testing.

Spatially Encoded Assays. *M.S. Chee, J.A. Altin, W. Delport, B. Min, P. Capek, E. He, C.M. Dambacher, D.A. Routenberg.* Prognosys Biosciences, Inc., San Diego, CA.

Detailed information on spatial patterns of gene expression in complex tissues is needed to enable new insights into the molecular differences between normal and disease states. Although in situ hybridization has excellent resolution, it is limited in multiplexing. Conversely, microarrays and RNA-seq multiplex well but are not designed to provide spatial information. Laser capture microdissection enables highly multiplexed analysis of well-defined sites in a tissue section but is relatively low throughput and laborious. We developed a scalable assay system that is both spatially resolved and enables high multiplexing, overcoming limitations of the methods listed above. The assay involves binding of probes to target RNAs in the sample, and encoding the probes by spatially-addressed delivery of sequence-encoded adapter molecules. The sequences of the resulting assay products and their frequency provide both abundance and location data for each target RNA in the sample. We performed the spatial addressing using microfluidic devices that we designed to define a rectangular array of assay sites. Assay products were collected and sequenced in bulk using an Illumina next-generation DNA sequencer. We used the system to map the expression of 134 unique target RNA sequences from 69 genes across an array of 256 positions on formalin-fixed paraffin-embedded (FFPE) pancreas and liver samples. We constructed virtual images of the FFPE sections based on the data, revealing local regions of high gene expression that were well correlated with immunofluorescence data. For example, we mapped regions of high insulin mRNA abundance to islets of Langerhans in pancreas by correlation with insulin protein abundance determined by immunofluorescence. The technology is flexible. We have used the devices to analyze both individual sections of tissue and tissue microarrays. The method currently achieves an effective pixel resolution of ~ 50 x 50 microns by using disposable microfluidic devices instead of complex imaging instrumentation. Although the resolution of our devices is currently lower than that of optical imaging, our approach has the advantage of enabling multiplexed assays to be carried out at many sites in parallel. We are currently developing methods to assay proteins as well as RNAs using this novel technology, and we envision our assays enabling high-dimensional analysis of gene expression in both normal and disease samples.

1683S

Development of a novel methodology for RNA-microbiome enrichment. *L. Ettwiller, E. Yigit, E. Dimalanta, I. Schildkraut.* New England Biolabs, Ipswich, MA, USA.

The analysis of the metagenome of human microbiomes has highlighted the fundamental role of the microbiome in human health. Though the metagenomics field has just recently emerged, there is a paradigm shift from the understanding of the microbiome composition in terms of taxonomical classification towards a functional understanding of the microbiome (the metatranscriptome). Such shift is motivated by the recent findings that functional analysis of the metatranscriptome better addresses the underlying complex molecular interplay which affects the emergence of different phenotypes and diseases. This paradigm shift means that future microbiome studies will be complemented with a metatranscriptome analysis. Human microbial metatranscriptome sequencing poses significant challenges. Specifically, prokaryote non-ribosomal RNA typically constitutes a very small fraction of the total RNA, where ribosomal RNA (rRNA) and contaminating host RNA are the overwhelming majority of transcripts (up to 99%). Despite the urgent need to avoid sequencing rRNA, the existing technologies to deplete all rRNA using subtractive hybridization are far from perfect. Here we describe a novel technology that allows specific capture of the active and informative transcriptome of all species of bacteria and archaea while removing both the host RNA and rRNA in a single step. Unlike subtractive hybridization where the rRNA sequence must be known a priori to generate RNA probes, our strategy is universal. All prokaryotic and archaeal mRNAs and small RNAs will be captured. On the other hand, processed transcripts such as mature ribosomal and transfer RNAs (rRNA, tRNA) from all organisms and mRNA from eukaryotes will be discarded. As a proof of principle for metatranscriptome analysis, we demonstrated that mRNA from E. coli could be enriched 10 fold from a mixture of total human RNA and total E. coli RNA while maintaining the relative representation of each prokaryotic transcript.

Extremely low-coverage whole genome sequencing in South Asians captures population genomics information. *N. Rustagi[1], A. Zhuo[2], S. Wang[2,3], N. Ramesh[1], W.S. Watkins[4], D. Muzny[1], R.A Gibbs[1], L.B. Jorde[4], F. Yu[1], J. Xing[2,3].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Rutgers, the State University of New Jersey, Department of Genetics, Piscataway, NJ,; 3) 3Rutgers, the State University of New Jersey, Human Genetics Institute of New Jersey, Piscataway, NJ; 4) 4 University of Utah School of Medicine, Eccles Institute of Human Genetics, Salt Lake City, UT.

The cost of whole genome sequencing (WGS) has been reduced considerably in recent years due to advances in next-generation sequencing technology (NGS), but many aspects of large scale cohort WGS studies are still daunting. Challenges include the requirements for quick turn-around times and high variant calling accuracy. We have focused on sensitive variant site discovery, robust association study replication and comprehensive population genomics characterization. The ability to identify common variants (minor allele frequency (MAF) > 5.0%) is a central aim of such studies (Li Y. et al., 2011).

To develop a cost-effective path to variant discovery, we evaluated extremely low-coverage WGS (~1x) on 185 Indian individuals, followed by imputation using BEAGLE with reference panels from the HapMap project and the 1000 Genomes project. We applied two variant discovery pipelines, SNPTools and GATK, and generated a consensus call set. Comparisons with previous SNP microarray and sequencing results show the consensus set has an over 90% sensitivity for identifying variants with a MAF> 5%, with a false discovery rate (FDR) <15%. Imputation provides further improvement in sensitivity for both common and rare variants. Restricting standard population genetics analysis to shared regions with high overall coverage, shows a high level of consistency with past results. This data set will enable in-depth understanding of genomic diversity and detailed inference of demographic history in South Asia.

We further characterized expected sensitivity and accuracy of SNP calling in extremely low- coverage sequencing studies using simulations. We down-sampled from the 1000 Genomes data to reflect coverage of 0.25x and 0.75x and found ~ 500 samples with 0.75x coverage are sufficient to recover > 60% common SNPs (MAF > 5%) with an FDR of ~3%. For the dataset with ~ 0.25x coverage, > 40% SNPs are recovered from ~ 500 samples for MAF> 20% and FDR <3%. Only 350 samples with 0.75x coverage will yield 80% true SNPs, with MAF >= 20%. Overall, we demonstrate that extremely low-coverage WGS with imputation can be a useful study design for variant discovery with a dramatically reduced cost, even in populations without available reference data.

1685T

Advancing Clinical Diagnostics Using Whole Exome Sequencing. *D. Muzny[1], C. Buhay[1], J. Hu[1], M. Wang[1], Y. Han[1], H. Dinh[1], C. Kovar[1], H. Doddapaneni[1], M. Bellair[1], M. Bainbridge[1], Y. Yang[2], C. Eng[2], J. Lupski[2], A. Beaudet[2], E. Boerwinkle[1, 3], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX 77030; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Advancement of whole exome sequencing (WES) in the clinical diagnostic arena has required methods for rapid, robust delivery of high-quality sequencing data covering clinically relevant genes. We previously described a DNA capture reagent (VCRome 2.1), developed by the Baylor College of Medicine (BCM-HGSC) in collaboration with Roche/NimbleGen. Our CLIA/CAP certified clinical Whole Genome Laboratory (WGL) has now analyzed more than 3,650 cases of childhood disease with VCRome 2.1. We have also improved these methods by development of an innovative exome 'polishing' technique and fast workflow for quick WES library preparation and DNA capture. WES capture target designs have focused on the ~1,800 loci listed in the GeneTests series. We generated a novel 'spike-in' design comprising 220 Kb of additional oligonucleotide probes for use in conjunction with VCRome design for improved sequence coverage of inadequately (<20X) covered exonic regions in the GeneTests list. The addition of the 'spike in' converted >400 GenTests genes from partially covered to fully covered. Analysis has shown that the design effectively captures high GC regions (79-90% GC) but does not address low coverage regions in repetitive DNA. An expanded design comprising 3,671 additional unique gene targets derived from GeneTests, OMIM, selected cancer genes and WGL positive cases, is now under evaluation. This new design is anticipated to improve gene coverage even with relatively low total sequence input, and will therefore be compatible with analysis of standard research samples, where cost constraints the total sequence depth. Development of the quick WES protocols has allowed us to complete the entire NimbleGen-based whole exome sequencing process within 5 days including library generation through analysis. Both methods have been implemented in the WGL where they can impact applications in prenatal, neonatal intensive care and other critical settings as well as for undiagnosed genetic disease in clinical and research samples.

1686S

Next generation sequencing in a diagnostic laboratory: Pros and cons of enrichment technologies. *B.P. Dworniczak[1], S. Fleige-Menzen[1], P. Pennekamp[2].* 1) Institut fuer Humangenetik, Universitaetsklinikum Muenster, Germany; 2) Klinik fuer Kinder- und Jugendmedizin -Allgemeine Paediatrie-Universitaetsklinikum Muenster, Germany.

Molecular diagnosis of complex human genetic diseases is still challenging because in most cases multiple genes harboring putative deleterious mutations have to be analyzed. So far in most diagnostic laboratories Sanger sequencing is still used as the golden standard but capillary sequencing is excessive time-consuming and expensive at least for the screening of multiple genes. However, recently there was a shift away from Sanger sequencing after introduction of high-throughput sequencing methods, which are often collectively referred to as "next-generation" sequencing (NGS) which have facilitated substantial increases in sequencing content while dramatically decreasing the cost per base. But because these technologies are originally introduced especially for large sequencing projects it is difficult to scale down this technology for screening disease causing genes in a diagnostic laboratory with its specific needs and requirements. To fill this gap table top NGS Systems have been introduced by Life Sciences (Ion Torrent PGM and Proton) by Illumine (MiSeq) and by Roche (GS Junior). While Illumina and Roche launched sequencer adapted to established technology Ion Torrent introduced a sequencing device using a sequencing technology based on the detection of hydrogen ions that are released during the replication of DNA. To validate this technology in respect to usability, software requirements and accuracy we tested several gene panels comprising between 3 and 420 genes covering between 100 and 16000 exons. Regions of interest were enriched in different ways: single PCR; multiplex-PCR (AmpliSeq: Ion Torrent; GeneRead NGS System: Qiagen) or HaloPlex custom designed kits (Agilent). Our validation showed that technically multiplex PCR seems to be the superior technology for target enrichment because of its easy workflow, but that severe problems can emerge for proper detection of sequence variants if the user is not aware of its limitations. Especially the formation of sequencing blocks of the target region prevents the detection of complex variants at the ends of these blocks facilitating false negative claiming. This serious problem might impair the overall use of PCR amplification for target enrichment at least as long as software solutions cannot handle the problem.

Unique Haplotype structure determination in human genome using Single Molecule, Real-Time (SMRT) sequencing of targeted full-length fosmids. *K. Eng[1], R. Hall[1], L. Hon[1], C. Pyo[2], D. Geraghty[2], S. Ranade[1].* 1) Pacific Biosciences, Menlo Park, CA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Determination of unique individual haplotypes is an essential first step toward understanding how identical genotypes having different phases lead to different biological interpretations of function, phenotype, and disease. Genome-wide methods for identifying individual genetic variation have been limited in their ability to acquire phased, extended, and complete genomic sequences that are long enough to assemble haplotypes with high confidence. We explore a recombineering approach for isolation and sequencing of a tiling of targeted fosmids to capture interesting regions from human genome. Each individual fosmid contains large genomic fragments (~35 kb) that are sequenced with long-read SMRT® technology to generate contiguous long reads. These long reads can be easily de novo assembled for targeted haplotype resolution within an individual's genomes. The P5-C3 chemistry for SMRT sequencing generated contiguous, full-length fosmid sequences of 30 to 40 kb in a single read, allowing assembly of resolved haplotypes with minimal data processing. The phase preserved in fosmid clones spaned at least two heterozygous variant loci, providing the essential detail of precise haplotype structures. We show complete assembly of haplotypes for various targeted loci , including the complex haplotypes of the KIR locus (~150 to 200 kb) and conserved extended haplotypes (CEHs) of the MHC region. This method is easily applicable to other regions of the human genome, as well as other genomes.

Examination of the Performance of Whole Genome Amplified DNA across Multiple Capture Methodologies and Sequencing Platforms. *B. Hicks[1,2], C. Dagnall[1,2], M. Malasky[1,2], H. Lee[1,2], R. Eggebeen[1,2], J. Mitchell[1,2], W. Luo[1,2], X. Zhang[1,2], C. Chung[1,2], M. Yeager[1,2], K. Jones[1,2].* 1) Cancer Genomics Research Laboratory, Leidos Biomedical Research, DCEG, NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), Rockville, MD, USA.

While input requirements for targeted, whole exome and whole genome sequencing have been driven down considerably by the advent of new and improved technologies, often whole genome amplified DNA (wgaDNA) remains the only source of critical and informative subjects. Additionally, the advent of single cell technologies demands use of wgaDNA in downstream analysis. We performed whole exome and targeted sequencing on a series of matched genomic DNA (gDNA) and wgaDNA samples, utilizing different capture techniques, including the hybridization based Roche NimbleGen SeqCap EZ Human Exome v3.0, the amplification based ThermoFisher Ion AmpliSeq Exome, and two custom Ion AmpliSeq panels (47 amplicons and 856 amplicons). The captured libraries were sequenced on the Illumina HiSeq 2500, the ThermoFisher Ion Proton, and the Ion Torrent PGM, respectively. Data filtering, alignment and variant calling was done per internal standard protocols. We reviewed overall coverage statistics, as well as positional coverage variance in areas of high GC content, centromeric and telomeric regions. Sensitivity and specificity of the different approaches was determined via use of the NIST reference genotype data from the well characterized NA12878 (Genome in a Bottle). Assessment of coverage statistics (mean coverage for Illumina platform and uniformity for Ion platforms) show sequencing coverage is comparable between gDNA and matched wgaDNA samples. Duplication rates for the NimbleGen/Illumina samples were slightly (0.5%) higher for the wgaDNA source, but well within acceptable limits. All approaches showed some bias towards gDNA in coverage of high GC content areas and telomeric regions, with the amplification based capture methods being most susceptible to differential coverage in these specific areas. SNV concordance for the NimbleGen/HiSeq gDNA and wgaDNA as compared to the high confidence genotypes from GiaB was 99.7% and 99.8% respectively, with indel concordance rates of 98.3% and 98.2%. SNV concordance for the AmpliSeq Exome/Proton gDNA and wgaDNA was 98.9% and 99.1%, with indel concordance rates of 90.7% and 90.9%. False negative rates were higher when utilizing AmpliSeq Exome, but only a slight increase (1.8% for SNVs and 5.5% for indels) when comparing wgaDNA to gDNA. These results show an ability to utilize wgaDNA for all sequencing platforms, with some caution on use of amplification based capture techniques.

Improved Exclusion Amplification Chemistry Supports Sequencing TruSeq PCR-free Libraries for Human Whole Genome Sequencing on Illumina's HiSeq X Ten System. *A.C. Kwasniewska[1], P. McInerney[2], C. Bevis-Mott[1], J. Boutell[1], S. Hunter[2], M. Tsan[2], M. Fabani[2], A. Silbergleit[2], M. Chen[2], H. You[2], M. Niziolek[2], E. Guzman[2], E. Kanterakis[1], M. Pham[2], E. Bomati[2], M. He[2], R. Shen[2], S. Tousi[2], J. Whitacre[1].* 1) Illumina Cambridge Ltd, Chesterford Research Park, Essex, CB10 1XL, UK; 2) Illumina, Inc. - Worldwide Headquarters, 5200 Illumina Way, San Diego, CA 92122 USA.

The HiSeq X Ten was designed to unlock the potential of population sequencing, delivering the world's first $1000 human genome at 30x coverage. By using flow cells with billions of patterned nanowells at fixed locations, we have significantly increased the density of clusters that could be achieved by random clustering. To support clustering on patterned flow cells we developed a new cluster chemistry called Exclusion Amplification (ExAmp). Here we describe an improved ExAmp v2 formulation that supports simultaneous seeding and amplification of TruSeq PCR-free libraries, the gold-standard for genome sequencing due to more uniform coverage of regions that are typically underrepresented in amplified libraries (high GC-rich regions, promoters and repetitive regions). This new formulation continues to support amplification of TruSeq Nano PCR libraries and also offers a significant improvement in genomic coverage uniformity. We present data showing improved coverage uniformity for challenging regions of the genome whilst maintaining high quality sequence at genes and exons. Furthermore, by utilizing the Platinum genome data sets from the CEPH pedigree, we have validated our data and found excellent sensitivity and specificity of SNP calling with the improved ExAmp clustering.

Lower Cost, Higher Throughput Library Preparation with the Echo liquid handler® and the NuGEN Ovation® Single Cell RNA-Seq System. *J.D. Lesnick[1], J.D. Heath[2].* 1) Labcyte Inc, Sunnyvale, CA. USA; 2) NuGEN Technologies, San Carlos, CA. USA.

The rapid evolution of next-generation sequencing (NGS) technologies is accelerating our knowledge of gene expression, regulation and pathway complexities in mammalian cells. Transcriptome analysis with NGS offers increased transcript coverage to enable the detection of rare transcripts, novel alternative splice isoforms and the measurement of transcript abundance. However, traditional library preparation methods for NGS are often not amenable to transcriptome analysis. Traditional methods carry a requirement for a large amount of total RNA to yield sufficient mRNA to analyze which can be unobtainable or cost prohibitive in most experiments. The NuGEN Ovation Single Cell RNA-seq System is a highly sensitive and complete library preparation procedure for whole-transcriptome sequencing that requires total RNA from samples as small as a single cell or 10 picograms. In this study, the Ovation Single Cell RNA-Seq System was validated by examining the resulting library complexity, reproducibility, and evenness of transcript coverage. Furthermore, a majority of the sample and reagent transfers were automated using the Echo acoustic liquid handling technology. Echo liquid handlers transfer a wide range of fluids without contact of tips or recalibration between fluid types. The industry leading accuracy and precision of Echo liquid handlers at microliter and nanoliter volumes in combination with the NuGEN Ovation Single Cell RNA-Seq System increases library preparation throughput while reducing the costs to enable a broader application of transcriptome analysis with NGS.

1691T

Low to mid-throughput automation of hybridization based capture technologies using Apollo 324 NGS Library Prep System. *M. Srinivasan, R. Acob, J. Berger, L. Chan, S. Silveria, S. Wei, J. Dunne, S. Nasarabadi.* WaferGen Biosystems, Fremont, CA.

Targeted resequencing of exonic regions (subsets to whole exome) using hybridization-based capture has been used as a key discovery tool for understanding many biological problems including disease mechanisms of Mendelian diseases and cancer. In addition, discoveries from next generation sequencing (NGS) efforts are increasingly being used to design targeted panels for clinical research and diagnoses. However, as targeted sequencing moves to the clinical setting, very few automation solutions exist that minimize process variability and reagent costs for low and mid-tier labs. Furthermore, labs are asked to perform multiple tests with limited amount of material. To address these needs, we have tested our the Apollo 324 NGS Library Prep System to enrich for exomes from NGS libraries prepared from low input material. The Apollo 324 is a flexible automation system that has been shown previously to process up to 8 or 32 samples in a single run. The number of samples to run in a given day is matched to the amount of reagents/sample to eliminate reagent waste. Genomic DNA and cDNA library preparation kits for the Apollo 324 robot can process samples for whole genome sequencing, RNA-seq and Chip-Seq experiments. Now, we are extending the utility of automation to include the ability to perform targeted capture. Commercially available target enrichment kits (SureSelect, Nimblegen) were processed manually according to manufacturer's instructions and compared with the automated system at different input levels of gDNA from HapMap and tumor samples. Data will be presented from exome-enriched samples from manual and automated workflows, sequenced using a HiSeq system and compared for their ability to identify variants.

1692S

Sequencing Beyond the Read Length Officially Supported on HiSeq 2500: the Error Profile and Remedy. *W. Wang[1], D. Storton[1], J. Wiggins[1], L. Guo[1], J. Peng[2], P. Andolfatto[1,2].* 1) Institute for Integrative Genomics, Princeton University, Princeton , NJ; 2) Dept of Ecology and Evolutionary Biology, Princeton University, Princeton, NJ 08544.

Background: The throughput of Next-Generation Sequencers has increased dramatically since their advent. However, the read length remains relatively short among sequencers which are able to generate large number of reads, for example, the 150nt maximum officially supported by Illumina on HiSeq 2500. Such read length is generally sufficient for alignment to the genome, but longer read length, even to some small extent, is needed for de novo assembly of genomes and transcriptomes. Methods: The observed error rate of HiSeq 2500 Rapid Run is generally below 1% at the very end of 150nt reads, therefore further extending the read length might yield slightly decreased but still acceptable read quality as long as the sequencing reaction is optimized accordingly. Pair-End Rapid Runs of 215+230nt and 215+215nt reads were performed on HiSeq 2500 with slight modification of the standard sequencing procedure. Small amount of PhiX control library was spiked-in to each lane to estimate the actual sequencing error profile in addition to the Illumina Quality Score. Size-selected libraries of narrow size range were used to generate clusters of homogeneous size and the clustering density was reduced from the standard value to help improve the signal-to-noise ratio and read quality. Result: By controlling the raw cluster density around 600K/mm2, the overall error rate of 215nt read pairs could be kept below 1%, while the per cycle error rate at the very end of these reads remained below 2%. The Illumina Q30 bases of each lane could be maintained over 80%. The bias in the base call composition became more noticeable beyond the official read length of 150nt, especially when the cluster density is relatively high. Very low cluster density could lead to reduction in the base composition bias, although not much improvement in the base call accuracy. In conclusion, we have optimized the sequencing condition to extend the HiSeq 2500 read length from 150nt by 43% to 215nt. At the expense of reduced cluster density, the quality of the extended reads is mostly maintained.

Genome-wide transcriptome enrichment sequencing for research and clinical applications. *H. Doddapaneni[1], J. Hu[1], H. Chao[1], X. Liu[1], S. White[1], K. Walker[1], C.J. Buhay[1], M. Wang[1], M. Bellair[1], L. Wang[1], K.R. Covington[1], A. Roy[2,3], P. Sumazin[3], S.E. Plon[1,3,4], D.W. Parsons[1,3,4], D.A. Wheeler[1], E.A. Boerwinkle[1,5], D.M. Muzny[1], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Pathology & Immunology, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Transcriptome sequencing (RNA-Seq) together with whole exome sequencing (WES) offers an integrated informative dataset for clinical diagnosis and characterization of human transcriptome, especially for characterizing cancer etiology and outcomes. For example, detection of pathogenomic gene fusion events is important to accurately characterize childhood sarcomas where morphologic characteristics or WES is not sufficient. However, current RNA-Seq methods rely heavily on very high quality RNA samples, which are often not available in routine clinical setting. Towards the goal of incorporating RNA capture methods in a clinical setting, we have developed an RNA-Seq capture protocol combining the BCM-HGSC strand-specific RNA-Seq protocol with our CLIA certified WES protocol. Inclusion of a capture step enables RNA-Seq to become RNA quality independent as it provides probes to capture the targeted transcripts. Libraries were prepared using Universal Human Reference RNA and co-captured (4-plex) using VCRome 2.1 capture reagents and sequenced on HiSeq 2500. On average, 66 million reads were generated per sample and these data were compared to standard RNA-Seq data generated for the same sample. Capture libraries had a significantly higher mapping rate (95.1% vs 77.5%), higher exonic rate (93.4% vs 77%) and lower intergenic rate (0.2% vs 4.2%) compared to RNA-Seq libraries. Correlation of expression values (in FPKM) between the replicate capture libraries was excellent (R^2 = 0.9882). Capture libraries detected 18,903 protein coding genes compared to 18,611 genes found in RNA-Seq libraries. There were 756 genes unique to capture libraries (FPKM-0.22) and 465 genes unique to RNA-Seq libraries (FPKM- 2.8). The low FPKM values observed for the novel genes found in capture libraries suggest 'enrichment' of low expressed transcripts due to presence of their probes. Further, use of a genome-wide capture probe such as VCRome allows for capture and validation of novel fusion-transcripts. We are validating the protocol on samples with 13 known fusion transcripts found in hepatoblastoma and pediatric sarcoma samples that will then serve as test controls. Concurrently, we are also testing RNA of different types (RIN numbers, input amounts) and from FFPE. We anticipate that our RNA-Seq capture protocol will provide robustness and through high through-put process automation, will result in fast turnaround times to have practical utility in both research and clinical settings.

1694T

Whole Genome Sequencing on DNA extracted from Saliva: a systematic evaluation of SNV, CNV and Structural Variant Calling. *S. Germer[1], A.-K. Emde[1], A. Abyankar[1], B. Cornes[1], D.M. Oschwald[1], T. Hu-Seliger[2], P. Yurttas Beim[2], R.B. Darnell[1].* 1) New York Genome Center, New York, NY 10013; 2) Celmatix, 1 Little West 12th St. New York, NY 10014.

As whole genome sequencing (WGS) becomes increasingly affordable, DNA repositories are being established for a variety of research purposes. These repositories often rely on blood specimens, which presents several practical hurdles. The ability to source DNA from saliva would reduce costs and increase flexibility for many researchers. Given sample procurement is a common bottleneck in genomic studies, this development would have significant implications. Previously, it has been reported that saliva yields DNA of sufficient quality to reliably make single nucleotide variant (SNV) calls in WGS datasets. Here we address whether larger variants, including copy number and structural variants (CNVs and SVs) can also be reliably detected from saliva-extracted DNA. We evaluated WGS data (~30x coverage, Illumina HiSeq) generated from matched blood and saliva (DNA Genotek, Oragene) samples selected to represent a spectrum of bacterial contamination levels (avg=10%). Saliva DNA showed both a reduced alignment rate to the human genome (0.74-0.93) compared to blood sample DNA (>0.95) and a corresponding reduction in mean genome-wide coverage. A pre-sequencing qPCR assay predicted bacterial contamination rates that correlated with the alignment rates for the human genome (r=-0.94). SNV calls from both sets of samples (GATK best practices pipeline) showed similar rates of discordant calls between replicate saliva and blood samples (~0.02% at 99% VQSR tranche). Similarly, DNA from saliva and blood displayed very similar Mendelian inheritance errors (0.01%-0.05%). To investigate the impact on SV calls, we employed a dual analysis: a) paired saliva-blood somatic SV calls using CREST (SVs) and NBIC-seq (CNVs), and b) replicate analysis of saliva-blood SV calls from GenomeSTRiP. Across matched saliva-blood pairs we did not identify any somatic SVs that could be confirmed by replicates or any somatic CNVs. GenomeSTRiP calls exhibited greater variability, but the variability between blood and saliva was comparable to the variability between replicates and largely due to differences in genome coverage. Therefore, the discordant calls likely represent lack of sensitivity/specificity in the calls made by GenomeSTRiP. Our study suggests that DNA from saliva can yield comparable WGS results to DNA from blood across a range of variant sizes and types, especially when coupled to pre-sequencing estimation of bacterial contamination to allow for comparable mean genome coverage.

1695S

Precise Quantification of Bias in Whole-Genome Amplification Using Droplet Digital™ PCR. *N. Heredia, J. Berman, W. Yang, S. Hodges, E. Hefner.* Bio-Rad Laboratories Inc., Digital Biology Center, 5731 W Las Positas Blvd Pleasanton, CA 94588.

Whole-genome amplification (WGA) is commonly used upstream of next-generation sequencing and microarray protocols when available genetic material is severely limiting, such as in single cell work. However, WGA can suffer from sequence-specific bias, allelic drop out, and non-uniform coverage, hampering data interpretation. To quantitatively assess bias introduced by WGA, we used Droplet Digital™ PCR (ddPCR™), targeting multiple sites across the genome. Limited samples were prepared using standard WGA protocols. The use of droplets to improve WGA output will be discussed.

1696M

ThruPLEX-FD as high sensitivity library prep tool for whole exome and target panel sequencing. *J.P. Jerome, E. Jan, J. Wibbenmeyer, J. Langmore, K. Shazand.* Rubicon Genomics Inc., 4355 Varsity Dr., Suite E, - Ann Arbor, MI., USA.

Whole exome sequencing (WES) and target panel sequencing (TPS) are currently the most popular applications in the NGS community. Although ThruPLEX-FD has already been validated for WES and TPS applications in the laboratories of current customers, Rubicon wants to make its internal protocols available publically for the convenience of all its customers. Here, we describe experimental results answering the following questions: -Can ThruPLEX-FD be easily used for enrichment with Agilent XT2, Roche SeqCap EZ for WES and TPS? (protocol establishment) -How do ThruPLEX-FD enrichment metrics compare with the standard Roche (Kapa) and Agilent libraries? -What are the advantages of using ThruPLEX-FD? Library synthesis: Three inputs were used to build ThruPLEX-FD libraries with Covaris-sheared 200bp average human gDNA, respectively 500pg, 10ng and 50ng. Recommended low input libraries for Roche (10ng) and Agilent XT2 (100ng) were prepared with the same gDNA and enriched according to the vendor protocols. Capture: ThruPLEX-FD libraries were pooled with the Agilent library for hybridization (different barcode systems), however hybridized separately from the Kapa library (identical barcode system). Vendor-specified reagents and protocols were used except for addition of ThruPLEX-FD-compatible blocking oligonucleotides IDT xGen® Universal Blocking Oligo - TS-p5 and xGen® Universal Blocking Oligo - TS-p7 (6nt), spiked into ThruPLEX-FD hybridizations at the concentrations suggested by the vendor. Sequencing: Pools of the enriched libraries were sequenced on Illumina MiSeq, and the reads from each library were down-sampled to 3.9M read-pairs before removal of duplicates. Detailed data will be shown at the meeting. The following conclusions were drawn: -ThruPLEX-FD can be easily enriched using standard Agilent and Roche protocols and reagents by simply spiking in IDT universal blocking oligos. -ThruPLEX-FD was as highly enriched as Kapa and better than Agilent libraries. For comparable inputs, duplicate rates are often lower than other tools, enabling higher coverage. -Finally, the low input results open the possibility of efficient enrichment for the clinical studies such as CTC, plasma, FFPE or LCM applications. These data show that ThruPLEX can be efficiently used in any enrichment approach with metrics that equal or exceed other existing tools.

1697T

Identify enhancer elements at genome-wide scale using MIT-seq. *X. Wu, L. Su, D. Wells.* Cancer Research Technology Program, Frederick National Laboratory for Cancer Research, Frederick, MD.

Enhancer elements are important for regulation of gene expressions. However enhancers are not easy to identify and they can be far away from genes. Retrovirus integrates into the host genome as part of their life cycle and leaves a permanent tag at the location of integration. Different retroviruses use different mechanisms for target selection. Recently, we have demonstrated that murine leukemia virus (MLV) integration site clusters correlate highly with enhancer elements in the human genome. MLV retroviral vector has been widely used for gene delivery and is highly efficient to transduce a broad range of cells. Using linker-mediated PCR, we can easily identify millions of MLV integration tag by sequencing (MIT-seq). The MIT-seq tags are analyzed similarly as ChIP-seq tags to identify peaks and clusters, making this a new approach to identify enhancer elements in a variety of cells. (Funded by FNLCR Contract HHSN261200800001E).

Contiguity Preserving Transposition Sequencing (CPT-seq): Haplotype-resolved sequencing and assembly. *J. Fisher[1], C. Turk[1], L. Christiansen[1], F. Zhang[1], E. Kostem[1], S. Amini[1], M. Ronaghi[1], A. Adey[2], J. Shendure[2], K. Gunderson[1], F. Steemers[1].* 1) Advanced Research Group, Illumina, Inc, San Diego, CA, 92122, USA; 2) Department of Genome Sciences, University of Washington, Seattle, WA 98195, USA.

Haplotype-resolved genome sequencing enables the accurate interpretation of medically relevant genetic variation, deep inferences regarding population history, and the non-invasive prediction of fetal genomes. We describe a novel library preparation and haplotyping approach that enables haplotype assembly of short sequencing reads from as little as 50 ng gDNA using 2-4 lanes of Hiseq over the standard VCF. The method employs a Nextera Tn5 transposition approach that preserves the contiguity and ordering information of the target DNA sequence while inserting common primer, and optionally index sequences at 100-200 bp intervals. Subsequently, the contiguously linked-libraries are processed through the assay while maintaining this contiguity information. Finally, the individual short libraries of each DNA molecule are resolved through sequencing. The method effectively generates long-strobed reads that are on average ~30-50kb in length with ~5-15% coverage. Phased strobed reads can be as long as the physical length of input DNA. Additionally, we have greatly streamlined the haplotyping protocol. The total assay time is <3 h with ~ 30 min hands-on-time and the workflow can be integrated with robotic or microfluidic processing. As a proof-of-concept, we apply this method to phase over 95% of heterozygous variants from a HapMap trio into long, accurate haplotype blocks with N50 block sizes ranging from 1.4-2.3 Mb. We evaluated phasing yield and accuracy of the current method by plotting the probability that heterozygous SNP pairs are on the same phasing block as a function of distance between them. For all pairs that are on the same phasing block, the chance that a pair is phased correctly, again as a function of distance is plotted. From these results it can be concluded that phasing yield is in Mb-scale (>80% SNPs sharing phasing block) and accuracy of 99.9% and 99% extends to 100kb and 200kb pairwise SNP distances, respectively. We demonstrate utility of this imputation-free approach by accurate and complete phasing of de novo and compound heterozygous SNPs. We anticipate the scalable, rapid, and cost-effective workflow could enable haplotype resolution to become routine in human genome sequencing.

A Method for Selectively Enriching Microbial DNA from Contaminating Vertebrate Host DNA. *E. Yigit[1], G. R. Feehery[1], F. J Stewart[1], S. O. Oyola[2], Y. Wei Lim[3], B. W. Langhorst[1], V. T. Schmidt[4,5], E. T. Dimalanta[1], L. A. Amaral-Zettler[4,6], T. Davis[1], M. A. Quail[2], S. Pradhan[1].* 1) New England Biolabs, Ipswich, MA; 2) Wellcome Trust Sanger Institute, Cambridge, UK; 3) San Diego State University, San Diego, CA, USA; 4) The Josephine Bay Paul Center for Comparative Molecular Biology and Evolution, Marine Biological Laboratory, Woods Hole, MA, USA; 5) Department of Ecology and Evolutionary Biology, Brown University, Providence, RI, USA; 6) Department of Geological Sciences, Brown University, Providence, RI, USA.

Recent discoveries have implicated the human microbiome as playing a role in certain physical conditions and disease states, and these advances have opened up the potential for development of microbiome-based diagnostic and therapeutic tools. The majority of microbiome DNA studies to date have employed 16S analysis, but these provide very little information regarding function. In contrast, sequencing of the total DNA of a microbiome sample provides a broader range of information including genes, variants, polymorphisms, and putative functional information. However, many samples, including those derived from vertebrate skin, bodily cavities, and body fluids, contain both host and microbial DNA. Since a single human cell contains approximately 1,000 times more DNA than a single bacterial cell, even low-level human cell contamination can substantially complicate the analysis of a sample. In some cases, as low as 1% of sequencing reads may pertain to the microbes of interest and a large percentage of sequencing reads must be discarded, making such experiments impractical. To address this issue, we developed a method to enrich for microbial DNA using methyl-CpG binding domain (MBD) to separate methylated host DNA from microbial DNA. Importantly, microbial diversity and relative abundance is maintained after enrichment. This simple magnetic bead-based method was used to remove human or fish host DNA from bacterial and protistan DNA. We describe the enrichment of DNA samples from human saliva, human blood, a mock malaria-infected blood sample, human cystic fibrosis sputum, and a black molly fish, followed by next generation sequencing on multiple platforms. Sequence reads aligning to host genomes were reduced approximately 50-fold, while the percentage of sequence reads corresponding to microbial sequences increased approximately 10-fold. This new method for microbiome sequence analysis holds promise for use with a variety of sample types, enabling enrichment while accurately reflecting the diversity of the original sample.

Woman endometrium biopsy immediate single-cell analysis. *K. Krjutskov[1,2], S. Katayama[1], M. Saare[2], K. Samuel[2], D. Lubenets[3], S. Linnarsson[4], J. Kere[1], A. Salumets[2].* 1) BioNut, Karolinska Institutet, Stockholm, Sweden; 2) CCRMB, Tiigi 61b, Tartu, Estonia; 3) UT IMCB, Riia 23, Tartu, Estonia; 4) Med Biochem and Biophysics, Karolinska Institutet, Stockholm, Sweden.

The recent progress in single-cell analysis has unlocked clinical interests of women's health- and infertility research like endometrial pathologies, implantation failure and etiology of endometriosis. Although woman endometrium is extensively studied, the most essential players - individual endometrial cells, have gained little attention. The objective of my study is to take deeper view on endometrial functioning at individual cellular level by providing gene expression based phenotyping and defining the functionally active major cell populations and their molecular interactions. This goal will be achieved by using clinical endometrial biopsies and combining the most advanced cell- and molecular-biology techniques, like scrutinized biopsy handling from collection to treatment, multiple-color FACS analysis with single-cell sorting option, and highly multiplex single-cell transcriptome analysis by RNA-sequencing. Voluntary healthy fertile women donate the endometrial biopsies during the proliferative and mid-secretory, e.g. receptive phase of the natural menstrual cycle. The samples are cryopreserved in proper media and the thawed tissues are enzymatically disaggregated with the cell suspensions containing the epithelial- (CD9+), stromal- (CD13+), and the rest repertoire of living cells. During the sample treatment, minimum manipulation times at +4°C are used to retain the natural gene expression profile. Cells are labelled by combination of surface marker antibodies for single-cell FACS sorting directly into 96-well plate lysis buffer and are converted to 48-plex Illumina libraries using Single-cell Tagged Reverse Transcription (STRT) protocol. After cell sorting and cDNA synthesis, qPCR-based QC assay is used to evaluate each well/cell's sorting accuracy and cDNA yield before pooling and further library preparation. FACSArial single-cell sorting accuracy and cDNA turn-around success rate is 90-100%. This multidisciplinary study have faced us to different challenges like (i) proper biopsy cryopreservation and treatment procedure to prepare stable single-cell solution in minimum time, (ii) single-cell QC after FACS and cDNA synthesis, and (iii) STRT adaptation for differentiated low mRNA cells analysis. Here mentioned improvements enable us to study endometrium single-cells directly from biopsy and brings single-cell genomics closer to clinical needs.

High Accuracy Variant Detection using HaloPlex with Molecular Barcodes. *h. johansson, b. skarpas, e. agne, l. forsmark, p. eriksson, m. isaksson.* Agilent Technologies, santa clara, CA., Select a Country.

HaloPlex is a next generation PCR target enrichment method that enables enrichment of thousands of targets in a single tube. The protocol utilizes specificity gained form restriction enzyme recognition, hybridization and DNA ligation to capture molecules originating from the target region to be sequenced. The target region is fully customizable and may consist of either a continuous or up to several thousand discrete regions. Amplicon based methods for multiplex target enrichment are, in general, convenient methods for capturing a wide range target region sizes. In contrast to hybridization capture methods where random shearing is deployed, it is not possible for Haloplex and other amplicon based techniques to use read start point of paired end reads to identify duplicate reads. Duplicate read information can be useful for improving base calling accuracy and to monitor sampling to determine the degree of confidence to assign calls at different presumed allelic fractions. For somatic variants which are generally present in lower than 50% allelic fraction it is even more advantageous to know how many molecules have been sampled in a particular region. The main steps of the Haloplex protocol are restriction digestion, target hybridization and DNA ligation of motifs needed for sequencing on Ion Torrent or Illumina Platforms. To enable identification of duplicate reads in sequencing libraries prepared with Haloplex, we have added a molecular barcode to the introduced primer cassettes. The molecular barcode consists of ten degenerative bases allowing for over one million unique sequences to be present for tagging of molecules. Using information derived from the molecular barcode sequences we demonstrate observation of variants down to 5% allelic fraction in multiple molecules tagged with different molecular barcodes. The new protocol has, besides the introduction of molecular barcodes, been optimized in few additional aspects. Due to improved reagent formulations and streamlining of workflow, complete target enrichment can now be completed in less than 5 hours. Using 50 ng input we demonstrate >85% specificity and above 90% of target regions being covered at >10% of average depth.

Immune sequencing protocol for complete B-cell and T-cell repertoire sequencing. *F.J. Stewart[1], E.T. Dimalanta[1], A.W. Briggs[2], T. Gilbert[2], C. Clouser[2], W. Donahue[2], G. Yaari[2], L. Apone[1], S. Russello[1], T.B. Davis[1], F. Vigneault[2].* 1) New England Biolabs, Inc., Ipswich, MA; 2) AbVitro, Inc., Boston, MA.

Immune sequencing, which allows for the study of complex immunological diseases by sequencing B-cell antibodies and T-cell receptors, is gaining in popularity due to recent throughput and read length improvements in next-generation sequencing (NGS) technologies. However, the structural and sequence complexities of antibody genes have made reliable targeting approaches challenging. We have developed and optimized a method for accurate sequencing of the immune gene repertoires of B-cells and T-cells. In contrast to previous studies, our method generates full-length sequences of B-cell antibody and T-cell receptor genes. This allows for exhaustive somatic mutation profiling across complete V, D and J segments, full isotype information analysis (IgM, IgD, IgG, IgA and IgE), and the possibility for synthesis and expression of complete antibody chains for downstream immunological assays. By introduction of a unique barcode ID into every captured mRNA molecule, all PCR copies of each mRNA fragment can be collapsed into a single consensus sequence, making the assay extremely accurate by resolving PCR bias and sequencing errors, as well as allowing quantitative digital molecule counting. The assay can work with as low as sub-nanogram levels of input total RNA and is the first method that allows targeted amplification of all possible antibody heavy and light chains (IGH+IGK+IGL) and T-cell receptors (TCRA+TCRB) in a single reaction simultaneously.

1703T

Optimized DNA extraction and repair improves the yield and quality of sequencing libraries derived from FFPE samples. *L. Chen[1], E. Rudd[2], G. Durin[2], T. Evans[1], L. Ettwiller[1].* 1) New England Biolabs, Inc. Ipswich, MA 01938; 2) Covaris, Inc. Woburn, MA 01801.

Cancer biopsy samples are routinely formalin fixed and embedded in paraffin in order to preserve the morphological features of suspected tumor samples. While these formalin fixed, paraffin embedded (FFPE) samples are valuable for archiving histological data, the formalin treatment is detrimental to the quality of nucleic acids. Indeed, DNA isolated from archived tissue is often of poor quality and damaged due to fragmentation, oxidation, deamination, and protein-DNA crosslinks. Thus, it remains challenging to 1) extract DNA from FFPE samples and 2) obtain high quality DNA for NGS library preparation. Here we successfully coupled Covaris® truXTRAC™ to extract FFPE DNA with PreCR® -B Repair Mix to repair DNA damage. Covaris truXTRAC use highly controlled acoustic energy to efficiently remove paraffin from FFPE cores, sections, and slides enabling efficient tissue rehydration, tissue digestion, crosslink reversal, and nucleic acid release. The PreCR®-B Repair Mix is an enzyme cocktail formulated to repair damaged template DNA and blunt ends in one step. PreCR® is active on a broad range of DNA damage, including modified bases, nicks and gaps, and a variety of blocking moieties at the 3'end of DNA. We found that DNA repair pre-treatment of extracted FFPE DNA samples consistently increased library yield up to 2-fold in the four samples tested. Furthermore, downstream data analysis of the sequencing reads demonstrated a remarkable reduction of sequence miscalls. In conclusion, the incorporation of PreCR®-B in library preparation workflows remarkably improves the quantity and quality of NGS libraries from FFPE samples resulting in more robust library preparation and more reliable base calling.

1704S

Targeted enrichment of forensically relevant STRs for improved human DNA profiling. *M.R. Nandineni, S.R. Gadipally, A. Sarkar.* Lab of DNA Fingerprinting Services, Centre for DNA Fingerprinting and Diagnostics (CDFD), Hyderabad, Telangana, India.

Human DNA profiling is employed worldwide for unambiguous identification of individuals in mass fatality incidents, criminal cases and also to establish parentage by genotyping repeat length polymorphisms in 16-18 highly polymorphic short tandem repeats (STRs) or microsatellites. DNA typing involves a multiplex PCR-based assay to generate STR profiles from even trace amounts of available biological source in a reasonably short duration. In spite of the availability of various commercial STR kits for DNA typing, there is a need for development of newer technologies to overcome limitations posed by challenging and recalcitrant forensic samples like those containing excess non-human DNA and PCR inhibitors, which often leads to allele/locus dropouts, peak imbalances and loss of signal during STR profiling. In the present study, a sequence-specific DNA enrichment strategy has been developed and evaluated to selectively 'capture' and enrich the forensically relevant human STR regions from highly compromised samples. The strategy involved simultaneous enrichment of the 18 widely used STR loci (which includes the 13 core CODIS loci) with the aid of two sequence-specific biotinylated oligonucleotide probes targeting each locus. The enriched fragments were captured using streptavidin-coated magnetic beads, eluted and subsequently subjected to multiplex amplification using commercially available STR kits followed by fragment analysis. Experiments conducted with simulated forensic samples revealed that prior enrichment of STR regions greatly facilitated the generation of complete and/or improved DNA profiles even in the presence of 5- fold excess of non-human DNA contaminants and 3-4 fold of excess PCR inhibitors (than those normally tolerated by thermostable DNA polymerases incorporated into the commercial STR kits). The pre-PCR enrichment technique provides definite improvement over the existing methodologies for DNA (STR) profiling from challenging forensic samples and holds promise for increasing the success rate of DNA testing based human identification from skeletal remains in missing persons and mass disaster victim identification programmes.

Spatially resolved single cell miRNA expression analysis in tissue sections. *M. Asp[1], P. Ståhl[2], F. Salmén[1], J. Hällman[1], A. Lundmark[3], S. Vickovic[1], S. Giacomello[1], E. Berglund[1], J. Fernandez Navarro[2], J. Sjöstrand[2], E. Sjölund[1], J. Frisén[2], J. Lundeberg[1].* 1) Department of Gene Technology, Royal Institute of Technology, SciLifeLab, Stockholm, Sweden; 2) Department of Cell and Molecular Biology, Karolinska Institute, Stockholm, Sweden; 3) Department of Dental Medicine, Division of Periodontology, Karolinska Institute, Stockholm, Sweden.

In the course of the last decade, miRNA has been shown to play a key role in a range of carcinogenic processes. Due to its high level of interspecies conservation and its known importance in cell differentiation, proliferation and apoptosis, they have been natural targets of study for researchers investigating cancer formation. Many miRNAs have already been stated as important signatures in a variety of cancers because of their abnormal expression pattern. This gives us an enormous potential of using this knowledge in clinical diagnostic practice. Tumors are frequently heterogeneous with multiple subclonal populations and it is often difficult to distinguish the exact location of cells in a tissue that express tumor related miRNAs. Standard miRNA expression analysis of a tumor biopsy produces an average expression pattern of the entire tissue, which might mask abnormal miRNA expression patterns. We are developing a method by which miRNA expression on the single cell level and within the context of an entire tissue section is possible. By using microarrays covered with miRNA-specific surface probes, we are able to capture the entire miRNA population of every cell within a single tissue section. Clusters of surface probes are individually barcoded, which gives every cell a unique positional tag. This allows the miRNA material captured on the microarray surface to be analyzed in parallel retaining information of spatial position. The final miRNA libraries are then analyzed by Massively Parallel DNA Sequencing, and the obtained miRNA data can hereby be superimposed back onto the histology image using an in house developed software.

Microbial detection using Affymetrix' Axiom® Genotyping Solution. *M. Shapero[1], S. Gardner[2], M. Mittmann[1], K. McLoughlin[2], C. Jaing[2], L. Bellon[1], T. Slezak[2].* 1) Affymetrix, Inc., 3420 Central Expressway, Santa Clara, CA 95051; 2) Lawrence Livermore National Laboratories, Livermore, CA 94551.

The human body contains a diverse set of microbes including eukaryotes, archaea, bacteria, and viruses. These microbes play a key role in both human health and disease. As sequences of microbial genomes continue to expand, microarrays are well-positioned to capitalize on this evolving information content. Here we present an overview of Axiom® Genotyping Solution with regard to the design and testing of a microbial detection array (MDA) to evaluate differentiation of several model organisms at the species and strain level.

A pilot array was designed leveraging organisms where samples and full genome sequences are available for both the primary target species and relevant near-neighbors. Multiple probe designs that iterate on probe length and tolerance to position-specific mismatches were evaluated for six families, which include Bacillaceae, Burkholderiaceae, Enterobacteriaceae, Francisellaceae, Thermotogaceae, and Paramyxoviridae. Using pure and mixed samples of defined origin as the hybridization targets, probes were scored using a composite likelihood maximization algorithm for their ability to detect perfect match sequences as well as identify novel, previously uncharacterized species/strains within a known family. Probe- and system-level performance characteristics will be presented with regard to sensitivity and specificity.

In summary, new Axiom® applications in broad microbial detection further extend the platform's capabilities. The scalable sample throughput enabled by 24-, 96-, and 384-array layouts coupled with laboratory automation will allow processing of tens to thousands of samples per week with minimal manual intervention and is consistent with the need for cost-effective examination of the microbiome in the context of bioterrorism, environmental monitoring, food safety, and human and animal health.

1707S

Design of a biobanking genotype array optimised for Chinese populations. *R.G. Walters[1], I.Y. Millwood[1], Y. Lu[2], H. Lin[3], J. Brodsky[2], M.A. Ansari[4], Y. Zhan[2], W.W. Kretzschmar[5], N. Cai[5], R. Bowden[5], J. Flint[5], P. Donnelly[5], T. Webster[2], Q. Li[3], J. Schmidt[2], L. Li[6,7], R. Peto[1], R. Collins[1], Z. Chen[1].* 1) Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU), University of Oxford, UK; 2) Affymetrix, Inc., Santa Clara CA, USA; 3) BGI-Shenzhen, Shenzhen, China; 4) Department of Statistics, University of Oxford, UK; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 6) School of Public Health, Peking University Health Science Center, Beijing, China; 7) Chinese Academy of Medical Sciences, Beijing, China.

The China Kadoorie Biobank is a prospective study of 515,000 adults recruited from 10 geographically diverse areas of China. Preliminary genotyping of 82,494 subjects (after QC), conducted using a panel of 384 SNPs selected on the basis of previous genome-wide or candidate association with major clinical endpoints (e.g. stroke, diabetes, coronary artery disease) and intermediate phenotypes (adiposity, blood pressure, cholesterol), revealed substantial population stratification. Common SNPs varied in minor allele frequency (MAF) between different recruitment centres by as much as 4-fold — 311 out of 335 SNPs with overall MAF>0.05 displayed MAF differences between regions that were significant after Bonferroni correction. Even though data were available for only 216 unlinked common SNPs, principal component analysis nevertheless revealed a strong North-South axis. The scale and pattern of the differences across China strongly suggest that they are due to substantial admixture between northern and southern populations with distinct ancestries.

In part to address the challenges that admixed population structure presents for the investigation of genetic associations with disease and intermediate phenotypes, we have designed a new Affymetrix Axiom® genotyping array optimised specifically for Chinese populations, using data from diverse sources: 1000 genomes data from CHB/CHS subjects; high coverage sequence data for 156 of the same subjects and exome data from 1,746 subjects mainly from southern China, both from BGI; allele frequencies from 1,800 Taiwan Biobank subjects; and allele frequencies from the CONVERGE consortium, derived from sequence data for 9,000 subjects recruited at 59 hospitals across China. Together, these provided improved MAF estimates for known SNPs and indels, identified novel variation not previously reported in Chinese, and enabled efficient selection of array content to maximise genome-wide coverage. The array was designed following a strategy similar to that for the UK Biobank array, and includes: 142,454 variants selected on the grounds of known or suspected functional effects, including all previous GWAS hits; 81,522 variants not present in 1000 genomes CHB/CHS data; and a GWAS grid of 479,385 additional variants. With imputation, the array provides coverage of 93% of 1000 genomes variants with MAF>0.05, and 87% of variants with MAF>0.01.

High Performance Micro RNA Enrichment using Solid Phase Reverse Immobilization Magnetic Bead Technology. *B.N. Lee.* Beckman Coulter Life Sciences, Brea, CA.

Most extracted RNA samples contain ribosomal RNA and messenger RNA with only a low percentage of microRNA (miRNA). In order to measure miRNA more precisely and achieve better quality miRNA sequencing data, it is desirable to remove the larger unwanted ribosomal RNA as well as other species of RNAs. This abstract describes the use of Beckman Coulter's SPRIselect reagent kit for miRNA enrichment. The Solid Phase Reverse Immobilization (SPRI) magnetic bead method is a nucleic acid purification procedure that does not require centrifugation or filtration steps. This simple, rapid, automation friendly and produces high quality samples of miRNA for use in downstream applications Enrichment of miRNA from total RNA can be achieved in three binding steps. Step 1: Removal of large ribosomal RNA fragments. Step 2: Removal of intermediate RNA fragments. Step 3: Capturing of miRNAs and small RNAs. The micro-particles with bound miRNA are thoroughly washed with molecular biology-grade ethanol. In the elution step, the purified miRNA is easily recovered from the micro-particles using nuclease free water, which provides maximum flexibility for downstream applications. The poster presents that SPRIselect is a superior miRNA enrichment method. 1. It provides flexibility to separate different fragment sizes. 2. It shows higher miRNA binding efficiency. 3. It enables users to keep all fractions of RNA species during miRNA enrichment. Beckman Coulter, the stylized logo, SPRI, SPRIselect are registered trademarks of Beckman Coulter, Inc. All other trademarks are the property of their respective owners.

Standardizing High-Throughput Sequencing of Extracellular RNA from Human Plasma. *Y.E. Wang[1], K.M. Danielson[2], R. Rubio[1], S. Das[2].* 1) Center for Cancer Computational Biology, Dana-Farber Cancer Institute, Boston, MA; 2) Cardiovascular Institute, Beth Isreal Deaconess Medical Center, Boston, MA.

Background. Extracellular vesicles have been shown to regulate intercellular signaling by transmitting RNA materials such as mRNA, microRNA and snRNA. This phenomenon implies extracellular RNA (exRNA) may partially reflect cellular content within the human body and may show disease specific variation. As such, exRNA profiles have great potential as disease biomarker. While high-throughput sequencing technology offers a potentially sensitive means to characterize and quantify exRNA, there is a lack of a understanding of the efficacy and reliability of commercial kits for extracellular RNA sequencing. In this study, we aim to optimize protocols for sequencing extracellular RNA from human samples. **Methods.** Blood plasma samples were obtained from one healthy individual at a single time point. The samples were frozen and thawed to mimic clinical sample condition. The samples were treated as followed: a) RNA purification by Exiqon (miRcury) column; b) proteinase K treatment preceding Exiqon purification; c) addition of carrier glycoblue during proteinase K treatment/Exiqon purification. Sequencing libraries were generated using random hexamer based, SMART technology based, and smRNA specific library preparation kits. The resulting libraries were sequenced on a HiSeq 2000 on a Single Read 50 bp flowcell. The sequence data was mapped against the transcriptome using BWA and analyzed using miRDeep2 algorithm to quantify miRNA. **Results.** Approximately 10 million raw reads were obtained for majority of the samples but with variable mapping rates across library preparation protocols. The variation is less across different sample treatment process within a protocol. The NEB protocol resulted in the highest number of miRNA species identified in all three conditions. Proteinase K and glycoblue treatment appear to enhance the number of identifiable miRNA species. We then compared the sets of miRNA species derived from different library preparation and found large differences between them with some overlaps. This suggests miRNA species detection is confounded by the sequencing protocol used. **Conclusion.**In this study, sample treated with proteinase K treatment prior to vesicle lysis and prepared by smRNA specific protocol resulted in the best outcome. However, with sample preparation and sequencing protocol exerting strong impact on extracellular miRNA quantification and detection, additional studies is necessary to optimize the process.

1710S

RNA "SEQing" answers in the blood transcriptome: Benchmarking methods for globin message reduction. *N. Allaire, A. Day-Williams, S. Szaks, C. Sun, J. Carulli.* Department of Genetics and Genomics, Biogen Idec Inc., Cambridge, MA.

RNA sequencing (RNAseq) is gradually replacing micro-array technologies as the method of choice for transcriptional profiling studies. Greater resolution and lower processing costs are two important factors that are driving this trend; however technical limitations exist that have prevented more widespread adoption. RNA seq from whole blood represents a particular challenge in that ~ 50% of the transcriptome is encoding by globin. This issue of globin overabundance reduces detection of informative transcripts and increases processing and storage costs. Recently, several methods have been developed to address the problem of excessive globin; however no comprehensive comparison has been reported. To this end, we undertook a systematic and rigorous evaluation of three promising approaches; Insert dependent adapter cleavage (InDAC), globin removal prior to sequencing, and ultra-deep sequencing and report our findings here. Both InDAC and Globin removal reduced globin reads by from ~50% to 2% compared to untreated controls. Off target effects were few and linearity was maintained in the samples that had globin removed prior to sequencing. InDAC resulted in more detectable off-target sequences and slight compression of dynamic range, however all three approaches were largely correlated when compared in fold change space.

Very Low Input RNA-Seq is Enabled by Digital Microfluidics. *T.M. Hill, L.C. Watson, S.M. Gross, I. Khrebtukova, F. Schlesinger, S. Pathak, T. Singer, G.P. Schroth.* Illumina 5200 Illumina Way San Diego, Ca, 92122.

Recent advances in NGS library construction utilizing a digital microfluidics platform has enabled us to significantly lower the sample input requirements into TruSeq Stranded mRNA preparation workflow. We find that the reduced reaction volume of our digital microfluidics platform has greatly improved the kinetics of each enzymatic step. In addition to improved kinetics, the enclosed automated fluidics of this system facilitates improved sample recovery and yield of each step in the process. As a result of these efficiencies, it is possible to prep high quality RNA-Seq libraries even when starting with only nanogram levels of total RNA. We will show detailed sequencing results generated from libraries made with inputs of 100, 10, and 1 ng, or less, of total RNA using this new technology. Even at these levels, we observe a large dynamic range of gene expression, and see results that are typically observed with 100 ng of total RNA utilizing the standard bench protocol. Furthermore, the improved sensitivity of the system is demonstrated by detecting equivalent number of genes in 10 ng of RNA processed on the microfluidics platform versus 100 ng of RNA processed with the standard bench protocol. The digital microfluidics platform enables researchers to access sample types with limited RNA recovery such as RNA extracted from small numbers of isolated cells or fine needle aspirates (FNA) resulting in a greater understanding of gene expression at the cellular level. Finally, this microfluidics technology is very easy-to-use and automated.

1712T

Analysis of PCR duplicates and Library Diversity in RNA-Seq studies using very low input and degraded samples. *S. Pathak, I. Khrebtukova, S. Gross, F. Schlesinger, T. Hill, L. Watson, R. Kelley, T. Singer, G. Schroth.* Illumina, Inc., San Diego, CA.

In DNA sequencing, duplicates or reads that map to the same position are discarded but in RNA sequencing (RNA-Seq), these reads can represent highly expressed genes. The issue of duplicates in RNA-Seq is even more complicated in low input or degraded samples. Higher percentages of duplicates in very low input and degraded samples are routinely observed in RNA-Seq using standard bioinformatics tools such as picard but the source of duplicates is commonly misunderstood. Under normal assay conditions and with recommended input levels, three different RNA-seq assays give different apparent numbers of duplicates on the same UHRR and Brain samples: <20% duplicates for targeted RNA seq, <10% duplicates for mRNA-Seq and <6% duplicates for Total RNA-seq. These differences are not necessarily due to PCR artifacts but occur because of the differences in complexity between the coding regions, the mRNA, and the total RNA of a cell. When we measure true PCR duplicates using a molecular bar coding approach, it becomes clear that there are in fact much lower levels (much less than 1%) of potential PCR duplicates in standard RNA-Seq preps. However, we find that when reducing DNA input amounts for any of these three assays to 1ng or less, we observe dramatic increases in percentage of duplicates. This value then becomes an important metric for overall efficacy of the experiment.

1713S

SureSelect Clinical Exome Panels for NGS Research Applications. *E. Lin, M. Corioni, F. Useche, M. Issakson, D. Lande, B. Novak, A. Vadapalli, C. LeCoq, C. Pabon, M. Visitacion, D. Roberts.* Genomics, Agilent Technologies, Santa Clara, CA.

Protein coding genes constitute approximately 1% of the human genome but harbor most of the disease-associated variants. By focusing on only the protein-coding regions of the human genome, scientists are now able to more efficiently detect these variants. Targeted re-sequencing enables highly sensitive and comprehensive detection of variants and provides insights into the biology behind a given phenotype. With recent major advances in this technology, combined with a better understanding of biological pathways, NGS is now being considered for use in clinical research. To efficiently and comprehensively catalogue variants within a sample, we developed a new set of SureSelect target enrichment research panels optimized for analysis of disease-associated regions. 1) Our latest Clinical Research Exome targets the full human exome for broad research applications. It is specifically designed to achieve excellent coverage of disease-associated content, especially those relevant to constitutional disease research. It provides deep and comprehensive coverage of genomic content derived from highly curated databases including CCDS, RefSeq, GENCODE, Vega, MirBase, UCSC known genes, Human Gene Mutation Database (HGMD®), ClinVar and Online Mendelian Inheritance in Man (OMIM™); 2) The Focused Clinical Research Exome narrows the capture regions to only include ~5000 targets with strong association to disease and annotated within HGMD®, OMIM™ and ClinVar; 3) The Inherited Disease Panel further narrows the focus to cover only a set of ~2700 genes within OMIM™ that are highly relevant targets for Mendelian disease research. These three exome options allow researchers to maximize efficiency depending on their application space and sequencing platform. Here we demonstrate capture efficiency for these exome designs and describe sequencing coverage statistics as well as sensitivity and concordance for SNP determination. Additionally we show low-input SureSelect workflows that enable greatly reduced hybridization and turn-around times. Further, we provide data analysis and visualization using Agilent's SureCall software.

1714M

Flexible Content TaqMan® Pathway Panels. *M. Laig[1], J. Clarke[1], K. Lee[1], M. Augustine[2], E. Shelton[1], K. Varma[1], P. Farahani[1].* 1) Thermo Fisher Scientific, South San Francisco, CA; 2) Ceino Technologies Inc., Menlo Park, CA.

Identifying patterns of gene expression and SNP alleles related to a pathway or disease can help identify specific genes of interest. Fixed content panels are a good first approach, but there are frequently additional genes pertinent to the pathway. To this end, we are developing customizable TaqMan® assay panels as flexible research tools for pathway and disease related genes and markers. The panels contain assays for a suggested list of target genes and SNP markers that are customizable to omit and add assays of interest. The researcher can choose between three platforms: TaqMan® OpenArray®, TaqMan® Array Card and TaqMan® Array Plate. The initial panels are gene expression assay sets covering 15 popular research areas in human, mouse and rat: Alzheimer's disease, Cardiotoxicity, Hepatotoxicity, Nephrotoxicity, Neurotoxicity, Inflammation, Diabetes, Cell cycle, Apoptosis, Hypertension, Angiogenesis, Glycosylation, Parkinson's disease, Cardiovascular disease and p53 Signaling. Each panel contains up to 92 markers as a core assay set, and some panels contain additional assays in the "Off Your Array" list that may be used to substitute core assays. Additional assays of interest may be added, pre-designed or custom assays. The repertoire of panels will be expanded to include additional gene expression panels and SNP genotyping panels. Flexible Content TaqMan® Pathway Panels enable a better selection of assays for the immediate research interest.

1715T

Design and implementation of a transplantation-targeted whole genome genotyping array. *A. Shaked[1], Y.R. Li[2,3], F.W. Asselbergs[4], S. Bala[5], K. Karczewski[6], K. Birdwell[7], W. Oetting[8], P. de Bakker[9], P. Jacobson[8], D. MacArthur[6], Y. Lu[11], G. Lord[10], A.K. Israni[8], B.J. Keating[1,2].* 1) Dept of Transplantation,University of Pennsylvania, Philadelphia, PA, USA; 2) The Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA;; 3) Medical Scientist Training Program; Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA;; 4) Department of Cardiology, Division Heart & Lungs, University Medical Center Utrecht, Utrecht, Utrecht, Netherlands; 5) Yale Medical School; 6) Harvard Medical School and Broad Institute, Massachusetts General Hospital, MA, USA; 7) School of Medicine, Vanderbilt University; 8) College of Pharmacy, University of Minnesota; 9) Epidemiology and Bioinformatics at UMC Utrecht; 10) Dept of Nephrology, Transplantation and Internal Medicine, Guy's and St. Thomas' Hospital and King's College London, UK; 11) Affymetrix, Santa Clara, California.

More than 559,000 solid organ transplantations (kidney, liver, heart and lung) have been performed in the United States since 1988, with nearly 30,000 occurring annually in the US. Despite significant improvements in transplant outcomes, chronic organ rejection affects up to 60 percent of patients representing a major cause of morbidity and mortality following allogeneic transplantation. Whole genome sequencing projects have identified millions of common and rare genetic polymorphisms across human populations, which are thought to contribute to genetically-associated risk factors for transplant and immunosuppression-related adverse event, as well as serve as a source of genetic disparity between donors and recipients that can lead to both acute and chronic organ rejection. Array-based genotyping technologies permit significant flexibility in choosing the scope and density of SNPs to examine for disease or phenotype-specific genome-wide association studies. We report and discuss the design, implementation, and preliminary results from thousands of samples typed on a state-of-art transplantation-focused SNP array utilizing an Affymetrix custom genotyping platform composing of nearly 800,000 markers with coverage of a number of genomic features of interest in particular to the transplant community: 1. Exonic and Loss of Function (LoF) variants (274K) from >40K human exomes; 2. Imputation panel (463K) with all available EUR ancestry data from the 1000 genome project and ~90K African ancestry panels SNPs to boost coverage and improve fine-mapping. We added significant content (55K) for UTRs, pharmacogenomic markers (7.5K) from PharmaADME.org, PharmaGKB, and the candidate studies in the literature related to immunosuppression therapy response, and copy number variant probes (16.4K) from the Wellcome Trust and UKbiobank (n=2.4K) and analysis of 68K GWAS samples from CHOP; 5. Expression QTL markers (17.4 K SNPs) from NCBI/NIH GTEx eQTL database; 6. Dense coverage across the MHC and KIR regions; and 7. Cardiovascular & metabolic disease related ontent for analysis of new onset of diabetes after tx (NODAT) & Cardiac allograft vasculopathy (CAV) by collation of SNPs from >600 PubMed manuscripts. This genotyping array offers rich information for the transplant community utilizing state-of-the-art array design technology and data from large-scale resequencing projects and publicly available functional and gene expression dataset.

1716S

Performance of seven mutation pathogenicity prediction methods in the classification of missense variants of the CYP1B1 gene. *G. Chavarria-Soley.* Biology, University of Costa Rica, San José, Costa Rica, San José, Costa Rica.

Nonsynonymous single nucleotide polymorphisms (SNPs) in the coding regions of genes can lead to aminoacid changes and potentially affect protein function and, therefore, susceptibility to disease. Several computational methods have been developed for the classification of SNPs according to their predicted effect on protein function and resulting pathogenic potential. In this study, we evaluated the performance of seven commonly used pathogenicity prediction methods available on the Internet (SIFT, nsSNPAnalyzer, Panther, pMut, PolyPhen, PhD-SNP, and SNAP). In order to test them, nonsynonymous SNPs in the CYP1B1 gene- which codes for the cytochrome P450 1B1 enzyme-were selected. A total of 129 missense variants in CYP1B1 were identified in the literature, from which 87 could be classified as pathogenic or neutral according to criteria such as segregation with disease phenotype, effect on function, among others. The algorithms showed significant variation in the assignment of the variants to three categories (non-neutral, neutral, no prediction), with a low 37% prediction rate for Panther. Pairwise concordance between methods in the classification of variants as pathogenic or neutral varied between 37% and 94%. The accuracy in the prediction of the pathogenicity of the variants was higher than 68% with all methods except pMut (47%). The highest false positive and false negative rates were found for SIFT and pMut, respectively. Taking into account the rate of prediction, accuracy of prediction, false positive, and false negative rates, the method with the overall best performance in the present study was nsSNPanalyzer, closely followed by SIFT, Polyphen and SNAP.

1717M

A Comprehensive IT System to Support GTEx Biospecimen Collection Operations. *P. Guan[1], C. Shive[2], L. Qi[2], D. Tabor[2], P. Hariharan[2], S. Wu[2], K. Um[2], V. Santhanam[2], P. Kigonya[2], J. McLean[2], J. Vaught[1], H.M. Moore[1] on behalf of GTEx consortium.* 1) National Cancer Institute, Bethesda, MD; 2) Leidos Biomedical Research Inc., Frederick, MD.

The NIH Common Fund's Genotype-Tissue Expression (GTEx) project aims to study gene expression and regulation across multiple human tissues (30+ tissue types) from approximately 900 healthy normal donors. It is expected to provide valuable insights into gene regulation and its tissue specificity, to identify correlation between genetic variations and variations in gene expression levels as expression quantitative trait loci (eQTLs), and to help understand inherited susceptibility to diseases. To meet the challenge of GTEx requirements for collecting and tracking high quality biospecimen samples, a custom-built software system, the Comprehensive Data Resource (CDR) was developed to support sample collection workflow, clinical data entry, case management, and review and curation of study data. CDR is built with a combination of technologies from Grails, Oracle, Groovy, jQuery, and Apache Solr. CDR provides secure data access based on pre-defined user roles and privileges. Personally Identifiable Information (PII) and Protected Health Information (PHI) are restricted to a limited data set (LDS) and to authorized users through dynamic content redaction. Intuitive graphic user interfaces for Biospecimen Source Sites streamline data entry workflow by following detailed SOPs for sample collection and processing. Automated data check and business rule validation confirm data integrity and SOP adherence simultaneously. Web service API's allow a Pathology Resource Center to access digital imaging data housed remotely at a Comprehensive Biospecimen Resource (CBR). API's connect to the CBR's LIMS system for real-time sample inventory data. De-identified data is provided to the Laboratory Data Analysis and Coordinating Center (LDACC) at the Broad Institute through a private API before the final release into dbGaP. CDR's analytics and reporting module supports data analysis and aggregation, report generation and real-time operational data snapshots. CDR is a distributed web-based bioinformatics system that has supported GTEx biospecimen operations from an earlier pilot phase to the current scale-up stage. CDR manages and maintains multi-dimensional data models around each donor case (average 500+ data elements per case). As an efficient case management tool capable of connecting to various remote informatics systems, CDR could be adapted by the broader research community to standardize and streamline biobanking operations.

Clinical phenotype-based gene prioritization using semantic similarity and the Human Phenotype Ontology. *A. Masino[1], E. Dechene[2], M. Dulik[2,3], A. Wilkens[2], N. Spinner[3,4,5], I. Krantz[2,5], J. Pennington[1], P. White[6,7].* 1) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 5) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 6) Department of Pediatrics, Cincinnati Children's Hospital and Medical Center, Cincinnati, OH; 7) Department of Biomedical Informatics, University of Cincinnati, College of Medicine.

Exome sequencing is a promising method for diagnosing patients with a complex phenotype. However, variant interpretation relative to patient phenotype can be challenging in some scenarios, particularly clinical assessment of rare complex phenotypes. Each patient's sequence reveals many possibly pathogenic variants that must be individually assessed. Variant impact to gene function alone is insufficient to determine clinical relevance. Clear association between a gene harboring a damaging variant and patient phenotype is also required for accurate clinical diagnosis. We implemented an algorithm that can assist this process by ranking a given set of genes relative to patient phenotype. The model orders genes by the semantic similarity between Human Phenotype Ontology terms associated with a gene and those describing the patient. Model validation was performed for 33 Mendelian diseases with 100 simulated baseline patients per disease. Each patient was assigned phenotypic features with probability based on published feature penetrance. To measure robustness, we modeled likely clinical conditions by adding noise, i.e. terms unrelated to the disease, and imprecision, i.e. terms less specific than the actual disease terms, to each patient. For optimal and noise conditions, the disease gene median rank was 1 of 2488. We also provisionally examined a clinical cohort of subjects with hearing impairment. The disease gene median rank was 22 of 2488. However, considering the patient's exome data and filtering non-exomic and common variants, improved median causative gene rank to 3 of 125.5. We have demonstrated that the addition of phenotypic information can substantially improve the ability to prioritize genes, and by extension variants, for clinical characterization. With continued research, we expect that automated gene prioritization based on phenotypic descriptors may increase accuracy and decrease effort for predicting genomic variant significance.

The Orphanet Rare Diseases Ontology (ORDO) : a reference tool integrating clinical and genetic data. *A.M. Rath[1], A. Olry[1], C. Gonthier[1], L. Chanas[1], H. Parkinson[2], J. Malone[2], D. Vasant[2], M. Hanauer[1], B. Urbéro[1], S. Aymé[1].* 1) US14, INSERM, Paris, Paris, France; 2) EMBL-EBI, Hinxton, UK.

The growing complexity of genetic knowledge, the scattered phenotype data in clinical databases, as well as the multiplicity of medical terminologies in use impose the need for a reference tool in which all these data are integrated in a normalised fashion in order to render them accessible for health information systems and for research. Since 1997, Orphanet maintains a multilingual database of rare diseases (RD), based on the available literature and on expert advice. This data is manually curated, comprised of a nosology (classification of RD), relationships (genes-diseases, epidemiological data, orphan drugs) and cross-references with other terminologies (MeSH, SNOMED CT, UMLS), databases (OMIM) or classifications (ICD10) in use. Genes are cross-referenced with other scientific databases (HGNC, OMIM, UniProt, Genatlas, Reactome, ensembl, IUPHAR). These data are already freely available for download via the OrphaData platform (www.orphadata.org). However, it is necessary to make data available for researchers in a machine-readable format, ready to be integrated to any technical environment (obo and owl formats). In order to achieve this, Orphanet set up a collaboration with the European Bioinformatics Institute (EBI, Hinxton, UK) in order to produce the Ontology of Rare Diseases, which provides a robust and consistent modeling of data and their semantic relationships, as well as interoperability standards with other scientific resources in use in both research and in public health. The Orphanet Rare Diseases Ontology is available on BioPortal (http://bioportal.bioontology.org/ontologies/ORDO) and OrphaData and is updated monthly.

Comprehensive Transcriptome Analysis Reveals that Nonsense-Mediated mRNA Decay Is Not Globally Suppressed in Lung Adenocarcinomas. *L. Hu, P. Zhang.* State Key Lab of MedicalGenomics, SIBS, Shanghai, China.

The nonsense-mediated mRNA decay (NMD) pathway ensures the rapid degradation of mRNAs containing premature translation termination codons (PTC). Prior research has shown that the tumor microenvironment, which exhibits hypoxia and amino acid deprivation, might inhibit NMD activity. Using next-generation RNA-seq data of cancerous tissue, we show that, in spite of several important differences in the expression of NMD factors and NMD targets, such as down-regulation of SMG6, cancer cells probably manipulate the NMD mechanism for their own benefits rather than globally inhibiting the process. Cancer cells strategically prefer different degradation targets that might confer a growth advantage in the tumor microenvironment. We also found that genes containing NMD targets tend to have high expression levels and low expression noise. Thus, we believe that cancer efficiently uses the NMD mechanism.

1721T

Combined use of mutant loxP sites, JT15 and JTZ17, is a useful approach for sophisticated genome engineering. *K.C. Chen[1], P.L. Chen[1,2,3,4].* 1) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan.

Cre-mediated site-specific integrative recombination system is a useful tool for genome engineering. Integrative recombination with a pair of mutant loxP sites is a developed and successfully strategy to increase the diversity and possible combinations. Using several mutant loxP sites combination system for manipulation of multiple genes on knock-out or knock-in experiments can improve complex genetic studies. In 2003, Piedrahita *et al.* (*Genesis*, 2003, 36:162-167) reported a couple of mutant loxP combination, JT15 and JTZ17, which yielded the most efficient integration in E. coli. However, their recombination efficiency with wild-type loxP or other mutant loxP sites remains unclear. In order to address this issue, we constructed a series of neomycin selection cassette flanked with the wild-type or mutant loxP sites to test the frequency of site-specific integration. Our results showed that the frequency of targeted recombination between JT15 and JTZ17 was 74%. We also observed that the recombination between JT15 and the JT15:JTZ17 mutant loxP sequence was very low. There was no recombination between JTZ17 and the JT15:JTZ17 mutant loxP sequence. Most importantly, JT15, JTZ17 and JT15:JTZ17 could not recombine with wild-type loxP sites. In conclusion, we suggest that combined use of JT15 and JTZ17 is a useful approach in sophisticated genome engineering strategies.

1722S

Identification of rare causal variants in sequence-based studies: methods and applications to VPS13B, a gene involved in Cohen syndrome and autism. *I. Ionita-Laza[1], M. Capanu[2], S. De Rubeis[3], K. McCallum[1], J. Buxbaum[2].* 1) Biostatistics, Columbia University, New York, NY; 2) Memorial Sloan-Kettering Cancer Center; 3) Icahn School of Medicine at Mount Sinai.

Pinpointing the small number of causal variants among the abundant naturally occurring genetic variation is a difficult challenge, but a crucial one for understanding precise molecular mechanisms of disease and follow-up functional studies. We propose and investigate two complementary statistical approaches for identification of rare causal variants in sequencing studies: a backward elimination procedure based on groupwise association tests, and a hierarchical approach that can integrate sequencing data with diverse functional and evolutionary annotations for individual variants. Using simulations, we show that incorporation of multiple bioinformatic predictors of deleteriousness, such as PolyPhen-2, SIFT and GERP++ scores, can improve the power to discover truly causal variants. As proof of principle, we apply the proposed methods to VPS13B, a gene mutated in the rare neurodevelopmental disorder called Cohen syndrome, and recently reported with recessive variants in autism. We identify a small set of promising candidates for causal variants, including two loss-of-function variants and a rare, homozygous probably-damaging variant that could contribute to autism risk.

1723M

Effect of Haplotype Estimation in Exact Tests for Association. *L. Ehwerhemuepha, A. Smith, C. Rakovski.* Chapman University, Orange, CA.

We compared the loss of power of three exact tests for association (Multinomial, Fisher's and Barnard's Exact Tests) due to haplotype frequency estimation in unphased data. Two methods for estimating haplotype frequencies were used: An EM algorithm implemented to determine weighted haplotype assignments of all subjects based on the haplotype pairs compatible with the unphased genotypes; and a Bayesian haplotype reconstruction method based on Bayesian Inference. The EM algorithm allows for population-level haplotype frequency estimation while the Bayesian counterpart allows for individual-level haplotype estimation from which the population haplotype frequency can be calculated under the assumption that each individual's estimated haplotype frequency is its true haplotype frequency. We performed extensive simulations (at several alpha levels) to assess the type I error rates under various null hypothesis and the power of the test under various alternative hypothesis.

1724T

Bootstrap Tests of Association For NextGen Sequence Data That Allow for Systematic Differences in Read Depth between Cases and Controls. *G.A. Satten[1], Y. Hu[2], H.R. Johnston[2], P. Liao[2], Y. Jiang[3], A.S. Allen[3,4].* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Dept of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 3) Dept of Biostatistics and Bioinformatics, Duke University, Durham, NC; 4) Duke Clinical Research Institute, Duke University, Durham, NC.

Background: The quality of genotype calling for next-generation sequence data depends on read depth. Loci with high coverage can typically be called reliably, while those with low coverage may be difficult to call. In a case-control study, if data from case participants is sequenced to a greater depth than data from controls, the difference in genotype quality can introduce a systematic bias. This can easily occur when historical controls (e.g., data from The 1000 Genomes Project) are used. This imbalance may also occur by design, to reduce genotyping costs among controls. For trios, bias can arise even when the coverage is the same in parents and offspring since errors in parental genotype calls are considered non-transmissions while errors in offspring genotype calls are detected as non-Mendelian transmissions.

Methods: We develop likelihood-based methods for analyzing data from case-control and trio studies that directly uses data on reads without first making intermediate genotype calls. When the location of polymorphic loci is known, we show these likelihood approaches have appropriate size and good power compared with methods that use called genotypes. When the locations of polymorphic loci are not known in advance, we develop screening methods to screen out loci that are estimated to be monomorphic, based on read data alone. We use a bootstrap approach to estimate which of the loci that screen in are truly polymorphic. Using these estimates, we then construct bootstrap tests for association that properly account for screening and preserve size. We further show that restricting to loci with estimated allele frequency $\geq 1/2N$, so that the expected number of alleles seen is greater than one, increases the power of our approach by excluding loci that have negligible effect.

Results: We illustrate our approach using data from the UK10K project. We use data from 784 cases from the Severe Childhood Onset Obesity Project, and are exome sequenced at 60x. Data for 1702 controls are from the Avon Longitudinal Study of Parents and Children and the TwinsUK study (only one twin used), and are whole genome sequenced at 6x coverage.

1725S

Binary Trait Analysis in Sequencing Studies under Trait-Dependent Sampling. *Z.Z. Tang[1], D.Y. Lin[2].* 1) Vanderbilt University, Nashville, TN; 2) University of North Carolina, Chapel Hill, NC.

Trait-dependent sampling design has been adopted in many sequencing studies to enrich causal signal and increase power of the association tests. In the National Heart, Lung, and Blood Institute Exome Sequencing Project (NHLBI ESP), subjects with the highest or lowest values of body mass index, low-density lipoprotein, or blood pressure were selected for whole-exome sequencing. However, such study design produces challenges for genetic association analysis. We provide a valid and efficient maximum likelihood framework for analyzing binary traits under the trait-dependent sampling. Under this framework, we produce the commonly used gene-based association tests including burden tests, variable-threshold tests and variance-component tests. We compare our methods with the naive methods, namely the standard logistic regression methods. We demonstrate through extensive simulations that our methods preserve type I errors, whereas naive methods can yield severely inflated type I errors. For a particular trait of interest, our approach properly combines the association results from all studies with measurements of that trait. This meta-analysis is substantially more powerful than the analysis of any single study. By contrast, meta-analysis of naive methods can be less powerful than the analysis of a single study. The usefulness of the proposed methods is further illustrated with data from NHLBI ESP.

Functional regression for genetic association studies. *O. Vsevolozhskaya[1], D. Zaykin[2], L. Qing[1].* 1) Epidemiology & Biostatistics, Michigan State University, East Lansing, MI; 2) Biostatistics Branch, NIEHS, Research Triangle Park, NC.

We propose a general framework to perform gene/region based analysis of sequencing data by regressing a functional response on one or multiple scalar predictors. Next generation sequencing technologies make it possible to uncover genetic information from millions of variants. Since the observed sequenced variants are very close in their genetic positions, we can consider them to be realizations of random continuous functions. Therefore, instead of analyzing multiple individual genetic variants per subject, we can estimate the underlying continuous function and treat it as a functional response in a regression model. Smoothing splines are used to fit these functional responses by maximizing the penalized likelihood. Covariates can also be incorporated in the analysis to control for confounding, including qualitative and quantitative predictors. By utilizing a connection between penalized spline regression and linear mixed models, we are able to fit our model using standard linear mixed models statistical packages. To illustrate our approach, we conduct simulation studies and apply our proposed methodology to sequencing data from the Dallas Heart Study.

1727T

A Generalized Similarity U test with application to multiple-trait sequencing association study. *C. Wei[1,2], Q. Lu[2].* 1) Department of Biostatistics and Epidemiology, University of North Texas, Fort Worth, TX; 2) Department of Epidmiology and Biostatistics, Michigan State University, East Lansing, MI.

Sequencing-based studies are emerging as a major tool for genetic association studies of complex diseases. It also poses great challenge to the traditional statistical methods (e.g., the single variant analysis) due to the high-dimensionality of the data and low frequency of the genetic variants. Joint test has been shown to be more suitable for sequencing studies, by jointly testing multiple variants to increase the power and reduce the dimensionality. Meanwhile, there are growing needs for statistical methods are distribution free and can handle multiple phenotypes. In this paper, we proposed a generalized similarity U test, referred to as GSU. GSU rst summarizes the genetic information and multiple traits into the genetic similarity and trait similarity, and then combines the two similarities in the framework of weighted U statistic. We derived the asymptotic distribution of GSU under null hypothesis so as to eciently calculate the signicance level. We also studied the asymptotic behavior of GSU under alternative and provide sample size and power calculation for study design. To evaluate the performance of GSU, we conducted extensive simulation studies and compare it with the existing methods. Through simulation, we found GSU had advantage over existing methods in terms of power comparison and robustness to trait distribution. Moreover, GSU is computationally more ecient than the existing methods. Finally, we applied GSU to the multiple traits analysis of Dallas Heart Study and identied joint association of 4 genes with 5 metabolic related traits.

Utilizing Private Variants in Large Genome-Wide Association Studies: Issues, Techniques, Experiences. *U. Bodenhofer, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University, Linz, Austria.

High-throughput sequencing technologies have facilitated the identification of large numbers of single-nucleotide variations (SNVs), many of which have already been proven to be associated with diseases or other complex traits. Several large sequencing studies, such as, the 1000 Genomes Project, the UK10K project, or the NHLBI-Exome Sequencing Project, have consistently reported a large proportion of private SNVs, that is, variants that are unique to a family or even a single individual. The role that private SNVs play in diseases and other traits is currently poorly understood — which is largely due to the fact that it is statistically very challenging to consider private SNVs in association testing. While it is generally impossible to use single-marker tests for private SNVs, burden tests are potentially able to deal with private SNVs, but only if the number of private SNVs occurring in a region is correlated with the trait under consideration. Moreover, burden tests have a disadvantage if deleterious and protective SNVs occur together in the same region. Non-burden tests like the popular SNP-set (Sequence) Kernel Association Test (SKAT) are typically utilizing correlations between SNVs — a strategy that is not applicable to private SNVs either, since singular events are generally uncorrelated. We propose the Position-Dependent Kernel Association Test (PODKAT), which is designed for detecting associations of very rare and private SNVs with the trait under consideration even if the burden scores are not correlated with the trait. PODKAT assumes that, the closer two SNVs are on the genome, the more likely they have similar effects on the trait under consideration. This assumption is fulfilled as long as deleterious, neutral, and protective variants are grouped sufficiently well along the genome. This contribution focuses on the use of PODKAT for large whole-genome studies. On the one hand, we will discuss issues related to data handling, computational complexity, and statistical significance. On the other hand, we will present results obtained for UK10K whole-genome cohorts that unveil the potential of considering private and very rare SNVs in genome-wide association studies.

1729M

A non-threshold region-specific method for detecting rare variants. *D.P. Chen[1], A.R. Hsieh[2], C.S.J. Fann[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Graduate Institute of Biostatistics, China Medical University, Taichung, Taiwan.

Rare variants have a proven role in some complex diseases. Many statistical methods proposed for the detection of rare variants associated with diseases have some limitations, such as the threshold of rare variants, and the direction of effects. Accordingly, we developed a region-specific method that do not use the threshold for defining rare variants and take the directions of effects into account. Our method also considers the linkage disequilibrium (LD) within the region, and can handle common and rare variants simultaneously. Our region-specific method used the concept of weighting variants according to their minor allele frequencies and odds ratios (OR) to combine effects of common and rare variants on disease occurrence into a single score, and provided a test statistic in assessing the significance of the score. To evaluate the performance of our method, we simulated extensively under different effect sizes according to Basu and Pan (2011). We found that the power of our method increased as the effect sizes increased. The type I error of our method was controlled well in spite of the simultaneous variations. Moreover, we compared our proposed method to several currently available methods, including kernel-based adaptive cluster (KBAC) and Sequence Kernel Association Test (SKAT). We found our method can generate comparable or better power in simulations. Results from our method showed a 15% increase in power comparing with SKAT (61% vs 47%) under small OR and lower LD, and 36% increase in power comparing with KBAC (98% vs 62%) while variants have different directions. However, our method performs well in 2-direction setting, but moderate in independent-variant scenario. We conclude that our proposed method can be used as a complementary tool with others to assist the dissection of the etiology of complex diseases.

1730T

Evaluating the calibration and power of three gene-based association tests for the X chromosome. *C. Ma, M. Boehnke, S. Lee.* Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

While genome-wide association studies (GWAS) have identified thousands of trait-associated genetic variants, the proportion of findings on the X chromosome lags behind those on the autosomal chromosomes. Existing X chromosome analysis methods focus on single marker association analysis. For analysis of rare variants (minor allele frequency < 0.5%), gene-based tests where multiple markers are analyzed jointly as a unit can be more powerful than single marker tests. To date, there are no gene-based tests designed to analyze the X chromosome. Using simulated case-control and quantitative trait (QT) studies, we evaluate the calibration and power of three gene-based tests for the X chromosome: burden, Sequence Kernel Association Test (SKAT), and optimal unified SKAT (SKAT-O). Specifically, we evaluate the impact of different ratios of males and females in cases and controls, and different coding of males alleles with X-inactivation (coding minor alleles as X=2) and without (X=1).

For case-control studies, all three tests are well-calibrated or slightly anti-conservative for all scenarios evaluated. As previously shown, power of the three tests depends on the underlying genetic architecture of the genomic region analyzed; burden is most powerful for multiple causal variants with the same direction of effect, SKAT is most powerful for causal variants with opposite directions of effect, and SKAT-O is generally powerful. For variants simulated assuming X-inactivation, coding male minor alleles as X=2 is slightly more powerful; for variants simulated assuming no X-inactivation, coding male minor alleles as X=1 is slightly more powerful. However, the power loss for misspecifying the generally unknown model is small. Different ratios of males and females in cases and controls have little effect on power. For QT studies, burden and SKAT are well-calibrated, while SKAT-O can be slightly anti-conservative across all scenarios. Power comparisons between tests for QTs are very similar to those for binary traits. We demonstrate that these three gene-based tests are well-calibrated and powerful for both binary and quantitative trait data, and can be directly applied to analyze rare variants on the X chromosome.

1731S

Exploiting correlation of genetic effects in rare variant association studies. *M.A. Rivas[1], M. Pirinen[2], L. Moutsianas[1], C. Spencer[1], K. Banasik[1], D. van Heel[3], K. Hunt[3], P. Soininen[4], A.J. Kangas[4], M. Ala-Korpela[4,5,6], M.J. Daly[7,8], F. Karpe[9], P. Donnelly[1,10], M.I. McCarthy[1,9].* 1) Wellcome Trust Centre for Human Genetics Research, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, UK; 2) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 3) Barts and The London School of Medicine and Dentistry, Queen Mary University of London; 4) Computational Medicine, Institute of Health Sciences, University of Oulu, FI; 5) NMR Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, Kuopio, FI; 6) Computational Medicine, School of Social and Community Medicine and the Medical Research Council, Integrative Epidemiology Unit, University of Bristol, UK; 7) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, US; 8) Broad Institute of MIT and Harvard, Cambridge, MA, USA; 9) Oxford Centre for Diabetes, Endocrinology, and Metabolism, University of Oxford, UK; 10) Department of Statistics, University of Oxford, Oxford, UK.

High-dimensional data present exciting opportunities in enhancing our understanding of the relationship between genetic variation and multiple diseases or health related quantitative traits. A first step towards utilizing high-dimensional phenotypes in genetic studies is to understand how their genetic components are related. A second step is to apply this knowledge in association studies.

Here we present novel statistical approaches that leverage estimates of the correlation of genetic effects for rare variant association studies that enable association testing (via extension of the C-alpha framework) and effects estimation in cross-disorder and cross-phenotype study designs. The intuition is simple: 1) for some groups of genetic variants, such as protein truncating variants, annotation suggests high correlation of effects; we want to exploit this by building models which incorporate information on the correlation between the effects of these variants on a single phenotype; 2) for any causal genetic variant that is pleiotropic, incorporation of the estimate of correlation of genetic effects obtained from genome-wide genotype data may improve power to detect association.

Simulations suggest that our approach improves power to detect association compared to standard univariate approaches. First, we consider the study of rare variants and multiple continuous traits. We apply the tests to coding rare variant data and plasma NMR metabolite levels in 4,522 healthy individuals from the population based Oxford Biobank study and identify novel genic signals that were not identified with univariate aggregate methods. As an example, we identify multivariate association ($p=1\times10^{-6}$) of protein-altering variants in *PAH* (phenylalanine hydrolase) to the amino-acid trait profile (univariate $\min(p) =4.5\times10^{-4}$). Second, we consider the study of rare variants, multiple diseases, and shared controls. We apply the tests to coding sequence data from 25 GWAS risk genes in 41,911 UK residents of white European origin, comprising 24,892 subjects with six autoimmune disease phenotypes and 17,019 controls and identify new association of protein truncating variants at *TNFAIP3*. Our framework is computationally efficient, making the analysis of large rare variant association study designs practical.

Integrated statistical model of genetic variation reveals new insights into the genetics of autism. *X. He[1], K. Roeder[1,2], B. Devlin[3], MJ. Daly[4,5], JD. Buxbaum[6,7,8,9], Autism Sequencing Consortium.* 1) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 3) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 5) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 6) Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, NY; 7) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY; 8) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 9) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY.

Analysis of de novo mutations has been effective in identifying susceptibility genes of developmental disorders such as autism. Recurrent de novo loss-of-function (LoF) mutations on the same gene generally provides strong evidence for the gene's involvement in risk. Recently we developed a statistical model, named TADA, that extends this approach by combining information on de novo LoF mutations, de novo missense mutations and inherited variants for the same gene (He et al, PLoS Genetics, 2013). In the current work, we improve the TADA model by refining the weights mapping onto different types of genetic variation. Under the new model, de novo LoF mutations contribute most to a gene's evidence, followed by de novo missense mutations, transmitted LoF mutations and transmitted missense mutations. We achieve this weighting strategy by using different prior distributions for the relative risks of different types of genetic variation. Using parameters derived from whole exome sequencing (WES) data of autism, we show through simulations that TADA is almost twice more powerful than using only de novo LoF mutations. Using TADA we analyzed a large WES dataset of autism, consisting of more than 2,000 parent-child trios and 7000 case-control samples. The data supported an estimate of more than 1,000 genes involved in risk for autism. We next used TADA to predict 33 high-confidence autism risk genes (FDR < 0.1) and 107 genes at a relaxed threshold (FDR < 0.3). We developed two strategies for estimating the relative risks of mutations, one based on counting genes with single de novo mutations vs. genes with multiple mutations and the other based on the different frequencies of mutations in affected male vs. female subjects. Both lead to an estimate of relative risk of about 20 for de novo LoF mutations in high-confidence genes and lower estimates for other classes of variants. A large fraction of the 107 genes are under strong evolutionary constraint, defined by a shortage of non-synonymous mutations relative to the rate of synonymous mutations. Other enrichment analyses identify important biological processes involved in autism (De Rubeis for the Autism Sequencing Consortium). Finally, a newly developed statistical method named DAWN was used to analyze the gene networks underlying autism. DAWN identified several subnetworks that are enriched with genes of high TADA scores and gene pairs of high co-expression in brain transcriptome data.

1733T

Meta-Analysis of rare variants association studies with multiple correlated traits. *X. Wang, X. Zhao, C. Huang.* P.O. Box 413, Zilber School of Public Health, University of Wisconsin-Milwaukee, Milwaukee, WI.

For many diseases such as asthma, attention deficit hyperactivity disorder, or hypertension, genetic association studies are often conducted to test multiple correlated traits which are routinely measured and thought to be more proximal to the biological etiology of the clinical disorder. Testing multiple correlated traits can identify quantitative trait loci (QTL) shared between correlated traits in addition to trait-specific QTL. Meta-analysis as a cost-efficient powerful tool for combining distinct genome-wide association studies (GWAS) has been widely used to detect common variants for single trait in GWAS. However, existing meta-analysis methods may not be optimal or even not be applicable for detecting rare variants in sequencing data with multiple correlated traits due to allelic heterogeneity, extreme rarity of individual variants, and correlation among traits. We propose a general statistical framework for meta-analysis of gene-based rare variants association studies with multiple correlated traits. Due to low minor frequencies of rare variants, it is often unstable or not feasible to estimate regression coefficients of rare variants in a multi-marker regression model. Thus, we developed a score test to test the effect of an optimally weighted combination of variants in a gene in each study for a single trait, and perform meta-analysis for each single trait with Lee's meta-analysis method and obtain the p value for each gene for all the studies. Then, we use the Brown's method to combine p values for the multiple correlated traits and obtain the p value of the meta-analysis with the multiple correlated traits. There are three key advantages of the proposed method: 1) through aggregating score statistics, it circumvents the estimation of the regression coefficients of rare variants; 2) it is computationally efficient even for whole-genome analysis since p values can be calculated analytically; 3) it can decrease the false-positive rate by incorporating the extra information provided by the cross trait covariance. To investigate the performance of the proposed method, we conducted extensive simulation studies for type I error rates and power comparison. The multiple correlated traits meta-analysis method maintained appropriate type I error rates in all the simulation settings. Further simulation studies are ongoing to compare power of the proposed method with the single trait meta-analysis method proposed by Lee et al.

1734S

Haplotype length regression for identifying rare disease-predisposing variants. *S.P. Sajuthi, C.D. Langefeld.* Biostatistical Sciences and Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC.

Van der meulen and te Meerman (1997) proposed using haplotype sharing statistics (HSS) to identify disease-predisposing loci. The two hypotheses that underlie the HSS paradigm: 1) affected individuals will share not only the same mutation but also the surrounding haplotypes, 2) the length of the haplotype sharing will be affected by the age of the disease variant, with newer variants residing on longer haplotypes than older variants. The second hypothesis is motivated by fewer generations will result in fewer recombination and mutation events in the sample that contains the newer variant. Building upon Van der meulen and Meerman (1997), Allen and Satten (2007) and Lange and Boehnke (2004), we have developed a novel statistical method, the haplotype length regression (HLR) that leverages these two important concepts to identify genomic regions that contain more recent disease-predisposing variants. Formally, our method uses a generalized linear model framework to test for association between haplotype sharing length and disease trait. To investigate the performance of our HLR for rare variants, we simulated a diploid population using the SimuPOP software (Peng 2005). Generation 0 was composed of 993 independent individuals from the HapMap Phase 3 dataset. This initial population underwent random mating for 500 generations until it reached 50,000 individuals; simulation assumes a mutation rate of 10-8/bp/generation and recombination rate of 10-8/bp/generation. After 500 generations, the disease allele is introduced and then the population continues random mating for another 150, 300, 450, 600, 750 and 900 generations. A range of penetrance functions for a disease allele frequence of 0.005 were employed to simulate the disease trait given the disease locus genotype. We compared our approach with other haplotype sharing statistics and SKAT-O (Lee 2012). For a single risk variant within the window of analysis, the HLR and haplotype regression methods had greater power than the HSS or SKAT-O. Although not as large a difference, HLR continue to have greater power than the other methods when three rare risk variants within the analysis window were simulated. The HLR approach is appropriate for discrete and continuous traits. We are expanding the HLR method to family data. In summary, leveraging evolutionary characteristics of rare variants via haplotype sharing length methods can increase our power to detect rare variants.

A fast and powerful test of independent assortment with implications for the analysis of 'big data'. *V. Hager[1], W.C.L. Stewart[1,2,3].* 1) Nationwide Children's Hospital, 700 Children's Drive Columbus, Ohio 43205; 2) The Ohio State University Department of Pediatrics, 700 Children's Drive Columbus, Ohio 43205; 3) The Ohio State University Department of Statistics, 1958 Neil Avenue, 404 Cockins Hall Columbus, OH 43210.

Quantitative methods for the analysis of genetic sequences on related individuals continue to place a high premium on computational and statistical efficiency. As such, the most commonly used methods tend to incorporate as much information as possible as quickly as possible. However, much less attention is paid to the perhaps more important issue of statistical significance. For example, although most modern workstations can easily handle the computations associated with a large-scale, genome-wide linkage scan, the p-value for such a scan is either accurate but time consuming, or fast but inaccurate. To address this issue, we developed a test of independent assortment (TIA) that permits the accurate and rapid computation of p-values for large-scale genome-wide linkage scans. Furthermore, we show that our proposed test (1) has a limiting distribution under the null hypothesis of no linkage; (2) yields an approximate 300x speed-up over existing methods like MERLIN1; and, (3) has the same statistical power as the widely used Kong & Cox lod2. Overall, these attractive features should facilitate the analysis of 'big data' genetics and genomics through the meta-analysis of linkage, association, and gene expression data.

1736T

Generation of sequence-based data for pedigrees-segregating Mendelian or Complex traits. *B. Li, G.T. Wang, S.M. Leal.* Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

There is great interest in analyzing next generation sequence data that have been generated for pedigrees. However, unlike rare variant association methods for population-based data there are limited rare variant methods which have been developed to analyze pedigree data. One of the limitations in developing methods to analyze pedigree data is the availability of software to generate realistic pedigree sequence data with the variants generated either conditionally or unconditionally on qualitative or quantitative phenotypes. Rare variant pedigree simulated data is necessary to evaluate type I and II errors and also to compare the power of different methods. Therefore, we have developed RarePedSim (rare-variant pedigree-based simulator), a program to simulate pedigree-based gene-level genotype and phenotype data for complex and Mendelian trait rare variant studies given any user-specified pedigree structures. For complex traits rare variant association studies, RarePedSim can generate genotypes of founders based on site-specific variant information and non-founders according to principles of segregation. Site-specific variant information including allele frequencies, positions and functionalities can be derived from simulated sequences under realistic demographic and genetic models or obtained from real sequence data. RarePedSim can generate phenotypes based on a wide range of genetic etiology for both qualitative and quantitative complex traits, including logistic model of odds ratios, population attributable risk model and linear mean-shift model. For Mendelian disease rare variant analysis RarePedSim generates genotypes for individuals within the family given their phenotypes and mode of inheritance, e.g. dominant and recessive. Allelic heterogeneity between and within families and locus heterogeneity can also be simulated. Currently, RarePedSim is the only available program that can generate both genotypes and phenotypes for gene-based rare variants regardless of pedigree structure. The data generated by RarePedSim are in standard Linkage file format, ready to be used for a variety of purposes including evaluating type I error and power, for association methods including mixed model tests and parametric and non-parametric linkage analysis.

GenLib: an R package for the analysis of genealogical data. *M.-H. Roy-Gagnon[1,2], H. Gauvin[2,3], J.-F. Lefebvre[2], C. Moreau[2], E.-M. Lavoie[4], D. Labuda[2,5], H. Vézina[4].* 1) Department of Epidemiology and Community Medicine, University of Ottawa, Ottawa, ON, Canada; 2) CHU Sainte-Justine Research Center, Montreal, QC, Canada; 3) Department of Social and Preventive Medicine, Université de Montréal, Montreal, QC, Canada; 4) BALSAC Project, Université du Québec à Chicoutimi, Chicoutimi, QC, Canada; 5) Department of Pediatrics, Université de Montréal, Montreal, QC, Canada.

Founder populations play an important role in the study of genetic diseases. Their advantages often include access to detailed genealogical records. These genealogical data provide unique information for researchers in evolutionary and population genetics, demography and genetic epidemiology. However, analyzing large genealogical datasets require specialized methods and software. The GenLib software was originally developed to study the large genealogies of the French Canadian population of Quebec, Canada. These genealogies are accessible through the BALSAC database, which contains over 3 million records covering the whole province of Quebec over four centuries. Using this resource, extended pedigrees of up to 17 generations can be constructed from a sample of present-day individuals. We have implemented GenLib as a package in the R environment for statistical computing and graphics, thus allowing optimal flexibility for users. GenLib includes functions to manage genealogical data, for example extracting part of a genealogy or selecting specific individuals. Functions to describe genealogies using relevant summary measures, such as genealogical completeness and generational depth, are also available. In addition, GenLib can compute measures of relatedness (kinship and inbreeding) and the genetic contribution of founders. Finally, functions for gene-dropping simulations are also available in GenLib. We illustrate the use of GenLib with a sample of 140 individuals from regional populations of Quebec previously described in Roy-Gagnon et al., 2011. Ascending genealogies were reconstructed for these individuals using BALSAC, yielding a large pedigree of 41,523 individuals. With GenLib, we provide a more detailed description of these genealogical data in terms of completeness, genetic contribution of founders, relatedness and inbreeding, further illustrating the regional differences reported in these data. We also present gene-dropping simulations based on the whole genealogy to estimate the probability of sharing, identical by descent, chromosomal segments of varying lengths introduced at varying frequencies by different number of founders. In conclusion, the R package GenLib provides a user friendly and flexible environment to analyze genealogical data, allowing a more efficient and easier integration of different types of data and analytical methods and making it ideal for further developments.

Genotype calling and phasing in sequence data from complex families. *L. CHANG[1], B. Li[2], S. Vrieze[3], M. McGue[4], W. Lacono[4], D. Weeks[1,5], G. Abecasis[6], G. Tseng[1], W. Chen[1,5,7].* 1) Biostatistics, University of Pittsburgh, PITTSBURGH, PA., USA; 2) Department of Molecular Physiology & Biophysics, and Neurology, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Psychology & Neuroscience, Institute for Behavioral Genetics, University of Colorado Boulder, CO; 4) Department of Psychology, University of Minnesota, MN; 5) Department of Human Genetics, University of Pittsburgh, PA; 6) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 7) Division of Pulmonary Medicine, Allergy and Immunology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA.

As sequencing technologies can help researchers detect common and rare variants across the human genome in many individuals, it is known that jointly calling genotypes across multiple individuals based on linkage disequilibrium (LD) can facilitate analysis of low to modest coverage sequence data. However, genotype-calling methods for family-based sequence data, particularly for complex families beyond parent-offspring trios, are still lacking. In this study, firstly, we proposed an algorithm that considers both linkage disequilibrium (LD) patterns and familial transmission in nuclear and multi-generational families while retaining the computational efficiency. Secondly, we extended our method to incorporate external reference panels (e.g., 1,000 Genome Project) to analyze family-based sequence data with a small sample size. In simulation studies, we show that modeling multiple offspring can dramatically increases genotype calling accuracy and reduce phasing and Mendelian errors, especially for data sets with low to modest coverage. In addition, we show that using external panels can greatly facilitate genotype calling of sequencing studies with a small number of individuals. We applied our method to a whole genome sequencing study of ~1,800 individuals at ~10X coverage from the Minnesota Center for Twin and Family Research. We show that our methods significantly outperform existing ones that ignore family constraints or LD information. In summary, we present a statistical and computational method for genotype calling and phasing in sequence data from complex families and anticipate that our method will be useful for many ongoing family-based sequencing projects.

Assessing mitochondrial DNA variation and copy number in lymphocytes of 2,077 Sardinians using tailored sequencing analysis tools. *J. Ding[1], C. Sidore[2,3], T.J. Butler[1], M.K. Wing[2], O. Meirelles[1], Y. Qian[1], F. Busonero[2,3], R. Nagaraja[1], F. Cucca[3], G.R. Abecasis[2], D. Schlessinger[1].* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy.

To quantitate mitochondrial DNA (mtDNA) variation, genotype calling and analytic programs developed for nuclear DNA must be modified, because each cell has 100-10,000 mtDNA copies that can vary at any site (i.e., heteroplasmy). We report an algorithm adapted to identify mtDNA variants. It incorporates the sequencing error rates of the reads at each base in a likelihood calculation, and allows for different allele fractions at a variant site across all individuals. In addition, the algorithm is adapted to the circular mitochondrial genome, a key difference from the linear chromosomes assumed by most read mapping algorithms.

In the sample case of sequence from lymphocytes of 2,077 SardiNIA Project participants, we find that both homoplasmic and heteroplasmic mtDNA variants show 5-fold higher transition/transversion ratios than variants in nuclear DNA. As expected, mothers and their children share essentially all homoplasmies but a lesser proportion of heteroplasmies. Overall, heteroplasmy increases with age, but on average only ~1 heteroplasmy reaches the 4% level between ages 20 and 80. The total extent of accumulation of variants, however, remains hard to assess because heteroplasmy levels could be similar to or even lower than sequencing error rates; but resolving power can be increased in several ways, including deep sequencing of mtDNA.

We have also made a sequence-based estimate of mtDNA copy number based on the observed ratio of sequence coverage between mtDNA and autosomal DNA. The average in the cohort studied was 112 copies ±25 per cell, a number in agreement with estimates from qPCR assays. The computational methods thus facilitate comprehensive mtDNA analysis from whole-genome sequencing data. The algorithms can also be applied to quantitate sequence variation in other instances of high DNA copy number, such as cancer.

1740S

Improving effective sample size using extrapolated log p-values. *B. Engelhardt[1,2], X. Guo[2], S. Mukherjee[2], J. Tung[3].* 1) Biostatistics & Bioinformatics, Duke University, Durham, NC; 2) Department of Statistical Science, Duke University, Durham, NC; 3) Evolutionary Anthropology, Duke University, Durham, NC.

While the per-sample cost of genomic data collection has plummeted in recent years, population-based genomic studies, counterintuitively, remain extremely expensive. This expense arises because attempts to maximize power have relied almost exclusively on increases in sample size. An alternative, more cost-effective approach is to improve the statistical power associated with a given sample through development of more sensitive statistics. This approach is particularly attractive in the context of association mapping, or identifying genetic variants that are associated with complex traits. In particular, a large number of genetic variants may have an effect on a given complex trait, and effect sizes across these associated variants are thought to have a double exponential distribution (i.e., a few large magnitude effects and many effect sizes close to zero). However, association mapping, both in genome-wide association studies (GWAS) and quantitative trait locus-mapping (QTL) studies of molecular phenotypes, are restricted in their ability to detect associated variants with low effect size because of the limited number of samples in each study and the large number of associations tested. We present a statistical approach to extrapolate association significance (extrapolated log p-values, or ELPs) in a given study using subsampling methods. We validate this approach by quantifying gains in statistical power using simulated trait values and real genotype information from 4,646 individuals in the Wellcome Trust Case Control Consortium (WTCCC) data set. Our simulations show substantial gains in statistical power to detect low effect associations for a given sample size using ELP. We quantify this increase in effective sample size for association mapping in three diverse data sets: case-control mapping of Crohn's disease, and quantitative trait mapping of gene expression levels (eQTL mapping) in HapMap phase 3 individuals and the Genotype-Tissue Expression Project. Despite the simplicity of ELP, the theoretical justification for this approach is elegant in the context of classical statistics. ELP enables the detection of small effects in studies where the sample size has prevented these associations from reaching statistical significance, making association studies possible for populations and phenotypes for which existing methods are ineffective due to insufficient power. Broadly, ELP maximizes the power to draw statistical signal from expensive samples.

1741M

Alternative peak calling methods on Hi-C data accommodating the whole spectrum of dispersion. *Z. Xu, Y. Li.* Department of Genetics and Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Advancement in chromatic conformation capture and next generation sequencing technologies are enabling genomewide investigation of dynamic chromatic interaction. To analyze Hi-C data, Ay et al (2014) developed a peak calling method (Fit-Hi-C) that assigns statistical confidence estimates to mid-range intra-chromosal contacts based on a varying-coefficient Binomial model with the success rate as a smoothing function of the distance between the midpoints of a fragment pair. Ay et al (2014)'s model assumes that Hi-C data are equal-dispersed given the distance between the midpoints of a fragment pair. We found that the dispersion (given the distance) for real Hi-C data within different domains, either before or after outlier/peak filtering, can be (1) under-dispersed, (2) equi-dispersed, (3) over-dispersed or (4) dispersed differently for different distances. To address the dispersion issue in real-hi-C data, we consider alternative peak calling methods: (1) varying-coefficient Poisson model, (2) varying-coefficient Negative Binomial model, (3) varying-coefficient COM-Poisson model and (4) nonparametric standardization method. We benchmark these methods together with Fit-Hi-C using the number of interactions between known enhancers and transcription start sites given the same number of total peaks called. We found that each method has its own advantages. For example, we found that varying-coefficient Negative Binomial model performs better than varying-coefficient Poisson model for the domains showing over-dispersion based on Jin et al (2013)'s Hi-C data. This motivates us to consider a combined two-step peak-calling method, where the level of dispersion is quantified in the first step to guide the method of choice in the second step.

Haplotype based fine mapping algorithms using meta-analysis summary results. *J. Zheng[1, 5], S. Rodriguez[1], J. White[2], C. Giambartolomei[2], D. Zabaneh[2], R. Morris[3], M. Kumari[2], J.P. Casas[2, 3], A. Hingorani[2, 4], T.R Gaunt[1, 5], I.N. Day[1], UCLEB Consortium.* 1) Bristol Genetic Epidemiology Laboratory, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) University College London Genetics Institute, Department of Genetics, Environment and Evolution, London, United Kingdom; 3) 3.Department of Primary Care & Population Health, University College London, Royal Free Campus, London, United Kingdom; 4) Centre for Clinical Pharmacology, University College London, London, United Kingdom; 5) MRC Integrative Epidemiology Unit, School of Social and Community Medicine, Bristol, United Kingdom.

Meta-analysis of multiple genome-wide association studies (GWAS) is becoming a popular method to increase statistical power and reduce false positive findings. As a follow-up procedure to meta-analysis, detecting secondary association signals at loci are necessary to determining variants with true causality. However, individual-level data is often not pooled, making fine mapping of associated loci via conditional analysis time consuming and impractical. Here, we present two statistical methods, Sequential Sentinel SNP Regional Association Plot" (SSS-RAP) (Zheng et al., 2013) and E-M algorithm HAPlotype-based Regional Association analysis Program (HAPRAP) (Zheng et al., 2014, under review). Both methods enable fine mapping using group-level summary statistics and reference haplotype information. SSS-RAP detects SNPs with independent effects conditional on the top associated signal. HAPRAP extends multiple regression and conditional analysis to meta-analysis levels. We demonstrate by a performance comparison that SSS-RAP is as accurate as conditional analysis and ten model selection methods in individual-level. We compare HAPRAP with existing methods using simulated data, BWHHS cohort and 1000 Genomes. The results of HAPRAP are highly consistent with multiple regression results using individual-level data. Moreover, HAPRAP consistently outperforms GCTA joint and conditional analysis (Yang et al., 2012) across different linkage disequilibrium (LD) correlations (r^2) and reference panel sample sizes. The Web-based interfaces of SSS-RAP and HAPRAP are available online: http://apps.biocompute.org.uk/sssrap/sssrap.cgi and http://apps.biocompute.org.uk/haprap.

1743S

PedBLIMP: A Linear Predictor based Approach to Impute Genotypes in Pedigrees. *W. Chen, D. Schaid.* Department of Health Sciences Research, Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN., USA.

Recently, Wen and Stephens proposed a linear predictor, called BLIMP, that uses conditional multivariate normal moments to impute genotypes with accuracy similar to current state-of-the-art methods. One novelty is that it regularized the estimated covariance matrix based on a model from population genetics. We extended multivariate moments to impute genotypes in pedigrees. Our proposed method, PedBLIMP, utilizes both the linkage disequilibrium (LD) information estimated from external panel data and the pedigree structure or identity by descent (IBD) information. By stacking the genotype matrix of single nucleotide polymorphisms (SNPs) for all individuals in a pedigree into a vector G, we showed that the mean of G is essentially the same as the mean of genotypes for any individual which can be estimated from external panel data. The covariance of G is a Kronecker product of two matrices. The first is the covariance matrix between SNPs within the same individual and the second is the correlation matrix between individuals in the pedigree. The first covariance matrix can be estimated from external panel data similarly as in BLIMP. The second matrix can be estimated in two ways. For global correlation, it is twice the kinship matrix which can be estimated from the pedigree structure. When genotype is available for pedigree members, local correlation of a specific locus or region between two individuals can be estimated based on inferred IBD in each region. *gl_auto* from MORGAN package is used to sample inheritance vectors and IBD is estimated accordingly. With the estimated mean and covariance of G, the best linear predictor is applied to estimate the expected dosage of untyped markers. The proposed method was evaluated on a pedigree design where some individuals were genotyped with dense markers and the rest with sparse markers. We found that incorporating the pedigree/IBD information can improve imputation accuracy compared to BLIMP. Because rare variants usually have low LD with other SNPs, incorporating pedigree/IBD information largely improved imputation accuracy for rare variants. We also compared PedBLIMP with IMPUTE2 and GIGI. Results show that when sparse markers are in a certain density range, our method can outperform both IMPUTE2 and GIGI. Our developed software PedBLIMP may be useful for imputing small to medium sized pedigrees where some individuals are densely genotyped and other individuals are sparsely genotyped.

1744M

Detecting maternal-offspring gene interactions using linear mixed effect models: The Quantitative-MFG Test. *M.M. Creek[1], E. Sobel[2], J.S. Sinsheimer[1,2,3].* 1) Department of Biostatistics, University of California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA; 3) Department of Biomathematics, University of California, Los Angeles, Los Angeles, CA.

The genetic etiology of many complex diseases remains to be discovered. Maternal and offspring gene interactions or maternal-fetal genotype (MFG) incompatibility may be a contributor. MFG incompatibilities occur when the effects of maternal genes on the offspring's phenotype vary depending on the offspring's genotype and have been shown to be involved in complex diseases such as schizophrenia and autism. Existing methods to investigate the effects of MFG incompatibility on quantitative traits using retrospective likelihoods are limited to case-parent trios. Presently, there are no methods to investigate the effects of MFG incompatibility on quantitative traits that are suitable for both small and large families. We propose the Quantitative-MFG (QMFG) Test, a prospective approach using a linear mixed effects model, which takes into account familial correlations by partitioning the variance. This approach can handle varying pedigree sizes, general and specific scenarios of MFG incompatibility, and the inclusion of covariates. We validate the model under two familiar maternal-offspring gene interaction scenarios, RHD and NIMA incompatibility. We estimate type I error rates and power by simulation and investigate the effect of risk allele frequency on power. The type I error rates for both scenarios are approximately 0.05 (SE=0.003). When the expected variance explained by a specified effect size is 1% the power is over 0.8 for RHD incompatibility and is over 0.7 for NIMA incompatibility when testing for any genetic effect, a NIMA effect, or an offspring effect with sample sizes of 500 nuclear families. Simulations demonstrate that parameters and variances are well estimated and that this method works with arbitrary sets of families. Additionally, we find that treating the nuclear families within an extended pedigree as independent results in inflated false positive rates, supporting the need of a test for association of MFG incompatibility and quantitative traits that utilizes all available family data.

1745T

On the null distribution of Bayes factors. *Y. Guan.* Pediatrics and Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

The p-value is the blood-love of many theoreticians and practitioners alike. A Bayesian procedure often faces an inconvenient demand of producing p-values. When a data analysis involves multiple testing, such as in a genome-wide association study, the significant threshold of the p-value is exceedingly small, owing to Bonferroni correction, and it requires a prohibitively large number of permutations to produce a p-value. Thus, characterizing the null distribution of Bayes factors, which enables one to compute p-values without the need of permutation, is of practical importance. On the other hand, it is beneficial to understand how priors affect Bayes factors under the null, which may in turn shed light on prior specification. We investigated how priors affect the null distribution of Bayes factors for Bayesian linear regression (of p covariates) under the Normal-Inverse-Gamma prior specification. For a finite sample, the null distribution of $2 log(ext{Bayes factor})$ under the independent prior is approximately a mean-shifted linear combination of chi_1^2, whose distribution function can be evaluated using an existing polynomial algorithm, and hence the corresponding p-value of a Bayes factor can be computed efficiently, without the need of permutation. The independent prior favors null for a large sample size; Zellner's g-prior does not--asymptotically, $2 log{(ext{Bayes factor})} sim g/(1+g) chi^2_p - p log(1+g) + O(1)$ under the g-prior.

1746S

Mixed model with correction for case-control ascertainment increases power in multiple sclerosis association study. *T. Hayeck[1], N. Zaitlen[2], P. Loh[3], B. Vilhjalmsson[1], S. Samuela[1], A. Gusev[1], J. Yang[3], G. Chen[3], M. Goddard[4], P. Visscher[3], N. Patterson[5], A. Price[1].* 1) Harvard School of Public Health, Boston, MA; 2) University of California, San Francisco, CA; 3) University of Queensland, Brisbane, Australia; 4) University of Melbourne, Melbourne, Australia; 5) Broad Institute, Cambridge, MA.

We introduce a Liability Threshold Mixed Linear Model (LTMLM) association statistic for ascertained case-control studies that increases power vs. existing mixed model methods, with well-controlled false-positive rate. Recent work has shown that existing mixed model methods suffer a loss in power under case-control ascertainment (Yang et al. 2014 Nat Genet), but no solution has been proposed. Here, we solve this problem using a chi-square score statistic computed from posterior mean liabilities (PML) under the liability threshold model. Each individual's PML is conditional not only on that individual's case-control status, but also on every individual's case-control status and on the genetic relationship matrix obtained from the data. For example, disease cases with higher genetic relationships to other disease cases are assigned a larger PML than disease cases with lower genetic relationships to other disease cases. The PML are estimated using a multivariate Gibbs sampler, with the liability-scale phenotypic covariance matrix based on the genetic relationship matrix (GRM) and a heritability parameter estimated via Haseman-Elston regression on case-control phenotypes followed by transformation to liability scale (Lee et al. 2011 AJHG). Leave One Chromosome Out (LOCO) analysis was used to calculate the GRMs, avoiding the decrease in power that arises from including candidate SNPs in the GRM (Yang et al. 2014 Nat Genet).The Gibbs sampler does not iterate over SNPs, thus overall running time is comparable to existing mixed model methods. In simulations of unrelated individuals, the LTMLM statistic was correctly calibrated and achieved higher power than existing mixed model methods in all scenarios tested, with the magnitude of the improvement depending on sample size and severity of case-control ascertainment. In a WTCCC2 multiple sclerosis data set with greater than 10,000 samples, LTMLM was correctly calibrated and attained a 4.1% improvement (P equal 0.007) in chi-square statistics (vs. existing mixed model methods) at 75 known associated SNPs, consistent with simulations. Larger increases in power are expected at larger sample sizes. In conclusion, an increase in power over existing mixed model methods is available for ascertained case-control studies of diseases with low prevalence.

1747M

GARFIELD - GWAS Analysis of Regulatory or Functional Information Enrichment with LD correction. *V. Iotchkova[1,2], M. Geihs[1], G. Ritchie[1,2], E. Birney[2], I. Dunham[2], N. Soranzo[1], UK10K Consortium Cohorts Group.* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, CB10 1HH, United Kingdom; 2) The EMBL-European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, CB10 1SD, United Kingdom.

Genome-Wide Association Studies (GWAS) have been increasingly fruitful in discovering genotype-phenotype associations. The mechanisms underlying these associations, however, are still largely unknown as only a small fraction of these SNPs directly alter protein-coding genes. The interpretation of functional consequences of non-coding variants has been greatly enhanced by large-scale efforts to identify regulatory genomic regions (e.g ENCODE). However, robust methods are still lacking to systematically evaluate the contribution of these regions to genetic variation implicated in diseases or quantitative traits. Here we propose a novel approach that leverages GWAS findings with regulatory or functional annotations to find features relevant to a phenotype of interest. We perform greedy pruning of GWAS SNPs (LD r^2>0.1) and then annotate them based on functional information overlap. Next, we quantify Fold Enrichment (FE) at various GWAS significance cutoffs and assess them by permutation testing, while matching for minor allele frequency, distance to nearest transcription start site and number of LD proxies (r^2>0.8). Within this framework, we account for major sources of confounding that current methods do no offer. Using our method, we analysed publicly available GWA summary statistics on 16 disease and quantitative traits in 1005 annotations, including genic elements from GENCODE and DNaseI hypersensitive sites (DHS) for a range of cell types from ENCODE and Roadmap Epigenomics. Results showed coding exons as consistently highly enriched among traits, but also uncovered various trait specific enrichment patterns. For example, Height was significantly enriched in nearly all DHS cell types, consistent with its polygenic nature, while Crohn's disease exhibited enrichment predominantly in blood and intestines. We then systematically compared enrichment levels between associations from whole genome sequencing (WGS from the UK10K project) and sparser genotyping datasets (e.g. HapMap). When applied to 4 main lipid subfractions, the method found predominantly larger FE values as well as larger number of significant enrichments in the WGS data, highlighting a greater sensitivity of WGS data. Finally, we developed new software to facilitate the application of our method by the research community. Overall, it is expected that a more accurate classification of enrichment patters might lead to biological insights and help prioritise variants for follow-up studies.

1748T

Comparison of machine-learning methodologies to prioritize genetic variants based on functional data. *S.A. Gagliano[1,2,3], R. Ravji[1,2,3], M.R. Barnes[4], M.E. Weale[5], J. Knight[1,2,3], Schizophrenia Working Group of the Psychiatric Genomics Consortium.* 1) Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Canada; 4) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom; 5) Department of Medical & Molecular Genetics, King's College London, Guy's Hospital, London, United Kingdom.

Incorporating a variety of functional characteristics as predictors, such as DNase I hypersensitive sites, transcription factor binding sites, and histone modifications, we developed a methodology using elastic net, a regularized regression, to prioritize genetic variants that are truly associated with complex disease (Gagliano et al. PLoS ONE 2014). We compared the results from our elastic net method to two other published methods: Ritchie et al. (Nat Methods 2014) and Kircher et al. (Nat Genetics 2014). These models use different methodologies (modified random forest and a support vector machine, respectively) and different predictors with regard to the quantity, type and coding of the functional characteristics. We tested which methodology performed the best for prioritizing sub-genome-wide-significant variants (5E-8<p<1E-6) by investigating which one assigned higher scores to the sub-genome-wide-significant variants from the first round of a schizophrenia genome-wide association study (GWAS) that come up as associated in the second round, and lower scores to those variants that do not come up as associated. We obtained prediction values of the sub-genome-wide-significant variants in the first round of the schizophrenia GWAS by the Psychiatric Genomics Consortium (PGC1, Schizophrenia GWAS Consortium, 2011) for the three methodologies. A quantile-quantile plot was created using the p-values from the larger second round of the schizophrenia GWAS (PGC2, submitted) stratified for each of the methodologies by the sub-genome-wide-significant variants from the first round belonging to the top and bottom quartiles with regard to their prediction value. Elastic net outperforms the other two methodologies when it comes to identifying truly associated genetic variants in the schizophrenia GWAS. We are also exploring the use of the different algorithms, for instance, elastic net compared to random forest, while holding constant the functional characteristics used in order to discriminate performance differences as being attributed to the methodology and/or the functional predictors.

1749S

A mixed model methodology to correct technical artifacts and enable meta-analysis of sequence based association studies. *C. Murphy[1], P. Syrris[2], P. Lambiase[3], D. Speed[1], V. Plagnol[1], UCL-exomes Consortium.* 1) Genetics Institute, University College London, London, United Kingdom; 2) Institute of Cardiovascular Science, University College London, United Kingdom; 3) Heart Hospital 16-18 Westmoreland Street London W1G 8PH.

High throughput DNA sequencing technologies, either whole exome (WES) or whole genome (WGS) sequencing are revolutionizing the diagnosis and novel gene discovery for rare disorders. As the field transitions from the early discovery for Mendelian and near Mendelian diseases to more complex and oligo-genic diseases, there is substantial benefit in being able to combine data across studies, performing the type of meta-analysis for cases and controls that have proven to be so successful for genome-wide association studies (GWAS). However, WGS and WES are substantially more affected by sequencing errors and technical artifacts than genome-wide genotyping arrays. As a consequence, meta-analysis of sequence based association studies are often dominated by spurious associations, which result in technical limitations. Here, we show that it is possible to take advantage of the type of mixed models developed initially to control for population structure in GWAS studies, and apply these ideas to control for technical artifacts. We developed computational improvements to optimize the estimation of the mixed model parameters to enable genome-wide testing in a realistic time (from days to minutes). These techniques are being implemented as part of the LDAK package (www.ldak.org). Using a dataset of 2,800 WES (UCL-exomes), which aggregates a diverse set of studies, we demonstrate that substantial reduction in the association statistic inflation can be achieved by applying these novel analytical techniques, both for single variant and gene based tests, while preserving the sensitivity of the test. We focus on several cardio-vascular diseases (ARVC and sudden cardiac death) to illustrate the ability of these novel methods to produce more interpretable results. Our methodology provides a general framework to facilitate current and future meta-analysis of sequence based association studies.

Sparse heterogenetic sequence association mapping with arbitrary population structure and cryptic relatedness. *H. Qin[1], W. Ouyang[1], X. Chen[2], M. Xiong[3], G. Gao[4], HS. Chen[5], YP. Wang[6], HW. Deng[1], X. Zhu[7].* 1) Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA 23298, USA; 3) Human Genetics Center and Division of Biostatistics, The University of Texas School of Public Health, Houston, TX 77030, USA; 4) Department of Biostatistics, Virginia Commonwealth University School of Medicine, Richmond, VA 23298, USA; 5) Surveillance Research Program, Division of Cancer Control and Population Sciences, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892, USA; 6) Department of Biomedical Engineering, Tulane University, New Orleans, LA 70118, USA; 7) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH 44106,USA.

High-throughput DNA sequencing technologies have been generating datasets of massive rare and common genetic variants. In a typical sequence dataset, a short genomic region may contain sequences of many single-nucleotide polymorphisms (SNPs). For example, in the sequence data of Mexican pedigrees from GAW18, 68% of all the 11,933 non-overlapped 100-kb regions on odd chromosomes contain more than 500 SNPs. It is a fundamental challenge to identify a high-dimensional SNP set with sparse functional variants, where the set size m is close to or larger than the sample size n. Existent prominent association methods appear suitable to identify dense low dimension SNP sets, i.e., m/n<10%, and >20% of set wise SNPs are functional loci. Such methods are ineffective and insufficient to identify sparse high-dimensional SNP sets due to perceived limitations. First, they may be severely confounded by inherent population structure and cryptic relatedness when applied to high-dimensional sets of rare and/or common variants. Second, they suffer unnecessarily large degrees of freedom due to massive neutral variants. Third, they model mean genetic effects only and ignore inherent heterogeneity. In this report, we propose an efficient method for identifying sparse high- dimensional sets from sequence data with arbitrary population structure and cryptic relatedness. In this method, we first perform a heterogenetic feature selection to search for k (< n×10%) SNPs that best explain phenotypic data; we then link the selected variants with the confounders by a hetero heterogenetic mixed-effect model and perform likelihood ratio test for the genetic effects. In both feature screening and formal association test, we model population structure as fixed effect and model cryptic relatedness as a random effect in respective heterogenetic mixed-effect models. Under extensive simulations, the proposed method properly controlled type I error rates and appeared more powerful than existent prominent sequence association methods (e.g., SKAT, famSKAT and fastLMM). The proposed method is computationally efficient, integrates heterogeneity and diverse genetic effects, and simultaneously adjusts for arbitrary covariates and cryptic relatedness. Application to the deep sequence data of Mexican American pedigrees from GAW18 demonstrated practical utility of the proposed method.

Estimation of prognostic marker genes by public microarray data in patients with ovarian cancer epithelial. *S. Yang, J. Kim.* Biomedical Sciences Dept, Seoul National University College of Medicine 103 Daehakno, Jongnogu, Seoul 110-799, KOREA.

Lymphatic invasion is regarded as a predictor of aggressiveness of ovarian cancer. However, lymphatic invasion do not accurately represent 5 years survival. To diagnosis and treatment of ovarian cancer, we analyzed the differentially expressed genes between 5 years survival group and 5 years death group of lymphatic invasion in serous ovarian epithelial cancer with DNA microarray. Data from 63 ovarian cancer patients with lymphatic invasion and 35 ovarian cancer patients without lymphatic invasion from TCGA data were analyzed. Among these 98 patients, 16 patients were survived 5 years or more. DEGs identified by Bioconductor R package. Functional analysis of genes that were analyzed with DAVID web tool. We found 20 DEGs (P value<0.001) from 5 years survival 64 patients and 5 years death 8 patients without lymphatic invasion. Also we found 55 DEGs (P value<0.01) from 5 years survival 55 patients and 5 years death 8 patients with lymphatic invasion. Pathway analysis showed that the lymphatic invasion related DEGs were related with starch and sucrose metabolism pathways while lymphatic invasion related DEGs were related with renal cell carcinoma pathways. These DEGs for ovarian cancer results in high grade serous ovarian cancer patient survival, particularly in 5 years death and survival patients with and without lymphatic invasion. These findings may have implications for the diagnosis and treatment of the ovarian cancer.

1752S

Modeling Temporal Changes in Phenotypes in Pediatric Populations. *R. Hoffmann.* QHS, Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Statement of Purpose: During the first year of life, pathways develop and change in importance leading to the presentation of different phenotypes over time. Thus statistical genetic methods are needed which allow the phenotype-genotype model to change over time. This model developed here allows both regular and irregular sampling time points to be incorporated. **Methods:** A generalized linear mixed model (GLMM) was used to model the change in phenotype over time. This allows variability in the phenotype between subjects to be modeled, changes in the phenotype-genetic relationship over time within subjects to be modeled, the choice of different types of phenotypic relationships to be modeled (binary, categorical, normal and skewed-continuous) and testing of whether different models are appropriate for different variants at the same locus. In addition the functional form can be adjusted to the times at which the data was collected. In our case, 2 days, 7 days, 30 days, 90 days, 180 days and 360 days. We compared smooth parametric models for the relationships with non-parametric models which allow the values to be estimated at each sampling time point. Simulations were based on using an underlying fractional polynomial model over time so that sufficient differences in shape could be tested. **Results:** While the parametric model had more power if the model was known, in practical situations where the model is not known, the non-parametric model had both more power and more sensitivity to detect unknown relationships. The non-parametric GLMM also had a substantial advantage in correctly identifying models where the data was irregularly sampled at different time points and models with irregular behavior (peaks and troughs) over time. These relationships were poorly modeled by parametric models, even with sin-cosine terms (standard time series) because of the tendency to over-smooth the relationship over time.

1753M

A novel meta-analysis approach for genome-wide association studies with sex-specific effects. *E. Kang[1], J. Joo[2], N. Furlotte[1], E. Kostem[1], B. Han[3,4,5,6], E. Eskin[1,7].* 1) Department of Computer Science, UCLA, Los Angeles, CA; 2) Interdepartmental Program in Bioinformatics, UCLA, Los Angeles, CA; 3) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Division of Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) Partners Center for Personalized Genetic Medicine, Harvard Medical School, Boston, MA; 6) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 7) Department of Human Genetics, UCLA, Los Angeles, CA.

Over the past several years, a significant amount of loci implicated in genome wide association studies show differences in effect sizes for males and females. The prevalence of sex-specific effects both motivates strategies for discovery of sex-specific effects as well as raises questions of how to analyze association studies consisting of both males and females. The traditional approach to discover sex-specific effects is to analyze each sex separately and the traditional approach to analyze association studies consisting of both males and females is to include sex as a covariate in the statistical model when performing association analysis. Unfortunately, these approaches may lead to a loss in power when sex-specific effects are present at the loci being tested. In this paper, we present a novel meta-analytic approach for the analysis of genome-wide association studies consisting of both males and females. In our approach, males and females are analyzed separately and the results are combined using a random effects meta-analysis approach allowing for differences in effect sizes between sexes. We show that by analyzing males and females separately, our method reduces the overall variance in each study leading to an increase in statistical power. Through simulations and application of our method to the Northern Finland Birth Cohort data, we show that our method has increased power over the traditional approaches for discovering associated loci with and without sex-specific effects while controlling for false positives.

1754T

Mapping of novel regulatory influences on genes encoding subunits of the L-type calcium channel, using digital measurement of allelic skew. *N. Kamitaki[1,2], S. Ghosh[2,3], K. Eggan[2,3,4], S.A. McCarroll[1,2].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Harvard Stem Cell Institute, Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, MA; 4) Howard Hughes Medical Institute, Cambridge, MA.

Most of the SNP haplotypes implicated by genome-wide association studies (GWAS) do not include protein-coding variants, suggesting that the functional variant(s) has a regulatory function. One of the more proximal phenotypes to genotype is gene expression, but precise quantification of gene-regulatory effects in brain has both biological and technical challenges - in particular, genetic background and sample-to-sample variability from varying mixtures of different cell types in a complex tissue. Allele-specific expression can be used to control for environmental and trans-acting genetic influences, but techniques for measuring allele-specific expression often exhibit amplification bias or are insufficiently sensitive to detect modest, quantitative effects on gene expression. We developed a set of new molecular and statistical methods for making precise digital measurements of allele-specific expression and using such measurements to map gene-expression effects. These methods include: 1) A novel molecular method for measuring allele-specific expression with high precision, by digital counting of alleles in RNA. 2) A novel molecular method for inferring the chromosomal phase of candidate regulatory variants with transcribed sequence variants; this method is fast and scalable, and we have validated it at genomic distances up to 200 kb. 3) Companion statistical methods for combining the results of these assays with genome-variation data to map regulatory effects on gene expression. We applied these methods to *post mortem* brain samples from 5 brain regions in 105 individuals, focusing initially on genes encoding subunits of the L-type calcium channel, now implicated in genetic studies of schizophrenia and bipolar disorder. Using this approach, we were able to map novel regulatory effects that have not been identified in expression QTL studies of the same genes. For example, we find multiple LD-independent effects on the expression of *CACNA1C*; both effects replicated in an independent set of post mortem brains. Some regulatory effects were brain-region-specific while another showed a regulatory effect consistent in magnitude across brain regions. We have introduced several variants into embryonic stem cells using the Crispr/Cas9 system and are currently differentiating these into neurons to evaluate effects on expression.

1755S

A Candidate Pathway Approach Identifies Multiple Gene-Environment Interactions in Association with Colon Cancer Risk and Survival. *N. Sharaf Eldin[1], M.L. Slattery[2], Q. Liu[1], C. Franco-Villalobos[1], B.J. Caan[3], J.D. Potter[4,5,6], Y. Yasui[1].* 1) School of Public Health, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Internal Medicine, University of Utah Health Sciences Center, Salt Lake City, Utah, USA; 3) Division of Research, Kaiser Permanente Medical Care Program, Oakland, California, USA; 4) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 5) Department of Epidemiology, School of Public Health, University of Washington, Seattle, Washington, USA; 6) Centre for Public Health Research, Massey University, Wellington, New Zealand.

Genetic association studies have traditionally focused on effects of individual genetic markers, usually single nucleotide polymorphisms (SNPs), on disease or phenotype. A comprehensive approach more suited to decipher causal relationships and underlying molecular mechanisms, however, considers multiple genes implicated in the same pathway and furthermore interacting with environmental exposures. This analysis aimed at assessing the interaction effects of the angiogenesis gene-pathway with three main lifestyle exposures (dietary protein intake, smoking, and alcohol consumption) on colon cancer risk and survival. Logic regression, which identifies Boolean combinations of predictor variables, was used to assess gene-pathway effects, followed by assessments of gene-environment interactions (GEIs) using logistic regression for risk and Cox's proportional-hazards models for survival. We analyzed data of 1,541 colon cancer cases and 1,934 controls from the Diet, Activity and Lifestyle as a Risk Factor for Colon Cancer Study conducted at three centers in the United States. The study selected a total of 257 SNPs in 34 genes in the angiogenesis candidate gene-pathway based on standard pathway maps and experimental evidence. We found five statistically significant GEIs for colon cancer risk and three GEIs for colon cancer survival with increasing levels of all three environmental exposures. For risk: FLT1 rs678714 and ≥ 20pack-years smoking (interaction odds ratio (ORINT) = 1.64, 95% confidence interval (CI) (1.11, 2.41)); FLT1 (rs2387632 OR rs9513070) and high animal protein intake (ORINT =1.69, 95% CI (1.03, 2.77)); KDR rs6838752 and heavy alcohol consumption (ORINT =1.53, 95% CI (1.10, 2.13)); BMP4 rs17563 and ≥ 20pack-years smoking (ORINT =1.60, 95% CI (1.10, 2.32)); and TLR2 rs3804099 and heavy alcohol consumption (ORINT =1.59, 95% CI (1.05, 2.38)). For survival: TNF rs1800630 and high animal protein intake (interaction hazard ratio HRINT =1.80, 95% CI (1.13, 2.86)); BMP1 (rs13257482 OR rs4075478) and ≥ 20pack-years smoking (HRINT =1.78, 95% CI (1.03, 3.09)); and BMPR2 rs12477602 and heavy alcohol consumption (HRINT =7.78, 95% CI (1.66, 39.03)). Our study shows that GEI effects on colon cancer risk and survival can be identified by adopting a comprehensive candidate pathway approach that emphasizes the biologic hypothesis in the selection of the pathway genes and environmental exposures and carries that logic through to the analysis.

1756M

Genome-wide association study in West Africans identifies SEMA4D as a susceptibility gene for Obesity. *G. Chen, A. Bentley, A. Doumatey, D. Shriner, J. Zhou, A. Adeyemo, C. Rotimi.* Center for Research on Genomics and Global Health, National Human Genome Research Institute, NIH, Bethesda, Maryland, USA.

The burden of obesity, a major risk factor for several cardio-metabolic disorders and some cancers, has reach epidemic proportion in several global populations. Thus, understanding the etiology of excess weight gain is a scientific and public health imperative. Although, more than 20 GWAS have been reported for obesity and related traits, none has been conducted in continental Africans. Here, we report on the first GWAS for Body Mass Index (BMI) using a total of 21.2 million SNPs in 1624 West Africans. We identified a novel genome-wide significant locus at 9q22.2 (SEMA4D, rs80068415 p = 2.10 × 10-8). SEMA4D has been reported to be crucially involved in the activation and differentiation of T cells and the promotion of Th1 (T helper 1) differentiation. Interestingly, Th1 polarization in adipose tissues has been observed in mice with diet induced obesity. We also identified five suggestive evidences of association in 2q31.1 (NOSTRIN p = 1.30 × 10-7), 5q32 (PPP2R2B, p = 1.26 × 10-7), 11p13 (SLC1A2, p = 7.56 × 10-8), 14q21.1 (LRFN5p = 9.16 × 10-8), and 15q15.1 (NUSAP1, p = 2.15 × 10-7). We used 3,000 bootstraps and 3,000 simulation studies to confirm identified associations. Of the reported 92 GWAS loci, 83 were available for assessment for possible transferability in this sample of West Africans. Notably, 56 of the 83 loci (67.5%) displayed trans-ethnic implications for obesity. In all, this first GWAS for obesity in Africans identified a novel gene (SEMA4D) for obesity and confirms several reported loci in European ancestry populations to be potentially important for obesity in Africans.

1757T

Effect Fine Mapping: a method to identify association-driving variants in large genomic datasets. *N.A. Patsopoulos[1, 2, 3], J. Replogle[1, 2, 3], A.H. Beecham[4], A. Brandes[3], J. Oksenberg[5], J.L. McCauley[4], S.E. Baranzini[5], C. Cotsapas[3, 6, 7], P. De Jager[1, 2, 3].* 1) Department of Neurology, Brigham & Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, Florida, USA; 5) Department of Neurology, University of California, San Francisco, Sandler Neurosciences Center, San Francisco, California, USA; 6) Department of Neurology, Yale University School of Medicine, New Haven, Connecticut, USA; 7) Department of Genetics, Yale University School of Medicine, New Haven, Connecticut, USA.

Although genome-wide association studies (GWASs) have been extremely successful in identifying a plethora of validated genetic associations, only a handful of casual variants have been identified to date. Even fine-mapping efforts with dedicated, high-density arrays designed to capture the majority of variation in a locus (e.g. ImmunoChip), or extensive re-sequencing studies have not been as successful in identifying such variants as expected. In a recent ImmunoChip analysis of multiple sclerosis individuals, state of the art methods could fine-map only 8 out of 68 confirmed loci to high resolution. More importantly, in only 5 of these 8 could we identify one variant accounting for more than 50% of the posterior probability to drive the association. Here we argue that, beyond uncertainty due to linkage disequilibrium, fine-mapping may be impaired by the presence of multiple independent effects in a locus or by true causal alleles being non-SNP variation. We address these issues in a method, effect fine mapping (EFM), based on information criterion theory that aims to identify the group of genetic variants that drive the statistical association. The method can easily be implemented in existing analytical models, under a frequentist or Bayesian framework, with or without permutations. We demonstrate how it can be used to capture the set of SNPs that explain the statistical signal of association (EFM set), and, in cases of one driving variant, how it can be equivalent of fine-mapping methods aimed to prioritize causal variants,. By applying EFM in large-scale genetic data we illustrate that most of the identified effects are mediated not by a single genetic variant but by many, which in some cases overlap more than one genes. Next, we illustrate how one can use the EFM set to prioritize genes and use this information in pathway, network, and enrichment analysis. Finally, we use the EFM set to estimate, via model averaging, one effect size and p-value for the identified effect that can be used to minimize winner's curse and assign summary statistics to associated loci or genes.

The study of epistasis and pleiotropic effects using multi-association for metabolic syndrome in Korean population-based cohort. *Y. Lee, S. Park, B. Han, B. Kim, J. Lee.* Korea National Institute of Health, Chungcheongbuk-do, South Korea.

Metabolic syndrome (MetS) is a kind of disease which is determined co-occurrence of three of five following medical conditions: abdominal obesity, elevated blood pressure, elevated fasting plasma glucose, high serum triglycerides, and low high-density cholesterol levels. It is well known that people with MetS become more dangerous to cardiovascular disease (CAD) or type 2 diabets mellitus (T2D). For several years, many genome-wide association studies (GWASs) have been conducted, but the genetic determinants of the MetS were still unknown. Recently, MFQLS tool which is likely to analyze the association between multi traits and multi genetic information was developed. In this study, we conducted multi-association (both multi traits-unit SNP and multi traits-multi SNPs) with MetS while adjusting age and sex. For the multi-association study, we divided this analysis into two step: genetic association study using the Korea Association Resource (KARE) cohort and replication study using the Health Examinee (HEXA) cohort. Also, this analysis was performed whether common genetic variants have pleiotropic effects accounting for some of the interaction among five metabolic phenotypes that define MetS and common genetic variants have the epistasis effects to illustrate the gene-gene interaction for MetS.

1759M

Analysis of pleiotropy at a fine genomic scale. *D.J. Balding, D. Speed.* Inst Genetics, Univ College London, London, United Kingdom.

Bivariate SNP-based heritability analysis is being widely applied to measure the overlap in genetic architecture between pairs of diseases. It is especially popular for psychiatric diseases, as better understanding of the concordance or discordance between different traits can inform nosology and improve prediction of disease progression. Given SNP-level data for a pair of diseases, the approach implemented in the software GCTA returns an estimate of ρ, the genome-wide average correlation between the SNP effect sizes for each trait: ρ>0 indicates that risk alleles for the first disease tend to also increase risk for the second, and vice-versa. A recent study considered five psychiatric disorders (schizophrenia, bipolar disorder, major depressive disorder, autism spectrum disorders (ASD) and attention deficit hyperactivity disorder (ADHD)), and found significant concordance (ρ>0) for five of the ten pairings; the strongest concordance was reported for schizophrenia and bipolar disorder, in line with previous knowledge of the overlap between these two conditions. A major limitation of this approach is that ρ represents concordance averaged across the entire genome, which means that similarity in one genomic region can be cancelled out by dissimilarity in another. Furthermore, a significantly non-zero estimate of ρ provides no indication of which genomic regions are concordant or discordant, knowledge of which which would assist in identifying shared genes and pathways. We propose a tool for measuring concordance at a fine genomic scale, at the level of individual genes or short genomic regions. Using computational optimization, our algorithm is extremely fast, able to analyse genome-wide data for many thousands of individuals in a matter of minutes. As proof of principle, our method identified the overlap between Rheumatoid Arthritis and Type 1 Diabetes, with substantial concordance in the major histocompatibility region. For two major subtypes of Inflammatory Bowel Disease, Crohn's Disease and Ulcerative Colitis, it identifies a gene where risk alleles for the former are protective for the latter. We re-examine the study of five psychiatric disorders, and find significant genomically-local concordance even where none exists genome-wide.

1760T

Development of efficient polygenic risk scores for personalized medicine: methodological concepts and examples. *K. Fischer[1], K. Läll[1], R. Mägi[1], A. Morris[2,1], A. Metspalu[1].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Polygenic risk scores have great potential in predictive personalized medicine, even in cases where each of the individual variants identified by a genome-wide association study has a relatively weak effect on the disease of interest. There are, however, several methodological issues that need to be considered while constructing such scores. First, the genetic variants to be used in such scores, as well as their relative weights, are often chosen on the basis of a discovery study. This may lead to overestimation of the real effect of the score, due to selection bias towards variants that have an effect that is overestimated by chance ("winners curse"). Another potential source of biases is present when the outcome is binary and the discovery study (or a replication study) uses simple logistic regression to estimate the effects. Due to non-collapsibility of the odds ratios, such estimates are biased estimates for the corresponding multiple regression coefficients (and for the optimal weights while combining the SNP allele counts to a polygenic score). A third source of biases is created by evaluating the score in a cohort that was included in the initial discovery study - especially when genetic variants with relatively weak effects are included. We demonstrate by simulations, as well as by application to polygenic risk scores for Type II Diabetes (T2D) in the Estonian Biobank cohort, how such biases can be corrected for. We will also show that the efficiency of the predictive score can be increased by adding more than just the genome-wide significant variants to the score, but only up to certain threshold. Adding too many variants with no clear effect would lead to decreased predictive power. In addition, we discuss ways to estimate the predictive ability of a polygenic risk score in the context of other predictors, such as the Body Mass Index, as well as communicate its effect to a public, using the example of T2D risk prediction in the Estonian Biobank.

1761S

A Proper and Efficient Approach to Integrative Analysis of Sequencing and GWAS Data for Rare Variant Associations. *Y.J. Hu[1], Y. Li[2,3], P. Auer[4], D.Y. Lin[2].* 1) Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 2) Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Genetics, University of North Carolina, Chapel Hill, NC; 4) Joseph J. Zilber School of Public Health, University of Wisconsin, Milwaukee, WI.

In the large cohorts typically used for genome-wide association studies (GWAS), it is not economically feasible to sequence all cohort members. A cost-effective strategy is to sequence subjects with extreme values of quantitative traits or those with specific diseases. By imputing the sequencing data from the GWAS data for the cohort members who are not selected for sequencing, one can dramatically increase the number of subjects with information on rare variants. However, treating the imputed rare variants as observed quantities in downstream association analysis may inflate the type I error, especially when the sequenced subjects are not a random subset of the whole cohort. Although this problem can be alleviated by restricting the analysis to the variants that are accurately imputed, a large number of rare variants will be excluded with this strategy. In this article, we show how to properly account for the uncertainties in the imputation of rare variants. We consider all commonly used gene-level association tests, including the burden test, variable threshold (VT) test, and sequence-kernel association test (SKAT), all of which are based on the score statistic for assessing the effects of individual variants on the trait of interest. We show that the score statistic based on the observed genotypes for sequenced subjects and the imputed genotypes for non-sequenced subjects is unbiased. We construct a robust variance estimator that reflects the true variability of the score statistic regardless of the sampling scheme and imputation quality, such that the corresponding association tests always have correct type I error. Through extensive simulation studies, we demonstrate that the proposed tests are substantially more powerful than the use of accurately imputed variants only or the use of sequencing data alone. An application to the data from the Women's Health Initiative (WHI) is provided. The relevant software is freely available.

1762M

Genetic Studies of Functional Quantitative Trait with both GWAS and Next-Generation Sequencing Data. *D. Lee[1], C. Hanis[2], G. Bell[3], D. Aguilar[4], B. Cade[5], J. Below[3], M. Xiong[2].* 1) Biostatistics, University of Texas School of Public Health, Houston, TX; 2) Human Genetic Center, University of Texas School of Public Health, Houston, TX; 3) Department of Human Genetics, University of Chicago, Chicago, IL; 4) Cardiology, Baylor College of Medicine, Houston, TX; 5) Division of Sleep Medicine, Harvard medical school, Boston, MA.

Traditional quantitative genetics has primarily studied traits with cross section data. However, in real biologic world, many quantitative traits change over time. These quantitative traits are repeatedly measured as functions of time or complete curves. The traditional methods for such genetic studies summarize the time or space varying traits as means across the time or space interval and reduce these functional quantitative traits as scalar traits. Another challenge for genetic studies of quantitative traits is to study genetics with next-generation sequencing (NGS) data. NGS can generate millions of genetic variation data. As a consequence, these genetic variation data are so densely distributed across the genome that can be modeled as a function of genomic location. In summary, random functions appear as either responses or predictors, or both. Although the current widely used statistical methods for QTL analysis are based on multivariate analysis, this method often fails with functional data. To overcome the limitations of the traditional QTL analysis for functional quantitative traits and NGS data, we use a functional linear model (FLM) in which a trait curve is modeled as a response function, the genetic variation in a genomic region is modeled as a functional predictor, and the genetic effects are modeled as a function of both time and genomic position. By extensive simulations, we demonstrate that the FLM for genetic studies of the temporal quantitative traits has the correct type 1 error rates and much higher power to detect association than the current regression methods. The proposed method is applied to 833 individuals with 20,763 genes from Starr County health studies sleep data where oxygen saturation were measured for 22,670 seconds on average. We found 65 genes that were significantly associated with oxygen functional trait with P-values ranging from 2.4E-6 to 2.5E-21, including gene RELB, which are confirmed in the literature. Among them, 8 genes that were located in metabolic pathways and NF-kappa B signaling pathway. The excellent QQ plot of our results showed that we did not inflate the false positive rates. However, using mean of oxygen saturation over the whole sleep time period as a quantitative trait, we only identified two genes associated with oxygen saturation. Our results clearly demonstrate that the FLM with both functional response and predictors substantially outperform the traditional genetic models with scalar trait.

1763T

Genotype risk score may mislead physiological interpretation of quantitative trait associations. *N. Wang[1,2,3], Y. Shu[1,2,3], H. Allayee[1,3], A. Xiang[4], T. Buchanan[5,2], R. Watanabe[1,2,3].* 1) Department of Preventive Medicine, Keck School of Medicine of USC, Los Angeles, CA; 2) Physiology and Biophysics, Keck School of Medicine of USC, Los Angeles, CA; 3) USC Diabetes & Obesity Research Institute, Keck School of Medicine of USC, Los Angeles, CA; 4) Department of Research and Evaluation, Kaiser Permanente Southern California, Pasadena, CA; 5) Department of Medicine, Division of Endocrinology, Keck School of Medicine of USC, Los Angeles, CA.

The genotype risk score (GRS) has been used as a measure of total genetic risk and a predictor of complex disease risk. Better understanding of the physiology of complex disease can be achieved by studying disease-related quantitative traits (QTs). GRS has recently been increasingly used to explore association with disease-related QTs, although its validity has not been examined. We tested 38 type 2 diabetes (T2D) risk SNPs for association with 17 T2D-related QTs in the BetaGene study, which consists of Mexican American families of probands with or without previous gestational diabetes. We compared association by single-SNP, GRS, and stepwise forward selection (FS), to assess which method provides clear physiological interpretation. We tested each SNP for univariate association with Bonferroni correction for 646 tests (38 SNPs×17 QTs), which is overly conservative due to correlation among QTs. GRS was constructed by summing risk alleles without weighting and testing for association. FS picked SNPs with a threshold of $P \leq 0.1$, followed by omnibus likelihood ratio test for association. All tests were adjusted for age, sex and familial correlation. 727 subjects with complete data, to ensure fair comparison, were included. Univariate testing identified KCNQ1 rs2237892 (P=0.030) and MTNR1B rs10830963 (P=0.041) associated with disposition index (DI) and GCKR rs780094 with triglyceride (P=0.036). The proportion of variation explained by GRS for the 17 QTs ranged from 0-2.7% (median=0.14%). GRS was only associated with 3 QTs: DI ($P=1.6\times10^{-5}$; 2.5% variation explained), acute insulin response (AIR, $P=4.6\times10^{-5}$; 2.7% variation explained), and glucose effectiveness (P=0.022; 0.68% variation explained). FS showed significant association with 16 of 17 QTs, with 3-11 SNPs entering into final models. The proportion of variation explained ranged from 1.1-8.5% (median=3.8%). The two strongest associations were for AIR ($P=2.7\times10^{-7}$; 11 SNPs accounting for 8.5% of variation) and DI ($P=9.9\times10^{-9}$; 8 SNPs accounting for 7.6% of variation). In summary, GRS was only associated with 3 of 17 QTs, while FS was associated with 16. GRS does not identify which loci contribute to the association with a given QT. FS identifies the subset of SNPs contributing to the association, providing detailed information facilitating physiologic interpretation. We conclude GRS may lead to misleading physiologic interpretation of genotype-phenotype relationships due to lack of detailed information.

Development and application of a population based statistical framework addressing the n=1 problem in human genetics. *A.B. Wilfert[1], M. Lek[2,3], J.N. Constantino[4], W.A. Gahl[5,6,7], E. Flynn[5,7], E. Valkanas[5,7], D.G. MacArthur[2,3], D.F. Conrad[1].* 1) Genetics, Washington University in St. Louis, St. Louis, MO; 2) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Psychiatry, Washington University in St. Louis, St. Louis, MO; 5) NIH Undiagnosed Diseases Program, NIH, Bethesda, MD; 6) Office of the clinical director, NHGRI, NIH, Bethesda, MD; 7) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

The diagnosis of rare, idiopathic diseases is emerging as a primary application of medical genome sequencing, and has motivated high-profile research efforts such as the NIH's Undiagnosed Diseases Program (UDP). However, the application of standard tools from genetic epidemiology for many of these cases is frustrated by a combination of small sample sizes, genetic heterogeneity and gene by environment interactions. In response, we have developed an inference framework that uses massive control population sequencing datasets to measure the disease potential of a genotype or diplotype in a sample size as small as a single individual, what we refer to as the "n=1" problem. Our framework is built on 3 principles that are advances on historically applied pathogenicity prediction algorithms. (1) Like others, we integrate multiple prediction algorithms to estimate the probability that a variant damages protein function. (2) Most prediction methods that we incorporate are **generic** in that they use the same model to annotate variation in all genes and are naïve to ploidy. We believe the best predictors will be **gene-specific** and **genetic** in nature and have taken steps towards this by integrating information on gene physiology using model-based measures of haploinsufficiency for all genes in the genome. (3) We use simulation, mutation rate modeling, and exome sequencing data from over 15,000 individuals to create a null model of "normal" genetic variation and estimate the probability of sampling a genotype or diplotype of a given pathogenicity score from healthy individuals. Our models have unmatched ability to discriminate putative disease mutations in the Human Gene Mutation Database (HGMD) from variants identified by population re-sequencing (AUC of 91% and 97%, respectively). We simulate over 30 million cases of the n=1 problem by spiking HGMD variants into 1092 healthy exomes from the 1000 Genomes Project. For 30% of all HGMD variants our gene-specific and genetic model always ranks them into the top 10 most pathogenic variants in an exome. The results of our modeling and spike-in analyses replicate when replacing HGMD with ClinVar data. We discuss the weaknesses of our approach and our attempts to identify areas for improvement. Finally, we apply our framework to a number of real-life n=1 cases, including a pair of twins from a consanguineous marriage concordant for Autism and several hundred cases from the NIH's Undiagnosed Diseases Program.

Meta-analysis on polygenic effects. *J.H. Zhao, J.A. Luan, S.J. Sharp.* MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, Cambridge Biomedical Campus, Cambridge, CB2 0QQ, United Kingdom.

Background: It has been shown recently that whole genome data can facilitate estimation of genetic contributions to a variety of traits via a mixed model framework (Yang et al. Nat Genet 2010, 42:565-9; Zhao & Luan. J Prob Stat 2012, doi 10.1155/2012.485174). Our aim was to use this approach to investigate the impact of meta-analysis using study specific summary statistics such as (the genomic) heritabilities and/or polygenic/residual variance components as composed to those estimates from individual level data. Methods: We analysed body mass index from population-based and family-based cohorts, EPIC-Norfolk, Fenland, and Framingham studies involving Affymetrix 500K and Affymetrix 6.0 SNPs, involving ~10,000 individuals in total. We obtained genomic relationship matrices, which were then used in mixed models as implemented in the computer program GCTA and alternative procedures in PLINK, R. We compared results from meta-analysis using summary statistics and from individual level data. We also conducted simulation experiments. Results: Although the participants in the three cohorts were all European descent, there was variability in their genomic heritability estimates, with point heritability estimates being ~20%, 30% and ~50%, respectively. In the case of Framingham data, although the familial and genomic relationship matrices did not necessarily take equal values numerically they yielded comparable estimates. When polygenic effects are involved, meta-analysis using either heritability or variance components generally agreed with those from individual level data but with larger standard errors, which were likely to be larger than those assuming independence between inter-cohort participants in other scenarios not involving polygenic effects. The availability of whole-genome data seamlessly allows for meta-analysis of population-based and family-based data under the polygenic model. We have made the relevant implementations available in the R/gap package. Conclusion: The work supports the utility of whole genome data in heritability estimation as well as availability of individual level data so as to account for correlation among all individuals. Further work will be to assess the uncertainty due to sampling of the genome as with other aspects of association analysis in the presence of polygenic effects.

Estimation of causal effects distribution from genome-wide association studies. *L. Zhang[1], Y.F. Pei[1], Y. Lin[2].* 1) School of public health, Soochow university, Suzhou, JiangSu, China; 2) University of Shanghai for Science and Technology, Shanghai, China.

Estimation of the distribution of causal SNP effects and their heritability from genome-wide association study has been a research interest as it could explain in part the mystery of missing heritability. In this study, we propose a novel statistical method for such estimation. Specifically, we study the full range of GWAS summary results and link observed p-values and unobserved effect sizes by (non-central) chi-square distributions. By modeling the observed full set of GWAS p-values into a multinomial event, we build likelihood function in terms of causal SNP effects. We present both parametric and non-parametric forms of maximal likelihood estimation. The simulation studies showed that the proposed method had the ability to accurately estimate the number of causal SNPs and their effect sizes. As a real application, we analyzed a publicly available GWAS summary dataset that was released by the GIANT consortium, for height trait. Our analyses showed that there was a total of over 6,000 SNPs that might be associated with height, and explained ~40% heritability, where the number was much larger than that was previously estimated. As a conclusion, our proposed method has the potential to estimate common SNP-based genetic basis of complex traits from large-scale GWAS meta-analyses results.

Price[1,4].* 1) Harvard School of Public Health, Boston, MA; 2) The University of Queensland, Brisbane, Queensland, Australia; 3) Massachusetts General Hospital, MA, USA; 4) Broad Institute, Cambridge, MA, USA; 5) Brigham & Women's Hospital, Boston, MA, USA; 6) Harvard Medical School, Boston, MA, USA; 7) Keck School of Medicine, USC, Los Angeles, CA, USA; 8) Schizophrenia Working Group of the Psychiatric Genomics Consortium; 9) Icahn School of Medicine at Mount Sinai, New York, NY USA; 10) UCSF, San Francisco, CA USA; 11) UCLA, CA Los Angeles USA; 12) The University of Melbourne, Parkville, Victoria, Australia.

Polygenic risk scores are a promising approach for predicting disease risk, with prediction accuracy expected to improve substantially as sample sizes increase (Chatterjee *et al.* 2013 Nat Genet; Dudbridge *et al.* 2013 PLoS Genet). The standard approach involves pruning variants in linkage disequilibrium (LD) and applying a P-value threshold to association statistics, but this discards information and may limit predictive accuracy. We developed a Bayesian polygenic risk score, LDpred (https://bitbucket.org/bjarni_vilhjalmsson/ldpred), that uses LD from a reference panel to estimate posterior mean causal effect sizes from GWAS summary statistics, producing optimal (best linear unbiased prediction) polygenic risk scores when model assumptions hold. These estimates have a closed-form solution under an infinitesimal prior where every marker is causal and effect sizes are drawn from a mean-zero normal distribution. Under a non-infinitesimal prior where only a fraction of markers are causal, we approximate them via Markov chain Monte Carlo (MCMC). In simulations using real genotypes, our LDpred method is more accurate than existing methods (particularly at large samples sizes), well-calibrated, and computationally efficient. We applied LDpred to seven WTCCC diseases and observed substantial improvements in prediction R^2 (Nagelkerke), e.g. for type-1 diabetes it improved from 30.4% to 37.8%. We also applied LDpred to two diseases for which we had GWAS summary statistics in large sample size and an independent validation dataset. The prediction R^2 (Nagelkerke) improved from 15.7% to18.3% for schizophrenia (SCZ) and 9.8% to 12.1% for multiple sclerosis. The relative improvement was larger when predicting in African-American SCZ validation samples (R^2 improved from 2.0% to 2.6%).

Mediation Analysis of Integrated Genetic and Genomic Data in the Presence of Missing Data. *R. Barfield, X. Lin.* Harvard University, Boston, MA.

It is of increasing interest to analyze integrated different types of genetic and genomic data. Mediation analysis provides a useful tool for analysis of integrated genetic and genomic data to understand disease causing mechanisms. In genetic and genomic studies, SNP data, such as GWAS or sequencing data, are often collected on all individuals enrolled in a study. The genomic data, such as gene expressions and DNA methylations are often collected in a subset of study subjects. When the two types of data are combined to perform an functional analysis, the individuals who only had the SNP data collected are typically ignored. These individuals however can still provide useful information to the analysis. We propose a mediation analysis method using all the data by leveraging the information from the individuals with only the SNP data. We show using all available data, we gained more efficient estimators of the direct effects of SNPs and the indirect effects of SNPs mediated through gene expressions/DNA methylations on a phenotype with varying levels of missingness. As the proportion of individuals with missing data increased, we gain an increase in the efficiency of our estimates. We also show power gain in detecting genetic and genomic associations using all available data. We applied our method to data from the MESA cohort using DNA methylation data and SNP data with obstructive sleep apnea as the outcome.

Discovering Disease Susceptibility Genes Using Predictors of the Transcriptome - PrediXcan. *H.K. Im, E.R. Gamazon, K. Shah, S. Mozaffari, H.E. Wheeler, J. Torres, L. Davis, N.J. Cox.* The University of Chicago, Chicago, IL.

Genome-wide association studies have found thousands of variants robustly associated with complex traits. However, for most of them the underlying biological mechanisms are not well understood. The enrichment of gene expression associated variants (eQTLs) among disease-associated variants indicates that a substantial component of trait variability is likely to be determined through the regulation of the transcriptome. We propose a method termed PrediXcan that directly tests this hypothesis by correlating genetically predicted gene expression levels with the phenotype. For this purpose, we developed prediction models of gene expression using data from multiple eQTL studies (GTEx pilot data, GEUVADIS/1KGenomes, Framingham). Among advantages of PrediXcan are that 1) actual gene expression levels are not needed since they are calculated directly from the genetic data, 2) mechanism of the effect is directly built into the test making biological interpretation straightforward, 3) unlike actual differential expression studies, disease status cannot affect in silico levels thus ruling out reverse causality, 4) it tells whether up or down regulation drives the risk, 5) multiple testing burden is greatly reduced. Using these models we computed the in-silico expression levels of 15200 genes in six disease studies from the Wellcome Trust Case Control Consortium (WTCCC). For example, in Rheumatoid Arthritis 23 HLA region genes were differentially expressed (genomewide significant threshold p<3.3e-6). Outside of the HLA region, RSBN1 (p=2.4e-6) and PSME1 (p=1.5e-7) were of interest. We found many positive control genes as well as many novel ones with replication efforts under way. In conclusion, we propose a powerful gene based association test that directly tests the hypothesis that genetic variants affect disease status through the regulation of genes. Application to the WTCCC data identified many novel genome-wide significant genes.

Statistics for genetic association in the presence of covariates - genome scanning considerations. *H. Lin[1], E. Feingold[1, 2], Y. Lin[1].* 1) Department of Biostatistics , University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

A number of different statistics are available for genetic association analysis in the presence of covariates. In the context of a genome-wide association study, hundreds of thousands to millions of SNPs are tested, and whatever covariate model we specify is likely to be imperfect., In addition, the results of the study often focus on the list of SNPs ordered according to the statistics rather than on certain p-value cutoffs. Therefore, it is important to investigate the behavior of extreme values of the statistics rather than the behavior of the expected values. Gail et al. (2008) discussed this issue and proposed “detection probability” and “proportion positive” to measure the success (power) of a genomic study when ranked lists are the primary outcome. In theory, the ranked lists can be dominated by SNPs with misfit models rather than by true positive results. We are conducting a comprehensive comparative study to investigate the behavior of different association statistics that model covariates. We evaluate the statistics from the perspective of which statistics can provide robust ranked lists of “top hits.” These are not necessarily the same statistics that have the highest power in a conventional single-test context.

1771M

Addressing Potential Bias in Heritability and Coheritability Estimates within Ancestrally Homogeneous Populations. *J. Liu[1,2,3], T.J. Hoffmann[1,2], J.S. Witte[1,2,3,4].* 1) Department of Epidemiology & Biostatistics, UCSF, San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Diller Family Cancer Center , UCSF, San Francisco, CA; 4) Department of Urology, UCSF, San Francisco, CA.

A substantial heritability of complex traits can be explained by considering all SNPs across the genome simultaneously using linear mixed-effects models with an estimated genetic relationship matrix (GRM). This approach has been extended to assess the coheritability—or potential shared genetic basis—among different traits, including psychiatric disorders, inflammatory bowel disease, and major chronic obstructive pulmonary disease-related traits. However, the estimated GRM used in such (co)heritability analyses depends on sample-based allele frequency estimates across the genome. Any systematic differences in allele frequency estimates among the study sample can lead to a biased GRM and incorrect (co)heritability estimates. For example, when calculating the coheritability of a trait across different ancestral populations, differences in their allele frequencies can over- or under-estimate the relatedness between ancestrally similar individuals, resulting in more exclusions of samples from the analysis, and biased GRM and (co)heritability. As shown previously, one can address this issue with (co)heritability among ancestrally distinct or admixed populations by calculating the GRM by using individual-specific (or population-specific) SNP allele frequencies based on the individual ancestry. However, little if any consideration has been given to the potential impact of this issue on (co)heritability estimation in relatively homogeneous populations. It is increasingly common to combine samples from different studies with similar ancestral backgrounds for (co)heritability analysis. Here, samples from different studies may typed on different genotype platforms or have distinct cryptic relatedness. As with ancestrally distinct or admixed populations, ignoring these differences can bias the GRM and in turn biased (co)heritability estimates. We highlight this issue with two examples: 1) the bias in estimating lung cancer heritability within a European population comprised of samples from three studies; and 2) the bias in estimating the coheritability of lung-breast cancer within European population in which the traits are measured on different samples. In addition, we show that the allele frequency adjustment approach mentioned above is able to correct the bias efficiently. Our findings emphasize the need to control for the bias due to allele frequency differences between groups of samples even when they appear to be from a relatively homogeneous population.

A new prognostic model to predict renal outcome in autosomal dominant polycystic kidney disease (ADPKD). *E. Cornec-Le Gall[1-4], MP. Audrézet[2-4], M. Hourmant[5], MP. Morin[6], C. Charasse[7], E. Renaudineau[8], B. Wehbe[10], P. Jousset[11], MP. Guillodo[12], N. Terki[13], S. Benarbia[14], R. Perrichot[16], T. Sawadogo[9], S. Régnier-Le Coz[15], C. Savoiu[17], Y. le Meur[1-2], C. Ferec[2-4, 18], the Genkyst Study Group.* 1) Department of Nephrology, Centre Hospitalier Universitaire de Brest; 2) Université Occidentale de Bretagne; 3) INSERM U1078; 4) Department of Molecular Genetics, Epidemiologic Genetic and Histocompatibility, Centre Hospitalier Universitaire de Brest; 5) Department of Nephrology, Centre Hospitalier Universitaire de Nantes; 6) Department of Nephrology, Centre Hospitalier Universitaire de Rennes; 7) Department of Nephrology, Centre Hospitalier de Saint Brieuc; 8) Department of Nephrology, Centre Hospitalier de Saint Malo; 9) Department of Nephrology, Centre Hospitalier de Lorient; 10) Department of Nephrology, Centre Hospitalier de Quimper; 11) Department of Nephrology, Centre Hospitalier de Pontivy; 12) Centre de Dialyse, Association des urémiques de Bretagne, Brest; 13) Société Brestoise du Rein Artificiel, Brest; 14) Centre de Dialyse, Association des urémiques de Bretagne, Quimper; 15) Department of Nephrology, Centre Hospitalier de Saint Nazaire; 16) Department of Nephrology, Centre Hospitalier de Vannes; 17) Centre associatif de Dialyse, ECHO, Nantes; 18) Etablissement Français du Sang, Brest.

ADPKD is marked by a high clinical variability, especially in regards of age at end-stage renal disease (ESRD). As we are shifting to the era of targeted therapies in ADPKD, one needs to target the patients who are more likely to develop ESRD and thus to benefit from those therapies. In that setting, we conducted a cross-sectional study in a population of 1130 patients (525 males) from all the nephrology centers (n=17) of a single area, Brittany, France. We evaluated the effect of 10 clinical variables and of the molecular genetic data (mutation of PKD2, non truncating mutation (NTM) of PKD1 or truncating mutation (TM) of PKD1) using Kaplan-Meier curves and univariate followed by multivariate Cox regression analyses and built a score weighting each significant factor according to the HR obtained. Internal validation was assessed using non parametric bootstrapping with replacement. Discrimination of the model was evaluated using the c-statistic, which represents area under time-dependant ROC curves. Median age at inclusion was 54.3 yrs [5.45-94.3]. After multivariate analysis, 4 factors remained significantly associated with renal survival : Gender (HR=1.55, 0.95 CI=1.25-2.93), Hypertension onset before age 35 (HR=2.24, 0.95 CI= 1.76-2.86), first urological complication before age 35 (at least 1 amongst gross hematuria, flank pains related to cysts or cyst infection) (HR=2.1, 0.95 CI=1.62-2.73), and genetic status (PKD2 vs NTM of PKD1 HR=1.93, 0.95CI= 1.27-2.93, vs TM of PKD1 HR=4.88 0.95CI=3.39-7.02). We thus defined a score ranging from 0 to 9 (male gender:1 pt, hypertension onset before age 35: 2 pts, first urological complication before age 35: 2 pts, PKD2 mutation: 0 pt, NTM of PKD1: 2 pts and TM of PKD1: 4 pts). The accuracy of the PRO-PKD score applied to the sample was high, with a c-statistic of 0.863 at 65 yrs. To facilitate ease-of-use, we defined 3 risk categories: low risk, intermediate and High-Risk of early progression to ESRD with median ages at ESRD of respectively 73.6, 57.7 and 48.5 yrs (HR: Intermediate Risk= 3.99, High-Risk=13). Predicted probabilities of ESRD at age 60 were 16.5%, 57.5%, and 91.2%; for the Low, Intermediate, and High Risk Group, and accorded well with observed ESRD frequencies. The PRO-PKD score is a simple, accurate and easy-to-use prognostic score that might be of interest in the selection of the patients who should be included in the ADPKD clinical trials and be a valuable tool for personalized medicine in ADPKD.

1773S

A fast and accurate p-value imputation approach for genome-wide association study. *J. Kwan, M. Li, J. Deng, P. Sham.* HKU, Hong Kong, Hong Kong, Hong Kong.

Imputing individual-level genotypes (or genotype imputation) is now a standard procedure in genome-wide association studies (GWAS) to examine disease associations at untyped genetic markers. But the increasing GWAS sample and marker density of imputation reference panel means that more time is needed for imputing a single chromosome, while researchers are only interested in assessing the evidence of disease association at different markers in GWAS. Also, meta-analysis or expanded meta-analysis of publicly available GWAS summary statistics can allow more disease-associated loci to be discovered, but these data are usually provided for various marker sets and this makes such analyses difficult. Therefore, we develop a fast and efficient method that utilizes summary statistics only for imputation, called P-value Imputation (PI) at common variants. Its computational cost is linearly with the number of untyped markers and has little loss in accuracy compared with IMPUTE2, one of the leading methods in genotype imputation. In addition, based on the PI idea, we develop a metric to detect abnormal association at a marker using the association p-values at neighboring markers in LD and showed that it had a significantly greater power compared to LD-PAC, a method that quantifies the evidence of spurious associations based on likelihood ratio. All of our methods are implemented in a user-friendly software tool freely available at http://statgenpro.psychiatry.hku.hk/pi for meta-analysis conveniently.

1774M

Generalized likelihood ratios ensure statistically and clinically significant findings: application to genetic association with cystic fibrosis lung disease. *W. Li[1,2], L. Strug[1,2].* 1) Department of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 2) Child Health Evaluative Sciences, Hospital for Sick Children, Toronto, ON, Canada.

P-values have been criticized for their use as a measure of statistical evidence. One reason is that it can lead to statistically significant but clinically irrelevant findings, especially with large sample sizes as we see in GWAS. The evidential paradigm uses the likelihood ratio evaluated at two simple hypotheses (LR) as a measure of statistical evidence, with k=8 or 32 as commonly used benchmarks for declaring strong evidence. The probability of observing a large LR favoring an incorrect hypothesis, M, is bounded for normal data and fixed-dimensional parametric models in large samples (Royall, 2000), suggesting the LR is a valid evidence function and does not lead one to incorrect conclusions often. However, the requirement of a simple alternative hypothesis can limit applicability in genomic applications such as GWAS, where the focus is on hypothesis testing rather than estimation, and there is no a-priori reason for choosing a specific alternative hypothesis value. Zhang (2009) and Bickel (2012) provided theoretical justification for extending the evidential framework to accommodate composite hypotheses through the use of a generalized likelihood ratio (GLR), where the evidence in support of one composite hypothesis $\theta_1 \in \theta$ over its composite complement, $\theta_2=\theta_1^c$ is given by the ratio of the two likelihoods maximized over θ_1 and θ_2, separately. We analytically derive the operational characteristics associated with the use of GLR. For normal data, we show that M has the same bound as shown in Royall (2000), and it appears to hold generally outside of the normal model. In a candidate gene study of Cystic Fibrosis (CF) lung disease (n=753), we compare the association evidence between the maximized likelihood ratio (LR_m) test p-value and GLR at 8 SNPs across 3 genes. We define θ_1=[-C, C] and $\theta_2=\theta_1^c$ with C > 0 chosen to define a null region, θ_1. The LR_m, its p-value and GLRs with C=0.001 and 0.05 are computed. As $C \to 0$, $GLR \to LR_m$, e.g. when LR_m=8.14, GLR=7.93 for C= 0.001. For C=0.05, corresponding to a 1 percent change in the lung phenotype, the GLR provides evidence that 2 SNPs are associated with CF lung disease at k=8, the same conclusion as from the multiple comparison adjusted LR_m test p-value. The GLR extends the evidential framework by accommodating composite hypotheses, making the paradigm more applicable to GWAS. GLRs capture clinically meaningful findings, avoiding one of the major limitations of p-values in studies with extremely large sample sizes.

1775T

Fine-mapping of additive and dominance effect SNPs using group-LASSO and Fractional Resample Model Averaging. *J.A. Sabourin[1,2], A.B. Nobel[3,4], W. Valdar[2].* 1) Genometrics Section, CSGB, NHGRI, NIH, Baltimore, MD; 2) Department of Genetics and Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Statistics and Operations Research, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Genome-wide association studies sometimes identify loci where both the number and identities of the underlying causal variants are ambiguous. In such cases, statistical methods that model effects of multiple SNPs simultaneously can help disentangle the observed patterns of association and provide information about how those SNPs could be prioritized for follow-up studies. Current multi-SNP methods, however, tend to assume that SNP effects are well captured by additive genetics. However, when genetic dominance is present, this assumption translates to reduced power and faulty prioritizations. We describe a statistical procedure for prioritizing SNPs at GWAS loci that efficiently models both additive and dominance effects. Our method, LLARRMA-dawg, combines a group LASSO procedure for sparse modeling of multiple SNP effects with a resampling procedure based on fractional observation weights. It estimates for each SNP the robustness of association with the phenotype both to sampling variation and to competing explanations from other SNPs. In producing a SNP prioritization that best identifies underlying true signals, we show that: 1) our method outperforms a single marker analysis; 2) when additive-only signals are present, our joint model for additive and dominance is equivalent to or only slightly less powerful than modeling additive-only effects; and 3) when dominance signals are present, even in combination with substantial additive effects, our joint model is more powerful than a model assuming additivity.

1776S

Allele Specific Expression Can Reduce Apparent Genotype/Phenotype Relations: A Simulation Study. *J.L. Dannemiller.* Psychology Dept, Rice University, Houston, TX.

Allele specific expression (ASE) can affect phenotypes. **Purpose:** To estimate the effects of unrecognized ASE on a gene association study in which it is incorrectly assumed that both alleles are equally expressed. **Methods:** Gillespie's (1976) Monte Carlo method of simulating transcription and translation was used to estimate the effects of unrecognized ASE on a standard effect size measure: the percentage of phenotypic variance explained by genotype (ExplVar). Representative rates were assumed for mRNA transcription and degradation and for protein translation and degradation. A biallelic gene (p = q = 0.5) in Hardy-Weinberg equilibrium was modeled. In each experiment, 200 cells were simulated for each of 600 subjects until the protein levels from the two alleles in each cell reached independent equilibria. One of the alleles produced a protein that was 25% more biologically active than the other protein. In no-ASE experiments, the rates of mRNA expression for both alleles were the same. In ASE experiments, the mRNA expression rate for the low activity allele was the same as it was in the no-ASE experiments; the rate for the other allele was randomly drawn from a lognormal PDF similar to a distribution of ASE ratios in Valle et al. (2008) for the gene *TGFBR1*. The mean ASE ratio in the theoretical distribution was approximately 2:1. I am also exploring MCMC to generate the ASE ratios with a sum of weighted Gaussian kernels approximating the Valle et al. target distribution. The final phenotype for each cell was the sum of the number of protein molecules at equilibrium times the activity level of each of the protein molecules (1.00 or 1.25). Zero-mean, constant variance Gaussian noise was added to the average final activity level for each of the 600 subjects across their 200 cells to reduce the average percentage of explained variance under no-ASE conditions to approximately 6% - a level indicating a polygenic phenotype. Genotype values of 0, 1, or 2 (number of higher-activity allele doses) were used in the computation of ExplVar. **Results:** Across 100 experiments of each type, unrecognized ASE approximately halved the mean percentage of ExplVar from 6% to 3%. There were two sources of additional within-genotype variance in the ASE experiments: 1) random variance in the ASE ratios, and 2) higher variance in final protein levels because of generally higher mRNA expression rates. Unrecognized ASE can reduce estimates of genotype/phenotype relations.

Parent of origin and recurrence risk bias: probabilistic modeling explains the broken symmetry of transmission genetics. *C. Shaw[1], I. Campbell[1], P. Olofsson[2].* 1) Dept Molecular & Human Gen, Baylor Col Medicine, Houston, TX; 2) Mathematics Department, Trinity University, San Antonio, TX.

Most de novo human mutations are observed to arise in fathers, and increasing paternal age strongly correlates with increased risk of paternally transmitted mutations. Strikingly, de novo mutations in X-linked recessive disease show strongly elevated familial recurrence rates, and in male offspring these mutations must be transmitted from mothers. We were intrigued by these contrasting patterns of mutation transmission and their consequences for human genetics. We developed a comprehensive stochastic process model of mutation in the human germ line, closely modeling the sexual dimorphisms between males and females and considering the effect of increasing paternal age. We extended our prior work on exact sampling formulas for multi-type Galton-Watson branching processes to develop new formulas for the mean and variance of the proportion of mutant gametes in each parent. Analysis of these models and new mathematical results for updating the mean and variance of the proportion of mutant gametes based on observation of an affected child led to unexpected predictions for recurrence risk that implicate parent of origin as a central variable in the analysis of recurrence risk. Consistent with empirical data, our model predicts that more transmitted mutations arise in fathers, and that this tendency increases with a father's age. Surprisingly, the variance in the proportion of mutant gametes is lower in fathers and decreases with age, so that knowledge of a transmitted mutation has small effect on updating the expected proportion of mutants and therefore recurrence in another offspring. Quite differently, for the female germ line, which arrests after clonal expansion in early development, variance in the proportion of mutants is much higher, and observation of a transmitted mutation in an affected child dramatically increases the risk of recurrence in another pregnancy. Review of the literature where parent of origin was determined in families with recurrent genetic disease shows that the predictions of our model are strongly consistent with data that support a maternal origin bias of recurrent de novo mutations. Our findings have important consequences for genetic counseling and for understanding the patterns of recurrence in transmission genetics.

What are genome-wide association studies detecting? Our experience predicting cystic fibrosis-related diabetes onset. *D. Soave[1,2], M. Miller[1], K. Keenan[3], W. Li[1,2], J. Gong[1], W. Ip[3], P. Durie[3,4], L. Sun[2,5], J. Rommens[6,7], L. Strug[1,2].* 1) Program in Child Health Evaluative Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Program in Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada; 5) Department of Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 6) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

It is assumed that genome-wide association studies are identifying genetic determinants of the phenotype under study. However, we were reminded that this may not always be the case when a recent genome-wide association study for Cystic Fibrosis (CF)-related diabetes (CFRD) identified associated SNPs in *SLC26A9* (HR=1.34, at rs7512462). SLC26A9 is an apical epithelial cell transporter expressed in human pancreas, but is unlikely to have a direct role in the endocrine compartment as its protein payload is delivered to the bloodstream and surrounding cells without a specialized ductal system. We recently showed that rs7512462 accounts for >10% variability in early exocrine pancreatic damage in children with severe CF; and Mendelian randomization provided evidence that this early exocrine pancreatic damage causes later-onset of CFRD. These findings may explain how the SLC26A9 epithelial transporter contributes to CFRD. Despite only an indirect association between *SLC26A9* and CFRD risk, we hypothesized that *SLC26A9* may still assist with predicting CFRD onset. We developed and validated CFRD predictive models using 126 participants from the Canadian CF Gene Modifier Study on whom longitudinal measures of immunoreactive trypsinogen (IRT; the early exocrine pancreatic damage biomarker) and rs7512462 genotype were available. Cox proportional hazards models with 10-fold cross-validation were used to generate risk scores for each individual and these risk scores were used to assess the CFRD predictive ability for various ages using time-dependent receiver operating characteristic curves and the corresponding area under the curve (AUC). Using risk scores calculated from estimated IRT at birth and its rate of decline to predict CFRD by age 12, 16, 20 and 24y, our cross-validated AUC's were 65%, 64%, 64% and 78%, respectively. With the addition of rs7512462 genotype into the risk score calculation, the predictive accuracy improved significantly to 73%, 74%, 74% and 80%, respectively. Although we are cognizant that genome-wide significant SNPs require follow-up to identify the underlying causal variant that induced the association, less consideration is paid to identifying the underlying phenotype to which the variant is more proximally associated. Our findings suggest that once we better model the pancreatic phenotypic complexity, the addition of rs7512462 genotype can significantly improve predictive accuracy despite having only a weak and indirect effect on CFRD.

1779S

Test of Genotypic Association Allowing for Errors. *L. Zhou, A. Musolf, D. Londono, D. Gordon, T. Matise.* Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ.

Genome-wide association studies (GWAS), have led to identification of an ever-increasing number of single nucleotide polymorphisms (SNPs) for further studies. However, the presence of genotype misclassification errors, differential or non-differential, among cases and controls may cause either an increase in the false positive rate or a decrease in the power of statistical tests. A commonly used statistic to test for association between SNPs in cases and controls is the chi-square test of independence. This statistic tests whether genotype frequencies (single or multi-locus) differ between case and control groups. This is commonly referred to as a test of association. Regions of the genome where frequencies significantly differ are regions that may harbor a disease locus or loci. Several researchers have documented that genotype misclassification errors may adversely affect the chi-square test. There are three main reasons for genotype errors. First, as a result of inaccurate genotyping technology, the sequencing procedure may introduce errors in the output. The second reason may be low quality of the sequencing samples. Last, if samples from cases and controls are sequenced at different times or by different methods, this approach may lead to different error rates between cases and controls (differential misclassification). Our overall objective is the development of a statistical test of association that uses NGS data and is robust to random sequencing error, both non-differential and differential. More concretely, we develop a chi-square test of independence that uses parameters such as the observed alternative variant reads at a given polymorphic site, the coverage per individual, the individual's phenotype, and error model parameters. This statistic is developed in a log-likelihood framework.

1780M

Statistical method for analyzing allele-specific expression across individuals for multiple statuses. *Y. Lee, X. Wen, M. Boehnke.* Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

It is well known that genetic variants in cis-regulatory regions can have large effects on the expression level of the target genes. Such effects can be detected by eQTL mapping and allele-specific expression (ASE) analysis. In this study, we are interested in examining the concordance between eQTL and ASE analysis, especially when the regulatory variants show state or tissue-specific effects. To this end, we develop a novel statistical method to perform ASE analysis using RNA-seq data across multiple individuals. One of the unique features of our method is that we require genuine ASE signals to be consistent across individuals, while accounting for potential heterogeneity among individuals. Also, using Bayesian model averaging, we effectively take phasing uncertainty into account. We apply this method to the RNA-seq data from GEUVADIS and Genotype-Tissue Expression (GTEx) project. In particular, we attempt to confirm strong (tissue-specific) eQTL signals using ASE analysis, and we also evaluate the consistency of effect size from eQTL mapping and ASE analysis.

A New Approach to finding Association with Complex, Longitudinal Phenotypes using Population Data. *A.M. Musolf[1], D. Londono[1], A.Q. Nato, Jr.[2], P. Vuistiner[3], J. Brandon[4], J.A. Herring[5], C.A. Wise[4,6], H. Zou[7], M. Jin[7,8], L. Yu[1,9], S.J. Finch[10], P. Bovet[11], M. Bochud[3], T.C. Matise[1], D. Gordon[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Statistical Genetics Lab, Division of Medical Genetics, University of Washington, Seattle, WA 98195, USA; 3) Swiss Institute of Bioinformatics, 1015 Lausanne, Switzerland; 4) Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX 75219, USA; 5) Department of Orthopedic Surgery, Texas Scottish Rite Hospital for Children, Dallas TX 75219, USA; 6) Department of Orthopedic Surgery, University of Texas Southwestern Medical Center, Dallas, TX 75219, USA; 7) Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China; 8) ShanghaiBio China, Pudong, Shanghai 201203, China; 9) Center of Alcohol Studies, Rutgers University, Piscataway, NJ 08854, USA; 10) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY 11790, USA; 11) Ministry of Health, P.O. Box 52, Mont Fleuri, Republic of Seychelles.

Previously, we detailed a new method for testing for association between longitudinal phenotypes and causal genotypes. The method uses growth mixture models to determine longitudinal trajectory curves. The Bayesian posterior probability (BPP) of belonging to a specific curve was then used as a quantitative phenotype in association analyses. To identify association for multiple SNPs, we did not perform association analyses on individual SNPs; instead the genome was sliced into blocks of 50 SNPs. A significance value was obtained on each block via the program TDT-HET. This method displayed greater than 80% empirical power in most simulations scenarios. This method exclusively used family-based data. Here, we extend the method to population-based data sets. The method maintains many ideas from the family-based method. However, the program SumStat is used to acquire significance levels on each block, instead of TDT-HET. Multiple scenarios are tested including four causal variants located within a single locus and eight causal variants spread between two loci on different chromosomes. Reduced models using environmental covariates were also considered. Our data set was highly stratified to ensure robustness in the presence of population stratification. To correct for population stratification, ancestry fractions from the program ADMIXTURE are regressed on the BPPs and the residuals are used as the phenotype for association analyses. Our method also utilized three distinct data sets, which represent a discovery data set and two confirmatory data sets. The final p-values of the association analyses were combined via Fisher's method and corrected for multiple testing by the false discovery rate (FDR). We report that our simulations: 1) maintain the proper type I error in the presence of population stratification and 2) have greater than 90% power for all simulations. We conclude that our method can detect multiple causal SNPs located in multiple loci in population data sets. We believe that is method will be use to researchers who are studying complex diseases that display longitudinal phenotypes. It allows for high detection of causal loci (and the causal variants within) for both population and family studies, even in the presence of confounding elements such as population stratification and environmental variables.

1782S

Multiple testing procedures for GWAS with high-dimensional phenotypes. *C.B. Peterson[1], M. Bogomolov[2], Y. Benjamini[3], C. Sabatti[1].* 1) Department of Health Research and Policy, Stanford University, Stanford, CA; 2) Faculty of Industrial Engineering and Management, Technion - Israel Institute of Technology, Technion City, Haifa, Israel; 3) Department of Statistics and Operations Research, Tel Aviv University, Tel Aviv, Israel.

We are developing statistical methods to both improve power and reduce errors in identifying genetic variants that are relevant to multivariate phenotypes such as imaging features, actigraphy measures, or gene expression. Since both the predictor and response variables are high dimensional, this represents a massive multiple testing problem.

A standard approach to handle this multiplicity is to control the false discovery rate across the entire set of hypotheses representing the association of each SNP to each phenotype. Unfortunately, this method does not control the false discovery rate for SNPs or the average false discovery rate for selected SNPs. This is a serious drawback for gene mapping studies, where the identification of SNPs with functional effects is one of the primary goals. In addition, it fails to account for the genetic architecture of traits. In this type of study, most genetic variants will not affect any of the phenotypes of interest, but those with functional effects are likely to influence multiple traits. In applying error control to the pooled set of hypotheses across all SNPs, we are reducing power to detect the effects of functional SNPs, while increasing errors for SNPs that have no influence on any traits.

In this work, we employ a two-step selection procedure recently proposed by Benjamini and Bogomolov that allows us to both gain control of the appropriate error rates and improve power by taking advantage of the genetic structure of the problem. Here we explore the application of this strategy and its performance in the context of GWAS. Specifically, we define families of hypotheses by SNP, where each family consists of hypotheses on the association of a particular SNP to each of the phenotypes under study. In step (1), we perform selection of SNPs that affect one or more phenotypes under study, based on a summary statistic for each SNP family. In step (2), we apply an error controlling procedure within each selected family using an adjusted level to account for the selection bias incurred in step (1). We demonstrate the advantages of this method in terms of error control and power through simulation studies using both independent predictors and real genotypes obtained from the North Finland Birth Cohort (NFBC) study.

1783M

Making use of parental phenotypes in case-parent genetic studies. *M. Shi, D.M. Umbach, C.R. Weinberg.* Biostatistics Br, NIEHS, Res Triangle Park, NC.

In studies of case-parent triads, information may be available about occurrence of the condition in the parents. Typically parental phenotypes are ignored, but including that information in analyses may increase power to detect genetic association for autosomal variants. We propose a method of using parental phenotypes that assesses association independently of the usual case-parent-based association test. Our proposed method enjoys many advantages of case-parents designs: it is robust to population stratification and allows testing of maternally-mediated genetics effects as well as inherited-gene effects. The parental information can enable a natural internal replication for findings based on offspring and their parents, and it can be used to improve power. We develop composite tests that combine evidence from this parent-phenotype-based test with the traditional log-linear transmission-based test. A likelihood-based approach builds information from these two sources into a single coherent model: The model can impose equality of parental and offspring relative risks and permit testing of that equality. This model also allows us to use the expectation-maximization algorithm when some parental genotypes are missing. We evaluate the proposed method through non-centrality parameter calculations and simulation studies. We show that incorporation of parental phenotype data often improves power to detect a genetic contribution to the phenotype. As illustration, we apply our method to a nuclear-family-based study of young-onset breast cancer.

1784T

Efficient multiple imputation for missing phenotype using genome-wide DNA methylation data. *W. Guan[1], C. Wu[1], B. Wu[1], Y. Li[2,3], J. Pankow[4], E.W. Demerath[4], J. Bressler[5], M. Fornage[5], M.L. Grove[5], T. Mosley[6], C. Hicks[6], E. Boerwinkle[6].* 1) Division of Biostatistics, Univ of Minnesota, Minneapolis, MN; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC 27516; 3) Department of Biostatistics, University of North Carolina, Chapel Hill, NC 27516; 4) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, MN 55455; 5) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX 77030; 6) Department Neurology and Department of Medicine, School of Medicine, University of Mississippi, Jackson, MS 39216.

DNA methylation is a widely studied epigenetic mechanism and alterations in methylation patterns may be involved in the development of common diseases. Unlike inherited changes in genetic sequence, variation in site-specific methylation varies by tissue, developmental stage, disease status, and may be impacted by aging and exposure to environmental factors such as diet or smoking. While these wide-range correlations pose analytical challenges, including reverse causality and confounding by non-genetic factors in epigenome-wide association studies (EWASs), it brings opportunities to infer missing phenotype values using rich methylation data. We propose a multiple imputation method using large-scale methylation data, such as that provided by the Illumina Infinium HumanMethylation450 (HM450) BeadChip. Based on established methylation-phenotype association at multiple CpG sites, plausible values for missing data in phenotype variables can be drawn multiple times. The imputed datasets can then be analyzed separately using standard complete-case analysis, with the point estimates and corresponding covariance matrix being combined subsequently for final inference. Through simulations, we show that the proposed method can make appropriate association inference while maintaining correct false positive rate. We also illustrate our method with data from the Atherosclerosis Risk in Communities (ARIC) study to carry out an EWAS between methylation levels and smoking status, in which missing cell type compositions and white blood cell counts are imputed.

1785S

Using local multiplicity to improve effect estimation from a hypothesis generating study. *W. Zou[1], H. Ouyang[2].* 1) InVentiv Clinical Health, LLC, 504 Carnegie Center, Princeton, NJ 08540 USA; 2) Lilly Corporate Center, Eli Lilly and Company, Indianapolis, Indiana 46285.

We propose a multiple estimation adjustment (mea) estimator as an alternative way to correct for the effect over-estimation in a selection of strong genetic associations from a hypothesis generating study (HGS). Mea uses a hierarchical Bayesian approach to model maximal likelihood estimation (MLE) of individual effects and to integrate local multiplicity by borrowing effect information from neighboring variations. Unlike many other adjustment methods that model certain types of selection bias specifically, mea attempts to improve effect estimation without stipulating a selection scheme. Nevertheless, between naive MLE, mea and conditional likelihood adjustment (CLA) method that models ascertainment selection bias, we compared their mean square errors (MSE) among top signals that pass a threshold selection, a ranking selection or their combination though simulation studies. We show that selection and data-generating parameters impact MSE of all methods, and no methods dominate the others under all settings for both null and causal effects. We observe that mea effectively reduces MSE from MLE on null effects with or without selection, and has a clearer advantage over CLA for effects that are far away from a selection threshold. We believe mea is a valuable complement to available methods and an actionable tool on its own when interpreting results from HGS and designing follow-up studies.

1786M

Confounded by Ancestry? Considerations for Ancestry Adjustments in Genetic Association Tests. *E.R. Martin[1], I. Tunc[1], Z. Liu[1], M.A. Schmidt[1], C.D. Bustamante[2], G.W. Beecham[1].* 1) Hussman Institute for Human Genomics, Dr. John T. Macdonald Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Genetics, Stanford University. Palo Alto, CA.

It is well known that ancestry differences can lead to confounding in genetic association tests. It has now become standard practice to adjust for principal components that capture global ancestry of samples, but this is often done without assessment of whether they are true confounders. Adjusting for covariates that are not true confounders can lead to loss of power; thus, judiciously assessing whether ancestry is a confounder prior to analysis is likely to improve power in association tests. In addition, there have been recent reports considering whether it is preferable to adjust for local or global ancestry, but the conclusions depend highly on the model for population structure and trait/disease model. Here, we review the definition of statistical confounding in general and the properties of covariate adjustment (with and without confounding) in relation to statistical power. We then examine theoretical expectations to illustrate when we might expect confounding and the consequence of ancestry adjustment in genetic association tests in the context of various genetic models for population structure and admixture. Theoretical calculations were verified and generalized to more complex situations using simulations. We show that in a single admixed population, when testing the trait locus itself there is no confounding by ancestry, and in this scenario, adjusting unnecessarily for ancestry can lead to a substantial decrease in power. In stratified admixed populations when the trait values or disease prevalence differ between strata, global ancestry is a confounder and must be adjusted for to obtain valid inference. Generally adjusting for global ancestry captures the effect and there is no additional benefit adjusting for local ancestry. The one scenario that we examined where we observed a local ancestry effect in addition to a global ancestry effect was testing a nearby marker locus rather than the trait locus itself. Since the true population dynamics and genetic model are usually unknown, we propose a variable-selection strategy for assessing whether ancestry adjustment is necessary. Our simulations show that this strategy maintains correct Type I error, has good power compared to the true model, and has greater power than arbitrarily adjusting for ancestry covariates. This data-informed strategy provides a viable alternative to ubiquitous adjustment that preserves power while protecting against spurious results.

1787T

Towards Estimation of the all-Phenotype by all-Phenotype Genetic Correlation Matrix. *B. Bulik-Sullivan[1,4], H. Finucane[3], A. Price[2,5], B. Neale[1].* 1) Medical and Population Genetics, Broad Institute, CAMBRIDGE, MA; 2) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 3) MIT Department of Mathematics, Cambridge, MA; 4) VU University Amsterdam, Amsterdam, NL; 5) Department of Epidemiology, Harvard School of Public Health, Boston, MA.

Quantification of the extent of shared genetic architecture between disease phenotypes is an issue of fundamental interest to statistical genetics. Such quantification could help refine nosology, explain co-morbidity, and increase power in association studies and precision in genetic risk prediction by leveraging GWAS data collected for related phenotypes Existing methods for estimating genetic correlation from genotype data, e.g., bivariate Haseman-Elston (HE) regression, and bivariate linear mixed models (LMM) require researchers to obtain access to large datasets with genotype and phenotype data for multiple traits; however, this is often infeasible because of privacy concerns that limit sharing of identifiable genetic data and medical records. For this reason, estimates of genetic correlation published in the literature to date have been limited to pairs of phenotypes studied within one consortium or lab. We present a bivariate extension of the recently proposed LD Score regression method (Bulik-Sullivan, et al, 2014, biorxiv) that allows estimation of genetic correlation from GWAS summary statistics. This method is supported by theory and extensive simulation, and performs robustly under various genetic architectures, even when one or both GWAS is confounded by cryptic relatedness or mild population stratification (similar to univariate LD Score regression). In addition, this method remains unbiased no matter how many samples are shared between the two GWAS, which is of great practical importance, since many GWAS consortia (e.g., the Psychiatric Genomics Consortium) use the same control set for many phenotypes. We validated the method on real data by replicating the genetic correlation estimates from the PGC Cross-Disorder Group Nature Genetics 2013 paper with similar standard error (as a representative example, the PGC CDG paper reports the genetic correlation between bipolar disorder and sczhiophrenia to be 0.68 (0.04); we get 0.64 (0.06) using summary statistics from the same samples). We present results from the application of this method to a large set of GWAS summary statistics, including many meta-analyses for which genotype data are not shared even within the consortium (e.g., BMI and diabetes). Finally, we discuss the mathematical interpretation of LD Score regression as a linear time (in the number of samples) approximation to existing methods (such as HE-regression and LMM) that require raw genotypes and quadratic or cubic time.

1788S

Effective genetic risk prediction using mixed models. *D. Golan, S. Rosset.* Statistics, Tel-Aviv University, Tel-Aviv, Israel.

Despite identifying thousands of genetic variants associated with dozens of high-impact diseases using genome-wide association studies, our ability to accurately predict the disease status using genetic data remains disappointingly low for many highly heritable diseases. One leading theory is that highly heritable diseases for which prediction is difficult (e.g., bipolar disorder, type-2 diabetes and hypertension) are typically driven by many common variants with small effects. The effects of most variants are too small to reach significance, but cumulatively these variants account for a considerable portion of the disease burden. This theory suggests that using only those variants which were found to be significantly associated with the disease is too conservative, and that a more permissive inclusion criterion should be used when selecting variants for the purpose of prediction. However, there is an obvious trade-off: when the inclusion criterion is stringent, a considerable part of the signal is left out, but when using a more permissive inclusion criterion, the number of estimated parameters (effect sizes), increases dramatically, resulting in overfitting problems and leading to poor performance. We propose a novel statistical approach for genetic risk score inference (GeRSI), based on mixed-effects models. Variants with strong associations are included in the model as fixed effects, just as in standard approaches. Additionally, variants with no significant association are not discarded, but instead are treated as random effects, thus circumventing the need to estimate their respective effects and considerably reducing the number of parameters in the model. By doing so, GeRSI takes advantage of all variants for better prediction, without losing accuracy due to estimating a huge number of parameters. We demonstrate the superiority of GeRSI to state-of-the-art methods in extensive simulation. When applying GeRSI to seven phenotypes from the WTCCC study, we confirm that the use of random effects is most beneficial for diseases that are known to be highly polygenic: hypertension (HT) and bipolar disorder (BD). For HT, there are no significant associations in the WTCCC data. The best existing model yields an AUC of 54%, while GeRSI improves it to 59%. For BD, using GeRSI improves the AUC from 55% to 62%. For individuals ranked at the top 10% of BD risk predictions, using GeRSI substantially increases the BD relative risk from 1.4 to 2.5.

1789M

Allele-specific DNase I hypersensitive sites exhibit H3K27ac enrichment in GM12878. *J.M. Peralta[1], M. Almeida[1], L.J. Abraham[2], E. Moses[2], J. Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Centre for Genetic Origins of Health and Disease, University of Western Australia, WA.

Open chromatin accessibility is often assessed by the presence of DNase I hypersensitivity sites (DHSs). It correlates with cis-located elements that regulate the expression of a gene, like promoters and transcription binding sites. The acetylation of Lysine 27 of histone H3 (H3K27ac) is a modification strongly correlated with the active state of enhancers to promote transcription and gene expression. Non-coding variants that affect the binding of proteins to cis-regulatory elements can change the local sensitivity to DNase I digestion, leading to allele-specific DHSs that can serve as an indication of variants with a potentially functional effect on the regulation of neighboring genes. These allele-specific DHSs can be detected, in heterozygotes, as a significant deviation from the expectation of equal allele depth coverage at SNP sites within DHSs. We refer to the significance of this effect, in the -log10[p] scale and derived from a likelyhood ratio based test, as the functional potential (FP) of a SNP. Using mapped short sequencing reads (reads) from DNase-seq of five pooled GM12878 lymphoblastoid cell line replicates (R1-R5) for NA12878, released by the ENCODE Project, we examined the allele-specific chromatin accessibility at 2423308 known heterozygous SNPs sites, based on Illumina's Platinum WGS of NA12878. FP estimates were obtained from independent tests for 48237(1.99%) SNPs using the read depths from each of the two SNP alleles from GM12878's pooled DNase-seq reads. A stringent Bonferroni threshold (-log10[α]=6) was used to classify our FP estimates in two groups, FP$\geq$6 (n=161, 0.33%) and FP<6 (n=48076, 99.67%). Then we determined the FP overlap (n=7971) with ENCODE's GM12878 H3K27ac signal peak (n=56069) and found a highly significant enrichment (p=2.15$\times$10^-47) of FP$\geq$6 (n=108) within H3K27ac signals. Relaxation of the cutoff threshold for the classification of FP estimates by 2 -log10 units lead to an even better enrichment signal (p=6.76$\times$10^-50). These results support a role for allelic-specific DHSs in the regulation of gene expression and suggest that the FP of SNPs can be used to quicky classify potentially functional non-coding variants.

1790T

Genetic modifiers in TGFβ pathway affect disease severity in Duchenne Muscular Dystrophy. *J. Punetha[1,2], H. Gordish-Dressman[1,2], L. Bello[2], A. Kesari[2], M. Giri[2], E.P. Hoffman[1,2], Cooperative International Neuromuscular Research Group.* 1) Department of Integrative Systems Biology, The George Washington University School of Medicine, Washington DC, USA; 2) Center for Genetic Medicine Research, Children's National Medical Center, Washington DC, USA.

Duchenne muscular dystrophy (DMD [MIM 310200]), the most common monogenetic disease in boys, shows marked heterogeneity in disease onset and progression. This inter-patient phenotypic variability observed in DMD can be attributed to the presence of genetic modifiers. Genetic modifiers of DMD (*SPP1* rs28357094, *LTBP4* rs10880) have been associated with loss of ambulation and lower grip strength in patients. Both known DMD genetic modifiers lie within the transforming growth factor-beta (TGF-β) signaling pathway, which is known to be dysregulated in DMD patients, thus increasing its significance in disease pathophysiology. We used a TGF-β pathway driven approach to help investigate potential genetic modifiers and their interactions in a large natural history cohort of DMD patients (CINRG) followed longitudinally for 5-8 years. Key single nucleotide polymorphisms (SNP's) in TGF-β pathway (*SPP1*, *LTBP4*, *TGFBR2*, and *IBSP*) genes were genotyped and tested for associations with outcome measures. Outcome measures chosen were those that could predict disease progression before loss of ambulation occurred i.e. time to run/walk, grip strength. In accordance with our previous studies, dominant *SPP1* rs28357094 genotype showed significant association with grip strength and appeared to be dependent on steroid use. We identified a novel genetic modifier in DMD; patients with the recessive *IBSP* rs2616262 TT genotype showed a significant association (p=0.01, n=150) with disease progression in the time to run/walk (TTRW) test. *IBSP* genotype also showed significant association with grip strength in the non-ambulatory patients (p=0.04, n=111). Preliminary data for SNP interaction studies between *SPP1* and *IBSP* polymorphisms show evidence for interaction of the two loci. Providing sufficient statistical confidence of genetic modifier effects in different patient cohorts has been problematic due to differences in steroid treatment regimens, ethnicity, outcome measures, age of study population, and study sites tested. In our cohort, there were differences in functional outcomes between different ethnic groups as well as different standards of care provided. Validation of SNP association studies requires selection of a homogenous population to reduce confounding factors and hidden stratification. Further analyses of multi-locus modifier approaches will help identify the key players in transition from successful to unsuccessful remodeling in muscular dystrophy.

Linkage disequilibrium clustering can improve power of weighted-sum-type multi-marker tests for genetic association analysis. *Y. Yoo[1,2], S. Kim[1], L. Sun[3,4], S. Bull[3,5].* 1) Mathematics Education, Seoul National University, Seoul, South Korea; 2) Interdisciplinary Program in Bioinformatics, Seoul National University, Seoul, South Korea; 3) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 4) Department of Statistical Science, University of Toronto, Toronto, Canada; 5) Prosserman Centre for Health Research, The Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Canada.

Background For gene-based analysis of genome-wide association study, a multi-SNP regression analysis using common and low frequency SNPs can be performed for a gene unit and global hypothesis tests can be constructed. Methods constructed as quadratic forms are especially effective in the presence of both deleterious and protective causal SNPs. On the other hand, weighted-sum type tests benefit from smaller df when causal SNPs are all deleterious. The power of both tests suffers in the presence of many neutral SNPs relative to causal SNPs. In this study, we investigate how clustering of correlated SNPs can improve power of a hybrid quadratic-linear combination test using weights incorporating the correlations between SNPs. **Methods** The Wald statistic is defined as a quadratic sum of beta coefficients with covariance matrix weights. The LC statistic is linear sum using weights incorporating variances and covariances between SNPs. We propose the MLC statistic defined as a quadratic sum over per-cluster linear combinations, and apply a spectral clustering algorithm to cluster closely correlated SNPs. The coding for base and risk alleles within each cluster is assigned using a pairwise LD coding method so that the number of pairs of SNPs with positive value of linkage disequilibrium measure r is as many as possible . We compared the power of Wald, LC, MLC tests with numerical calculation of asymptotic power over different disease model scenarios. For comparison over realistic correlation patterns, we selected 1000 genes, and specified genotype-phenotype models using the structure of SNPs from HapMap data for these genes. Three types of disease model scenarios were examined: A: one causal SNP, B: two causal SNPs in different clusters both with deleterious effects, C: two causal SNPs in different clusters with one deleterious effect and one protective effect. **Results and Conclusions** For a one causal SNP scenario with the number of neutral SNPs between 1~10, the power of the LC test exceeds that of the Wald test when the correlations between SNPs reach a certain positive value between 0.1~0.6. The power of the MLC test is usually higher than the other tests under all three disease model scenarios with one or two causal SNPs. These results suggest that clustering of highly correlated SNPs can improve the power of linear combination tests using weights incorporating the correlations with other SNPs.

1792M

A unified analysis approach for X-chromosome that accounts for random, skewed and escaping of X-chromosome inactivation. *J. Wang, R. Yu, S. Shete.* Dept Biostatistics, UT MD Anderson Cancer Ctr, Houston, TX.

X-chromosome inactivation (XCI) on female X-chromosome loci states that in females during early embryonic development, 1 of the 2 copies of the X-chromosome present in each cell is randomly selected to be inactivated to achieve dosage compensation of X-linked genes in males and females. Due to the random XCI, about half of the cells have one allele inactive while the other half of the cells have the other allele inactive. As a result, the homozygous genotypes in females have the similar effects as the hemizygous allele types in males. In general, the XCI process is random; however, recent studies have suggested that skewed XCI is a biological plausibility in which more than 75% of cells have the same allele active. Another complexity in analyzing X-chromosome data is the escaping of XCI outside the pseudo-autosomal regions on the female X-chromosome, that is, both alleles are active in all cells. Current statistical tests for X-chromosome genetic association studies either account for random XCI only (e.g., Clayton's approach) or escaping of XCI only (e.g., PLINK software). Because for females, the true XCI process is unknown and differs across different regions on X-chromosome, we proposed a unified approach for analyzing X-chromosomal genetic data, which will account for all such biological possibilities: random XCI, skewed XCI and escaping of XCI. Simulation studies were conducted to compare the performance of the proposed approach with Clayton's and PLINK approaches. For the scenarios where the XCI is skewed, the proposed approach has higher powers to identify the associated genetic variants than the Clayton's and PLINK approaches. We also analyzed the head and neck cancer X-chromosome genetic data using the proposed and existing approaches. The proposed approach identified an SNP rs12388803 associated with head and neck cancer risk: meta-analysis-based p values = 2.04×10^{-6}, 2.83×10^{-6} and 2.83×10^{-6} for Fisher's, fixed effect and random effect models, respectively.

1793T

Efficient Detection of Allelic Imbalance from SNP microarrays. *C. Hahn[1,4], S. Vattathil[2,4], Z. Weber[3], L. Huang[4], R. Xia[5], G.E. Davies[3], E. Ehli[3], P. Scheet[1,2,4].* 1) Biomathematics and Biostatics Program, The University of Texas Graduate School of Biomedical Sciences, Houston, Texas 77030, USA; 2) Human & Molecular Genetics Program, The University of Texas Graduate School of Biomedical Sciences, Houston, Texas 77030, USA; 3) Avera Institute for Human Genetics, Sioux Falls, South Dakota, USA; 4) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, Texas 77030, USA; 5) Biostatistics Program, The University of Texas School of Public Health, Houston, Texas 77030, USA.

Studies of tumor genomes in settings of high levels of normal DNA contamination or clonal heterogeneity require computational methods sensitive enough to detect subtle forms of allelic imbalance (AI) resulting when a small portion of the cells contain copy-number loss of heterozygosity, deletions or duplications. Detection of these forms can be enhanced by leveraging haplotype information to identify regions where there has been relative loss or gain of one of an individual's inherited chromosomes. Such regions may be representative of subclones or may indicate clonal mosaicism in non-tumor tissues. Due to lower levels of perturbation from the tumor genome in the BAFs of low-frequency mixed samples, the called genotypes from such samples represent the germline genotypes and we can apply these calls towards a single sample analysis. We present a framework to model the observed microarray data by combining parametric distributions for the magnitude of B allele frequencies (BAFs) with haplotype estimates informing the correlation expected in the BAFs in regions of AI. Specifically, we apply a mixture of bivariate normal distributions at consecutive heterozygous sites. Our framework allows for a probabilistic characterization of each bi-marker interval across a tumor genome, which can then be used to formulate emission probabilities for use in a hidden Markov model. Our method thus retains the speed of simple models that make use of haplotype information while capturing the important feature of correlated BAFs. We compared our method to other state-of-the-art packages (e.g. hapLOH, BAFsegmentation) to identify aberrations and improve detection performance in mixtures with aberrations in less than < 5% of the sample. We focus our comparisons on a novel data set, constructed from series of mixtures of DNA from cell lines derived from tumor and paired blood of a lung (T: HTB-172, N: CRL-5948) and breast (T: CRL-2343, N: CRL-2363) cancer. Methods such as hapLOH that capture haplotype information alone excel over those that simply model the magnitude of BAFs. However, the more subtle inflections in signal at lower tumor proportions (~5%) are difficult to recognize using hapLOH but in several instances are detectable by our method, as we incorporate a more use of the available data. Our flexible framework can be utilized in a variety of contexts, including testing specific regions of a priori interest for AI.

1794S

Imputing phenotypes for genome wide association studies. *F. Hormozdiari[1], E. Kang[1], C. Vulpe[4], S. McLachlan[5], A. Lusis[2,3], E. Eskin[1,2].* 1) Computer Science, UCLA, Los Angeles, CA; 2) Department of Human Genetics, University of California at Los Angeles; 3) Department of Medicine, University of California, Los Angeles, Los Angeles; 4) Department of Nutritional Science and Toxicology, University of California Berkeley; 5) Centre for Population Health Sciences, University of Edinburgh.

Genome wide association studies (GWAS) are extremely successful to detect the associated variants for various phenotypes. However, the power to detect these associated variants depends on the strength of the associated signals and the number of individuals whom their phenotypic values are collected. Thus, for phenotypes that are difficult to collect, we are likely to lack the sufficient number of individuals to have the desired power. In this work, we utilize a set of multiple phenotypes, which are easy to collect to predict (impute) an additional phenotype (target phenotype), which is difficult to collect to achieve a desired power for the association study of the target phenotype. We leverage the correlation structure between phenotypes to impute the phenotypic values of the target phenotype. The correlation structure can be estimated from the training data, where we collect all phenotypes including target phenotype. Then, we impute the target phenotype of the individuals whose target phenotype is not collected. We derive an analytical formula to compute power of the association study with imputed phenotype and show the correctness through rigorous simulations. We show that we can increase the power of detecting the significant variants by 9-25% through imputing the missing individuals in the Northern Finland Birth Cohort data. In addition, we show the utility of our method through applying our method to Hybrid Mouse Diversity Panel (HMDP) data. We use two versions of HMDP that were collected in two different times. We use the older version of the HMDP for training and then we impute the phenotypes in the newer version of HMDP. We manage to show that the correlation between the imputed phenotype and the real phenotypic values is high for most phenotypes.

Quality and accuracy assessment for NGS data analysis and interpretation. *J. Li[1], M. Mohiyuddin[1], A. Kiani[2], M. Carneiro[3], P. Jiang[3,4], S. Tabrizi[3,4], S. Schaffner[3,4], I. Shlyakhter[3,4], N. Asadi[1,2], P. Sabeti[3,4], W.H. Wong[5,6], H.Y.K. Lam[1].* 1) Department of Bioinformatics, Bina Technologies, Redwood City, CA; 2) Department of Engineering, Bina Technologies, Redwood City, CA; 3) Program in Medical and Population Genetics, the Broad Institute, Cambridge, MA; 4) Department of Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 5) Department of Statistics, Stanford University, Stanford, CA; 6) Department of Health Research and Policy, Stanford University School of Medicine, Stanford, CA.

Next-generation sequencing (NGS) has become the mainstream for characterizing genetic variations for both targeted genomic regions and whole genome. The quickly decreasing cost at increasing coverage is enabling numerous possible applications of large-scale studies, ranging from discovering genetic disease-causing mutations and pathways to identifying cancer somatic alterations.

To conduct meaningful research and generate correct interpretation based on the identified variations, quality assessment (QA) of the data becomes extremely important, especially in clinical settings. Accumulated cohort study results, in turn, provide learning resources for differentiating true variations from errors. Here we present a comprehensive, user-friendly quality control pipeline for NGS secondary and tertiary analysis. This pipeline, synergized with the secondary analysis framework, provides across-the-board quality measurements addressing potential quality issues residing in NGS reads, such as sequence quality, length, and adaptor detection; in alignment, such as coverage statistics, mapping distribution, and insert estimation; and in variant calling, such as known variant ratio, heterozygous/homozygous ratio, and transition/transversion ratio.

For tertiary analysis, to ensure the relevant biological interpretations are not caused by low quality or conflicting data, our pipeline provides a novel scheme for quality assurance by learning from accumulated homogeneous samples. A wide range of quality control is performed on the identified variations from the new samples, such as calculating missing data rate and heterozygosity rate, detecting duplicated or related individuals, checking for ethnicity, gender and blood type, identifying mitochondrial haplotype, and computing Hardy-Weinberg log p-value.

Visualization methods such as clustering heatmap, VQSR LOD score plots, and a novel method we have developed - QCRadar, are used in QC report for users to easily identify potential problems at a glance. We have applied our QC pipeline to a large number of samples, including recently to 20 Lassa fever patient genomes of a cohort in which we successfully identified the optimal VQSR LOD score to maximize the sensitivity of the high-confidence variant call set.

1796T

A comprehensive survey of genetic variation in 20,769 subjects from the Harvard Cohorts. *S. Lindstrom[1], S. Loomis[2,3], C. Chen[1], H. Huang[1], J. Huang[1], A. Chan[4], H. Choi[5], G. Curhan[6], I. De Vivo[1, 6], C. Fuchs[2,6,7], F. Hu[1], C. Kabrhel[2,4,6], L. Pasquale[2,3,6], E. Rimm[1], R. Tamimi[1,6], S. Tworoger[1,6], D. Hunter[1,6], P. Kraft[1].* 1) Harvard School of Public Health, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Massachusetts Eye and Ear Infirmary, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) Boston University School of Medicine, Boston , MA; 6) Brigham and Women's Hospital, Boston, MA; 7) Dana-Farber Cancer Institute, Boston, MA.

The Nurses' Health Study (NHS), Nurses' Health Study II (NHSII), Health Professionals Follow Up Study (HPFS) and the Physicians Health Study (PHS) have collected detailed longitudinal data on a wide range of exposures and traits for more than 310,000 study participants over the last 35 years. Across the four cohorts, more than 90,000 study participants donated a blood sample between 1982 and 1999 allowing for prospective analysis of biomarkers and genetic variation. Over the last eight years, 20,769 subjects have been genotyped as part of genome-wide association studies (GWAS) of 12 primary traits within the cohorts. However, these studies have utilized 6 different GWAS platforms, making it difficult to conduct analyses of secondary phenotypes or borrow controls from other studies. To allow for secondary analysis in this data, we have created new datasets merged by platform and imputed them to a common reference panel, the 1,000 Genomes Phase I release. We describe the methodology behind the data merging and imputation and present imputation quality statistics and association results from two GWAS based on the merged and imputed data: one of body mass index (BMI) and one of venous thromboembolism (VTE). Using a significance level of p=0.05, 19 out of 32 known BMI SNPs showed association with BMI with the strongest association for the FTO SNP rs55872725 (β=0.44, $p=1.31\times10^{-21}$). For VTE, 3 out 4 known VTE SNPs showed association with VTE with the rs144737447 SNP (OR=2.15, 95% CI: 1.78-2.61, $p=2.96\times10^{-15}$), located downstream of F5 showing the strongest association. This pooled resource can be used to boost power and study rare phenotypes and genotypes.

1797S

Heteroscedastic Extreme Sampling Strategy in Target Sequencing Studies. *W. Ouyang, HW. Deng, H. Qin.* Biostatistics & Bioinformatics, Tulane University, New Orleans, LA.

Judiciously selecting carriers of target genetic variants is crucial for the success of a target deep sequencing study. Extreme phenotype sampling (EPS) has been widely employed to identify complex trait genes. EPS can enrich rare genetic causal variants compared to naïve random sampling (NRS). An intuitive alternative is extreme residual sampling (ERS) - selecting individuals with extreme phenotypic residuals after adjusting for some covariates. However, it remains unclear when local genetic covariates within target genomic regions should be adjusted for to enrich target genetic variants at sampling stage. Heteroscedasticity is ubiquitous in real data but largely ignored in gene mapping for complex traits, especially that of admixed subjects. People pay most of attention on the phenotypic mean instead of phenotypic variance. In this article, we first formulated the powers of ERS with adjusting for the local genetic covariate and EPS to include carriers of the target variant under heteroscedasticity model. In terms of inclusion power, we specified diverse superiorities of EPS and ERS. Second, given budget restriction,, Our findings provide genomic researchers with novel sequencing extremes strategy combining EPS and ERS to determine the truncation threshold and design cost-effective target sequencing studies. Last, we apply our novel method in real data to identify genetic causal variants for complex diseases.

1798M

Use of exome sequencing data for the analysis of population structures, inbreeding, and familial linkage. *V. Pedergnana[1,2], A. Belkadi[1], A. Abhyankar[3], Q. Vincent[1], Y. Itan[4], B. Boisson[4], J.L. Casanova[1,4,5], L. Abel[1,4].* 1) Laboratory of Human Genetics of Infectious Disease, INSERM U1163, University Paris Descartes. Imagine Institute, Paris, France; 2) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 3) New York Genome Center, New York, NY, USA; 4) St. Giles Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, the Rockefeller University, New York, NY, USA; 5) Howard Hughes Medical Institute, New York, NY, USA.

Numerous methods have been proposed to analyze whole exome sequencing (WES) data in order to discover potential causal variants in Mendelian disorders and in more complex traits. These methods could benefit from additional information such as linkage studies in the study of Mendelian diseases. Population stratification could also be an issue in the analysis of WES data when focusing on complex traits. Both linkage and population structure analyses are classically conducted through genome-wide (GW) SNP arrays. Here, we compared the information yielded by WES data to that provided by SNP array data in terms of analyses usually performed by SNP array data such as principal component analyses (PCA), linkage studies, and homozygosity rate estimation. We analyzed 123 subjects originating from six world regions, including North Africa and Middle East which are regions poorly covered by public database and presenting a high consanguinity rate. A number of quality control (QC) filters were tested and applied to the WES data. Compared to results obtained with SNP array data, we found that WES data provided accurate prediction of population substructure and led to highly reliable estimation of homozygosity rates (correlation > 0.94 with the estimations provided by SNP array). Linkage analyses showed that the linkage information provided by WES data was on average 53% lower than the one provided by SNP array at the GW level, but 58% higher in the coding regions. In conclusion, WES data could be used after appropriate QC filters to perform PCA analysis and adjust for population substructure, to estimate homozygosity rates, and to perform linkage analyses at least in coding regions.

Less than 20% of familial breast cancer (BC) cases who undergo genetic testing for *BRCA1* and *BRCA2* carry a pathogenic mutation in one of the two genes. The GENESIS (GENE SISter) study was designed to identify new BC susceptibility genes in women attending the cancer genetics clinics and with no *BRCA1/2* mutation. The study is based on enrichment of the study population in genetic factors through case selection based on familial criteria, but also on the consideration of environmental factors and endophenotypes to assess potential genetic heterogeneity. For instance the study sample may be stratified on characteristics such as mammary density or tumour characteristics. The study involves the French national network of genetic counsellors, and the enrolment of patients, the collection of their clinical, epidemiological, familial and biological data are centralized by a coordinating centre. The purpose of this communication is the description of the study design and of the available resources. Index cases (and their affected sisters) were eligible when diagnosed with infiltrating mammary or ductal adenocarcinoma, having no *BRCA1/2* mutation, and having a sister with BC. In addition, unrelated controls and unaffected sisters were recruited. Inclusion of participants started in February 2007 and ended in December 2012. A total of 1,711 cases and 2,829 sisters and controls were included. 98% of participants completed the epidemiological questionnaire and provided a blood sample, 68% of them were able to provide mammograms. Index cases were on average 59 years old at inclusion, were born in 1950, and were 49.7 years at BC diagnosis. The mean age at diagnosis of affected sisters was slightly higher (51.4 years). One of the initial aims of GENESIS was to recruit affected sibpairs. A total of 785 affected sisters accepted to participate. The representativeness of the control group has been verified. The size of the study (over 4500 participants), the availability of biological specimen and the clinical data collection together with the detailed and complete epidemiological questionnaire makes it a unique national resource to investigate the missing heritability of BC by taking into account environmental and lifestyle factors and stratifying data on endophenotypes to decrease heterogeneity. Molecular analyses including high-throughput genotyping and massive-parallel sequencing projects have started.

SURVIVAL MONITORING DURING THE FIRST YEAR OF LIFE OF INFANTS WITH BIRTH DEFECTS IN A HIGH COMPLEXITY HOSPITAL OF THE CITY OF CALI, COLOMBIA, 2012-2013. *F. Ruiz[1], Y. Ariza[1], H. Pachajoa[1, 2].* 1) Centro de Investigaciones en Anomalías Congénitas y Enfermedades Raras (CIACER), Universidad Icesi, Cali, Colombia; 2) Fundación Clínica Valle del Lili, Cali, Colombia.

Introduction: Congenital anomalies are structural defects that can be fatal or produce physical and / or mental disabilities. In the literature numerous studies about the prevalence and etiology of birth defects are reported, that include mortality analysis that focus on the contribution of these conditions to the perinatal and infant death rates, and in few opportunities focuses on survival of those affected. This study aims to describe survival during the first year after birth in a group of children with birth defects. Methodology: A retrolective cohort study with internal comparison group was conducted. Primary and secondary sources of information were used. For patient identification it was resorted to the database of the birth defects surveillance registry that takes place in a clinical institution of higher complexity in the city of Cali. Identifying individuals born with birth defects in the period between t October 1, 2012 and May 31, 2013. The obtained data were analyzed by the Kaplan - Meier to determine the probability of survival. Results: This study showed that the probability of survival during gestation ranged from 98.4 % at week 20 to 79.0% during the first 24 hours after birth. In the subgroup of patients who survived the first day after birth, only one death was recorded, so by the end of week 96 of follow-up, the group had a survival probability of 91.7% average. Conclusion: It is of importance to extend the network of surveillance and monitoring of birth to other health institutions in the city of Cali, for the purpose of establishing a surveillance registry of birth defects that is representative of the city, and that allows an adequate sampling that provides an accurate overview of the current state of epidemiology, health care and survival of patients with birth defects in the city of Cali.

1801M

The simulation of the confounding effect on cryptic relatedness for environmental risks in cohort studies. *K. Shibata, A. Tatsukawa, S. Ogishima, K. Shimokawa, S. Nagaie, N. Nakamura, J. Nakaya.* Tohoku University.

The impact of cryptic relatedness (CR) on genomic association studies is well studied and known to inflate false-positive rates as reported. In contrast, conventional epidemiological studies for environmental risks, the confounding effect of CR is still uninvestigated. In our previous study, we showed that heritability for liability might reflect on the estimation of regression coefficients between systolic blood pressure and environmental risk factors using real data. On the other hand, it is difficult to examine the confounding effect on CR in more detail using real data under the changes to the setting. In our simulation study, we detail an investigation on the confounding effect of unadjusted CR among a rural cohort in the quantitative phenotype mean effect using simulation data under a different heritability setting. Using SIBSIM, we generated combined independent individual samples and family data contained with two generations, and one-way analysis of variance to determine whether the confounding effect of CR was affected by environmental variance as environmental risk factors in a different setting: sample size (<2000), the ratio of CR to the population, and heritability for liability (10%, 20%, 30%, 40%) in a simulation cohort population. We present a simple model to illustrate the effect of CR on the estimation of phenotype mean effect. We are now extensively analyzing this issue in different settings incorporated with the prevalence in the subpopulation without CR, the prevalence in CR, and the population prevalence using family data contained with two , three or four generations.

1802T

Assessing the potential impact of low participation in DNA buccal swab collection on the validity of effect estimates. *M.M. Jenkins[1], J. Reefhuis[1], H. Razzaghi[1,2], A. Herring[3], M.L. Gallagher[1], M.A. Honein[1], The National Birth Defects Prevention Study.* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Oak Ridge Institute for Science and Education, Oak Ridge, TN; 3) The University of North Carolina, Chapel Hill, NC.

Low participation and potential selection bias for specimen collection in gene-environment interaction studies threaten validity. To better understand if effect estimates obtained from participants who submitted DNA buccal swab samples will be impacted by selection bias, we examined the associations between self-reported pregestational diabetes mellitus (PGDM) and four birth defects among families who did and did not submit samples, stratified by maternal race-ethnicity (non-Hispanic white, non-Hispanic black, and Hispanic). Following a telephone interview in a multi-site, population-based, case-control study (National Birth Defects Prevention Study), mothers with estimated dates of delivery between 1997 and 2009 were asked to collect and submit buccal swab samples. Samples were submitted for 52% of interviewed mothers, their infants, or both. For each birth defect, maternal race-ethnicity-stratified ratio of odds ratios (ROR) and corresponding 95% confidence intervals (CI) were calculated using logistic regression, comparing the ORs for the PGDM/birth defect association of families who did not submit samples to the ORs for the PGDM/birth defect association of families who did submit samples, while adjusting for maternal age at delivery. Analyses included control families with live born infants who had no major structural birth defects (N=8775), families with pregnancies affected by limb reduction defects (N=958), neural tube defects (N=1615), orofacial clefts (N=3509), or septal heart defects (N=3762). 1% of control mothers reported PGDM versus up to 7% of case mothers. Submitting samples was not associated with reporting PGDM among non-Hispanic black and Hispanic control families but non-Hispanic white control families who submitted samples reported PGDM less often. Statistically significant differences in the effect estimates for the PGDM/birth defect association between families who did or did not submit samples were observed among non-Hispanic black families whose child had an orofacial cleft (ROR=7.58, 95% CI 1.02-56.49, P=0.048) and non-Hispanic white families whose child had a septal heart defect (ROR=0.32, 95% CI 0.13-0.76, P=0.010). We found no evidence to support different effect estimates of PGDM and birth defects in the 10 other analyses among these three race-ethnicities. Further analyses will be completed with other exposures and birth defects.

The Million Veteran Program (MVP): A National Resource for Genomic and Epidemiological Research. *S. Muralidhar[1], J.M. Gaziano[2], J.P. Concato[3], S. Whitbourne[2], J. Deen[2], J. Moser[1], K. Schaa[1], S. Pyarajan[2], R. Przygodzki[1], T.J. O'Leary[1].* 1) Office of Research and Development , Department of Veterans Affairs, Washington, DC; 2) VA Boston Healthcare System, 150 S. Huntington Ave, Boston, MA-02130,; 3) VA Connecticut Healthcare System, 950 Campbell Ave. Bldg 35A (151B), West Haven, CT 06516.

Genomic discoveries are critically dependent on having a well-defined cohort with a sufficiently large number of subjects to ensure statistically and clinically meaningful associations. The Department of Veterans Affairs Million Veteran Program (MVP) was launched in 2011 to create a cohort of Veterans, one-million strong to leverage the excellent electronic medical record resource and combine it with genomic data and self-reported survey data to allow for both original and replication studies on diseases and conditions prevalent in Veterans. With mail-based recruitment, face-to-face enrollment at approximately 50 VA medical centers and broad consent for research, MVP has enrolled over 275,000 Veterans to date. Future models of online enrollment are currently under development. A centralized resource for computation and data analysis called the Genomic Information System for Integrative Science (GenISIS), is under development to facilitate data analysis in a secure environment. Approximately 200,000 samples are currently being genotyped on a customized Affymetrix Axiom chip and smaller subsets of samples are undergoing whole exome and genome sequencing, all through contracted services. The initial focus of analysis will be on mental health conditions such as PTSD, schizophrenia and bipolar disorder, other conditions predominant in the MVP cohort, as well as the exceptionally aged. Approved researchers will access data within the GenISIS environment. Results of the recruitment strategies, overview of demographics and diseases prevalent in the cohort, and updates on the informatics infrastructure as well as genetic analysis will be presented.

Genotype imputation performance in multiple ethnicities via comparing with whole-genome sequencing data. *H. Zhan, N. Bing, S. Paciga, J. Wendland, S. John, B. Zhang.* Worldwide Research & Development, Pfizer Inc., Cambridge, MA., USA.

It is well known that genotype imputation can boost the power of genome-wide association studies by imputing genotypes not observed in the sample. It facilitates the identification of susceptibility loci for complex diseases. Over the past decade, many imputation algorithms and software have been developed to impute genotype for samples from various populations. In this study, we investigated the genotype imputation accuracy of IMPUTE2 and MaCH-Admix using 148 subjects from multi-ethnic populations (African, Asian, European and Hispanic). The subjects were genotyped in Illumina HumanOmniExpress plus exome array and at the same time whole genome sequenced at high coverage (30X). Instead of masking the genotypes in some specific loci, we directly assessed imputation accuracy by comparing the imputed genotype with the real genotype from sequencing data. In order to address the potential imputation bias, imputation accuracy is based on the concordance for heterogeneous genotype. We found that IMPUTE2 is more computationally efficient than MaCH-Admix. For common variants (MAF>0.01), IMPUTE2 and MaCH-Admix have similar imputation accuracy. However, MaCH-Admix has relatively higher imputation accuracy than IMPUTE2 for the rare variant (MAF<0.01). Both IMPUTE2 and MaCH-Admix show better imputation accuracy in common variants than rare variants. The imputation results also provide valuable information for post-imputation quality control. Optimal threshold for selecting imputed SNPs can be determined for one fixed imputation accuracy. In addition, we also imputed HLA classical alleles and compared with HLA loci called from sequencing data using HIBAG (an R package). HIBAG imputes seven HLA loci with increased accuracy across ethnicities correlated with increased posterior probability of imputed HLA type. In general, we demonstrated that genotype and HLA classical alleles can be accurately imputed for multiple ethnicities using current imputation methods via comparing sequencing data. IMPUTE2 and MaCH-Admix have similar accuracy performance, and IMPUTE2 has better computation efficiency.

A Strategy for Testing Zero Variance Components with Application to QTL Association Mapping in Admixture Population. *J. Zhou[1], H. Zhou[2].* 1) University of Arizona, Tucson, AZ; 2) North Carolina State University, Raleigh, AZ.

It is widely known that population substructure can distort the results of genetic association analysis, especially when rare variants are present such as in next-generation sequencing (NGS) studies. Linear mixed effects model (LMM) were proposed before for adjusting population substructure while testing typically common variant as a fixed effect. To improve the power of testing multiple rare variants while adjusting for population substructure, one can jointly test them as a random effect in conjunction with the random effect from population substructure. This brings challenge to the current testing methods that are computationally intensive and hard to scale to NGS. We propose a powerful and scalable strategy for testing zero variance component in presence of multiple variance components in LMM. Our approach combines the recent development of exact (restrictive) likelihood ratio test with single variance component and a strategy for reducing LMM with multiple variance components to that with a single one. The performance of the strategy is demonstrated on both synthetic and real data.

1806S

Estimating base-calling error rates in next-generation sequencing data using overlapping read pairs. *Y.Y. Lo[1], S. Zöllner[1,2], The BRIDGES Consortium.* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Genotype calling from short read sequencing data requires accurate estimates of base errors in the reads. Such errors can occur in multiple steps of the sequencing experiment, particularly during the PCR and sequencing steps. Base errors from all steps appear as mismatches to the reference genome on aligned reads, hence the error models typically aggregate errors from all sources. Besides, base information from non-independent sequence reads are often discarded or wrongly incorporated into the base-calling error model intended for independently sequenced reads. Disentangling the sources of base-calling errors would allow more efficient use of all sequencing reads.

Here we aim to distinguish between base-calling errors generated by PCR and by the sequencing machine (machine error), using overlapping read pairs (ORPs) arising from short PCR fragments in paired-end sequencing. ORPs replicate PCR errors in the overlapping region, while each read in the pair is independently sequenced. Therefore, per genomic position, discordant bases from an ORP are the result of at least one machine error but not PCR error, regardless of the true genotype. On the other hand, if an ORP reports the same base, but different from the reference allele, either the underlying base is a true variant, or the ORP has at least one PCR error or two machine errors. Based on these observations, we derive maximum-likelihood estimators for PCR error and machine error using the counts of discordant and concordant bases from ORPs. We calculate these estimates, as functions of read cycle and base quality score, using an expectation-maximization algorithm.

We apply our method to a subset of data from a whole-genome sequencing study (median 8x coverage, 806 individuals) with 40-60% ORPs. From these ORPs, we estimate that base-calling errors generated by the sequencing machine are approximately twice as common as PCR errors. We quantify the contribution of read cycle and base quality score to these base-calling error estimates. We evaluate the mean and variance of these predicted error rates across individuals. Understanding the contribution of both error sources to base-calling allows more efficient use of ORPs, hence better modeling of errors and improved accuracy in variant calling.

1807M

Overcoming Systematic Miscalibration of Linear Mixed Model Test Statistics in Genetic Association Studies by Leveraging Ancestry Representative Principal Components. *M.P. Conomos, T. Thornton.* Biostatistics, University of Washington, Seattle, WA.

A plethora of linear mixed model based procedures have been developed recently to control Type I error rates in genetic association studies of complex traits by simultaneously accounting for both population and pedigree structure among sample individuals. The general approach taken by these methods is to compute a genome-wide genetic similarity matrix to be included as part of the covariance structure of the phenotype when fitting the model. These mixed model based approaches control genomic inflation genome-wide; however, it has recently been shown that they may not adequately control for false positives at SNPs that are unusually differentiated between ancestral populations (Price et al., 2010). In reality, the differentiation in allele frequencies between ancestral populations varies greatly across the genome, and proper calibration of test statistics from these methods should be a concern even at SNPs that are not unusually differentiated. Through the use of simulation studies of samples from structured populations with related individuals, we demonstrate that adjusting for a genetic similarity matrix calculated genome-wide controls Type I error well at SNPs with an average amount of differentiation, but it also leads to a systematic inflation or deflation of test statistics for SNPs that are more or less differentiated. By including ancestry representative principal components as fixed effect covariates in the mean model in addition to the genetic similarity matrix included in the covariance structure, we are able to correct for this issue and obtain well-calibrated test statistics genome-wide. Additionally, we demonstrate that fitting the mixed model with an ancestry adjusted genetic similarity matrix may increase power to detect true associations with traits that are correlated with ancestral background. We apply our testing procedure to a variety of blood phenotypes measured on African American and Hispanic women in the Women's Health Initiative SNP Health Association Resource (WHI-SHARe) study, and we see increased significance over existing methods at SNPs associated with white blood cell count.

Evaluation of population stratification in a large biobank linked to Electronic Health Records. *M. de Andrade[1], G. Thromp[2], A. Burt[3], D.S. Kim[3,4], S.S. Verma[5], A.M. Lucas[5], S.M. Armasu[1], J.A. Heit[6], M.G. Hayes[7], H. Kuivaniemi[2], M.D. Ritchie[5], G. Garvik[3,4], D.R. Crosslin[3,4].* 1) Div Biomed Statistics & Informatics, Mayo Clinic, Rochester, MN; 2) The Sigfried and Janet Weis Center for Research, Geisinger Health System, Danville, PA; 3) Dept Genome Sciences, Univ of Washington, Seattle, WA; 4) Dept Medicine, Div Med Genet, Univ of Washington, Seattle, WA; 5) Center for Systems Genomics, Dept Biochemistry and Mol Biology, Pen State Univ, University Park, PA; 6) Div Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 7) Div Endo, Metabolism and Mol Medicine, Fienberg School of Medicine, Northwestern Univ, Chicago, IL.

For genomic association studies, combining samples across multiple studies in Networks or “Big Science” is standard practice. Increasing the number of subjects allows for power needed to assess association. Controlling for genomic ancestry is common, but there is a need to standardize the approach when calculating principal components (PCs) across cohorts such as elimination of SNPs with linkage disequilibrium (LD) pruning at $r = 0.5$ and a MAF < 0.03. Due to heterogeneity between sites, adjusting for PCs only, does not remove the site and platform bias. Therefore, we propose an alternative approach of generating PCs for our cohort to control for site and platform bias in addition to ancestry difference. Our approach consists on deriving the PCs using the loadings calculated from reference samples, much like generating PCs using the founders of families. We applied our approach using the electronic Medical Records and Genomics (eMERGE) Venous Thromboembolism African ancestry cohort that consists of four adult sites and four genotyping platforms that had previously been analyzed controlling for site, platform and ancestry. Our results showed that our approach provided similar association results while both controlling for inflation ($\theta = 1.01$ and 1.02 for standard and loadings, respectively) with the advantages of controlling for fewer covariates, thus less degrees of freedom. Therefore, we expect this approach will serve as a “Best Practices” for similar projects, and as a reference for assessing and controlling for confounders in addition to ancestry in genetic association studies.

1809S

Effects of Genotype Uncertainty on Statistical Analysis of Variant Association Studies. *C. Palmer, I. Pe'er.* Columbia University Medical Center, New York, NY.

Background: Standard genotype variant association methods assume high certainty in underlying genotype calls. The extent to which high certainty is actually present varies between genotyping method: array, sequencing, or genotype imputation. In all cases, widespread use of rounding methods ignores missingness in genotypes. Established statistical missingness theory shows that unmodeled bias in missingness patterns may introduce artifacts in downstream analysis. We have undertaken an evaluation of the effects of mishandling missingness in genotype association. **Methods:** We use as a case study genotype imputation, where genotype probabilities are readily accessed from existing software. We have simulated a multi-platform meta-analysis of an association study for complex traits in a simulated cohort of ~20000 individual genomes of stratified European ancestry. Each sample consists of variants at all 1000 Genomes European segregating sites. Sites not present on a particular simulated platform are masked and then imputed using standard genotype imputation with prephasing. We evaluate existing methods for simple linear and logistic regression on imputed genotypes, which handle missingness to varying degrees, and compare these results to similar analyses on the unmasked variants. We extend this testing to other more complex analysis tools (EMMAX, generalized estimating equations, ...), for which alternative strategies for handling genotype uncertainty are not currently available. **Results:** Existing analysis tools operating on uncertain genotype estimates generate directionally biased estimates of variant effect size, where the magnitude of bias tends to increase with increasing genotype uncertainty. Monte Carlo methods for sampling from the posterior distribution of genotypes outperform the best methods for handling missingness currently in use. We furthermore find that imputation probabilities in particular are not consistent, in the sense that they do not accurately reflect the true probability distributions they are estimating. Methods for analyzing imputed data must model and correct this bias. **Conclusion:** The current standard approximation of probabilistic genotype estimates with “best-guess” genotypes is suboptimal. Fortunately, this approximation can be readily avoided with simple resampling techniques. We recommend that uncertainty and bias correction be considered in all future analyses of uncertain genotype data.

Assessing the power of the Affymetrix Axiom® CEU array for studying rare and low-frequency variants in a European population sample. *B. Schormair[1,2,3], E. Tilch[1,2], D. Czamara[4], B. Pütz[4], J.S. Ried[5], P. Lichtner[1,2], C. Trenkwalder[6], W. Paulus[7], B. Högl[8], K. Berger[9], I. Fietze[10], W.H. Oertel[11], T. Meitinger[1,2], C. Gieger[5], B. Müller-Myhsok[4,12,13], J. Winkelmann[1,2,3,12,14], EU-RLS-GENE-Consortium.* 1) Institute of Human Genetics, Helmholtz Zentrum München, Munich, Germany; 2) Institute of Human Genetics, Klinikum rechts der Isar, Technische Universität München, Munich, Germany; 3) Neurologische Klinik und Poliklinik, Klinikum rechts der Isar, Technische Universität München, Munich, Germany; 4) Max Planck Institute of Psychiatry, Munich, Germany; 5) Institute of Genetic Epidemiology, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany; 6) Paracelsus Elena Klinik, Kassel, Germany; 7) Department of Clinical Neurophysiology, University Medical Center, Georg August Universität Göttingen, Göttingen, Germany; 8) Neurologische Klinik, Medizinische Universität Innsbruck, Innsbruck, Austria; 9) Institut für Epidemiologie und Sozialmedizin, Westfälische Wilhelms Universität Münster, Münster, Germany; 10) Zentrum für Schlafmedizin, Charité Universitätsmedizin, Berlin, Germany; 11) Neurologische Klinik, Philips Universität Marburg, Marburg, Germany; 12) Munich Cluster for Systems Neurology (SyNergy), Munich, Germany; 13) Institute of Translational Medicine, University of Liverpool, Liverpool, UK; 14) Department of Neurology and Neurosciences, Stanford Center for Sleep Medicine and Sciences, Stanford University, Palo Alto, California, USA.

Genome-wide association studies (GWAS) were initially designed to capture common variants with minor allele frequencies (MAFs) of ≥ 5%. However, for most complex diseases, risk loci identified by GWAS explain only a small proportion of the heritability. Rare (MAF < 1%) and low-frequency variants (1% ≤ MAF < 5%) are suspected to account for a part of the missing heritability. They require large sample sizes for sufficient study power, currently limiting the application of next-generation sequencing. Therefore, information about their coverage by commercial genotyping arrays based on experimental data is important to aid researchers in study design. The Axiom® CEU1 array is optimized for European populations, but only 20% of its content are variants with a MAF < 5%. Autosomal genotype data of 8,488 individuals of European descent, originating from Germany and Austria, was used to assess its performance for rare and low-frequency variants. Standard GWAS quality control was applied. Exclusion criteria for markers included a call rate <98%, discordant calls in duplicates, deviation from Hardy-Weinberg equilibrium with $p<10^{-5}$, and insufficient cluster quality. Subsequently, imputation to 1000Genomes Phase I v3 content was performed. Genotypes were prephased using SHAPEIT, followed by imputation with IMPUTE2 in 5MB-chunks. To optimize representation of rare haplotypes, samples were phased together with 8,752 samples from 7 other European populations genotyped on the same platform. Genotyping quality control had a stronger impact on rare variants compared to low-frequency and rare variants. Whereas 90% and 91.2% of these were retained, only 82% of rare variants were kept. Quality of imputation was judged using IMPUTE2's info criterion, using a value of ≥ 0.8 to indicate high-quality data. For rare variants, only 4% of the 1000 Genomes dataset were imputed with high quality. For low-frequency variants, this increased to 59.7% and for common variants to 85.9%. As a subset of the study samples were also genotyped on the Illumina HumanExome® array, concordance rates for the three categories were calculated. These were all > 99.9%, indicating comparable quality across MAF bins. Low-frequency variants are reasonably well covered by the Axiom® CEU 1 array, rare variants only very fragmentary. Imputation using a reference panel build from both Axiom and HumanExome array data might improve coverage in further samples.

1811T

Addressing population-specific multiple testing burdens in genetic association studies. *R.S. Sobota[1,2], D. Shriner[3], N. Kodaman[1,2], R. Goodloe[1], W. Zheng[4], Y.T. Gao[5], T.L. Edwards[1,4], C.I. Amos[2], S.M. Williams[2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Genetics, Dartmouth College, Hanover, NH; 3) Center for Research on Genomics and Global Health, NIH, Bethesda, MD; 4) Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, TN; 5) Shanghai Cancer Institute, Shanghai, China.

The number of effectively independent tests performed in genome-wide association studies and the corresponding genome-wide significance level varies by population. Therefore, a common p-value threshold may be inappropriate. To assess this, we estimated the number of independent SNPs for all Phase 3 HapMap samples using the LD pruning function in PLINK. We also used an autocorrelation-based approach to verify the HapMap findings, and tested it on 1000 Genomes data to estimate the number of independent tests in whole genome sequences. The number of independent tests is consistent with autocorrelation corresponding to LD pruning at r^2= 0.3. Using the number of independent tests from both methods, we calculated appropriate population-specific thresholds by Bonferroni correction. African populations had the most stringent thresholds (e.g., 1.49×10^-7 for YRI, r^2=0.3), followed by European/Indian populations (3.12×10^-7 for CEU, r^2=0.3), and East Asian populations (3.75×10^-7 for JPT, r^2=0.3). Applying our methods to a previously published GWAS of melanoma, we identified two additional SNPs as significant when data were LD-pruned at r^2=0.3, and five more when pruned at r^2=0.1. These SNPs all mapped to genes previously associated with melanoma; two SNPs were not significant at 5×10^-8, likely representing type 2 errors. Applying our method to a Chinese breast cancer GWAS (r^2=0.3) yielded 50 additional significant SNPs, 19 of which were in or near genes previously associated with the phenotype. Our methods indicate that the conventional correction threshold is not appropriate for many association studies, especially in populations that were recently founded.

1812S

Statistical tests for GWAS in small, admixed populations. *L. Skotte[1], I. Moltke[1,2], A. Albrechtsen[1].* 1) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 2) Department of Human Genetics, University of Chicago, Chicago, IL, USA.

It has recently been demonstrated that genetic association studies in small and isolated populations offer increased statistical power due to extended linkage equilibrium and increased genetic drift over many generations. Many historically small and isolated populations, like the Greenlandic, have recently experienced substantial admixture, which can complicate the association studies, but also further inform them. At a causal SNP locus, the risk allele assumably has the same effect regardless of the carrier's ancestry. However, if a nearby variant is not causative and the linkage disequilibrium pattern differs between the ancestral populations, the effect size may depend on which population the risk allele was inherited from. We introduce a new statistical method for association testing in small, admixed populations, where the effect sizes are allowed to depend on the unknown local ancestry of the allele, which enters as a latent variable. Our method does not rely on accurate inference of local ancestry, yet gives a dramatic increase in statistical power to detect associations and in addition allows for testing for difference in effect size between ancestral populations. Simulation studies show that the statistical power increase from 39% to 96% for a SNP locus with a modest effect size of 0.3 standard deviations in one of the ancestral population and no effect in the other (5000 samples with equally frequent admixture proportions in {0, 0.25, 0.5, 0.75, 1} and a p-value cutoff of 5e-10). In small populations, the samples included in the association study constitute a relatively large proportion of the population and therefore there will be a substantial amount of relatedness between the samples. Admixture and relatedness can lead to decreased power and increased type 2 error rates if not appropriately accounted for. To avoid increased type 2 error rates we use a linear mixed model approach that takes both admixture and relatedness into account.

1813M

The Power Comparison of the Haplotype-based Collapsing Tests and the Variant-based Collapsing Tests for Detecting Rare Variants in Pedigrees. *W. Guo, Y. Yao.* Unit of Statistical Genetics, NIMH, Bethesda, MD.

Abstract Background: Both common and rare genetic variants have been shown to contribute to the etiology of complex diseases. Recent genome-wide association studies (GWAS) have successfully investigated how common variants contribute to the genetic factors associated with common human diseases. However, understanding the impact of rare variants, which are abundant in the human population (one in every 17 bases), remains challenging. A number of statistical tests have been developed to analyze collapsed rare variants identified by association tests. Here, we propose a haplotype-based approach. This work inspired by an existing statistical framework of the pedigree disequilibrium test (PDT), which uses genetic data to assess the effects of variants in general pedigrees. We aim to compare the performance between the haplotype-based approach and the rare variant-based approach for detecting rare causal variants in pedigrees. Results: Extensive simulations in the sequencing setting were carried out to evaluate and compare the haplotype-based approach with the rare variant methods that drew on a more conventional collapsing strategy. As assessed through a variety of scenarios, the haplotype-based pedigree tests had enhanced statistical power compared with the rare variants based pedigree tests when the disease of interest was mainly caused by rare haplotypes (with multiple rare alleles), and vice versa when disease was caused by rare variants acting independently. For most of other situations when disease was caused both by haplotypes with multiple rare alleles and by rare variants with similar effects, these two approaches provided similar power in testing for association. Conclusions: The haplotype-based approach was designed to assess the role of rare and potentially causal haplotypes. The proposed rare variants-based pedigree tests were designed to assess the role of rare and potentially causal variants. This study clearly documented the situations under which either method performs better than the other. All tests have been implemented in a software, which was submitted to the Comprehensive R Archive Network (CRAN) for general use as a computer program named rvHPDT.

1814T

Variation in estimates of kinship observed between whole-genome and exome sequence data. *E. Blue.* Div Med Gen, Unversity of Washington, Seattle, WA.

Genotypic variation is often combined with Mendel's laws of inheritance and population genetic theory to estimate the relationships between individuals. These relationships are clearly important when identifying genetic variants influencing familial disease, when performing quality control to confirm pedigree relationships and when testing the co-segregation of a variant with the phenotype. However, it is also important when testing association of a genetic variant with case/control status in a set of "unrelated" subjects: this is why principal components or estimates of kinship are included as covariates to minimize the effects of population stratification on results. Reliable estimates of the relationship between subjects are necessary.

With the advent of next-generation sequencing technology and the focus on exome data for disease gene discovery, we need to know whether estimates of relationships between samples based on exome data are reliable. The exome represents ~1% of the genome, and definitely does not represent a random subsample of genomic variation. In this study, we compare a method-of-moments and the KING-robust estimator of kinship applied to analyze Illumina HumanOmni1-Quad SNPchip data, whole exome sequence data, and whole genome sequence data for four subjects with known pedigree relationships. SNPchip-based estimates of kinship are quite similar to the pedigree-based expectation, with the KING-robust estimates deviating slightly more than the method-of-moments estimate. However, the exome-based estimates are much more variable: overestimating some relationships by as much as a third and underestimating others by nearly a quarter of the pedigree-based expectation.

We explore the effects of minor allele frequency, linkage disequilibrium, and the number of markers on estimates of kinship drawn from whole genome sequence data. These results suggest that investigators must account for the non-random distribution of variation in the exome when estimating relationships for pedigree verification and disease gene identification.

1815S

Quality control procedures for Whole Exome Sequencing Studies with application to a large family-based study: The International Consortium of Prostate Cancer Genetics (ICPCG) Study. *SK. Eeles[18], J. Cunningham[2], DJ. Schaid[1], SN. Thibodeau[2] on behalf of the ICPCG.* 1) Dept of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Dept Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Medical Genome Facility, Mayo Clinic, Rochester, MN; 4) Dept of Internal Medicine, Univ of Utah School of Medicine, Salt Lake City, UT; 5) Fred Hutchinson Cancer Research Center, Seattle, WA; 6) Dept of Urology, The Johns Hopkins Hospital, Baltimore, MD; 7) Dept of Internal Medicine and Urology, Univ of Michigan Medical School, Ann Arbor, MI; 8) Medical Biochemistry and Genetics, Univ of Turku, Turku, Finland; 9) Integrated Cancer Genomics Division, The Translational Genomics Research Institute, Pheonix, AZ; 10) Service Urology-Batiment Gabriel, Hospital Tenon, Paris, France; 11) Cancer Epidemiology Centre, Cancer Council Victoria, Melbourne, Victoria; 12) Dept of Urology, University of Ulm, Ulm, Germany; 13) Dept Health Research and Policy, Standford University, Stanford, CA; 14) Dept of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 15) Northwestern University Feinberg School of Medicine, Chicago, IL; 16) Depts of Oncology and Human Genetics, Montreal General Hospital, Montreal, QC; 17) Dept of Genetics, LSU Health Sciences Center, New Orleans, LA; 18) Genetics and Epidemiology, Institute of Cancer Research, Sutton Surrey, UK.

With continued advances in Next-Generation Sequencing (NGS) technologies, Whole-Exome Sequencing (WES) is rapidly emerging as a popular approach to evaluate associations between genetic variation and complex phenotypes. WES provides a powerful tool to uncover disease-causing mutations and, when combined with a family-based study design, increases the chances of finding rare mutations. WES also introduces challenges due to the vast amount of data generated, complexity of bioinformatics processing, and potential batch effects. As relatively large sample sizes become more commonplace, there is an increasing need for fully automatable and methodical quality control procedures. We present a comprehensive yet flexible QC analysis pipeline for WES studies, illustrating its application on a large study of familial prostate cancer. The ICPCG has identified and sampled the most informative high-risk prostate cancer (PC) pedigrees known throughout the world. With the goal of identifying PC susceptibility loci utilizing this extraordinary collection of families, we have performed WES on 539 familial cases of PC derived from 366 families all having at least 3 affected men with PC: 257 cases from 84 families (the majority having 3 sequenced/family) and 282 singleton cases. 490 samples also have HumanOmniExpress array data for comparison of genotype calls. Sequencing used one of two Agilent capture kits (V3 or V4_UTR) and bioinformatic processing was completed using Novoalign alignment and GATK. Extensive quality control procedures were developed aimed at identifying poor quality samples, artifacts with the bioinformatics pipeline, and batch effects due to different sequencing conditions. QC analyses include: 1) coverage of the Agilent capture region; 2) alignment summaries; 3) comparison of variant call quality and counts by functional status; 4) call rates in the capture region; 4) concordance and discovery of array variants with WES variants; 5) sex verification; 6) relationship checks; 7) sample contamination; and 8) population stratification. Final quality control results from the WES of the 539 men will be presented.

Transportation of samples is essential for large-scale biobank projects. However, RNA degradation during pre-analytical operations prior to transportation can cause systematic bias in transcriptome data, which may prevent subsequent biomarker identification. Therefore, to collect high-quality biobank samples for expression analysis, specimens must be transported under stable conditions. In this study, we examined the effectiveness of RNA-stabilizing reagents to prevent RNA degradation during pre-analytical operations with an emphasis on RNA from peripheral blood mononuclear cells (PBMCs) to establish a protocol for reducing systematic bias. To this end, we obtained PBMCs from 11 healthy volunteers and analyzed the purity, yield, and integrity of extracted RNA after performing pre-analytical operations for freezing PBMCs at -80°C. We randomly chose 7 samples out of 11 samples, and systematic bias in expression levels was examined by real-time quantitative reverse transcription polymerase chain reaction (qRT-PCR) and RNA sequencing (RNA-Seq). Our data demonstrated that omission of stabilizing reagents significantly lowered RNA integrity, suggesting substantial degradation of RNA molecules due to pre-analytical freezing. qRT-PCR experiments for 19 selected transcripts revealed systematic bias in the expression levels of five transcripts. RNA-Seq for 25,223 transcripts also suggested that about 40% of transcripts were systematically biased. These results indicated that appropriate reduction in systematic bias is essential in protocols for collection of RNA from PBMCs for large-scale biobank projects. Among the seven commercially available stabilizing reagents examined in this study, qRT-PCR and RNA-Seq experiments consistently suggested that RNALock, RNA/DNA Stabilization Reagent for Blood and Bone Marrow, and 1-Thioglycerol/Homogenization solution could reduce systematic bias. On the basis of the results of this study, we established a protocol to reduce systematic bias in the expression levels of RNA transcripts isolated from PBMCs. We believe that these data provide a novel methodology for the collection of high-quality RNA from PBMCs for biobank researchers.

A Two Step Framework for Integrative Analysis of Genome Wide Methylation and Genotyping Studies. *N. Zhao, M. Wu.* Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA.

Integrative analysis of "multidimensional genomics data", especially genotypes (G) and DNA methylation (M), has been shown to be promising in elucidating the biological processes underlying the phenotype of interest. Currently many large GWAS consortia are expanding to simultaneously examine the joint role of DNA methylation. In this paper we propose a two-step model where in the first step we test for the joint genetic and epigenetic effect on certain phenotype and in the second step we evaluate the potential causal relationship between these variables. We develop statistical approaches that work at gene level for both genotype and methylation, allowing for common units between these two different data types. Powerful kernel machine framework was used in which pair-wise similarity in the trait values between individuals are compared to pairwise similarity in methylation and genotype values for a particular gene, with correspondence suggestive of association. Similarity in methylation and genotype is found by constructing an optimally weighted average of the similarities in methylation and genotype. For a significant gene, we continue to a second step which uses mediation analysis procedure which enables elucidation of the manner in which the different data types work, or do not work, together. We demonstrate through simulations and real data applications that our proposed testing approach often improves power to detect trait associated genes, while protecting type I error. Additionally, the approach can be easily applied to analysis of rare variants and sequencing studies.

Measuring population stratification in the Brazilian population: how accurate can we be? *L. AlvaradoArnez[1], T.P. Monteiro[2], C.S. Marques[1], C.C. Cardoso[3], M.O. Moraes[1], A.G. Pacheco[2].* 1) Laboratório Hanseníase, Instituto Oswaldo Cruz-RJ. Fiocruz, Brazil; 2) Programa Computação Científica-RJ, Fiocruz, Brazil; 3) Laboratório Virología Molecular, Departamento Genética, UFRJ, Brazil.

Stratification may affect genetic association studies in admixed populations. In Brazil, no study has thoroughly assessed the accuracy of different baseline populations used in controling stratification. We used simulations to compare the accuracy of 3 baseline populations (African and European from 1000 Genomes Browser and Amerindian from Northern Brazil). A stationary population of 30,000 individuals was evolved for 10 generations with starting SNP frequencies calculated from the original baseline. Migration was allowed between populations at varying rates with random mating and 20% fixation rate/generation. For each individual, 3 variables tracked ancestry background. Each scenario was repeated 100 times to account for simulation variability. Data was analyzed with the Admixture software set to obtain 3 clusters both considering as baseline population the same one utilized for simulation and using a different baseline population. Correlation coefficients and an extension of Kaplan-Meier curves were employed for comparisons. Fst was calculated to compare the degree of admixture considering 0.15-0.25 as great, 0.05-0.15 as moderate and 0-0.05 as small genetic divergence. The simulation process was implemented in Python with the library SimuPOP, and statistical analyzes were performed with the R environment. Our results indicate that the baseline population composed of individuals of African ancestry (YRI, LWK,ASW), European ancestry (FIN, GBR, IBS, TSI) and Amerindian (Northern Brazil) performed best in comparison to other baseline populations. Median correlation coefficients for this baseline population ranged from 0.97, 0.95 and 0.90 at migration rates of 0.005 (Fst= 0.45), 0.01 (Fst=0.34) and 0.02 (Fst=0.20) respectively. These results were robust when the other populations were used to start the simulation. The difference between the correlations from the 3 clusters using this baseline population presented a narrower interval as compared to other baseline populations tested. As expected, increased migration rates of 0.03 (Fst= 0.11) and 0.04 (Fst=0.06) reduced median correlation coefficients to 0.78 and 0.79, respectively. These results were also supported by Kaplan-Meier curves with a similar tendency. Our results point that one of the baseline population set is superior to other 2 tested and the accuracy decreases as admixture increases. Further studies are needed to address the impact in a scenario of an association study with stratification.

Genotyping of the UK Biobank resource, a large extensively phenotyped population collection. *D. Petkova[1], S. Murphy[2], C. Bycroft[1], C. Freeman[1], P. Donnelly[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) UK Biobank, Units 1-4 Spectrum Way, Adswood, Stockport, Cheshire, SK3 0SA, UK.

The UK Biobank project is a large prospective cohort study of 500,000 individuals aged 40-69 from the UK. With its large sample size and wealth of phenotypic information, the UK Biobank is a powerful resource to investigate how genetic and environmental factors influence a wide range of complex diseases. Samples of the participants' DNA are being genotyped at the Affymetrix Research Service Laboratory on the custom designed UK Biobank Affymetrix Axiom® array with over 800,000 SNPs, including content to provide good genome-wide imputation coverage for variants with frequency >1%, genome-wide content such as eQTLs, missense and loss of function variants, and content for cancers, metabolic and neurological disorders (including Alzheimer's). To introduce the UK Biobank resource, we describe results from quality control and analysis of the first 100,000 samples. In addition to standard QC methods, we discuss strategies for quality control of a very large dataset genotyped in multiple batches, with a large proportion of rare variants. We also characterize various aspects of the UK Biobank dataset: population structure, relatedness, gender misidentification and other sample statistics. The extension of the resource to include genome-wide genetic information on each individual is currently underway.

1820T

Spurious cryptic relatedness can be induced by population substructure, population admixture and sequencing batch effects. *D. Zhang, S. Li, G.T. Wang, S.M. Leal.* Center for Statistical Genetics, Baylor College of Medicine, Houston, TX.

It is important to identify cryptically related individuals in population-based association studies, since inclusion of related individuals can increase type I & II errors. Mixed models have been proposed to analyze data when related individuals are included in the study, but these methods can be computationally intensive and do not always sufficiently control type I & II errors. Another option is to only include one individual from a relative pair/group in the analysis. In population-based studies cryptically related individuals should be identified when performing data quality control. However, caution should be used, since population substructure/admixture and sequence data batch effects can cause detection of spurious relatedness. In order to investigate the problem we systematically evaluated the relatedness of 1,092 samples in the 1000 Genomes project and 2,300 African-American (AA) subjects from the NHLBI-Exome Sequencing project (ESP) via two published methods for kinship inference: (i) the PLINK algorithm which is based on identical-by-descent (IBD) statistic under the assumption of homogeneous population, and (ii) the KING-robust algorithm which uses an estimate of the genome-wide average heterozygosity across individuals to compute an estimator of kinship coefficient. For the 1,000 Genomes project we analyzed the data by country of origin, e.g. Japan, continent of origin e.g. Asia and sequencing batch by continent of origin and for the ESP data we analyzed the data for all AA individuals and separately by sequencing batch. We identified spurious cryptically related pairs of samples due to population substructure/admixture and sequencing batch effects with both methods, but the problem was more extreme for PLINK. For example, an excess of 3rd degree relatives were observed for AA individuals, when sequencing batch was not considered and also for 1000 Genomes project data when population substructure was introduced by analyzing the data by continent. Additionally, the kinship coefficients varied depending on how the analysis was performed, e.g. accounting for sequencing batch or not, caused reclassification of individuals, e.g from 1st degree to 2nd degree relatives. In addition to presenting the results of these analyses and showing the severity of the biases in the kinship coefficients, we also demonstrate strategies which can be used to evaluate if individuals are truly cryptically related or spurious relationships have been identified.

1821S

Correcting for population stratification in secondary genetic association studies using subsamples. *M.C. Babron[1,2], S. Benhamou[1,2,3], E. Génin[4], R. Kazma[5].* 1) Inserm U946, Variabilité Génétique et Maladies Humaines, Paris, France; 2) Université Paris-Diderot, Sorbonne Paris-Cité, UMRS-946, Paris, France; 3) Service de Biostatistique et d'Epidémiologie, Gustave Roussy, Villejuif, France; 4) Inserm U1078, Génétique, Génomique Fonctionnelle et Biotechnologies, CHU Morvan, Brest, France; 5) Centre National de Génotypage, Institut de Génomique, CEA, Evry, France.

Population stratification (PS) is a potential cause of false positive results in genome-wide association studies, when cases and controls are drawn from a population comprising multiple groups with different disease prevalences. To correct for PS, the inclusion of several principal components (PCs) of genome-wide genotypes as covariates has been shown to control for the inflation of association statistics and has become standard procedure. After testing for genetic association with a primary phenotype of interest, secondary hypotheses are often tested using a fraction of the initial sample for which the secondary phenotype is available. In practice, correction for subsample stratification is done using the PCs that were calculated for the full initial sample. This approach makes the assumption that the subsample has a population structure similar to that of the initial sample, used to calculate the PCs. However, this might not always be the case. In fact, the strategy that uses PCs calculated on the initial sample to correct for PS, when testing secondary hypotheses on a subsample, has not yet been evaluated. Here, we assess the robustness of PS correction using PCs calculated with the full initial sample or a subsample that comprises a distribution of subpopulations that is different from the initial population. First, the collection of 5,811 individual genome-wide genotypes (Illumina 317k) from 13 European countries is considered as the initial case-control sample. Then, to simulate subsamples with a different population structure, we randomly draw sets of cases and controls with different proportions from extremes. These extremes match up with the North-East and South-West quadrants of the space defined by the first two PCs calculated on the initial sample. Simulating 100 replicates of a subsample with 75% of cases and 25% of controls belonging to the North-East quadrant (the rest belonging to the South-West quadrant), the Q-Q plots show a strong type 1 error inflation ($\theta_{GC} = 1.3513$) without PS correction which is corrected satisfactorily with as low as 2 PCs calculated on the initial sample ($\theta_{GC} = 1.0019$) or on the subsample ($\theta_{GC} = 1.0014$). However, the use of PCs calculated on the subsample corrects PS better than PCs calculated on the initial sample for specific variants in genes which are strongly stratified along this axis (*LCT*). Further ongoing simulations will assess these approaches in different situations of subpopulation structure.

1822M

Correction for population stratification and relatedness in case-control studies using logistic mixed models. *H. Chen, C. Wang, Z. Li, X. Lin.* Biostatistics, Harvard School of Public Health, Boston, MA.

In genome-wide association studies (GWAS), population stratification and relatedness can result in spurious association findings. Principal component analysis (PCA) has been widely used to adjust for population structure. However, PCA does not work well in the presence of familial or cryptic relatedness in addition to population stratification. Linear mixed models have been proposed as an alternative method for correcting for population stratification and relatedness for continuous phenotypes. However, the normality assumption required by linear mixed models is violated for binary phenotypes in case-control studies. We propose to use logistic mixed models to control for both population stratification and familial or cryptic relatedness in GWAS for case-control data. We develop a computationally efficient score test for association analysis using logistic mixed models. Our simulation studies show that our method performs well in controlling type I error rates in the presence of population stratification and relatedness for case-control data. We illustrate our method in a real data example.

1823T

Control of population stratification in family data using pedigree information and ancestry principal components. *C. Wang, H. Chen, X. Lin.* Biostatistics, Harvard School of Public Health, Boston, MA.

Genetic data collected from families with disease affected members are more likely to enrich disease causal variants. Population-based association tests, when applied to family data, need to control for both population structure and family relatedness. Principal components analysis (PCA), which has been widely used to control for population structure in unrelated samples, does not work well in capturing the population structure in family data. We have previously developed a method called LASER, which can estimate individual ancestry in a reference principal component space based on a set of unrelated reference individuals. The LASER method is robust to the presence of family relatedness in the study sample. Based on ancestry coordinates estimated from LASER, we propose to control for population structure and family relatedness using mixed model and generalized estimation equation (GEE) approaches. We adjust the population structure by regressing on ancestry coordinates and account for family relatedness using the kinship matrix to specify the covariance structure in mixed models and GEEs. Using both simulations and empirical data from the Framingham Heart GWAS Studies, we show that this approach performs well for both continuous traits and binary traits. When genome-wide genotypes are available, our approach outperforms the standard PCA method. Furthermore, because LASER can accurately estimate individual ancestry using extremely low coverage sequencing data, our approach can be applied to targeted sequencing or exome sequencing studies where genome-wide data are not available.

1824S

Optimal strategies for studying singletons associated with quantitative traits. *S. Rashkin, G. Jun, G. Abecasis.* Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

As the focus genetic association studies shifts from common variants to rare variants, it is important to determine the optimal strategies for conducting studies of very rare variants. A common argument is that, in order to detect rare variants with high power, it is necessary to deeply sequence samples. However, some studies have shown that low-pass sequencing can also detect many rare variants while enabling larger sample sizes. We aim to identify sequencing strategies that maximize power (for a fixed sequencing effort) for studies that explore the role of rare variants in human disease. We specifically focused on variants that appear in a single sequenced sample as they are the most difficult type of variant to identify; designs with sufficient power to detect associations with disease for singletons should also work well for more common variants. Our previous work on binary traits indicates that power to detect association is maximized at 10x coverage. Here, we extend this analysis to quantitative traits.

We assessed the power to detect singletons using a simulated multi-sample caller using different read depths, sample sizes, sequencing error rates, and false positive rates. The power to detect singletons increases as coverage increases, reaching saturation at coverage about 15-20x. We validated these simulations by down-sampling deeply sequenced exome samples and assessing our ability to detect previously called singletons for different sample sizes and read depths.

We performed simulations to assess the power to detect association between the count of singletons in a gene and a quantitative trait, using a simple linear regression framework. We estimated association study power across a range of values for read depth (2-50x), sample size (100-5000), population frequency of singletons (0.001-0.5% per gene per person), effect size, baseline trait value, sequencing error rates (0.001-0.01), and false positive rate for detecting singletons (0.0001-0.05). Preliminary results indicate a similar trend as seen in binary traits: power to detect an association between singletons and a quantitative trait seems to be maximized around 10x and coverage should only be increased beyond this threshold if it does not require a decrease in sample size.

Accurate Error Rates: Calculating Reproducibility by Minor Allele Frequency. *J. Romm, P. Zhang, H. Ling, K.F. Doheny.* CIDR/JHU, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-generation sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. Many commercially available genotyping arrays (HumanExome, HumanOmni2.5, HumanOmni5 and all Illumina "plus exome" arrays) contain SNP content that enables users to assay low minor allele frequency (MAF) variants (<1%). Although overall sample reproducibility rates have not changed with the use of arrays containing a fraction of low MAF content, there are concerns about the accuracy of low MAF SNPs given the nature of the genotype cluster and calling algorithms. In order to get a better picture of the entire project, minor allele reproducibility rates from study duplicate pairs have been evaluated in different MAF bins (0-1%, 1%-5%, 5%-10%, 10%-50%). We exclude major allele homozygotes in the computation of reproducibility in order to alleviate the "overwhelming" effect when computing reproducibility on rare variants. As expected, SNPs in the lower MAF bins have lower reproducibility rates, especially when the sample call rate is lower for 1 sample in the pair being evaluated. As the MAF of the SNPs increase, the sample reproducibility rate increases, and this seems to be less dependent on sample call rate. We have also computed reproducibility using similar statistics, such as kappa coefficient, which allow us to use all of the data (including major allele homozygotes) and we have received similar results. Our data can be used to guide decisions on expected realistic error rates for variants of different allele frequencies. It can also be used to guide decisions on sample call rate cut-off decisions for data cleaning, based on the type of analysis being done - i.e. rare versus common variant analyses may require different sample level call rate threshold cut-offs.

1826T

Factors affecting relative telomere length measurements by quantitative PCR. *C.L. Dagnall[1,2], B.D. Hicks[1,2], A.A. Hutchinson[1,2], S.M. Gadalla[1], L. Mirabello[1], B.J. Ballew[1], J.D. Figueroa[1], C. Bodelon[1], J. Liu[1], J. Hofmann[1], S.A. Savage[1], M. Yeager[1,2].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI, National Institutes of Health (NIH), Bethesda, MD; 2) Cancer Genomics Research Laboratory, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD.

As variation in telomere length have been associated with risk of cancer, heart disease, and various other illnesses it is important to understand the pre-analytic and analytic factors affecting relative telomere length measured by quantitative PCR (qPCR). We have conducted multiple studies comparing various DNA extraction methods, methods of removing potential residual PCR inhibitors, and sample storage conditions as factors that may influence relative telomere length measurements obtained from qPCR assays which lead to discrepancies within study results. We have confirmed that the DNA extraction method affects the measurement of telomere length defined by T/S ratio (concentration of telomeric repeat sequence normalized by concentration of single copy gene sequence). We studied 40 individuals had DNA extracted from the same buffy coat source specimen by three extraction techniques. The dynamic ranges of the T/S ratios from Qiagen QIAamp- and QIAsymphony-extracted DNA samples were lower (0.39-0.87, and 0.29-0.74, respectively) than the Promega ReliaPrep-extracted DNA samples (0.51-1.46). We observed only moderate correlation between paired individuals and different extraction methods (R-squared ranges from 0.32 to 0.46). In addition, we evaluated the differences in telomere length measurements due to inter-plate variability and show that analysis techniques effectively standardize results across assay plates, significantly reducing the average %CV of replicates (from 17.4% to 8.2% in a data set of 170 replicates from 3 samples all extracted using the same extraction technique). Due to these large differences in dynamic range and correlation between extraction methods, it is advisable to only measure relative telomere length when samples have been extracted using the same technique. Eliminating the factors which cause variation in relative telomere length measurements increases the reliability of results when investigating associations between telomere length and various diseases. Results from inhibitor removal methods and sample storage conditions will also be presented.

1827S

Identifying relative pairs within large datasets. *Z. Zeng[1], D.E. Weeks[1,2], W. Chen[3], N. Mukhopadhyay[1], E. Feingold[1,2].* 1) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Division of Pediatric Pulmonary Medicine, Allergy and Immunology, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA.

When a large number of people from a small geographical region are sequenced (e.g., by a regional healthcare system), it is of interest to identify individuals within the datasets who are closely related. The first step in this process is to identify regions of identity-by-descent (IBD) between pairs of individuals. Shared IBD segments between individuals can be inferred by identity-by-status of streaks of SNPs using dense marker data. Existing methods for detecting IBD segments, such as implemented in BEAGLE, GERMLINE and PLINK, are likelihood-based. Some of these methods are extremely time-consuming (BEAGLE), and some require extra assumptions, such as independence of SNPs (PLINK) or correctly phased genotypes as input (GERMLINE). To strike a balance between computational time, accuracy, and extra requirements on the data, we propose an empirical method for detecting IBD segments and indentifying recombination events in close relative pairs. Our method first determines confident IBD status in small windows and then fills in the unsure gaps between the confident ones to generate the intact IBD segments. We explored combinations of different strategies (large sliding window vs. small fixed window; reference panel vs. no reference panel; windows based on physical distance vs. those based on a fixed number of SNPs) and developed a new algorithm that is computationally efficient and does not require knowledge of putative relationships. Our algorithm can be used as a building block for detecting relationships in large datasets of putatively unrelated individuals or for testing relationships in pedigree datasets. We applied our algorithm on a group of grandparent-grandchild pairs and evaluated its performance by comparing with a relationship-aware algorithm we are developing as well as on artificially synthesized IBD data. This research was funded under NIH (grant number: R01 38979).

Leveraging Family Structure for the Analysis of Rare Variants in Known Cancer Genes from WES of African American Hereditary Prostate Cancer. *C.D. Cropp[1], S.K. McDonnell[2], S. Middha[2], M.S. DeRycke[2], D. Karyadi[3], D. Schaid[2], S.N. Thibodeau[4], W.B. Isaacs[5], E.A. Ostrander[3], J. Stanford[6], K.A. Cooney[7], J.E. Bailey-Wilson[1], J.D. Carpten[8] On behalf of the International Consortium for Prostate Cancer Genetics (ICPCG).* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute/National Institutes of Health, Baltimore, MD; 2) Departmant of Health Science Research, Mayo Clinic, Rochester, MN; 3) Cancer Genetics Branch, National Human Genome Research Institute/National Institutes of Health, Bethesda, MD; 4) Departmant of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 5) Johns Hopkins University School of Medicine, Johns Hopkins Hospital, Baltimore, MD; 6) Public Health Sciences Division, Epidemiology Program, Fred Hutchinson Cancer Research Center, Seattle, WA; 7) University of Michigan Comprehensive Cancer Center, Ann Arbor, MI; 8) Integrated Cancer Genomics Division, Translational Genomics Research Institute (TGen), Phoenix, AZ.

Prostate cancer (PRCA) is the second leading cause of cancer death in North American men and it disproportionately affects African American (AA) men, who have higher incidence and mortality rates compared to men without known African ancestry. Although several studies of hereditary PRCA exist resulting in a few significant and reproducible loci associated with an increased risk of PRCA across different study populations (e.g. *HOXB13*), disentangling the environmental and genetic contributions towards the persistent health disparity in AA with hereditary PRCA remains elusive. As part of the international effort to address this disparity, the African American Hereditary Prostate Cancer Study (AAHPC) was developed as a national collaboration to explore the role of genetics in the causation of hereditary PRCA in AA. AAHPC is in partnership with the International Consortium for Prostate Cancer Genetics (ICPCG), which conducts collaborative studies of PRCA genetics in multiplex families. As part of an ICPCG sequencing study of 539 affected individuals from 366 PRCA pedigrees, we performed whole exome sequencing on 16 AAHPC affected men from 12 pedigrees. In the combined ICPCG AA cohort (N=22), there were 60/141 rare and/or novel coding variants (minor allele frequency, MAF $\leq$ 5%) in 15 known cancer-associated genes, 35 of which were non-synonymous. Post-variant calling AAHPC quality control was implemented using Golden Helix SVS 8 software with filters set for removal of variants with Read Depth < 10, Quality Score < 20, Quality Score:Read Depth Ratio < 0.5, Call Rate < 0.75. Variants were additionally filtered by MAF based on the NHLBI ESP650051-V2 exomes variant frequencies for AA population using a MAF threshold of 5%. After QC, 207,741 variants remained for further analysis. In these analyses, we focused on the same aforementioned cancer causing genes. Two AAHPC sequenced families had > 1 affected members (3 per family). Under the dominant model, all affecteds in Family 1 shared 2 variants in two of these genes (25 shared by 2 affecteds). All affecteds in Family 2 shared 9 variants in two different known cancer genes (29 shared by 2 affecteds). Of all 65 shared rare variants in these 2 families, 40 are shared by other ICPCG AA PRCA-affected men. Additional QC is underway to validate these variants and bioinformatic analyses are being used to predict effects of the variants in an effort to unravel the complex genetic heterogeneity of hereditary PRCA in AA.

1829T

Detection of meiotic breakpoints in families using dense genotyping data. *N. Mukhopadhyay[1], F. Begum[2], Z. Zeng[3], E. Feingold[3,4].* 1) Oral Biology, Univ Pittsburgh/Sch Dental Med, Pittsburgh, PA; 2) Dept of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Dept. of Biostatistics, School of Public Health, Pittsburgh, PA; 4) Dept. of Human Genetics, School of Public Health, Pittsburgh, PA.

Meiotic recombination is important for proper segregation of chromosomes; errors in recombination may result in chromosomal abnormalities and non- disjunction. Both the total number and the pattern of recombination events are known to vary genome-wide and from person to person. Using genome-wide genotype data to detect locations of recombination in probands is the first necessary tool to study recombination. Earlier methods, e.g. CRIMAP, used linkage-style modeling on three-generation families and sparse microsatellite markers to detect recombination events. More recently, methods that look for "streaks" of SNPs showing IBD status on dense GWAS SNP data have been used to score recombination locations in sibships. We have now developed a new SNP streak method and software to score recombination locations in pedigree types not previously handled, such as half-sibling pedigrees, and pedigrees with one or more ungenotyped individuals. Our method can be used to substantially increase sample sizes for performing GWAS on recombination phenotypes. We discuss ways to handle inherent problems such as uninformative mating combinations, genotyping errors and missing genotypes. Recombination scoring results on real family study datasets will be presented.

1830S

PIX-LRT: A parent-informed test for SNPs on the X chromosome using case-parent triads. *C.R. Weinberg[1], A. Wise[1,2], M. Shi[1].* 1) Biostatistics Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC., Select a Country; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC, USA.

The X-chromosome is generally understudied in association studies, in part because the analyst has limited methodological options. For nuclear-family-based association studies, most current methods extend the transmission disequilibrium test (TDT) to the X-chromosome. We present a new method to study association in case-parent triads: the parent-informed likelihood ratio test for the X-chromosome (PIX-LRT). Our method takes advantage of parental genotype information and the sex of the affected offspring to increase statistical power to detect an effect. Under a parental exchangeability assumption for the X, if case-parent triads are complete, the parents of affected offspring provide an independent replication sample for findings based on transmissions to the affected offspring. For each offspring sex we combine the parent-level and the offspring-level information to form a likelihood ratio test statistic; we then combine the two to form a composite test statistic. Our method can estimate relative risks under different modes of inheritance or a more general co-dominant model. In triads with missing parental genotypes, the method accounts for missingness with the Expectation-Maximization algorithm. We calculate non-centrality parameters to demonstrate the power gain and robustness of our method compared to alternative methods. We apply PIX-LRT to publically-available data from an international consortium of genotyped families affected by the birth defect oral cleft and find a strong, internally-replicated signal for a SNP marker related to cleft lip with or without cleft palate.

1831M

Simulation Analysis to Assess Linkage Results of Class III Malocclusion and Human Chromosome 11. *L.K AlOthman[1], N. Mukhopadhyay[1], L. Otero[2], R.M. Cruz[3], J. Turner[4], L.A. Morford[5,6], S. Oliveria[7], J.K. Hartsfield, Jr[5,6], M. Govil[1].* 1) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Centro de Investigaciones Odontológicas, Pontificia Universidad Javeriana, Bogota, Colombia; 3) Private Orthodontic Practice, Brasilia, Brazil; 4) Private Orthodontic Practice North Carolina, USA; 5) Division of Orthodontics, University of Kentucky College of Dentistry, Lexington, KY; 6) Hereditary Genomics/Genomics Core Laboratory, Center for Oral Health Research, University of Kentucky College of Dentistry, Lexington, KY; 7) Department of Genetics and Morphology, Universidade De Brasilia, Brasilia, Brazil.

A simulation study was conducted to evaluate multipoint linkage results for chromosome 11 genetic data from two multi-generational family-based cohorts located in South America with a high prevalence of class III malocclusion. Based on previous data implicating a region of chromosome 11 in the Class III phenotype, 4 single nucleotide polymorphisms (SNPs; rs666723, rs578169, rs1386719 and rs12416856) were genotyped within 17 Brazilian families (178 individuals) and 15 Colombian families (248 individuals). The families in each cohort varied greatly in the size, structure and the number of affected individuals. Class III affected and unaffected individuals were diagnosed based on cephalometric measurements, models, photographs and/or oral examination. MMLS multipoint HLODs maximized over different levels of heterogeneity and two genetic models (reduced penetrance dominant and recessive) were generated using SimWalk2. To estimate the empirical significance of these multipoint HLODs, 1000 replicates of unlinked genotype data based on real data pedigree structures, affection status and pattern of missing genotypes were simulated for the Brazilian and Colombian cohort using SLINK and SIMULATE respectively. These replicates were then analyzed using SimWalk2 with the original maximizing mode of inheritance (MOI). Power was estimated similarly for each cohort by generating 1000 replicates of pedigree data linked to the SNP with the highest HLOD. The corresponding cohort-specific MOI was used for the power simulation genetic parameters. For the Brazilian cohort: (a) the empirical HLOD for α= 0.05 was 0.51, (b) empirical p-value for HLOD=1.84 was <0.001, and (c) power for suggestive linkage (HLOD≥2) was 72%. For the Colombian cohort: (a) the empirical HLOD for α=0.05 was 0.29, and (b) an empirical p-value= 0.023 for HLOD=0.51 was observed. These simulation results support potential linkage on chromosome 11. The current linkage results are for the MMLS maximized (by definition) over two genetic models; work is underway to compute MODs, which will take into consideration the entire genetic parameter space. Due to complexity of the Colombian cohort pedigrees, power calculations are pending.

Rare Variant Association Test for Nuclear Families. *Z. He[1], N. Krumm[2], G. Wang[1], B. O'Road[3], E. Eichler[2], S. Leal[1], Simons Simplex Sequencing Consortium.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Molecular and Medical Genetics, Oregon Health and Science University, Portland, OR.

The development of next-generation sequencing (NGS) technologies, has led to many population-based complex trait association studies of rare variants (RVs). These studies are vulnerable to spurious associations due to population stratification. Approaches employing trio (two parents and an affected proband) data such as the transmission disequilibrium test [TDT (Spielman et al. 1993)] can avoid the problems of population stratification. Recently the TDT was extended to analyze RVs [RV-TDT (He et al. 2014)]. It was shown that RV-TDT controls type I error and also has considerable power to detect associations. The TDT analyses only employ information on an affected offspring and their parents. When there are additional siblings, it is advantageous to include them in analysis since they also provide association information. We extended the RV-TDT to analyze all types of independent nuclear families (NF) with at least one affected offspring (RV-NF) and test for RV associations using four commonly used methods: CMC (Li & Leal, 2008), WSS (Madsen & Browning 2009), BRV (Morris & Zeggini, 2010) and VT (Price et al. 2010). We demonstrate that for all RV-NF tests type I error is well controlled even when there is a high level of population stratification or admixture. The power of the RV-NF test was evaluated using a number of disease models and nuclear pedigree configurations. The RV-NF is considerably more powerful than the RV-TDT to detect associations. For example using the CMC version of the RV-TDT and RV-NF the power was evaluated by generating variant data for a 1,500bp gene for which the causal RVs [minor allele frequency (MAF)<1%] have an odds ratio of 2.0. The power to detect and association is: 0.49 for 1,000 trios: 0.58 for 1,000 nuclear families with one affected child and an unaffected child; and 0.65 for 1,000 nuclear families with two affected children. In order to illustrate the application of the RV-NF methods, the exome data from 600 autism spectrum disorder nuclear families with one affected child and one unaffected child were analyzed. RV associations with autism were found for several genes. Given the problem of adequately controlling for population stratification and admixture in RV association studies, the capability of analyzing all types of nuclear families and the growing number of nuclear family studies with NGS data, the RV-NF method is extremely beneficial to elucidate the involvement of RVs in the etiology of complex traits.

1833S

The collapsed haplotype pattern method for linkage analysis of next-generation sequencing data. *G.T. Wang, D. Zhang, B. Li, H. Dai, S.M. Leal.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Traditionally, linkage analysis was used to map Mendelian diseases and genes within the linked regions were sequenced to identify the causal variants. Recent advances in next generation sequencing (NGS) make it possible to directly sequence genomes and exomes of individuals with Mendelian diseases and identify causal mutations by filtering variants in an affected individual(s) family member(s), removing those variants with higher allele frequency, e.g. >0.1% in variant databases. Linkage analysis of SNP data are sometimes used in conjunction with NGS to increase the success of identifying the causal variant. With the reduction in cost of NGS, DNA samples from entire families can be sequenced and linkage analysis can be performed directly using NGS data. Inspired by "burden" tests which are used for complex trait rare variant association studies, we developed the collapsed haplotype pattern (CHP) method to generate markers from sequence data for linkage analysis. To demonstrate the power of the CHP method compared to analyzing individual variants, we analyzed and performed empirical power calculations using the allelic architecture for several known non-syndromic hearing loss genes, i.e. GJB2, SLC26A4, MYO7A & MYH6. Power analysis demonstrated that the CHP method is substantially more powerful than analyzing individual SNVs in the presence of inter-allelic familial heterogeneity, i.e. families have different pathological variants within a gene or intra-familial heterogeneity e.g. compound heterozygotes. Specifically for an autosomal recessive model with allelic heterogeneity and locus heterogeneity of 50%, it requires 12 families for the CHP method to achieve a power of 90% for the SLC26A4 gene, while analyzing individual SNVs requires >50 families to achieve the same power at a genome-wide significance level of α=0.05. Unlike the commonly practiced filtering approaches used for NGS data, the CHP method provides statistical evidence of the involvement of a gene in Mendelian disease etiology. Additionally because it incorporates inheritance information and penetrance models it is less likely than filtering to exclude causal variants in the presents of phenocopies and/or reduced penetrance. We recommend the use of the CHP method in parallel to filtering methods to take full advantage of the power of NGS in families. The CHP method is incorporated in the SEQLinkage software which is freely available http://www.bioinformatics.org/seqlink/.

1834M

Identifying rare variants in linkage regions through pedigree-based conditional linkage analysis. *C.W. Bartlett[1], S. Buyske[2,3], S.L. Wolock[1], L.M. Brzustowicz[3].* 1) Battelle Ctr Mathematical Med, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Statistics, Rutgers University, NJ; 3) Department of Genetics, Rutgers University, NJ.

Linkage analysis is sensitive for detection of rare mutations, even when multiple rare variants in that region are causal in the population, as long as the same single variant segregates with any single family. However, linkage analysis has poor resolution, implicating large genomic regions with many candidate genes and numerous candidate mutations within each candidate gene. Here we develop a method, based on a variation on likelihood ratio testing, to assess if a set of candidate variants in a linkage region underlie or produce the observed linkage. We show that our conditional linkage test can be used to determine which variants are responsible for an observed linkage signal. Our hypothesis that pedigrees contained information useful for conditional linkage was first validated using ball and urn model probability calculations to develop exact analytical demonstrations and to inform downstream modeling choices. Our approach involves calculating a pedigree likelihood stratifying subjects by liability classes determined by a candidate variant "propensity" score. When variants contributing to the propensity score are primarily responsible for the linkage signal, the linkage signal drops once liability classes based on that score are incorporated, demonstrating that the tested variants are required to observe the linkage signal. We use lasso logistic regression of all loci in the gene against affection status to generate subject-level propensity scores and apply a decision rule to create liability classes, though in in our simulations we did not observe ambiguous case that required more than 3 liability classes. Using an integrated (i.e., model-averaged) LOD score, we have derived an empirical null distribution for the variability in the integrated LOD with inclusion of liability classes relative to baseline, to allow us to define p-values for significance testing. Power was estimated through simulation over a range of generating conditions with varying numbers of causal and non-caudal SNPs within a linked region. In general, power increases as the absolute number of non-causal candidate variants decreases and the ratio of causal variant to total test variants increases. In combination with modest bioinformatic filtering of genes and variants, our pedigree method for conditional linkage analysis may provide statistical evidence for a specific gene, or gene set, to help reduce the testing in model organisms and systems.

1835T

A general framework for group-wise transmission/disequilibrium tests for identifying rare variant associations. *R. Chen[1], W. Chen[2], X. Zhan[3], B. Li[1].* 1) Molecular Physiology and Biophysics, Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Clinical Science, University of Texas Southwestern Medical Center, Dallas, TX.

A major focus of current sequencing studies for human genetics is to identify rare variants association with complex disease. Aside from reduced power of detecting associated rare variants, controlling for population stratification is particularly challenging for rare variants. Transmission/disequilibrium tests (TDT) based on family designs have been proved to be immune to population stratification and admixture, and therefore provide an effective approach to rare variant association studies to eliminate spurious associations. Moreover, group-wise strategies, originally proposed for population-based studies, have been extended to family designs to collectively analyze multiple rare variants as a single unit. In this study we describe a general framework for group-wise TDT (gTDT) and develop an efficient tool that implemented several common genetic models, including additive, dominate and compound heterozygous models. Another important feature of gTDT is that it's a flexible haplotype-based framework that can encompass a variety of other genetic models as well. For example, we implemented a hybrid model, which combines compound heterozygous and weighted additive models to test for recessive models while incorporating prior knowledge assigned to different variants. Unlike existing methods, gTDT constructs haplotypes by transmission when possible and inherently takes into account the LD among variants. Through extensive simulations we showed that type I error is correctly controlled for rare variants under all models investigated, and it is also true in the presence of population stratification and admixture. Under a variety of genetic models gTDT is more powerful than the classical TDT. We hope that gTDT is useful to analyze pedigree data with the flexibility to test for different models for genetic studies of complex disease.

Rare Variant Association Analysis of Quantitative Traits in Pedigrees of Arbitrary Size and Structure. *Y. Jiang[1], K. Conneely[2], M. Epstein[2].* 1) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 2) Department of Human Genetics, Emory University, Atlanta, GA.

Family-based rare-variants sequencing studies have attractive characteristics: they can be more powerful compared to case-control and population-based studies due to increased genetic load and can further enable the implementation of rare-variant association tests that, by design, are robust to confounding due to population stratification. However, current methods for family-based studies mainly focus on nuclear families or parent-offspring trios while ignoring the information provided by other types of relatives. With this in mind, we propose a powerful rare-variant test for analysis of quantitative traits in extended pedigrees that can accommodate any family size, and is robust to population stratification. For each non-founder, our method partitions rare variants in a region of interest into two components: a between-family component (sensitive to population stratification but less sensitive to genotyping error) based on information from all ancestors as well as an orthogonal within-family component (which is robust to population stratification). We then test for association between the robust within-family component and the trait of interest using a variance-component score test that accounts for relatedness among family members. As ignoring the between-family component may lead to power loss, we further adopted a two-stage test to enhance power: at the first stage, we construct a variance-component score test using the between-family component to identify top hits; at the second stage, we follow up these top hits by constructing the variance-component score test on the independent within-family component. Our method maintains power when a region harbors variants acting in different directions on outcome, accommodates covariates, and efficiently calculates p-value using an asymptotic distribution. As more and more studies have re-sequenced large pedigrees from previous linkage studies, our method is in need. We will show the robustness and power of our method using simulated data and further illustrate the approach using sequencing data from the SardiNIA Medical Sequencing Discovery Project.

Dissecting the Genetic Architecture of Longevity with Millions of Individuals. *J. Kaplanis[1,2], B. Markus[1], M. Gershovits[1], M. Sheikh[1], A. Price[2,3], D. MacArthur[4], Y. Erlich[1].* 1) Whitehead Institute for Biomedical Research, Cambridge, MA; 2) Harvard School of Public Health, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge MA; 4) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA.

Understanding the genetic architecture of complex traits is one of the top missions of human genetics. Emerging lines of studies have highlighted the entangled etiologies of these traits, which can include epistasis, parent-of-origin effects, sex and age interactions, and environmental risk factors. To conduct robust genetic epidemiological analysis, statistical models require sampling substantial amount of data from large families. However, the recruitment of large cohorts of extended kinships is both logistically challenging and cost-prohibitive. Here, we present a big data strategy to address this challenge: harnessing existing, free, and massive Web 2.0 social network resources to trace the aggregation of complex traits in extremely large families. We collected millions of public profiles from Geni.com, the world's largest genealogy-driven social network. Using this information, we constructed a single pedigree of 13 million individuals spanning many generations up to the 15th century. In addition, Natural Language Processing was used to convert genealogical information into birth and death locations to obtain a proxy for environmental factors. We obtained multiple of phenotypes from this resource including longevity, fertility, and migration patterns. This dataset provides a wide range of kinships for familial aggregation studies. We compiled this data in a new resource called FamiLinx which will be free available for the entire scientific community. We will show the utility of FamiLinx for heritability estimates across distant relatives to disentangle analysis of epistasis, parent-of-origin, and shared environments.

1838T

Adaptive Combination of P-values for Family-based Association Testing with Sequence Data. *W. Lin.* Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan.

Family-based study design will play a key role in identifying rare causal variants, because rare causal variants can be enriched in families with multiple affected subjects. Furthermore, different from population-based studies, family studies are robust to any bias induced by population substructure. It is well known that rare causal variants are difficult to detect with single-locus tests. Therefore, burden tests and non-burden tests have been developed to combine signals of multiple variants in a chromosomal region or a functional unit. This inevitably incorporates some neutral variants into the test statistics, which can dilute the power of statistical methods. To guard against the noise caused by neutral variants, we here propose an 'adaptive combination of P-values method' (abbreviated as 'ADA'). This method combines per-site P-values of variants that are more likely to be causal. Variants with large P-values (which are more likely to be neutral variants) are discarded from the combined statistic. In addition to performing extensive simulation studies, we applied these tests to the Genetic Analysis Workshop 17 data sets, where real sequence data were generated according to the 1000 Genomes Project. We show that this ADA method outperforms the burden tests and non-burden tests when the percentage of causal variants is small. ADA is recommended for its potential to guard against the noise induced by neutral variants.

Exome sequencing in an isolated population reveals multiple rare variants affecting both high-density lipoprotein cholesterol and the levels of certain blood metabolites. *E.M. van Leeuwen[1], A. Demirkan[1,2], N. Amin[1], A. Verhoeven[3], A. Meissner[3], R.W.W. Brouwer[4], W.F.J. van Ijcken[4], A. Isaacs[1], T. Hankemeier[5,6], K. Willems van Dijk[2,7], C.M. van Duijn[1].* 1) Epidemiology, Erasmus MC, Rotterdam, Zuid-Holland, Netherlands; 2) Department of Human Genetics, Leiden University Medical Center, Leiden, the Netherlands; 3) Center for Proteomics and Metabolomics, Leiden University Medical Center, Leiden, the Netherlands; 4) Center for Biomics, Erasmus MC, Rotterdam, the Netherlands; 5) Leiden Academic Center for Drug Research, Division of Analytical Biosciences, Leiden University, Leiden, The Netherlands; 6) The Netherlands Metabolomics Centre, Leiden University, Leiden, the Netherlands; 7) Department of Endocrinology, Leiden University Medical Center, Leiden, the Netherlands.

Finding rare variants implicated in complex diseases has proven to be difficult. Large family-based studies in isolated populations yield increased power for identifying rare coding variants among others due to underlying founder effects. We explored this in the ERF study, a genetic isolate from the Netherlands. We tested if rare variants coding for high density lipoprotein cholesterol (HDL-C) also influence other metabolic traits which are also known to be under strong genetic control (30-80%). Participants of the ERF study include 3000 related individuals selected on the basis of genealogy. Exome sequencing was conducted in 1300 individuals. HDL-C was determined by the enzymatic method, whereas 400 metabolites (glycerophospholipids, triglycerides, amino-acids, acyl-carnitines, small metabolic compounds) were determined by NMR or MS. We tested around 550,000 coding variants within the exomes of 1300 samples for associations with the HDL-C level, followed by segregation analysis in families. We found both common (minor allele frequency (MAF) > 0.1) and rare variants (MAF < 0.02) to be associated with HDL-C. The common variants are all located within the CETP region, a region which is known to be associated with HDL-C level. We found nine rare variants to be significant (p-value < $2.57 \bullet 10^{-6}$, Bonferroni corrected for the number of unique genes tested) after adjusting for multiple testing and family structure. Each of the rare variants segregated within families. Of note is that all carriers of the rare variants have a (extremely) high HDL-C, and thus the rare variants may be of interest for therapy development. Each rare variant was also associated with several metabolites (p-value < $3.09 \bullet 10^{-6}$) which may help us understand the mechanisms involved. This study shows that combining next-generation sequencing with metabolomics within large family studies can help us unravelling the process from variant into biological processes influencing a clinical measurement. The fact that we found variants associated with high HDL-C levels opens up opportunities to translational research for medication.

Efficiently Incorporating Annotation Information into the Analysis of Genomic Sequence Variants in Pedigree Samples. *Q. Li, J. Bailey-Wilson.* NHGRI/NIH, 333 Cassell Dr. Suite 1200, Baltimore, MD.

Family-based analyses are an effective way to detect disease predisposing variants, especially in rare variants. However, when analyzing sequencing data, a long list of plausible variants that may account for disease susceptibility are usually identified and further filtering is needed to narrow down the list to a more manageable handful of variants for follow-up. Incorporating biological information about genetic markers in the analysis and interpretation of results has been shown to be a useful and successful approach. Here we propose a streamlined R process to analyze sequence data in pedigree samples for quantitative traits based on famSKAT software and variant annotation files from the Combined Annotation Dependent Depletion (CADD) server [1]. The famSKAT program is designed to analyze sequence data in family samples for quantitative traits. It has the advantage of using biological information as weights to adjust the statistical evidence for the variants. To get the weights, we extracted the CADD scores from the annotation files on the CADD server, because the scores measure the deleteriousness of single nucleotide mutations as well as insertion/deletion mutations in the human genome.

Due to the large amount of data produced by whole genome sequence (WGS) and whole exome sequence (WES) studies and the long processing time to conducting famSKAT tests in large studies, the analysis process is likely to be terminated prematurely due to technical problems even on fully redundant servers and clusters. Therefore, it is important to implement a recapture mechanism in our program, to find the endpoint of an aborted analysis session and restart the analysis from that point without redundantly repeating work already completed. In our implemented R programs, we periodically write out analysis results and enable the program to restart after the last completed analysis.

We tested our computer program on a simulated Mini-Exome dataset for extended families and show the performance in terms of type-I error and power. We also recorded metrics to assess the processing time for WES data analysis.

Efficient gene-gene interaction test for discordant sib pairs in genome-wide association studies. *R. Chung[1], P. Song[2], Y. Wang[2], P. Lin[2], W. Tsai[1].* 1) National Health Research Institu, Zhunan, Taiwan; 2) National Tsing-Hua University, Hsinchu, Taiwan.

Genome-wide association studies (GWAS) have been a popular strategy to identify single nucleotide polymorphisms (SNPs) associated with complex diseases. Gene-gene interactions may play an important role in complex diseases. Therefore, many methods have been developed for gene-gene interactions for GWAS. However, most of the methods are developed for case-control studies, and only a few methods are available for family-based interaction analysis for complex diseases. Moreover, current family-based interaction methods are computationally intensive, which are not applicable to genome-wide interaction studies, which test all possible pairs of SNPs across the genome. We propose an efficient family-based gene-gene interaction test, which compares the difference in log odds ratios for a pair of SNPs between cases and controls. Extended from the sib TDT (S-TDT), cases and controls are defined as genotypes in affected and unaffected sibs in discordant sib pairs (DSP), respectively. A multivariate hypergeometric distribution is used to calculate the variance and covariance for the test statistic. We used simulations to demonstrate that the proposed test has correct type I error rates under different scenarios, such as different sample sizes and minor allele frequencies. We also performed power studies to evaluate the power for the proposed test with other family-based interaction methods under different scenarios. The results suggested that the proposed test is a valid test and has comparable power to the existing tests. We also used simulations to show that the proposed test can run 20 times faster than the regression-based interaction test. Finally, we applied the test to a family GWAS study for hypertension and several promising SNP-SNP interactions were identified for the disease.

1842S

Robust and powerful family test for rare variant association. *K. Lin[1], S. Zöllner[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Modern sequencing technology allows investigating the impact of rare variant on complex disease. However, in a conventional case-control design, large samples are needed to achieve sufficient power for testing association of suspected loci to complex disease. In such large samples, population structure can cause spurious signals. One approach to overcome low power and population stratification is family-based study design since the count of risk variants can be enriched in a family containing multiple affected members with the same genetic background. Traditional methods such as the TDT and the FBAT are not very powerful when applied to rare variants. Thus, there is a need to develop a method to directly incorporate the advantage of family-based design to discover association between rare variants and disease phenotypes.

We propose a novel test for a sample of families. In each family, we first determine the chromosomes shared IBD/non-IBD at the locus of interest for all family members. Conditional on the sharing status, we evaluate the number of risk alleles shared IBD among affected family members. Since risk variants are more likely to be shared among affected members, we test for an excess of shared rare variants among affected members by comparing the observed count of shared variants to the expected count of shared variants under the null. This expectation can be calculated conditional on the founders' haplotypes. The proposed test is robust to population stratification since each family is a matched unit. We evaluate the power of this approach analytically as well as with computer simulations using a general model for the effect size of rare risk variants. We compare our method with existing methods for family-based data as well as the conventional case-control design. Considering different models from rare to common variants, we show that the proposed approach is especially powerful for rare variants as compared to the conventional case-control design.

1843M

Family-based rare variant association methods for quantitative traits in the presence of population structure. *W-M. Chen, A. Manichaikul, S.S. Rich.* Ctr Pub Hlth Genomics, Univ Virginia, Charlottesville, VA.

Technological advances in high-throughput sequencing platforms have made it possible to extend genome-wide association studies to rare variants by exome, whole-genome, and targeted sequencing. Custom genotyping arrays such as the ExomeChip have been utilized for their low cost in genotyping rare variants. Family data can enrich rare variant association analyses, and allow the use of well characterized pedigree data that were collected previously in linkage and association studies. Population structure (such as in admixed populations) presents great challenges to statistical methods that analyze datasets with rare variants. The standard approach of including principal components of ancestry as covariates in the regression of a trait may not be sufficient to eliminate the effect of population structure on the rare variant association.

We extend the sequence kernel association test (SKAT) to family studies, and present several novel kernels for rare variant association in the presence of population structure: 1) weighted linear kernel (to confirm the existing results from SKAT); 2) distance kernel that adjusts pedigree structure; 3) distance kernel that adjusts pedigree and global population structure; and 4) distance kernel that adjusts pedigree and local population structure. In addition to including principal components of ancestry as covariates in the linear regression model, we standardize the distance between any pair of individuals at a gene by dividing their global or local distance across the genome. Extensive computer simulations show that our distance kernels can effectively eliminate population stratification as well as increase the power of association test. Finally we apply our methods to a data set of rare variants genotyped in African American and Hispanic populations.

1844T

TIMBER - personalized computationally-efficient filtering of GERMLINE-discovered putative IBD segments. *M. Barber[1], K. Noto[1], Y. Wang[1], R.E. Curtis[2], J.M. Granka[1], J.K. Byrnes[1], N.M. Myres[2], C.A. Ball[1], K.G. Chahine[2].* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Provo, UT.

Discovering regions of pairs of genomes that are identical by descent (IBD) is an important part of many genetic analyses. Given a large sample size (over 100K people and beyond), the problem is for IBD discovery to be both computationally feasible and accurate. GERMLINE is a computationally efficient algorithm (as it uses a hashing approach and a separate extension algorithm) but it lacks the accuracy of other approaches on its own. RefinedIBD is an accurate algorithm, as it evaluates all putative IBD segments with a haplotype model. However, RefinedIBD is not computationally efficient, even though it uses the GERMLINE algorithm to discover the putative IBD segments. TIMBER is an algorithm that decides if a putative IBD segment discovered by GERMLINE has a sufficient level of evidence for IBD to be retained. TIMBER uses GERMLINE-discovered putative IBD segments to filter the very same segments. Within GERMLINE, the genome is split up into non-overlapping windows, where TIMBER calculates a weight for each of these windows. Each weight provides the relative level of evidence of IBD from that window in a GERMLINE-discovered putative IBD segment. TIMBER's main action is to down-weight windows of the genome that show excessively high degree of putative IBD segments. TIMBER is made possible given the large amount of putative IBD segments that are discovered in running GERMLINE on a large data set (over 100K people). We have evidence that TIMBER is a very useful IBD filter from both real and simulated data given a large data set of over 100K people. While TIMBER is not as accurate as a method such as RefinedIBD, it provides a significant improvement in accuracy over running GERMLINE on its own and it is computationally efficient for a large data set.

1845S

Statistical Tests for Co-Segregation of Genetic Variants with Disease in Pedigrees. *D. Schaid[1], S. McDonnell[1], J. Sinnwell[1], L. Cannon Albright[2], C. Teerlink[2], J. Stanford[3], E. Sequencing studies for rare variants in pedigrees often evaluate whether affected pedigree members carry the same variant - an evaluation of co-segregation of variant with disease. This approach, however, requires conditional probabilities, because pedigrees without any carriers are not informative. That is, statistical assessment of co-segregation requires comparing the observed number of affected carriers with random expectation, where expectation is based on Mendelian segregation of variants, conditional on at least one affected pedigree member carrying a variant. We developed new statistical methods to test for co-segregation of genetic variants with disease, for studies that genotype only affected pedigree members. Our methods, a simple comparison of observed and expected carrier counts, as well as methods based on quasi-likelihood score (QLS) statistics, provide was to perform gene-level tests, important for situations where different pedigrees have different segregating variants, yet all within the same gene. Our gene-level test allows use of weights for different variants, such as weights based on allele frequencies or based on likely function. Furthermore, our QLS method accounts for correlations in the data, such as correlations from related subjects, or correlation among multiple variants (e.g., linkage disequilibrium).We will present simulations to illustrate the power of our approach, as well as results from application to a whole exome scan of familial prostate cancer.

1846M

Cross pedigree shared ancestry reveals rare, disease-causing variants in the presence of locus heterogeneity. *H.J. Abel, MA. Province.* Genetics, Washington University School of Medicine, St. Louis, MO.

Currently, there is great interest in the use of family studies to identify rare variants underlying complex disease. Attempts at fine mapping, however, are often confounded by locus heterogeneity, which can produce noisy and poorly localized linkage signals, as well as by an abundance of rare variants, which frequently segregate with phenotype by chance. Because rare variants shared across pedigrees are likely to be of recent origin, we have developed an approach to leverage identity-by-descent (IBD) sharing between pedigree founders in order to better localize linkage signals in the presence of heterogeneity. Our method relies on the lengths of segments shared identically-by-state (IBS) across pedigrees, using as test statistic a score based on the sum of maximal pairwise shared lengths at each locus, and optimized over all genotyped pedigree members. Use of unphased IBS renders it both computationally efficient, so that pedigree-based permutation tests assessing significance are tractable, and robust to genotyping/sequencing and haplotype phase switch errors. Further, our approach produces a cross-family metric to facilitate local clustering of families near IBD regions which, in simulations, accurately recovers ancestral relationships and permits stratification by recent shared ancestry. We have evaluated the performance of our method using a combination of coalescent simulation of founder individuals, followed by gene-dropping onto pedigrees. Under a variety of scenarios, with rare causal variants (population MAF<0.01) and modest effect sizes (OR=5-10), our approach achieves 60-90% power, and is able to detect shared ancestral segments harboring rare causal variants when multipoint linkage and rare-variant burden tests fail.

1847T

Increasing Power to Detect Rare Variant Associations by Integrating Linkage Data: A Bayesian Approach. *s. Lutz, A.L. Peljto, T.E. Fingerlin.* Biostatistics, University of Colorado, Denver, CO.

Large resequencing studies often combine familial cases of disease from linkage studies with sporadic cases to achieve the large sample sizes necessary for detecting low-frequency alleles. In general, these studies include only a single case from each family. As a result, family-based association tests cannot be applied and standard tests for rare variants generally ignore family-specific allele-sharing information that may be available, resulting in an inefficient use of resources and loss of power for this common study design. We propose a Bayesian approach for testing associations between groups of variants and a phenotype that uses family-specific linkage information in the prior to increase power to detect associations with rare variants and the phenotype of interest. Our method directly combines family-specific linkage and rare variant data by giving more weight in the prior to familial cases with evidence for excess allele sharing at the position of the variant being tested. To assess the performance of our method, we simulated genetic data for familial cases, singleton cases, and controls under various genetic models. We then compared our Bayesian approach that incorporates family-specific linkage information to the sequence kernel association test (SKAT) and several burden tests. We show that our method has increased power compared to the standard methods (SKAT and burden tests), which do not incorporate the family-specific allele-sharing information for several underlying genetic models. Our method provides a framework for tests of association with rare variants that are more statistically efficient when family-specific linkage information is available on at least a subset of cases, while leveraging the resources that have been devoted to recruiting, describing, and genotyping familial linkage cohorts.

Impact of screening for precancerous lesions on family-based genetic association tests: an example of colorectal polyps and cancer. *S.L. Stenzel[1], J.C. Figueiredo[1], V.K. Cortessis[1,2], D.C. Thomas[1].* 1) Dept of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Dept of Obstetrics and Gynecology, Keck School of Medicine, University of Southern California, Los Angeles, CA.

Estimates of the association between genetic variants and cancer risk may be biased by screening and subsequent removal of detected precancerous lesions. We conducted a simulation study using a discordant sibship case-control design assuming various screening and prevention parameters and determined the association between genetic variation and risk of colorectal cancer (CRC) under four analysis strategies: 1) CRC cases vs. all non-cases with no adjustment for polyp history; 2) same as (1) with adjustment; 3) CRC vs. polyp-free non-cases; 4) CRC or polyp cases vs. neither. We considered genes involved in polyp development (G1), in cancer risk but not polyps (G2), and in progression from polyps to carcinoma (G3). We then applied these strategies to a family-based case-control study of folate-related genes and risk of CRC. In our simulation, estimates of the association between G2 or G3 and CRC comparing CRC cases against all non-cases without adjustment for polyp history were not biased, but estimates were underestimated for G1 if detection of a polyp led to reduction in CRC risk. Analysis strategies 2 through 4 led to substantial biases, with directions varying across strategy and gene type. Type I errors were correct for all approaches, but strategy 1 was the most powerful. In our application, estimates of relative risk differed for selected variants when controls with polyps were excluded or when individuals with polyps were treated as cases. Although estimates of gene-CRC associations may be biased due to detection of precancerous lesions, the degree of bias appears to differ only modestly by analytic strategy in applied studies with population-based recruitment. The impact may be more unpredictable in studies that are not population-based.

TITLE: Familial aggregation of blood pressure in Ramadasia population of north-west Punjab. *R. KUMAR[1], B. DOZA[2].* 1) GHS MARI KAMBO KE, TARNTARAN; 2) GURU NANAK DEV UNIVERISITY, AMRITSAR.

In India, the burden of hypertension has increased many folds in recent times due to increase of westernized diets, life styles and the increasing mean age of populations. Therefore, it is essential to understand how blood pressure is influenced by familial factors (both genetic and environmental) and how these contribute to the risk for cardiovascular diseases. The major objective of the study was to describe the genetic heritability and familial household contribution to the phenotypic variation for cardiovascular risk factors especially for SBP and DBP. Three generations i.e. grandparental, parental and offspring generation, aged 7 years and above, from Ramadasia, a scheduled caste population, were selected for the study. The questionnaire grossly included socio-economic lifestyle variables, physiometric measurements and anthropometric measurements. A total of 600 families with 1827 individuals were sampled. Results demonstrated familial aggregation of CVD risk factors. The brother-sister, father-offspring (male/female), mother-offspring (male/female) correlations were all greater than spouse correlations (brother-sister: 34% for SBP, 31% for DBP, 38% for BMI; father-male offspring: 31% for SBP, 30% for DBP, 21% for BMI; father-female offspring: 21% for SBP, 20% for DBP, 15% for BMI; mother-male offspring: 17% for SBP, 15% for DBP, 23% for BMI; female offspring: 20% for SBP, 18% for DBP, 29% for BMI; spouse: 4% for SBP, 5% for DBP, 9% for BMI).. The magnitudes of these correlations for SBP, DBP and BMI were lower in grandparent-offspring. Therefore, the higher estimates of correlations among parent-offspring generations and siblings suggested the genetic closeness. But the correlation between siblings was even larger than correlation between parent-offspring and others. Familial aggregation of blood pressure was observed to be largely due to genes rather than familial environment from the heritability explained by the genetic variation in blood pressure. Therefore, the present study has a great potential for the study of quantitative genetic variations within and between the generations. The estimates of heritabilities through variance-component approach produced a wide range of heritabilities (10%-98.7%) for selected anthropometric and physiometric phenotypes between different combinations of the three generations.

Mixed Model Association Mapping on the X Chromosome. *C. McHugh, T. Thornton.* Department of Biostatistics, Univ Washington, Seattle, WA.

Genetic variants on the X chromosome could potentially play an important role in some complex traits. However, statistical methods for genetic association studies have primarily been developed for variants on the autosomal chromosomes with significantly less attention given to the X chromosome. Mixed linear models (MLMs) have recently emerged as a powerful and effective method of choice for association mapping in the presence of sample structure such as population structure and/or relatedness. Existing MLM approaches are not directly applicable to association testing on the X chromosome. Here, we propose a MLM approach for genetic association testing on the X chromosome in samples with related individuals. In simulation studies with both unrelated and related individuals, we demonstrate that our proposed MLM has the correct type I error for association testing with SNPs on the X chromosome. We also show that existing mixed model approaches are not properly calibrated and have inflated type I error for X-linked traits. We further demonstrate that our proposed MLM method for the X has high power to detect genetic association with X-linked markers.

1851S

lincRNA-mRNA transcriptional regulatory co-expression network from RNA-seq data in 624 Sardinian individuals. *P. Forabosco[1], M. Pala[1,2,6], M. Marongiu[1], A. Mulas[1], R. Cusano[1], F. Crobu[1], F. Reinier[3], R. Berutti[3,6], M.G. Piras[1], C. Jones[3], D. Schlessinger[5], G. Abecasis[4], A. Angius[1], S. Sanna[1], S.B. Montgomery[2,7], F. Cucca[1,6,7].* 1) Research Institute of Genetics and Biomedicine, CNR, Cagliari, Italy; 2) Pathology and Genetics Department, Stanford University, Stanford, CA, USA; 3) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 5) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA; 6) Department of Biomedical Science, University of Sassari, Sassari, Italy; 7) co-senior authors.

Long non-coding intergenic RNAs (lincRNAs) are thought to play important roles in regulating gene expression, but the exact function of the majority of them remains unknown. RNA-seq represents an effective tool for high-throughput analysis of lincRNA expression, as it provides a far more precise and accurate measurement of transcript levels than other methods. Bioinformatics approaches might be useful in providing insight into lincRNA functions. In particular, co-expression network analysis of lincRNA and mRNA transcripts enables a systematic and global interpretation of expression data, by assessing co-expression patterns (through correlation matrices), and by identifying functionally relevant modules. Annotation of lincRNAs probable functions can be predicted and linked to biological pathways based on module sharing, i.e. by assigning functions according to the functional enrichment of coding transcripts in the same module. Analysis of co-expression of lincRNAs with mRNA can therefore help prediction of their functional role as a foundation for further mechanism studies. Here we present the construction of a regulatory network comprising both coding and long non-coding transcripts. Gene expression levels have been quantified with RNA-seq from PolyA(+) PBMC samples in 624 Sardinian individuals. We construct a co-expression network, where nodes are transcripts and edges represent co-expression strength, using the Weighted Gene Co-expression Network Analysis package (WGCNA) implemented in R. We inspect the network in detail in terms of connectivity and density patterns, network hubs, and module identification. Compared to microarray technologies, RNA-seq data results in more interconnections among transcripts (e.g. higher mean connectivity is observed in a subsample of 188 unrelated subjects when using the suggested soft thresholding power in the adjacency transformation in order to meet scale free topology). Using gene significance (a measure correlated with intramodular connectivity) encoding lincRNA status, we identify modules where lincRNAs are most relevant. This study is the first to explore genome-wide lincRNA expression and co-expression with mRNAs using RNA-seq technology.

Sample-specific gene co-expression networks controlling for confounding effects. *C. Gao[1], S. Zhao[2], B.E. Engelhardt[1,3].* 1) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC; 2) Department of Computational Biology and Bioinformatics, Durham, NC, USA; 3) Department of Statistical Science, Duke University, Durham, NC, USA.

It is well known that genes form sparse sets of co-regulated modules to achieve unique biological functions. Biological complexity suggests that there could be thousands of co-regulated modules interacting simultaneously in a single cell and therefore extracting a large number of small co-regulated clusters of genes is essential. Two types of methods have been proposed to address this challenge. First, gene co-expression networks identify regulatory interactions across all genes based on correlations of those genes. These methods are generally sensitive to confounding effects and the parameter settings. Sparse latent factor models, on the other hand, identify a small number of unstructured clusters of co-regulated genes and may account for confounding effects; however, due to computational tractability and signal recovery accuracy, sparse latent factor models only focus on small numbers of clusters, and, to our knowledge, have not been used to identify networks for individual genes. To address these discrepancies, we developed a Bayesian statistical model to recover large number of small clusters of co-regulated genes from gene expression data. We use this framework to cluster both the genes and the samples in order to allow heterogeneous samples with subtype-specific gene interactions; furthermore, we used the recovered sparse gene sets to reconstruct biologically meaningful gene co-expression networks that control for confounders and are specific to sample subtypes. Our method uses Bayesian sparse factor analysis, with the gene expression matrix is decomposed into a sparse loading matrix and a corresponding factor matrix, where the genes loaded on the same factor have the interpretation of being jointly regulated by the same covariate. To induce sparsity, we used a flexible Three Parameter Beta (TPB) prior that scales with the sparsity in the data. To address the latent biological and technical confounders, we modeled each factor and loading as a mixture of sparse and dense components, where dense vectors capture technical or biological confounding when estimating the sparse co-regulated gene sets. We used simulated data to quantify and compare our method relative to other biclustering methods. We analyzed gene expression data from the GTEx project, extracting large numbers of sparse groups of co-regulated genes. We discuss the implications of the recovered gene networks in revealing important biological, and potentially disease-related, mechanisms.

1853T

Random forest for genetic analysis: Integrating the X chromosome. *G. Jenkins, J. Biernacka, S. Winham.* Mayo Clinic, Rochester, MN.

Despite the fact that it is known to play a major role in many Mendelian disorders, the X chromosome is routinely excluded from genome-wide association studies. Data mining methods such as Random Forest (RF) have been proposed to investigate complex genetic models involving many variants. However, for traits associated with sex, inclusion of X chromosome SNPs in RF analysis yields biased results, as we illustrate using simulations and an example from a case-control study of alcohol dependence. We propose three extensions of the RF algorithm to include X chromosome SNPs, based on (1) the principle of X chromosome inactivation (XCI), (2) stratification of the forest by sex, and (3) incorporation of sex as a variable in the RF. We compare the performance of these three new approaches to the traditional RF implementation using simulations and application to data from the Study of Addiction: Genes and Environment (SAGE). Comparison of the SAGE analysis results for autosomal vs. X SNPs shows that traditional RF consistently ranks the X SNPs highly, whereas the three new approaches all rank the X SNPs similarly to the autosomes. To better understand statistical properties of the alternative approaches to incorporate X-chromosome data into RF, we compare the importance measures for X chromosome and autosomal SNPs produced by the different methods, using data simulated with and without genetic effects. Specifically, we examine performance using data simulated under varying degrees of trait or sex imbalance, effect of sex on the trait, and patterns of linkage disequilibrium. Our results show that all methods rank X SNPs similarly to the autosomes if sex was not associated with the trait (with no genetic effect). But if sex is associated with the trait, traditional RF leads to inflated variable importance for the X chromosome. Incorporating sex data in RF produces biased X importance across scenarios. However, the methods based on XCI and stratified forests do not inflate the importance of the X chromosome, although X importance was slightly lower than the autosomes if the number of cases and controls are not equal. If sex is not associated with the trait in the sample, regular RF may be appropriate to analyze X chromosome data. If sex is associated, either stratification of the forest or extension based on XCI will not inflate the importance of the X chromosome, although these methods may underestimate X importance if the data is unbalanced based on the trait.

1854S

Integrative Metabolomics of Asthma Severity using Bayesian Networks. *J. Lasky-Su[1], M. McGeachie[1], W. Qiu[1], J. Savage[1], A. Dahlin[1], A. AlGarawi[1], D. Croteau-Chonka[1], J. Sordillo[1], A. Wu[1], E. Chen[1], D. DeMeo[1], A. Litonjua[1], C. Clish[2], B. Raby[1], S. Weiss[1].* 1) Brigham & Women's Hosp, Boston, MA; 2) Broad Institute, Cambridge, MA.

Asthma is a heritable disease with both environmental and genetic components. Although a number of molecular determinants have been identified, much remains to be understood about how these variants impact the disease. Metabolites have the distinct advantage of being more proximal markers of disease processes than transcriptional, translational or post-translational changes. Therefore the integration of metabolomics, with genetics, genomics, and epigenetics may more effectively link disease outcomes with genetic determinants. We generated lipidomic pilot data using liquid chromatography tandem mass spectrometry (LC-MS) using plasma samples from 20 Caucasian individuals from the Asthma BioRepository for Integrative Genomic Exploration (Asthma BRIDGE), an open-access repository from 1,435 asthmatics. A total 64 metabolites were generated of which 26 were identifiable. We used two asthma severity phenotypes, a binary measurement, “hospitalized overnight for asthma” and a continuous, composite measurement, “acute asthma control.” We performed the following analyses for all 64 metabolites: 1) GWAS analyses for each metabolite and all genetic variants; 2) regression analyses for each metabolite and genome-wide gene expression variants; 3) regression analyses for each metabolite and the genome-wide CpG methylation data. We then identified the top variants from each of these analyses including the top SNPs, mRNA transcripts, and CpG sites that were associated with any metabolites. We then applied a Conditional Gaussian Bayesian Network analysis to the top findings from these analyses, using the asthma severity phenotypes as the outcome of interest. We first used 5-fold cross-validation to arrive at hyper-parameters for the Bayesian likelihood calculations. We then performed 100 bootstrap iterations of the dataset, and learned an exhaustive network for each bootstrap iteration. From the sample of 100 networks, we built a consensus network by including the edges present in more than 25% of the bootstrap networks. From this, we developed networks with predictive accuracy as high as 98% for asthma severity phenotypes. This approach illustrates the strength of integrating metabolomics data with genetic, gene expression, and epigenetic data for disease prediction.

1855M

Closed-form Wald tests for genome-wide analysis of gene-gene interactions. *Z. Yu[1], M. Demetriou[2], D. Gillen[1].* 1) Department of Statistics, University of California, Irvine, CA; 2) Department of Neurology, University of California, Irvine, CA.

Despite the successful discovery of hundreds of variants for complex human traits using genome-wide association studies, the degree to which genes jointly affect disease risk is largely unknown. One obstacle toward this goal is that the computational effort required for testing gene-gene interactions is enormous. As a result, numerous computationally efficient tests were recently proposed. However, the validity of these methods often relies on unrealistic assumptions such as additive main effects, main effects at only one SNP, and no linkage disequilibrium. Here we propose to use closed-form Wald tests. The Wald tests are asymptotically equivalent to the corresponding likelihood ratio tests, largely considered to be the gold standard tests but generally too computationally demanding for genome-wide interaction analysis. Simulation studies show that the Wald tests have very similar performance with their computationally intensive counterparts. Applying the proposed tests to a genome-wide study of multiple sclerosis, we identify interactions within the major histocompatibility complex region. In this application, we found that (1) focusing on pairs where both single nucleotide polymorphisms (SNPs) are marginally significant leads to more significant interactions when compared to focusing on pairs where at least one SNP is marginally significant; and (2) parsimonious parameterization of interaction effects might decrease, rather than increase, statistical power.

1856T

Gene based analyses of sympathetic nervous system genes on long term blood pressure: The GenSalt study. *C. Li[1], J. He[1,3], J.E. Hixson[4], D. Gu[2], D.C. Rao[5], L.C. Shimmin[4], J. Huang[2], C.C. Gu[5], J. Chen[2], F. Liu[2], J. Li[2], T.N. Kelly[1].* 1) Department of Epidemiology, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) State Key Laboratory of Cardiovascular Disease, Fuwai Hospital, National Center of Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; 3) Department of Medicine, Tulane University School of Medicine, New Orleans, LA; 4) Department of Epidemiology, Human Genetics and Environmental Sciences, University of Texas School of Public Health, Houston, TX; 5) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO.

Although genomic factors are known to influence BP, much of the heritability of the BP phenotype remains unexplained. Gene-based analysis of long term BP may increase power to detect genetic factors underlying BP phenotypes. The objective of the current study was to examine the influence of sympathetic nervous system (SNS) genes and gene-gene interactions on long term average BP among 1,881 Han Chinese participants of the family-based Genetic Epidemiology Network of Salt Sensitivity (GenSalt) follow-up study. Nine BP measures were collected at a 2003 baseline examination and at each of two follow-up visits in 2007 and 2011. Single marker associations of 448 tag SNPs in 20 SNS genes and the pairwise interactions of SNPs between each pair of genes were assessed for association with long term BP using mixed models to accommodate the repeated BP measures and GenSalt family structure. For single gene analysis, single-marker analysis *P*-values for SNPs within each gene were combined using the truncated product method (TPM) to estimate an overall gene-based *P*-value. TPM was also used to combine *P*-values for all SNP interaction terms within each gene pair to generate a gene-gene interaction *P*-value. Nominally significant findings from GenSalt were evaluated for replication using publicly available data from the Multi-Ethnic Study of Atherosclerosis (MESA). Findings from both studies were combined using meta-analysis. Statistical significance was determined by nominal significance in both GenSalt and MESA studies, along with significance after Bonferroni correction to meta-analysis results (α-theshold=0.0025 and 0.00026 for single-gene and gene-gene interaction analyses, respectively). In single-gene analysis, *CACNA1C* was associated with long term systolic BP (P=0.0014), while *ADRA1D* was associated with long term diastolic BP (P=0.0004). In addition, multiple gene-gene interactions influencing BP phenotypes were identified, including: *CACNA1A*×*ADRA1A*, *CACNA1A*×*CACNA1C*, *CACNA1C*×*CACNA1B*, *CACNA1C*×*ADRA1A*, *CACNA1C*×*ADRA1D*, *CACNA1D*×*ADRA1D*, *CACNA1D*×*SLC6A2* for both systolic and diastolic BP (all $P<1.0\times10^{-4}$); *CACNA1A*×*ADRA1D*, *CACNA1C*×*ADRB2*, *ADRA1A*×*ADRA1B*, *ADRA1A*×*SLC6A2* for systolic BP (all $P<1.0\times10^{-4}$); and *CACNA1A*×*CACNA1D*, *CACNA1A*×*SLC6A2*, *CACNA1C*×*SLC18A1*, *ADRA1D*×*ADRA1A*, *ADRA1D*×*DBH*, *ADRA1D*×*SLC18A2* for diastolic BP (all $P<1.0\times10^{-4}$); and These findings provide strong evidence for influence of SNS genes and gene-gene interaction.

1857S

Rapid Variance Component Aggregation Test (RVCAT) for evaluating interaction effects of rare-variants. *R. Marceau[1], W. Lu[1], F.-C. Hsu[2], J.-Y. Tzeng[1,3].* 1) Department of Statistics, North Carolina State University, Raleigh, NC; 2) Department of Biostatistical Sciences, Division of Public Health Sciences, Wake Forest University Health Sciences, Winston-Salem, NC; 3) Bioinformatics Research Center, North Carolina State University, Raleigh, NC.

Studying gene-environment (GxE) and gene-gene (GxG) interactions in genetic association studies allows us to better understand complex disease etiology, uncover missing heritability, and opens the door for personalized medicine. Marker-set aggregation approaches have been shown to be powerful alternatives to the more traditional single SNP GxE tests, especially for rare variants. There are two categories of aggregation approaches that are commonly used: fixed effects methods, which collapse at the genotype level (e.g., the burden test), and random effects methods, which collapse at the similarity level (e.g., kernel machine regression and similarity regression). For assessing interaction effects, random effects models have found to be more robust to model misspecifications than fixed effect approaches. That is, these approaches are still valid when the genetic main effect term and/or the GxE term are misspecified. However, because random effects models use variance components (VCs) to capture the effects, such robustness comes at the cost of increased computational burden from having to estimate nuisance VCs for each effect when assessing GxE effect. These nuisance VCs are computationally intensive to calculate when the trait of interest is non-quantitative. In this work, we propose a rapid variance component aggregation test (RVCAT) which sidesteps the need to estimate the nuisance VCs by treating the genetic main effect as a fixed effect term. We show that while RVCAT maintains the validity and power of the traditional VC tests, it is also computationally efficient—for a quantitative trait analysis with a sample of 5000 subjects, it was over 6.5 times faster than the fully random effect model. Moreover, the proposed algorithm can be conducted on any current software package that is designed for main effect analysis (i.e., no estimation of nuisance VCs). We demonstrate the utility of our proposed method to quantitative, survival, and binary traits using extensive simulations, and apply our method to the Vitamin Intervention for Stroke Prevention (VISP) trial to better understand the effect of genotype on recurrent stroke and its risk factors.

1858M

Studying the elusive exposome and its interaction with the genome in large-scale. *C.J. Patel[1], J.P.A. Ioannidis[2].* 1) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 2) Stanford Center for Prevention Research, Stanford University School of Medicine, Stanford, CA.

It is hypothesized that greater than 50% of complex disease risk is attributed to differences in an individual's environment, but we lack ways of investigating the exposome -- the totality of exposure load that occurs throughout a lifetime - in disease risk. Further, we have yet to incorporate the exposome in genome-wide association studies (GWAS) to assess how environment modifies genetic risk for complex disease. Furthermore, investigating one or a handful of exposures at a time has led to a highly fragmented literature of epidemiologic association and much of that literature is not reproducible. A new model is required to discover environmental exposures, and how they interact with the genome, in disease.

Here, we discuss ways of to remedy this problem through a strategy known as the "Environment-wide association study" (EWAS), where investigators assess 100s-1000s of personal exposures simultaneously. Analogous to GWAS, we will show how multiple personal exposures can be assessed simultaneously in terms of their association with diseases such as type 2 diabetes (T2D), heart disease risk factors, and mortality in cohorts from the United States National Health Nutrition Examination Survey and the International Study of Macronutrients in Blood Pressure (N~5K-30K). In these studies, we show how an array of exposures ranging from pollutants, nutrients, and pesticides are associated with these diseases and have effect sizes that are comparable or exceed GWAS findings. We will discuss the hurdles, including biases such as reverse causality, confounding, and challenges of inferring independence in midst of the dense correlation structure of the exposome.

We outline and show preliminary findings that combine the exposome with genome to assess how genetic risk for disease may be dependent on environmental exposure, known as gene-environment interactions (GxE). Because searching for interactions requires prohibitively large sample sizes and hypothesis tests, we describe how to increase chances for discovery and replication by consideration of interactions between top EWAS and GWAS findings. Specifically, we describe a strategy that tests the interaction between a summary of genetic risk (via a validated polygenic risk score) in interaction with EWAS-derived exposures. We show examples of the strategy in complex traits including body mass index and blood pressure as well as a disease, T2D.

1859T

To evaluate the determinants of pre-hypertension and hypertension among Punjabi adolescent population using path analysis and structural equation modelling. *S.K. Brar, H. Kaur, B. Badaruddoza.* Deptt. of Human Genetics, Guru Nanak Dev University, Amritsar, India.

Punjabi ethnic population in India is at high risk for obesity and hypertension. It is believed that these disorders begin in childhood especially in adolescent period. Keeping in mind the complex nature of these disorders, a cross-sectional study with a sample of 3060 (1530 boys and 1530 girls) adolescents aged 10 to 18 years was carried out. The study has applied a path analysis of structural equation modeling for all studied anthropometric and socio-economic lifestyle variables to evaluate the determinants of pre-hypertension and hypertension. The study first tested the adequacy of hypothesized path model which contain the inter-correlated variables, such as body mass index (BMI), waist circumference (WC), waist to hip ratio (WHR), sum of skinfolds (SumSF), food habits (FH), exercise (EX), screen time (ScT) and family status (FS). Next, the study tested the relative strengths of association of independent variables with SBP and DBP on the basis of the magnitude of path coefficients of regression, covariances and variance. The study adopted maximum likelihood estimation, 95% confidence limit and critical ratio in generating the estimate of path coefficients and its significance. The regression path coefficients of BMI, waist circumference and WHR were found significant among both boys and girls. The estimates of variance and critical ratio for all the studied risk factors for SBP and DBP have been found significant on SBP and DBP for both boys and girls. The whole analysis confirmed that the waist circumference, BMI and family income status have significant contribution to increase blood pressure among Punjabi adolescents.

1860S

Study design and statistical tests for detecting gene-environment interaction on environmental exposure-defined phenotypes. *C. Chen[1], P. Kraft[2], B. Neale[1], J. Smoller[1,2].* 1) Massachusetts General Hospital, Boston, MA; 2) Harvard School of Public Health, Boston, MA.

There is an increasing interest in investigating gene-environment interaction for phenotypes with a prerequisite of certain environmental exposure (e.g. post-traumatic stress disorder, substance dependence). However, the nature of these phenotypes, which exclude the possibility that an individual becomes a case without the required exposure, poses unique challenges in choosing the optimal study design and statistical test for gene-environment interaction analysis. We explored the best strategy to detect gene-environment interaction for environmental exposure-defined phenotypes, where the exposure had four ordered levels (unexposed; and low, medium, high exposure). We compared the statistical power and Type 1 error of 4 different tests that are commonly used in this context: 1) gene main effect test (G); 2) conventional gene-environment interaction test (GE); 3) case-only gene-environment interaction test (CO); 4) joint test of both the gene main effect and the interaction (GGE). We considered factors that may affect the power and Type 1 error of these tests, including: genetic risk allele frequency; environmental exposure frequency; genotype-exposure correlation in the population; effect sizes of exposure, gene and gene-environment interaction; and exposure misclassification. Finally, we compared analyses for non-exposure-defined phenotype and exposure-defined phenotype with both exposed and non-exposed controls, or with exposed controls only. When only main effects were present with no interaction effect, the G test showed higher power than the GGE test. When main and interaction effects were present, the CO test showed higher power than the GE test for non-exposure-defined and exposure-defined phenotypes. We note that the power of GE test reduced dramatically when restricting to exposed controls for exposure-defined phenotypes. For non-exposure-defined phenotype, the GGE test showed higher power than the G test (2% increase in power). However, for exposure-defined phenotype, the G test showed higher power than the GGE test (12% increase in power). Restriction to exposed controls improved the power of the G test and the GGE test for exposure-defined phenotype. Based on these results, we recommend the CO test for investigating gene-environment interaction, with a caveat on inflated type 1 error due to G-E correlation, and restriction to the exposed controls for detecting genetic effects on exposure-defined phenotypes.

1861M

A simulation study of gene-by-environment interactions in GWAS implies ample hidden effects. *U.M. Marigorta, G. Gibson.* School of Biology, Georgia Institute of Technology, Atlanta, GA., USA.

The recent switch to a modern lifestyle has coincided with a rapid increase in prevalence of obesity and other diseases. Paradoxically, these conditions present large heritability values. The shifts in prevalence could be explained by the release of genetic susceptibility for disease in the form of gene-by-environment (GxE) interactions. However, the detection of interaction effects requires large sample sizes, little replication has been reported, and a few studies have demonstrated environmental effects only after summing the risk of GWAS alleles into genetic risk scores (GRSxE). We performed extensive simulations of a quantitative trait controlled by 2,500 common causal variants to inspect the feasibility to detect gene-by-environment interactions in the context of GWAS. To mimic the switch in human lifestyle, the simulated individuals were assigned either to an ancestral or a modern setting that alters the phenotype by increasing the effect size by 1.05 to 2-fold at a varying fraction of perturbed SNPs (from 1% to 20%). We report two main results. First, and for a wide range of realistic scenarios, we confirm that GxE interactions may remain hidden at the level of individual loci but be easily detected through GRSxE analyses. Second, we observe that a pervasive hidden presence of GxE interactions can heavily reduce the power to discover susceptibility variants by GWAS upon mixed cohorts. We conclude that a pervasive presence of gene-by-environment effects can remain hidden even though it contributes to the genetic architecture of complex traits.

A novel functional data analysis approach to detecting gene by longitudinal environmental exposure interaction. *P. Wei[1], H. Tang[2], D. Li[2].* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Dept of Gastrointestinal Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston, TX.

Most complex diseases are likely the consequence of the joint actions of genetic and environmental factors. Identification of gene-environment (GxE) interactions not only contributes to a better understanding of the disease mechanisms, but also improves disease risk prediction and targeted intervention. In contrast to the large number of genetic susceptibility loci discovered by genome-wide association studies, there have been very few successes in identifying GxE interactions which may be partly due to limited statistical power and inaccurately measured exposures. While existing statistical methods only consider interactions between genes and static environmental exposures, many environmental factors, such as air pollution and diet, change over time, and cannot be accurately captured at one measurement time point. There is a dearth of statistical methods for detecting gene by time-varying environmental exposure interactions. Here we propose a powerful functional logistic regression (FLR) approach to model the time-varying effect of longitudinal environmental exposure and its interaction with genetic factors on disease risk. Capitalizing on the powerful functional data analysis framework, our proposed FLR model is capable of accommodating longitudinal exposures measured at irregular time points and contaminated by measurement errors. We use extensive simulations to show that the proposed method can control the Type I error and is more powerful than alternative ad hoc methods. We demonstrate the utility of this new method using data from a candidate gene-based case-control study of pancreatic cancer to identify the windows of vulnerability of lifetime body mass index (BMI) on the risk of pancreatic cancer as well as genes which may modify this association. SNP rs8050136 in the FTO gene was found to be nominally significantly modifying the association between the lifetime BMI, especially early-adulthood overweight, and the pancreatic cancer risk (p-value = 0.02 based on the FLR model).

GWAS for a longitudinal trait with non-uniform errors: Recovery of CD4 cell counts after initiation of anti-retroviral therapy in two Ugandan cohorts. *J. Mefford, J. Micheli, J. Witte, D. Kroetz.* UC San Francisco,.

We present results and an assessment of alternative models for a genome-wide association study of a longitudinal trait -- CD4 T-cell recovery trajectories from a total of 516 subjects with advanced HIV disease. Subjects were from two cohorts: 396 subjects from UARTO (Uganda AIDS Rural Treatment Outcomes), and 120 from ARKS (Anti-Retrovirals for Karposi's Sarcoma). Subjects were genotyped, with 681230 markers passing QC and imputed to a 1KG reference panel. A GWAS was then run using a longitudinal model to search for genetic variants that are associated with either the rate of CD4-cell recovery after initiation of ART, or overall levels of CD4 counts. As count data, the CD4 measurements have sampling variances dependent on the CD4 level, so models are considered where a variance-stabilizing square-root transformation is applied to the CD4 measurements, or where the variance is stabilized while keeping observations on the original scale through weighting observations by their inverse variance. On either scale, the rate of increase in CD4 counts appears to be rapid in the first year and then to taper off, so piece-wise linear mixed models were used to show the time course of CD4 recovery, with breakpoints at 3 and 12 months. CD4 counts vary widely between subjects so mixed models with random intercepts and adjustments for fixed covariates were used (cohort, age, sex, and ten genetic principal components). Genetic effects were modeled as a genetic main effects and interactions of genotype with the piecewise linear time effect. Multiple degree-of-freedom likelihood ratio tests were used to compare the full models to reduced models with no genetic effects. The component genetic effects (main genetic effect and the time interaction) are examined to help interpret the GWAS results from the global genetic test. Analyses of the CD4 trajectories on the square-root transformed scale and the variance-weighted analysis on the untransformed scale show similar patterns of results with suggestive effects on chromosomes 1, 9 and 10. The total genetic effects seem driven by the gene-time interaction more than the genetic main effects. The weighted analysis on the untransformed scale has the advantage of allowing an interpretation of the gene*time effect as an additive contribution to the CD4 trajectories.

Detecting clusters of disease-associated SNPs. *D. Swanson, J. Laramie.* GNS Healthcare, Cambridge, MA.

Many methods have been developed for associating SNPs with disease, and databases exist that catalogue these SNP-phenotype associations. While genome-wide knowledge of these SNP-phenotype associations can enable researchers to locate clusters of disease-associated SNPs, thereby helping to relate them to an underlying feature such as all being found in a common gene, there do not exist methods for principled identification of such clusters. Identification of SNP-disease association clusters is made slightly more complicated because existing databases such as those found on NCBI are informed by GWAS, whose hypothesis tests are generally performed in the context of univariate regression analysis and, as a result, do not control for the non-trivial LD structure present between many adjacent SNPs--a seeming ‘cluster’ of disease-associated SNPs could therefore be driven by a single primary disease-associated SNP in LD with many other SNPs that have no association with the outcome, controlling for the primary SNP. We propose 2 methods for principled cluster detection of disease associated SNPs, one in which the measure of SNP-disease association is continuous, such as a Z-statistic, and one in which the measure of association is binary (i.e., the SNP is or is not associated with the outcome). Both methods draw on existing work coming from the disease surveillance and spatial statistics literature. We apply the two methods to two publicly available sets of GWAS results, one in which genome-wide significant SNPs are simply identified for rheumatoid arthritis and one in which there exists a continuous test statistic for each analyzed SNP for Alzheimers disease. In both cases, we detect clusters of disease-associated SNPs.

1865T

Biochemical network-driven analysis of genetic control of human metabolome. *Y.A. Tsepilov[1,2], K. Strauch[3,4], C. Gieger[3], Y.S. Aulchenko[1,2].* 1) Institute of Cytology and Genetics SD RAS, Novosibirsk, Russia; 2) Novosibirsk State University, Novosibirsk, Russia; 3) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 4) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Genetic Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany.

Genome-wide association analysis (GWAS) is one of the most popular methods of identification of alleles that affect complex traits. Recent accumulation of functional genomics data ("ome" data, e.g. transcriptome, metabolome etc) could give a new insight into the functional role of specific changes in the genome. Such data require special statistical methods for their analysis, as they are characteristically high dimensional and contain statistical interactions and functional relationships between individual components, which usually reflect biological interactions. Development of such methods is of current importance as the progress of molecular biology techniques marches on. We introduce a new approach to evaluate the impact of genetic variants to "omics" phenotypes with relatively high power and rather modest computational intensities. Our approach is based on the idea that if biological pathways and relationships in data could be reconstructed, we can use the knowledge about biochemical neighbors for chosen trait and include this information into analysis of this trait. The sources of biological relationship information can vary: biological pathway databases or reconstructed net from the data. We assessed our approach using real population study data from big German study KORA (n=1,784, 2M SNPs) with measured metabolomics data (151 metabolites). For reconstruction of the pathways we used Gaussian Graphical Models (GGM) which was shown as effective tool for the unbiased reconstruction of metabolic reaction. Previously it was demonstrated that using GGM-driven ratios instead of all ratios leads to comparable power with much less computational expenses. Our approach as well has shown the comparable power with all ratio approach with computational complexity similar to the analysis of original concentrations only (n instead of n^2). Using of biochemically related covariates decreases the phenotype variances and the noise driven by network influences between metabolites with the dissolution of induced signals and the improvement of actual associations that helps with further functional annotation.

1866S

Joint Analysis of Genetic Interaction and Imprinting in Family Studies. *C.C. Wu[1], S. Shete[2].* 1) Environmental/Occupational Health, National Cheng Kung University, Tainan, Taiwan; 2) Biostatistics, The University of Texas MD Anderson Cancer Center, Houston, Texas, USA.

Genomic imprinting is considered a primary epigenetic phenomenon, which results in 2 alleles at a locus being expressed differentially depending on the parental origin of the chromosome. The role of imprinted genes and gene-gene interactions in disease susceptibility is well recognized. Imprinting leads to manifestation of parent-of-origin effects. More than 1000 individual genetic variants associated with common diseases have been detected by recent whole genome studies; the efforts to map interacting genes have been less successful. In response, we proposed a method to detect genetic interaction effects in the presence of genomic imprinting. We extended our previous allele-sharing method that accounts for parent-of-origin effects in the affected sib pairs framework. We derived 3 mathematical two-locus models that incorporate parent-of-origin effects: additive, multiplicative, and general models. We further proposed to use a novel test to assess the gene-gene interaction and parent-of-origin effects individually and jointly. The statistical properties and performance of the proposed method will be evaluated using simulated data.

1867M

Gene-gene interactions in admixed populations. *E. Ziv, D. Hu, L. Fejerman.* Department of Medicine, Institute for Human Genetics, Helen Diller Family Comprehensive Cancer Center, UCSF, San Francisco, CA.

Identifying gene-gene interactions is a challenge in human genetics due to the limitations of power after adjusting for the large number of potential interactions tested. We examine the approach to identifying gene-gene interactions in an admixed population. We model a dichotomous trait (disease vs. no disease) in an admixed population consisting of two ancestral populations. First, we consider how the type of genetic interaction and the range of allele frequencies in the ancestral populations affect the association between genetic ancestry and disease. We demonstrate that there are distinct non-linear patterns of the association between disease risk and genetic ancestry depending on the allele frequency differences between ancestral populations. Furthermore, we consider how, by capitalizing on these patterns, investigators can design studies that enhance the power to detect gene-gene interactions. We illustrate the approach using simulations and a study of breast cancer in a U.S. Latina population.

1868T

Integration of multiple types of functional annotation with genotype data in genetic association studies at gene and pathway levels. *Y. Guo[1,2], D.V. Conti[1,2], G.K. Chen[1,2], K. Wang[1,3,4].* 1) Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA; 2) Division of Biostatistics, Department of Preventive Medicine, University of Southern California, Los Angeles, CA; 3) Department of Psychiatry & Behavioral Sciences, University of Southern California, Los Angeles, CA; 4) Division of Bioinformatics, Department of Preventive Medicine, University of Southern California, Los Angeles, CA.

Association tests on multiple levels of regions, such as genes and biological pathways provide an alternative to conventional genome-wide association studies (GWAS). Compared with single SNP-based methods, this approach may have increased power, can facilitate direct comparison across different populations or genotyping platforms, and can ease interpretation. Quintana and Conti (Genetic Epidemiology, 2011) proposed to use a combination of Bayesian model uncertainty and a hierarchical model to construct a Bayesian risk index as a measurement for strength of regional association. In their method, various sources of biological annotations can be incorporated into the model to help select variants and Metropolis-Hastings (MH) and Gibbs Sampling techniques are used for inference. There are, however, two major hurdles for this approach. First, computational cost associated with MH method grows cubically with the number of variants, limiting its scalability with next-generation sequencing data. Second, the approach is limited to a few sources of biological information and it is unclear how to select annotations from thousands of options available. Here we alter the algorithm to gain efficiency in computation. At the beginning of the MH procedure, reversible jump Markov Chain Monte Carlo is used to select a subset of variants, which constitute a more plausible model, as a starting point. In each iteration of the stochastic search, a proposal kernel is more likely to add a variant that is close to elevated signal of activity or in high linkage disequilibrium with a nearby GWAS hit. To select prior information, we applied the statistical model (fgwas) by Pickrell (American Journal of Human Genetics, 2014) to pick a few annotations that most differentiate associated variants from non-associated variants. Using this approach, we incorporated multiple DNase, chromHMM, ChIP annotation data tracks from UCSC genome browser. Our method has several conceptual advantages than existing approaches and can be easily scaled up from GWAS to sequencing studies on large population cohorts. Through simulation and real data analysis, we demonstrate the applicability of our method and show performance improvements compared to competing methods.

1869S

Identification of shared genetic aetiology between epidemiologically linked disorders with an application to obesity and osteoarthritis. *J. Asimit[1], K. Panoutsopoulou[1], E. Wheeler[1], S. Berndt[4], A.P. Morris[2,3], I. Barroso[1], E. Zeggini[1], the GIANT consortium, the arcOGEN consortium.* 1) Human Genetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom; 4) US Department of Health and Human Services, Division of Cancer Epidemiology and Genetics, National Cancer Institute, US National Institutes of Health, Bethesda, Maryland, USA.

Diseases often co-occur in individuals more likely than expected by chance. Shared genetic aetiology may explain this, and the discovery of shared variants may suggest a common biological process. A common approach to a genetic overlap analysis is to select a p-value threshold and compare the signals from the genome-wide association study (GWAS) of each trait. However, p-values do not account for differences in power, whereas Bayes' factors do, and may be approximated using summary statistics. We use simulation studies to compare the power of frequentist and Bayesian approaches to overlap analyses, and to decide on appropriate thresholds for comparison between the two methods. It is empirically illustrated in single-disease associations that BFs have the advantage over p-values of a decreasing proportion of false positives (PFP) as study size increases. For a $\log_{10}$(BF) threshold $L\theta$ of 1.69 (R=type II error cost/type I error cost=2, π_0 = Pr(no association at SNP)=0.99), the PFP decreases from 7.38×10^{-4} (N=2,000 each cases/controls) to 3.37×10^{-4} (N=20,000) , while for p-values the PFP fluctuates near the p-value threshold α regardless of study size. Power increases with sample size are more noticeable for the Bayesian approach. For OR=1.2 and MAF 0.1, the power in studies with N=3,000 are 0.413 ($L\theta$=1.69) and 0.365 ($\alpha=5\times10^{-4}$), while at N=5,000 the respective powers rise to 0.750 and 0.716. In a preliminary overlap analysis of obesity (GIANT consortium) with OA (arcOGEN consortium), the number of signals is similar at comparable threshold levels between BFs and p-values. The two sets of results are not always overlapping and additional signals are often in already detected genes. For $L\theta$=0.91 (R=type II error cost/type I error cost=12, π_0=Pr(no association at variant)=0.99), there are 18 shared variants identified as associated, and the comparable α levels of 0.003 and 0.004 yield 15 and 28 hits, respectively. The most notable difference is that the Bayesian list contains rs13107325 (in *SLC39A8/ZIP8*), a variant previously associated with obesity-related phenotypes such as BMI, blood pressure, and HDL cholesterol, and animal studies have shown that the zinc-ZIP8-MTF1 axis regulates OA pathogenesis. This variant is only detected via p-values if we increase α to 0.005. We are pursuing replication of this finding. Extensive simulations to systematically evaluate power differences between the BF and p-value-based overlap analysis approaches are underway.

Multilevel dimensionality reduction algorithms for high-dimensional genetics data. *K. Cho[1, 2], D.R. Gagnon[2, 3], H. Wu[2, 4].* 1) Division of Aging, Brigham and Women's Hospital/Harvard Medical School, Boston, MA. USA; 2) Massachusetts Veterans Epidemiology Research and Information Center; VA Boston Healthcare System, Boston, MA, USA; 3) Boston University School of Public Health, Boston, MA, USA; 4) Computer Science and Networking, Wentworth Institute of Technology; Boston, MA, USA.

With rapid advancements in genotyping and sequencing technologies, there are more genetic data available than one can thoroughly analyze with existing tools and methods. This has become one of the analytical challenges in the initial phases of big scale studies. In whole-genome or genome-wide exploration of novel associations, without a priori knowledge of specific regions or genes of interest, researchers rely on the available techniques that perform association tests based on a way of summarization or assuming independence. In addition, traditional statistical procedures present eminent challenges in using these data, where the number of parameters p is scalably larger than number of observations n. These limitations may compromise the level of false positive results and power to conduct studies with acceptable level of confidence. One of the ways to reduce the initial efficiency burden with high dimensional genetic data is to first perform a data dimension reduction process and then evaluate the resulting panels of markers. We propose several algorithms using traditional PCA based algorithms, LASSO, and combinations of these to evaluate the impact of type one error. Using the Genetic Analysis Workshop 18 simulated data, we apply the several algorithms on null regions of chromosome 3 with regards to the diastolic blood pressure phenotype. Then we use SKAT as the evaluation tool to perform association analysis using the resulting panels from each algorithm. We then systematically compare type I error rates among different algorithms with respect to the baseline panel. Our preliminary work using 360,717 SNPs containing 1431 gene groups in unrelated samples, shows a substantial reduction of the markers through applying proposed algorithms. Our PCA based algorithm was applied to individual SNP sets and also to gene group sets. Among these, the PCA top SNP and PCA genes algorithms resulted in 106 and 23297 unique SNPs, respectively, at 85% variation. At 95% variation, 127 and 35382 resulting SNPs remained, respectively. We are also investigating PCA followed by LASSO algorithm and PCA incorporating heritability approaches using the family datasets. As the amount and dimensionality of the network of genomics data is only escalating in the coming years, a timely, robust and practical analytical pipeline through multilevel dimensionality reduction techniques provides an efficient approach for the initial screening tool.

1871T

Estimating genetic distance-dependent effects of environmental exposures by functional models. *D. Zaykin[1], O. Vsevolozhskaya[2], Q. Lu[2].* 1) National Institute of Environmental Health Sciences; 2) Michigan State University.

We present a functional method for fitting simultaneously the effects of scalar predictors, confounding factors and environmental exposures on sequenced allelic variants in a genetic region. These effects are fitted as continuous curves smoothly varying over genetic loci to help researchers shed light on which regions harbor causal variants. In a densely sequenced region, one can plot genotypic values on the y-axis versus variant position on the x-axis and 'connect the dots'. The resulting continuous genotype curve will change over variants position. By utilizing continuous curves, our method exploits linkage disequilibrium among variants in the ways that otherwise is difficult to achieve. For example, one can regress genotype curves on a set of environmental variables and obtain a subject-specific set of curves for each environmental effect that will also change over variants position. The regression on the genotype curve is produced based on a penalized spline regression and can be linked to linear mixed models which allows utilization of standard statistical software packages. We investigate advantages and disadvantages of our approach by conducting an extensive simulation study. We illustrate the approach with sequencing data from the Dallas Heart Study.

1872S

Multivariate approach for finding gene sets differentially expressed by complex phenotype. *E. Drigalenko, H.H.H. Göring.* Dept Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Genes almost never act alone in a biological system; they typically work in a cascade of networks. This motivates the consideration of clusters of genes, instead of individual genes, as functional genomic units. Variations of certain phenotypes, including complex diseases and quantitative traits, may be associated with differential expressions of multiple genes instead of a single gene.

Transcriptome sequencing (RNA-seq) technology allows measuring of the expression levels of tens of thousands of genes simultaneously. Expression profiles of multiple genes are correlated and thus are appropriately modeled as mutually correlated variables in a statistical testing framework.

Here, we propose three multivariate methods for testing the association of sets of correlated genes with discrete or continuous phenotypic outcomes: (1) comparison of covariate matrices under different conditions using Box's M test; (2) joint regression of all genes in a pathway; (3) orthogonal decomposition of the variance and the regression of principal components (PC) using Kaiser's criteria for the number of essential PCs. KEGG pathway classes C, B, and A were studied separately. We use programs implemented in R. The last two methods can be used for quantitative traits.

To demonstrate the performance, we apply these methods to publicly available data from the NCBI Gene Expression Omnibus database. For this presentation, we used the genes expression (RNA-seq) data from 21 individuals (Akula et al, 2014; GSE53239) - 10 with bipolar disorder and 11 controls. As an example of gene sets, here we have used Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways.

We found that the proposed methods do identify differentially expressed gene pathways. In our example, the PC-based method identified the most pathways. Using it, after the Bonferroni correction for the number of pathways is a class, we found that 27 pathways are significant of total 282 in KEGG Class C, 23 of 39 in Class B, and all 6 of 6 in Class A. When examining several other example gene expression datasets, the PC-based method identified the most pathways in all instances.

1873M

Estimating and interpreting pairwise genetic correlations between hundreds of quantitative traits from population samples of thousands of individuals. *M. Pirinen[1], C. Benner[1], M.A. Rivas[2], T. Lehtimäki[3], A.J. Kangas[4,5], P. Soininen[4,5], M. Ala-Korpela[4,5,6], J.G. Eriksson[7,8,9], O.T. Raitakari[10,11], M.R. Järvelin[12,13,14], V. Salomaa[7], S. Ripatti[1,15,16].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Department of Clinical Chemistry, Fimlab Laboratories, University of Tampere School of Medicine, Tampere, Finland; 4) Computational Medicine, Institute of Health Sciences, University of Oulu and Oulu University Hospital, Oulu, Finland; 5) NMR Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, Kuopio, Finland; 6) Computational Medicine, School of Social and Community Medicine and the Medical Research Council Integrative Epidemiology Unit, University of Bristol, Bristol, UK; 7) Department of Chronic Disease Prevention, National Institute for Health and Welfare, Finland; 8) Department of General Practice and Primary Health Care, University of Helsinki, Finland; 9) Unit of General Practice, Helsinki University Central Hospital, Finland; 10) Department of Clinical Physiology and Nuclear Medicine, University of Turku and Turku University Hospital, Turku, Finland; 11) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku and Department of Clinical Physiology and Nuclear Medicine, Turku University Hospital, Turku, Finland; 12) Department of Epidemiology and Biostatistics, MRC Health Protection Agency (HPA) Centre for Environment and Health, School of Public Health, Imperial College London, UK; 13) Institute of Health Sciences, University of Oulu, Finland; 14) Biocenter Oulu, University of Oulu, Finland; 15) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 16) Hjelt Institute, University of Helsinki, Helsinki, Finland.

Several modern technologies, such as nuclear magnetic resonance and mass spectrometry platforms, produce high-dimensional phenotype data on individuals. A first step towards utilising high-dimensional phenotypes in genetic studies is to understand how their genetic components are related. Recent algorithmic advances in multivariate linear mixed models have enabled variance component estimation for pairs of traits using population samples of individuals and genome-wide panels of SNPs. However, current methods have not been tailored for situations where hundreds of traits are available on the same set of individuals. For such settings, we introduce an algorithm that efficiently decomposes pairwise phenotypic correlations into genetic and environmental components. We illustrate our approach with an application to thousands of pairs of metabolic and anthropometric traits measured on up to 14,000 Finnish individuals. For example, we estimate that the observed phenotypic correlation (-0.41) between triglyserides and HDL cholesterol decomposes into an additive genetic correlation (-0.59, s.e. 0.06) and an environmental correlation (-0.36 s.e. 0.02). We assess the interpretation of genetic correlations as correlations between locus-wise genetic effects by applying multivariate statistical models on the results of a recent genome-wide meta-analysis on lipid levels. Finally, we consider settings where prior information about genetic correlation increases statistical power to identify pleiotropic loci, i.e. loci that contribute to multiple traits.

1874T

Systemic genetics of Systemic Sclerosis through protein-protein interaction network-based analysis. *J. HAMON[1], Y. ALLANORE[2], M. MARTINEZ[1].* 1) INSERM UMR1043, Hôpital Purpan, Toulouse, France; 2) INSERM UMR1016, Hôpital Cochin, Paris, France.

Genome-wide association studies (GWAS) of complex traits have revealed reproducible genetic associations with human complex disorders, including Systemic Sclerosis. However, these studies rely on analysis at the single-nucleotide polymorphisms (SNP) level and, consequently, lack power in presence of allelic heterogeneity (multiple independent risk variants within a given gene/genomic region) and/or for detecting interacting risk variants (with low marginal effects). This complexity has generated considerable interest in multi-locus analysis techniques as, for instance, knowledge-driven methods that integrate known functional and interaction networks. These approaches vary according to the type of known information (protein-protein network/gene function pathways) that is integrated to the GWAS data; the way GWAS data in genes is used (single-SNP or SNP-set statistical significance); and the model used to test for association between a module/pathway of genes and the phenotype. Here, we present results from various study designs for network-based analysis integrated to our Systemic Sclerosis GWAS data (564 cases and 1,776 controls). We have built a robust two-stage network analysis by randomly splitting our GWAS data into a scan and a replication dataset. In the scan dataset we performed a PPI network-based approach using a dense module search strategy and using different approaches to assess GW : for instance, from the lowest single-SNP P value unadjusted (Min) or Bonferroni-adjusted (Bonf) for the number of SNPs within the gene, or by combining all single-SNP P values with the Fisher's method. We first compared the results obtained under the different strategies according to the length (i.e., number of genes) of the enriched modules and the characteristics of the genes within the modules. The top (5 and 10%) most enriched modules were further tested for enrichment analysis in the replication dataset. We finally assessed whether the genes from the replicated sub-networks were significantly clustered within KEGG pathways. Our results show that the gene-wise association P-value modeling has a large impact on the results, i.e., length (number of genes) of sub-networks, characteristics of their genes and replication rate of top most enriched sub-networks. Overall, we found low consistency across the results from the different strategies: the different strategies tend to select different sets of genes but also different KEGG pathways.

1875S

Mixed-model analysis of common variation reveals pathways explaining variance in AMD risk. *J. Hall[1], M. Pericak-Vance[2], W. Scott[2], J. Kovach[2], S. Schwartz[2], A. Agarwal[3], M. Brantley[3], J. Haines[1], W. Bush[1].* 1) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Ophthalmology and Visual Sciences, Vanderbilt University, Nashville, TN.

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness in the elderly in developed countries and can affect more than 10% of individuals over the age of 80 in many populations. AMD has a large genetic component, with overall heritability estimated to be between 45% & 70%. Numerous AMD loci have been identified and implicate various molecular mechanisms and pathways in AMD pathogenesis. Eight pathways, including angiogenesis, antioxidant activity, apoptosis, complement activation, inflammatory response, nicotine metabolism, oxidative phosphorylation, and the tricarboxylic acid cycle, were selected for our study based on an extensive literature review. While these pathways have been proposed in literature, the overall extent that each pathway contributes to AMD risk is unknown. In a dataset of 1,154 AMD cases and 668 controls, we used Genome-wide Complex Trait Analysis (GCTA) to conduct mixed-model regression to estimate the proportion of variance in AMD risk explained by all SNPs in each pathway. Genes were assigned to pathways using Gene Ontology terms and SNPs were mapped to these genes and then assessed using GCTA. To extend the analysis beyond coding variation, nearby SNPs within a 50 kilobases region flanking each gene, many likely to be regulatory, were assessed, as well as more distant, putatively regulatory SNPs within 500 kilobases of each gene, based on retinal pigment epithelium (RPE) DNase I Hypersinsitivity mappings from the ENCODE project. To account for baseline known risk, we tested 19 established AMD risk SNPs and found that they contributed to 13.3% of the variation in risk in our dataset, while the remaining 659,181 SNPs contributed to 36.7%. After adjusting for these 19 risk SNPs, the complement activation and inflammatory response pathways explained a significant ($P = 6.8 \times 10^{-26}$ and 9.5×10^{-8}, respectively) proportion of additional variance in AMD risk (9.8% and 17.9%, respectively), with other pathways showing no significant effects (0.3% - 4.4%). Our results show that additional variants associated with complement activation and inflammation genes contribute to AMD risk and that these variants are likely in coding and nearby regulatory regions.

1876M

A non-parametric approach for detecting gene-gene interactions associated with age-at-onset outcomes. *M. Li[1], J.C. Gardiner[2], N. Breslau[2], J.C. Anthony[2], Q. Lu[2].* 1) Section of Biostatistics at Department of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI.

Cox-regression-based methods have been commonly used for the analyses of survival outcomes, such as age-at-disease-onset. These methods generally assume the hazard functions are proportional among various risk groups. However, such an assumption may not be valid in genetic association studies, especially when complex interactions are involved. In addition, genetic association studies commonly adopt case-control designs. Direct use of Cox regression to case-control data may yield biased estimators and incorrect statistical inference. We propose a non-parametric approach, the weighted Nelson-Aalen (WNA) approach, for detecting genetic variants that are associated with age-dependent outcomes. The proposed approach can be directly applied to prospective cohort studies, and can be easily extended for population-based case-control studies. Moreover, it does not rely on any assumptions of the disease inheritance models, and is able to capture high-order gene-gene interactions. Through simulations, we show the proposed approach outperforms Cox-regression-based methods in various scenarios. We also conduct an empirical study of progression of nicotine dependence by applying the WNA approach to three independent datasets from the Study of Addiction: Genetics and Environment. In the initial dataset, two SNPs, rs6570989 and rs2930357, located in genes GRIK2 and CSMD1, are found to be significantly associated with the progression of nicotine dependence (ND). The joint association is further replicated in two independent datasets. Further analysis suggests that these two genes may interact and be associated with the progression of ND.

1877T

Estimation of Heritability and Association for Quantitative Traits with Repeated HbA1c Measures: Biomarker for Metformin Response. *L. Wu[1], J. Mefford[1], S.Y. Yee[2], K.M. Giacomini[2], J.S. Witte[3].* 1) Department of Epidemiology/Biostatistics University of California , San Francisco, CA; 2) Department of Bioengineering and Therapeutic Sciences,University of California , San Francisco, CA; 3) Department of Epidemiology/Biostatistics and Urology, University of California , San Francisco, CA.

Assessing heritability is important for understanding the genetic architecture of quantitative traits. Heritability explained by typed SNPs is commonly calculated using linear mixed-effects models with an estimated genetic relationship matrix (e.g., with GCTA). We adopt a linear mixed-effects model to estimate heritability and carry out association study of quantitative traits with repeated measures. We also propose a new estimate of the genetic relationship matrix whose elements are the cosine similarity of mean-centered genotype vectors of two individuals; assuming no inbreeding, this method guarantees that the diagonal elements equal one, which provides a better characterization of additive genetic relationship of the same individual. In contrast, conventional methods only guarantee the average of diagonal elements to be close to one. The marginal model implied by the linear mixed-effects model is used to lower the computational burden in association analyses. And following an initial screen, the top-ranked SNPs can be reevaluated one at a time to produce more accurate p-values of their association. In our study, we use hemoglobin A1c as a biomarker for response to anti-diabetic drugs such as metformin. We estimate the heritability of metformin response in a cohort of 500 African American diabetic patients with 1,320 repeated HbA1c measures after metformin treatment. For this data, the genetic relationship matrix obtained from GCTA has diagonal elements ranging from 0.926 to 1.511 (average = 1.004, SD 0.014); in contrast, our approach gives values all equal to 1. The off-diagonal elements of the genetic relationship matrices are similar: -0.002 (SD 0.015) from GCTA and -0.002 (SD 0.014) from our proposed method. When calculating heritability of metformin response, using the genetic relationship matrix from GCTA gives a value of 0.19 while our approach gives a value of 0.16. In conclusion, our new method can be used with repeated phenotypic measures to calculate the genetic relationship matrix in estimating heritability. The method guarantees that the diagonal elements of an estimated genetic relationship matrix equal one, offering a potentially valuable alternative to the conventional approaches in estimation of heritability and genetic association study.

Genome-Wide Association and Gene-Gene Interaction Studies to Explore Etiology of Glaucoma and Ocular Hypertension. *S. Verma[1], A. Verma[1], A. Lucas[1], J. Linneman[2], P. Peissig[2], M. Brilliant[2], C. McCarty[3], J. Haines[4], T. Vrabec[5], G. Tromp[5], J. Pathak[6], C. Chute[6], D. Crosslin[7,8], G. Jarvik[7,8], E. Larson[9], M. Hayes[9], M. Ritchie[1].* 1) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Marshfield Clinic, Marshfield WI; 3) Essentia Rural Health, Duluth, MN; 4) Case Western University, Cleveland, OH; 5) Geisinger Health System, Danville, PA; 6) Mayo Clinic, Rochester, MN; 7) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 8) Group Health Research Institute, Seattle WA; 9) Northwestern University, Chicago, IL.

Ocular hypertension (OHT) is a leading risk factor for glaucoma. Previous studies have identified interesting genetic and environmental factors for these two traits, which are among the leading causes of blindness worldwide. In the electronic MEdical Records and GEnomics (eMERGE) network, sites extracted phenotype information on patients with glaucoma and OHT from the EHR who were already genotyped and part of DNA biobanks. We performed GWAS and gene-gene interaction (GxG) studies for both of these traits using data imputed to 1000Genomes. A total of 3,253 and 3,154 unrelated samples of ages 40-90 across five different eMERGE site biorepositories were assembled for glaucoma and OHT studies respectively. We observed novel genome-wide significant variations on Chr1 (rs4147800) associated with glaucoma ($p= 1.04\times10^{-9}$) and on Chr13 (rs4646227) and Chr16 (rs36120466) associated with OHT ($p= 3.92\times10^{-9}$ and 4.52×10^{-9}). To examine epistasis between multiple genetic variants, considering extensive computational demands and multiple testing burden of exhaustive testing, we applied a main effect filter (SNPs with p-value less than 0.01 from GWAS) and then performed genome-wide interaction study (GWIS) using regression methods. We found several interesting interactions that remain significant after Bonferroni correction. ABCA4 shows a significant interaction with GAD2 in OHT (LRT $p= 2.71\times10^{-11}$) and also we observed significant interaction (LRT $p= 1.85\times10^{-7}$) between two genes (PON3 and PON2) in member of paraoxonase family that validates previously published associations between primary open-angle glaucoma and antioxidant enzymes affecting high-density lipoprotein (HDL). We also merged these results and performed pathway-enrichment analysis for all results with main effect $p<1\times10^{-4}$. KEGG Pathway analysis found 10 pathways that are shared for glaucoma and OHT. Notably, ABC transporter pathway contain the most significant genes associated with both Glaucoma and OHT. Similarly Serotonin 5-HT(2) receptor agonists (LTB4R and AGRP genes) linked to neuroactive ligand-receptor interactions (most significant association in OHT) are associated with both phenotypes and they have been also identified as potential agents for the treatment of both OHT and glaucoma. Our findings indicate novel SNP associations and GxG interactions for both of these traits and demonstrate the relationship between these two phenotypes at a potential molecular level with the guide of pathway analysis.

1879M

Major-Effect Loci for Lipids also Impact Phenotype Variability in the Old Order Amish. *L. Yerges-Armstrong, J. O'Connell.* Program in Personalized and Genomic Medicine, and Department of Medicine, Division of Endocrinology, Diabetes and Nutrition - University of Maryland School of Medicine, USA. Baltimore, MD 21201.

Association studies for complex traits have traditionally focused on identifying loci that shift the mean of a quantitative trait. Several recent papers describe methods for modeling genetic loci that instead impact trait variability. These phenotypic variance quantitative trait loci (or vQTL) are of particular interest as they may indicate undetected genetic or environmental interaction. With this in mind, we tested three loci for lipids segregating in the Old Order Amish (OOA) for the presence of vQTL effects. Analyses were conducted on over 1500 participants genotyped on the Illumina Human Exome BeadChip. All analyses were conducted using our mixed models analysis for pedigrees and populations (MMAP) software. Levene's F-test was implemented in MMAP to allow us to model genotype differences accounting for polygenic effects, age and sex. Both the mean and median F-tests were calculated but only the median test is presented. The first variant tested was the *APOC3* null mutation (R19X) associated with markedly lower mean triglycerides ($p=2\times10^{-23}$). In addition to the large effect on the mean, there was a significant vQTL effect ($p=4.6\times10^{-6}$). The second variant was the common, promoter variant in *CETP* (rs3764261), which was highly significant for mean differences in high-density lipoprotein cholesterol ($p=2.6\times10^{-10}$) but had only a modest vQTL effect (p=0.02). Due to a founder effect ~10% of Amish are carriers of the *APOB* 3500Q allele which is associated with ~60mg/dL higher low-density lipoprotein (LDL) cholesterol ($p=1.2\times10^{-94}$). We observed a significant vQTL ($p=1.3\times10^{-6}$) for LDL with this variant. We have previously reported on the higher coronary artery calcification (CAC) in 3500Q carriers thought to be caused by high LDL cholesterol. In 896 OOA with CAC measures we continue to see a strong vQTL for LDL cholesterol ($p=1.7\times10^{-8}$) but not for CAC (p=0.17) despite the much higher mean CAC levels in mutation carriers. To our knowledge, the vQTL effects for R19X and R3500Q are the first reported for lipids. The lack of vQTL effect for *CETP* may indicate that highly-penetrant, rare variants are more likely to be vQTLs. Interestingly, we only detected a vQTL for *APOB* with LDL and not with CAC despite the highly significant mean effect on both traits. This could be a reflection of R3500Q increasing CAC through LDL and not impacting calcification directly, but additional work with other pleiotropic variants is needed before this generalization can be made.

1880T

An integrative imputation method for multi-omic datasets. *D. LIN[1,2], J. ZHANG[2,3], J. LI[1,2], H. DENG[2,3,4], Y. WANG[1,2,3,4].* 1) Biomedical Engineering, Tulane University, New Orleans, LA,70118,USA; 2) Center of Genomics and Bioinformatics, Tulane University, New Orleans, LA, 70112, USA; 3) Department of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA, 70112, USA; 4) Center for Systems Medicine, Shanghai University for Science and Technology, Shanghai, CHINA.

Despite the increasing significance of integrating diverse types of genomic and epigenetic data (e.g. mRNA, microRNA and DNA methylation), the currently available multi-omics datasets inevitably suffer missing values due to technical limitations and various constrains in an experiment. Those missing values will severely hinder the downstream analysis such as the construction of regulation patterns among genetic and epigenetic factors, and the identification of differential expressed biomarkers. Currently, imputation methods for single data type have been well studied and compared. More evidence has shown the biological interconnections among these genomic and epigenetic data. It is significant to integrate these correlated multi-omic datasets for improving the imputation accuracy of missing data. In this study, a novel imputation method was proposed to address this issue by :1) combining the estimates of missing value from individual omic datasets in a way of model stacking to obtain an optimal estimate; and 2) incorporating prior biological knowledge into the imputation across different datasets. The real Glioma cancer datasets from TCGA including 50 patients with mRNA measurements of 5939 genes, expression data of 104 microRNAs and DNA methylation measurements of 5013 genes were included in the analysis. We compared the our method with five single data imputation methods (kNN, LLS, ILLS, BPCA, and SVD) in different noise levels, sample sizes and missing rates, and the performance was evaluated by normalized root mean square error. The results indicated that our integrative method showed the lowest imputation error among all other methods across all situations. The superior performance was more prominent in cases of smaller sample size and higher noise level. We concluded that our proposed imputation method will improve the imputation accuracy by incorporating more omic datasets as well as prior biological information.

Combining allele-specific and population signal boosts power for association mapping of multiple DNA sequence-based cellular traits. *N. Kumasaka, D. Gaffney.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Association mapping of cellular traits, such as gene expression or epigenetic marking, is a powerful method for uncovering the function of genetic variation. When cellular traits are quantified using high-throughput DNA-sequencing, association signals can be detected using two orthogonal sources of information: population level differences between individuals, and allele specific differences within individuals. Here, we develop a unified probabilistic model for combining allele-specific and population level sequencing data that significantly boosts power for association detection in DNA sequencing-based cell traits, and apply this to multiple publicly available population level data sets of RNA-seq, DNase-seq and ChIP-seq data. A couple of similar approaches has already been proposed (Sun, 2012; and McVicker et al 2013). However those methods integrate allele-specific information within individuals that are heterozygous at the variant within sequenced feature (Sun 2012) or those for heterozygous at the linked putative causal variant (McVicker 2013). Our approach combines information not only from heterozygoutes but also homozygotes across multiple biallelic SNPs within a sequenced feature. It shows a significant improvement over the publicly available approaches, in particular, it significantly improves power for association detection in small sample sizes, with an approximately 7.5% increase in sensitivity at FDR 5% over the next best performing method (Sun 2012) in a sample size of 24 individuals and a 14.3% increase over simple linear regression. In addition, an internal analysis also shows that using information from both heterozygotes and homozygotes gives better power than just using heterozygotes with 4% additional power for the same data set. Our approach also explicitly models important experimental biases including mapping errors, genotype uncertainty and reference mapping bias. We believe our method is a general approach that will significantly improve association detection for any cellular phenotype in which allele-specific signature can be quantified, and will be particularly useful in cases where sample sizes are small.

Combining the association and ancestry signals through a multivariate model. *S. Eyheramendy, C. Parada.* Pontificia Universidad Catolica de Chile, Santiago, RM, Chile.

Over the past several thousand years many genetic variants have been selected, and many of these are particular to continental groups, leading to a substantial variation in the prevalence of many simple and complex diseases. The genome of individuals from recently admixed populations is a mosaic of segments from two or more ancestral populations. Thus, recently admixed populations are likely to have a larger number of genetic variants with functional effects. In recently admixed population, candidate causal risks can be search by performing the usual comparison in allele frequency between cases and controls (correcting for population structure), by performing an analysis of cases-only (admixture mapping), or by using cases-and-controls to search for unusual deviation in local ancestry. SNP and admixture association signals contain different information that can complement each other with which more powerful tests have been developed. In our study we propose to simultaneously model the two signals. We show the advantages and disadvantages of our method.

1883T

Explaining missing heritability using Gaussian Process Regression. *K.J. Sharp[1], W. Wiegerinck[1], A. Arias-Vasquez[2,3], B. Franke[2,3], C.A. Albers[2,4], H.J. Kappen[1].* 1) Biophysics, Radboud University, Nijmegen, Netherlands; 2) Human Genetics, Radboud University Medical Centre, Nijmegen, Netherlands; 3) Psychiatry, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Centre, Nijmegen, Netherlands; 4) Molecular Developmental Biology, Nijmegen Centre for Molecular Life Sciences, Radboud University Medical Centre, Nijmegen, Netherlands.

For many traits and common human diseases, causal loci uncovered by genetic association studies account for little of the known heritable variation. 'Missing heritability' might lie in the effect of non-additive interactions between multiple loci, but this has been difficult to test using existing parametric approaches. We employed a non-parametric, Bayesian method, based on Gaussian Process Regression, for identifying associated loci in the presence of interactions of arbitrary order. On both simulated and real datasets we demonstrate that the method has considerable power to detect high-order interactions and explain missing heritability.

As a proof of principle, we analysed 46 quantitative yeast phenotypes. Whereas detected pairwise QTL-QTL interactions accounted for little of the variance (a median of 3% per trait), we found that over 70% of the total known missing heritability could be explained using common genetic variants, many without significant marginal effects. Interestingly, the availability of biological replicates significantly improved the power to identify such loci and, hence, to explain variance.

These results already represent a significant advance in approaches to understanding the missing heritability problem with potentially important implications for studies of complex, quantitative traits. Importantly, however, features of the algorithm can be exploited to permit application to datasets incorporating much larger numbers of putative QTLs. In particular, the most computationally expensive steps consist of large numbers of independent computations that conform to the SIMT parallel computation model of Graphics Processing Units (GPUs). We also describe work in progress to develop such an implementation. Using a single Nvidia Tesla M2090 GPU we already achieve two orders of magnitude improvement in wall-clock time per iteration over a serial implementation. This indicates the potential of the approach for application to human GWAS datasets.

1884S

Comparison of GWAS results from imputed SNPs and multiple anchor and partner genotyped SNPs in an isolated population, Samoa. *R.L. Minster[1], O.D. Buhule[2], N.L. Hawley[3,4], G. Sun[5], S. Viali[6], R. Deka[5], D.E. Weeks[1,2], S.T. McGarvey[7].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 3) Weight Control and Diabetes Research Center, the Miriam Hospital, Providence, RI, USA; 4) The Alpert Medical School, Brown University, Providence, RI, USA; 5) Department of Environmental Health, School of Medicine, University of Cincinnati, Cincinnati, OH, USA; 6) Medical Specialist Clinic and National Health Services, Government of Samoa, Apia, Samoa; 7) Department of Epidemiology, International Health Institute, School of Public Health, Brown University, Providence, RI, USA.

Imputation of genotypes using reference panels such as the 1000 Genomes Project allows for testing at markers absent from GWAS genotyping arrays. Signals have been observed using imputed genotypes that were unobserved at lab-genotyped markers. It has also been shown that supplementing global reference panels with haplotypes specific to the population under examination improves imputation quality. For isolated populations where haplotype panels have yet to be constructed, the global reference panels for imputation may therefore be of reduced value. Additionally, imputing genotypes has high computational costs, both in processing time and data storage. Howey and Cordell (2014; PMID: 24535679) proposed a method called SnipSnip that purports, in some situations, to circumvent the uncertainties and costs of imputation. SnipSnip uses pairs of typed SNPs to detect associations at untyped SNPs. We have genotypes, after stringent QC, for 895,103 markers in 3,122 study participants from Samoa, but data are not available to build a Samoa-specific haplotype panel. Thus, a method that allows us to detect associated variants absent from our genotyping array would be valuable. Here we compare three methods for the detection of association: (1) GWAS SNPs alone using mixed linear models, (2) GWAS SNPs plus SNPs imputed with SHAPEIT/IMPUTE2 from the 1000 Genomes phased reference data using PLINK and (3) GWAS SNPs alone using SnipSnip. We examined two regions of the genome in particular: (1) 5q35, for which we have a prior strong GWAS association with body mass index; and (2) 4q13, for which we have a prior marginally genomewide-significant association with fasting glucose, but a strong SnipSnip association. At 5q35 the peak p value for the GWAS was 4.93e-14; for the GWAS + imputation was 5.01e-16; and for SnipSnip was 1.85e-11. At 4q13 the peak p value for the GWAS was 5.05e-08; for the GWAS + imputation was 2.96e-08; and for SnipSnip was 1.09e-15. Our comparison of the three methods in these regions bears out the hypothesis that SnipSnip will provide improved evidence of association at some but not all loci. The signal at 4q13 was substantially increased, while the association at 5q35 was attenuated. Our comparison between these alternative analysis approaches will provide insights into their relative strengths and weaknesses in the context of a real study. This work was supported by U.S. N.I.H. grant R01HL093093 (P.I.: S. McGarvey).

Incorporating Functional Information in Tests of Excess De Novo Load. *Y. Jiang[1], Y. Han[2], S. Petrovski[2], K. Owzar[1], D. Goldstein[2], A. Allen[1,2].* 1) Biostatistics and Bioinformatics, Duke University, Durham, NC; 2) Center for Human Genome Variation, Duke University School of Medicine, Durham, NC.

A number of recent studies have investigated the role of de novo mutations in various disorders including epilepsy, autism, intellectual disability and schizophrenia. These studies attempt to implicate causal genes by looking for an excess load of de novos within a gene. Current statistical methods for assessing this excess are based on the underlying assumption that all qualifying mutations in a gene contribute equally to disease. However, it is well established that different mutations can have radically different effects on the ultimate protein product and, as a result, on disease. Here we propose a method that incorporates functional information in the excess load assessment. Specifically, we derive score statistics from a retrospective likelihood that incorporates the probability of a mutation being deleterious to gene function. We show that, under the null, the resulting test statistic is distributed as a weighted sum of Poisson random variables and we implement a saddlepoint approximation of this distribution to obtain accurate p-values. Using simulation, we show that our method outperforms current methods in terms of statistical power while maintaining validity. We apply this approach to four, currently available, de novo mutation datasets of neurodevelopmental/neuropsychiatric disorders: Autism spectrum disorder, schizophrenia, severe intellectual disability and epileptic encephalopathy. Our method identifies a new, potentially causal, autism gene [SUV420H1] that is not implicated by current methods. Further, for all genes that were implicated by existing methods, our approach also implicated them but with smaller p-values. Further, our analyses suggest the existence of shared genetic causes among the four neurodevelopmental/neuropsychiatric disorders investigated.

1886T

Beyond random effects meta-analysis: explaining why effect sizes differ between studies. *E. Eskin.* Dept Computer Sci, Univ California, Los Angeles, Los Angeles, CA.

Over the past few years, the aggregation of the results of many genome-wide association studies (GWAS) utilizing a technique referred to as "meta-analysis" has led to the discovery of thousands of variants implicated in hundreds of disease related traits. While most of the analysis of meta-analysis has focused on discovering additional genetic variants associated with the disease trait which were not statistically significant in any of the original studies due to low statistical power, meta-analysis opens up the door to the investigation of other interesting phenomena. In particular, it can be observed that the effect sizes of the association often differ among the studies included in meta-analysis. These differences are referred to as heterogeneity. The current method for taking into account these effect size differences is the random effects model which attempts to model the differences when combining the studies. The goal of the random effects model is to increase the power of identifying variants associated with the trait in the presence of heterogeneity. However, the presence of heterogeneity raises several questions which are not addressed by random effects models. Most importantly, what are the sources of the heterogeneity and how can they be discovered utilizing covariate information from the studies? Does heterogeneity suggest the presence of interactions? What is the correct interpretation of the results of a random effects meta-analysis? In this work, I describe a novel framework for meta-analysis which is based in the inference of causal graphs. In this framework, both fixed effects and random effects meta-analysis are just special cases of the framework. The framework allows for the construction of novel meta-analysis algorithms that can incorporate additional information about the studies leading to higher power and easier interpretability.

1887S

Association mapping from sequencing reads using k-mers. *A. Rahman, I. Hallgrímsdóttir, M.B. Eisen, L. Pachter.* University of California, Berkeley.

Association studies typically begin with the determination of SNP variants for a set of cases and controls. Genotypes are obtained either from arrays, or more recently by mapping whole-genome sequencing reads to a reference genome for variant discovery. Both of these approaches require prior sequencing of a reference genome for the organism on which the association study is to be performed. We present an alignment free method for association mapping using sequencing reads which is based on counting k-mers in sequencing reads, testing for associations directly between k-mers and the trait, and local assembly of the statistically significant k-mers. Both results with simulated data and an analysis using 1000 genomes provide a proof of principle for the approach. In a pairwise comparison of the Toscani in Italia (TSI) and the Yoruba in Ibadan, Nigera (YRI) populations we find that sequences identified by our method largely agree with results obtained using standard GWAS based on genotyping via SNP calling from mapped reads, yet also reveal novel sites missed due to indels and structural variation.

1888M

Haplotype eQTLs in response to trivalent influenza vaccine. *H. Xu[1,2], LM. Franco[1,4], RB. Couch[4], Y. Shen[5], JW. Belmont[1,4], Y. Guan[1,3,4].* 1) USDA/ARS Children's Nutrition Research Center, Baylor College of Medicine, Houston, TX; 2) Department of Biomedical Engineering, Southeast University, Nanjing, Jiangsu, China; 3) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Systems Biology, Columbia University, New York, NY.

Understanding how gene expressions respond to trivalent influenza vaccine and what genetic factors affect differential response among healthy individuals are of great importance to public health. In a previous study (Franco et al, 2013), a cohort of healthy individuals (225) were recruited, genotyped, and their blood gene-expression were assayed on the day before (designated as day 0) and multiple time points after (at the day 1, 3, and 14 respectively) the trivalent influenza vaccination. Here we reanalyze the data using a new method and report novel findings.

The novel method combines the multi-phenotype analysis (Stephens, 2013) and the haplotype association method (Xu and Guan, 2014), developed particularly for the data set. First, we jointly analyze the four time points simultaneously, treating expressions of a gene over time as correlated phenotypes (Stephens, 2013), which empowers us to detect expression quantitative loci (eQTL) responding to vaccination. Second, in addition to single SNP analysis to detect snp-eQTLs, we focus on haplotype analysis to detect hap-eQTLs, which is more powerful when there exists allelic heterogeneity (Xu and Guan, 2014).

The multi-phenotype analysis produced 425 genes with cis (defined as 1M base pairs up- and down-stream) hap-eQTLs that have Bayes factor > 10^6. These genes are enriched in alternative splicing ($p<6 \times 10^{-4}$) and splicing variants ($p<2\times 10^{-3}$). As expected, these genes are also enriched in immune response ($p<2\times 10^{-3}$), antigen presenting and processing ($p<2\times 10^{-7}$), and positive regulation of immune system process ($p<2\times 10^{-3}$, all p-values are Fisher's exact test obtained from DAVID). As a baseline for comparison, we obtained snp-eQTL for each day, and used the max Bayes factor (among four days) to declare significant cis-acting snp-eQTL (same threshold of 10^6). There are 60 genes that can only be discovered by the haplotype analysis, and 77 genes that can only be discovered by the multi-phenotype analysis.

We also discovered a single trans-acting hap-eQTL with Bayes factor of 10^{16}: haplotype variants in an interferon receptor gene affecting expression of an olfactory receptor, whose probe can be uniquely mapped on a different chromosome.

1889T

Novel gene discovery through proximity clustering of de novo mutations in rare diseases. *J. McRae, M. Hurles on behalf of the DDD study.* Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

Rare developmental disorders affect children and generally have a genetic basis. It can be difficult to identify pathogenic genetic variants in children with these disorders. Genes known to be associated with rare disorders frequently contain pathogenic variants. However, additional, currently undiscovered, genes would improve prioritising variants for diagnosis. One method of identifying novel genes is through recurrent de novo mutations occurring in genes across independent affected families. Often novel genes are identified as genes enriched with de novo mutations, where, given the gene length and mutation rate, the number of recurrent mutations significantly exceeds expectations. This work provides another method to identify novel genes. We examined recurrent de novo mutations from 1133 trios with developmental disorders. Genes known to be associated with developmental disorders were excluded from analysis. De novo variants were examined for their tendency to cluster within the coding sequence of genes, by comparing the proximity of observed de novo sites to a distribution from simulated de novos. The chance of selecting a site within a gene was weighted by mutation rates for the local sequence context and the consequence of the mutation. From a set of 84 genes with recurrent de novo mutations in 1133 trios, 16 genes showed significant clustering ($P < 0.05$). A meta-analysis that combined de novo mutations from the 1133 trios with de novo variants from independent studies of rare diseases found 35 out of 283 genes showed significantly clustering. When results from proximity clustering results were combined with results from gene enrichment, 12 genes were classified as novel genes in developmental disorders, adding diagnoses that would otherwise be unobtainable.

1890S

Power of paternity exclusion with DNA markers and its current use: Some corrective actions. *R. Chakraborty, M.R. Nolan.* Department of Molecular and Medical Genetics, Univ N Texas Health Sci Ctr, Fort Worth, TX.

Utility of a DNA marker for paternity testing is judged by evaluating how often a random person can be excluded as a biological parent of a child (with or without having the data on the mother of the child). This can be evaluated for every mother-child combination as well as for the locus on an average. Called probability of exclusion (*PE*), for an autosomal locus with codominant alleles, algorithms for computing expected *PE* for a multiallelic locus has been developed in terms of allele frequencies at the locus almost forty years back. Subsequently, such algorithms have been simplified giving average *PE* at a locus as a function of sum of powers of allele frequencies. While such algebraic results use the assumption of independence of alleles within the locus and codominance of alleles, alternatively average *PE* has also been approximated in terms of heterozygosity (*H*) and homozygosity ($h = 1 - H$) at the locus, given by $PE_{avg} = h^2 . [1 - 2hH^2]$. Although both methods of evaluation of PE_{avg} is based on the assumption of no mutation at the locus, there is a tradition of using PE_{avg} to evaluate paternity index (*PI*) when the probable father shows inconsistencies of transmitting the allele(s) he is obligated to pass on to the child due to meiotic mutation (e.g., $PI = m/PE_{avg}$, m is the locus mutation rate). With data on autosomal STR loci currently in use in paternity testing, we show that homozygosity-heterozygosity (*H-h*) based value of PE_{avg} can be considerably different from the one evaluated from the powers of allele frequencies (e.g., 41.0% as opposed to 46.6% for the D13S317 locus in African-Americans, and 29.9% versus 36.1% for the TPOX locus in US Hispanics). More importantly, the claim that the *H-h* based value of PE_{avg} is a valid approximation for loci having nearly equal frequencies of all alleles is shown to be grossly incorrect. Further, we show that computation of *PI* in cases where the paternity exclusion is ascribed to mutation should not be based on PE_{avg}, since the specific mother-child data is not used, and the logic is inconsistent with the computation of *PI* where allelic transmission between parents and the child are fully consistent. In summation, although we do not recommend the use of PE_{avg} to evaluate the statistical strength of paternity testing results, current discussions on computational aspects of PE_{avg} should be revised based on the present numerical validation study of this research.

1891S

Genetic ancestry associated with obesity and diabetes risks in a Mexican-American population from Houston, Texas. *H. Hu, C.D. Huff, Y. Yamamura, X. Wu, S.S. Strom.* Epidemiology, UT MD Anderson Cancer Center, Houston, TX.

The Mexican-American population is an admixed ethnic group with varying proportions of Native American, European and African ancestries. African Americans and Native Americans have higher incidence rates of obesity and diabetes compared to Europeans due to a combination of environment and genetic factors. However, the relative contribution of genetic ancestry is not clear. In this study, we focus on a well-defined Mexican-American population in Houston, Texas, which is a socioeconomically homogeneous but genetically diverse population, making it ideal for studying the genetic epidemiology of inherited diseases. We genotyped 96 ancestry informative markers in 4,817 individuals, and used ADMIXTURE to estimate the composition of genetic ancestry in each individual. The mean proportions of Native American, European and African ancestries among all individuals were 62.9%±0.3%, 30.7%±0.3%, and 6.4%±0.1%, respectively. Multivariate logistic regression models were constructed. In females, we found that African ancestry was significantly associated with obesity after controlling for confounders. Specifically, a 5% increase in African ancestry corresponded to a 12% increased risk of grade 2 obesity (BMI between 35 and 40; p=0.037) and an 18% increased risk of grade 3 obesity (BMI>40; p=0.006). In contrast, Native American ancestry was associated with increased risk of being overweight (BMI between 25 and 30; p=0.031), while its association with grade 1 obesity was positive but non-significant. In males, we did not observe any significant association between genetic ancestry and obesity (p>0.1). Our preliminary analysis on the risk of diabetes identified a positive and significant correlation between Native American ancestry and diabetes risk in females, after controlling for age, socioeconomic status, physical activity, smoking, alcohol consumption, and BMI (p=0.018). We estimated that 10% increase in Native American ancestry increases the risk of diabetes by 0.7%. We found no association between African ancestry and diabetes risk. In conclusion, our study suggests that among the Mexican-African population, African ancestry is a strong risk factor for obesity, and Native American ancestry is a modest risk factor for overweight and diabetes. Interestingly, both associations were only observed in females, indicating that the increased risk could be related to the lifestyle characteristic of females in this population.

1892M

Investigating European admixture in GERA East Asians. *Y. Banda[1], M. Kvale[1], T. Hoffmann[1,3], S. Hasselson[1], D. Ranatunga[2], L. Walter[2], C. Schaefer[2], P. Kwok[1,4], N. Risch[1,2,3].* 1) Institute Human Genetics, University California San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA; 4) Cardiovascular Research Institute, University of California, San Francisco, CA.

A number of analyses have been performed to understand East Asian genetic substructure. Most of these studies have utilized samples with 100% East Asian ancestry and not much has been done concerning European admixture in these groups. We describe the genetic structure in a sample of 7,520 subjects of East Asian ancestry from Northern California who are part of the Genetic Epidemiology Research on Aging (GERA) cohort. We observe individuals who are 100% East Asian, but also individuals with mixed East Asian-European ancestry. Subjects of Filipino ethnicity have a more continous European ancestry proportion distribution compared to other subjects, having, on average, a minimum of 5% European ancestry proportion. For these subjects we analyse expected allele frequencies given the admixture process and also calculate timing of the admixture events that gave rise to the current genetic structure of Filipinos. Analyses of some Y-chromsome loci also give further evidence of European admixture in Filipinos.

1893S

A Comparative Genomic Approach to Introgression Detection. *L. Nakhleh, K. Liu, J. Dai, K. Truong, Y. Song, M. Kohn.* Computer Science, Rice University, Houston, TX.

One outcome of interspecific hybridization and subsequent effects of evolutionary forces is introgression, which is the integration of genetic material from one species into the genome of an individual in another species. The evolution of several groups of eukaryotic species has involved hybridization, and cases of adaptation through introgression have been already established. In this work, we report on PhyloNet-HMM - a new comparative genomic framework for detecting introgression in genomes. PhyloNet-HMM combines phylogenetic networks with hidden Markov models (HMMs) to simultaneously capture the (potentially reticulate) evolutionary history of the genomes and dependencies within genomes. A novel aspect of our work is that it also accounts for incomplete lineage sorting and dependence across loci. Application of our model to variation data from chromosome 7 in the mouse (Mus musculus domesticus) genome detected a recently reported adaptive introgression event involving the rodent poison resistance gene Vkorc1, in addition to other newly detected introgressed genomic regions. Based on our analysis, it is estimated that about 9% of all sites within chromosome 7 are of introgressive origin (these cover about 13 Mbp of chromosome 7, and over 300 genes). Further, our model detected no introgression in a negative control data set. We also found that our model accurately detected introgression and other evolutionary processes from synthetic data sets simulated under the coalescent model with recombination, isolation, and migration. Our work provides a powerful framework for systematic analysis of introgression while simultaneously accounting for dependence across sites, point mutations, recombination, and ancestral polymorphism.

Rapid radiation of common Eurasian Y chromosome haplogroups occurred significantly later than the out of Africa migration. *M. Järve, International Consortium of the Estonian Centre for Genomics.* Estonian Biocentre and Department of Evolutionary Biology, University of Tartu, Tartu, Estonia.

Human genetic diversity outside Africa is low, which is commonly ascribed to a recent out of Africa bottleneck and subsequent rapid colonization of the rest of the world. Previous studies of the male-specific Y chromosome have shown that haplogroups common throughout non-African populations all coalesce to a small number of shared ancestral lineages, the branching order of which is only partly understood. Using 475 high coverage whole Y chromosome sequences, including 317 newly reported here, we selected reliable regions within the Y chromosome based on coverage analysis, mappability and sequence class. Based on these data, we refined the Y chromosome haplogroup tree, applying phylogenetic methods to establish the branching order and temporal dynamics of splits in non-African Y chromosome haplogroups. Compared to the length of the branches that separate African and non-African diversity, the internal branches distinguishing continental and sub-continental differences outside Africa are generally short, consistent with the model of a rapid initial colonization of Eurasia and Oceania. Following the split between African and non-African haplogroups [90 KYA (95% CI: 87-94 KYA)], the differentiation of South and Southeast Asian haplogroups H, S, M, and C did not begin until around 43 KYA, and haplogroups N and R, widely spread among Northeast and Northwest Eurasian populations, started to diversify significantly later [17 KYA (95% CI: 16-19 KYA) and 26 KYA (95% CI: 25-28 KYA), respectively]. Many major phylogenetic groups in different geographic regions seem to originate from the period around 50 KYA.

1895S

Ancestral Components of Admixed genomes of Chileans from Northern and Central Chile - The ChileGenomico Project Release 1. *R.A. Verdugo[1], A. DiGenova[2], L. Herrera[1], M. Acuña[1], M. Moraga[1], S. Berríos[1], E. Llop[1], D. Digman[1], M.L. Bustamante[1], C.Y. Valenzuela[1], F. Caba[3], E. Barozet[4], M. Villalón[5], S. Alvarado[5], D. Cáceres[5], A.M. Naranjo[6], K. Salgado[6], P. Portales[7], A. Moreno-Estrada[8], C.R. Gignoux[8], C.D. Bustamante[8], C. Eng[9], S. Huntsman[9], E.G. Burchard[10], N. Loira[2], A. Maass[2,11], L. Cifuentes[1].* 1) Programa de Genética Humana ICBM, Facultad de Medicina, Universidad de Chile, Santiago, RM, Chile; 2) Mathomics, Centro de Modelamiento Matemático y Centro para la Regulación del Genoma, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Santiago, Chile; 3) Facultad de Salud y Ciencias de la Actividad Física, Universidad Sek, Santiago, Chile; 4) Departamento de Sociología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile; 5) Instituto de Salud Poblacional "Escuela de Salud Pública", Universidad de Chile, Santiago, Chile; 6) Facultad de Ciencias de la Salud, Universidad de Tarapacá, Arica, Chile; 7) Corporación Municipal de Desarrollo Social, Departamento de Salud, Iquique, Chile; 8) Department of Genetics, Stanford University, Stanford, California; 9) Department of Medicine, University of California, San Francisco, California; 10) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, California; 11) Departamento de Ingeniería Matemática, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Santiago, Chile.

The Human Genome Diversity Project, the Hapmap Project, and the 1000 Genomes Project (1000G) have provided valuable surveys of Human genetic diversity worldwide. This has allowed modeling the structure of populations originating admixture from different continents. However, sub-continental components inference is limited for South America; there is currently no population southern from Lima in any of these projects. The ChileGenomico project aims to close this gap for the Chilean population by creating a detailed characterization of its genetic structure. We collected informed-consented DNA from over 3000 volunteers born in 208 districts from Arica to Punta Arenas, i.e. 4000 km of continental Chile. Our first data release includes whole-genome sequencing and genotyping with the Axiom Genome-Wide LAT 1 Array for individuals selected for putative indigenous ancestry: 9 from the north (Aymara) and 9 from the south of Chile (Mapuche). Sequencing at the National Center for Genomics and Bioinformatics of Chile gave a 3.6x average, covering 88% of the genome. We identified 4,716,457 SNPs (260,367 novel) and 544,079 INDELs (266,973 novel) using GATK. Precision (0.98), recall (0.74), false discovery rate (0.03), and accuracy (0.83) for our SNPs predictions. Genotype imputation with 66 Mexican and 60 Colombian sequenced at low coverage by 1000G increased accuracy to 98%. Global ancestry was inferred with ADMIXTURE and a panel of 30 CEU, 30 YRI, and 43 AMR unrelated individuals from 1000G. The average ancestry proportions for the Chilean sample were 20% (European), 1% (African), and 78% (Amerindian). The Amerindian percentage was higher in individuals with Aymara ancestry (82%) than those with Mapuche ancestry (74%). Two individuals had more than 97% AMR component, indicating that they were non-admixed. The Fst between the Amerindian and Europeans components (k=3) was 0.128 and between the Aymara and Mapuche components (k=5) was 0.049, i.e. 32 times larger than Fst for German vs Spanish. Local ancestry inference was done with PCAdmix using 411,674 SNPs that allowed inference in 3,259 non-overlapping genomic windows. Pseudo-Amerindian genomes were generated by removing regions of European or African origin, used to select optimal sets of Ancestry Informative Markers for the Chilean population. All results will be made public through the ChileGenomico database that integrates the GBrowse and BioMart tools with custom web reports (http://chilegenomico.uchile.cl).

1896M

High degree of admixture in an urban Brazilian population. *M.B. Melo[1], G. Ananina[1], M.A. Bezerra[2], A.S. Araujo[2], P.R.S. Cruz[1], M. Simioni[3], V.L. Gil da Silva Lopes[3], F.F. Costa[4].* 1) CBMEG, Univ Campinas, Campinas SP, Brazil; 2) Haematology and Hemotherapy Center of Pernambuco/HEMOPE, Recife, PE, Brazil; 3) Department of Medical Genetics, FCM, Univ Campinas, Campinas SP, Brazil; 4) Hematology and Hemotherapy Center/HEMOCENTRO, Univ Campinas, Campinas SP, Brazil.

The Brazilian population is the largest Latin American population rather distinct from others by their demographic and cultural history; however, it is still poorly studied genetically. Absence of a detailed genetic profile is an obstacle for many genetic studies. Here we report the results of our genome-wide study of a sample of the Brazilian population. Subjects (n=62) were recruited at two Brazilian cities: Campinas (SP) and Recife (PE). This study was approved by the Ethics Committee (FCM-UNICAMP, Campinas, SP, Brazil) in accordance to the Basic Principles of the Declaration of Helsinki. The genotyping protocol was carried out using Affymetrix® Genome-Wide Human SNP 6.0 Array (Affymetrix Inc., CA, USA) following manufacturer's recommendations. Genotyping Console v.4.1 was employed to obtain genotype calls. Publically available population data (15 populations) of HapMap and 1000 Genomes Project were used for comparisons. All SNPs were coerced to the common for all populations list and quality control filters were applied per-individual and per-marker: exclusion of related individuals and individuals with high genotype missing rate (>5%); exclusion thresholds for a SNP - MAF<5%, HWE P-value<1e-6, per SNP call rate <5%, Mendelian errors in any of the population under consideration. Basic manipulations of the data were performed with the aid of PLINK software; population structure and admixture were analyzed applying EIGENSOFT and ADMIXTURE softwares. All Brazilian samples passed inclusion control. We started with 861,474 SNPs successfully genotyped in the Brazilian cohort. The coerced list included 840,856 markers. After pruning procedure, we obtained 297,115 markers. PCA analysis was applied to the groups of 42-45 individuals (randomly picked up from the largest populations) demonstrating that Brazilian samples are gradually distributed between the populations of European and African origins. Admixture analysis identified 7 groups in our dataset revealing a highly admixed pattern for the Brazilian sample. The Brazilian population is highly admixed, challenging for genetic analysis. Studies of extended sample size are desirable for a better characterization of the degree of admixture in the whole population and in regional groups. Financial support: CNPq, Brazil (8367/2011-1, 150398/2013-1); FAPESP, Brazil (2008/57441-0).

Whole genome association and genetic admixture analysis of EEG phenotypes in a Native American community sample. *Q. Peng[1], N.J. Schork[1], K.C. Wilhelmsen[2], C.L. Ehlers[3].* 1) J. Craig Venter Institute, La Jolla, CA; 2) University of North Carolina, Chapel Hill, NC; 3) The Scripps Research Institute, La Jolla, CA.

PURPOSE. Resting EEG features are shown to be genetically influenced. EEG patterns, such as low & high voltage alpha activity, remain highly stable over most of an adult lifespan and have been associated with phenotypes such as addictions. Genetic studies of complex phenotypes such as EEG & addictions can be advantageously conducted in well-defined populations such as Native Americans (NA). This work is part of a larger study exploring risk factors for substance dependence in a NA community. We previously reported that EEG alpha power is highly heritable in this community (h2 = 0.62 frontal, 0.67 posterior scalps). We also observed that low voltage alpha (LVA) was correlated with higher fronto-parietal connectivity (FPC). The current study aims to: 1) assess ancestry admixture influence on the EEG LVA & FPC; 2) conduct GWAS on the phenotypes in this NA population (N=612). **METHODS.** EEG was transformed using fourier analyses and the alpha power determined. Wavelet analysis was used to determine the degree of phase locking between frontal (FZ) & parietal (PZ) electrodes, a measure of connectivity. Blood derived DNA was sequenced using Illumina low-coverage WGS. Ancestry & degree of admixture were estimated with a genome-wide panel of SNPs. Multiple linear regression was used to assess the relation between NA ancestry degree and EEG LVA & FPC. A variance component approach was used in the association test to control for admixture and familial relatedness. **RESULTS.** FPC showed significant correlation with NA ancestry (β=0.05±0.02, p=0.02). LVA was negatively associated with NA (β=-30.1±10.1, p=0.003). A variant downstream of *HEXIM1* was negatively associated with FPC with genome-wide significance (β=-0.07, p=4.5e-10). Nearly 20% of the NA samples were heterozygous on the variant, yet it is absent from dbSNP & 1000Genomes, suggesting its uniqueness to the NAs. Analysis of the ancestral background of the genomic region around the variant showed it resides in a region of lower NA. Of individuals carrying the variant, FPC was uncorrelated with local NA. Of those with the wild-type genotype, FPC was significantly correlated with local NA (β=0.11±0.05, p=0.004), suggesting a polygenic background effect of the NA on the phenotype. **CONCLUSIONS.** Overall a higher NA ancestry degree is associated with higher FPC & negatively associated with LVA. A likely NA-specific variant was found to be significantly negatively associated with FPC. (Supported by AA10201, DA030976).

A Genome Wide Admixture Association Study of a Sleep Disturbance Phenotype in Adults with Sickle Cell Anemia. *C. Liu[1], Z. Wang[1], L. Diaw[1], A. Oguhebe[1], C. Okungi[1], K. Vaughan[1], D. Darbari[1,2], J. Taylor[1].* 1) Genomic Medicine Section, Hematology Branch, NHLBI, NIH, Bethesda, MD; 2) Center for Cancer and Blood Diseases, Childrens National Medical Center, Washington, DC.

Population admixture is a variable which can lead to spurious associations in genome wide association studies. However, mapping by admixture linkage disequilibrium (MALD) is statistically advantageous for genome wide studies in admixed, rare disease populations. Sickle cell disease (SCD) is a Mendelian disease caused by mutation of beta-hemoglobin. SCD has systemic manifestations including hemolytic anemia, recurrent episodes of severe pain and premature mortality. Our recent work has shown that more than 70% of SCD adults have sleep disturbance defined by the Pittsburgh Sleep Quality Index (PSQI). A significant independent risk factor for sleep disturbance in SCD is more frequent hospitalizations for SCD pain crises. Prior twin and sibling studies in the general population suggest that sleep disturbance is a moderately heritable trait, although no data is available to estimate heritability in SCD. We hypothesized that sleep disturbance in SCD is a complex trait attributable to modifier genes that can be identified by MALD. To test this hypothesis, we identified ancestry informative markers (AIMs) from 3,804,602 SNPs genotyped by HapMap Phase III CEU and YRI populations. These SNPs were combined with a published admixture panel, yielding a new MALD panel of 1795 AIMs. We genotyped these AIMs in 221 HapMap subjects and 489 adults from the Bethesda Sickle Cell Cohort Study using Illumina iSelect arrays. Using our HapMap genotype data, this admixture panel has a mean Δ (difference in allele frequencies between populations) of 0.707 (SD 0.114) with an average inter-marker distance of 1.692 Mb. We then performed a MALD association study of sleep disturbance, dividing them into cases with PSQI scores >5 or controls with lower PSQI scores. We identified a region on chromosome 13p21 approaching genome wide significance (defined by a locus genome score or LGS of 5 or more) and suggestive of a sleep disturbance association (locus genome score 4.007 at rs17088390). SNPs with a case control statistics >2 span a region of approximately 4 Mb on chromosome 13, including 1 within the DACH1 gene. Ongoing work is incorporating fine mapping and modeling with known sleep disturbance variables. Overall, our results suggest that MALD may be advantageous for SCD association studies due to a high degree of population admixture and modest sample sizes due to the rarity of SCD.

1899S

Use of Long-read-sequence Aided Phasing for Inference of Ancestry Assignment in Admixed Populations. *F.L. Mendez[1], S.S. Shringarpure[1], A. Moreno[1], E.R. Martin[2], M.L. Cuccaro[2], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Center for Genetic Epidemiology and Statistical Genetics, University of Miami, Miami, FL.

Correct phase reconstruction of individual chromosomes is important for numerous genetic analyses, including inferring demographic parameters in admixture processes. Admixture is the result of interbreeding of previously differentiated populations. The chromosomes of admixed individuals are composed of segments that can be traced individually to one of the ancestral populations. The abundance and length distributions of these chromosomal segments provide crucial information on the admixture process; however, the correct inference of their length and ancestry requires phasing data from the admixed individuals. Phase reconstruction can be performed applying the rules of Mendelian segregation of variants or using statistical methods that rely on population data. Alternatively, molecular phasing (the observation of different polymorphisms in the same chromosomal sequence) provides direct evidence of phase. In this fashion, methods of molecular-phasing, like long-read sequencing, may be used to extend the range of confident phasing. We simulate long-read sequence data and explore improvement brought by molecular phasing on accuracy of ancestry assignment of chromosomal segments, in definition of segment boundaries, and in overall admixture inference. We then use genotype information from 5 trios of Latino individuals, including 10 individuals with long-read sequence information, together with three reference panels of haplotypes of European, African, and Native American ancestry to evaluate the effect of molecular phasing on inference of the admixture process.

Characterizing the Local Ancestry of Established Multiple Sclerosis Risk Loci in Hispanics. *A.H. Beecham[1,2], Z. Liu[1,2], P. Antoine-Gourraud[3], P. Manrique[1], A. Hadjixenofontos[1], I. Konidari[1], P. Whitehead[1], D. Seo[4], C. Cotsapas[5], N.A. Patsopoulos[6], P. De Jager[6], J.L. Haines[7], M.A. Pericak-Vance[1,2], G.W. Beecham[1,2], S.R. Delgado[8], J.R. Oksenberg[3], J.L. McCauley[1,2].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Department of Neurology, University of California at San Francisco, San Francisco, CA, USA; 4) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL, USA; 5) Program in Medical and Population Genetics, Broad Institute of Harvard University and MIT, Cambridge, MA, USA; 6) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham & Women's Hospital, Boston, MA, USA; 7) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 8) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple sclerosis (MS) is an inflammatory demyelinating disorder of the central nervous system with variable prevalence across populations. European populations have a higher prevalence and have traditionally been considered more susceptible to MS than either Hispanic or African. This could be due in part to a greater genetic risk in European populations. Through genetic association studies in individuals of European descent, 110 established MS risk variants in 103 discrete loci outside of the Major Histocompatibility Complex have been identified. Our goal is to characterize the local ancestry at these 110 risk variants, first in a sample of European descent (1691 individuals affected with MS and 5542 controls), and second in a Hispanic sample (200 individuals affected with MS and 1000 population controls). We hypothesize that given the increased prevalence of disease in European populations; there will be an increased percentage of European ancestry in Hispanics affected with MS versus Hispanic population controls at these 110 risk variants. Individuals affected with MS and the controls of European descent have been genotyped using the ImmunoChip genotyping array. The Hispanic population controls have been genotyped using the Affymetrix 6.0 genotyping array. Analyses of a risk score using the 110 risk variants show a difference in risk between Hispanics affected with MS and population controls (p=3.2E-05), indicating that these risk loci are also important in Hispanics. We do not see a significant difference in the risk score between Hispanics and Europeans affected with MS (p=2.0E-01), in support of the hypothesis that the ancestry at these loci is similar amongst cases from both populations. Haplotype phasing based on the reference populations of European, African, and Asian individuals from the 1000 Genomes Project was done using SHAPEIT. With LAMP-LD/LAMP-ANC, we are currently computing local ancestry using a representative subset of possible haplotype pairs and reference populations of Europeans and Africans from the 1000 Genomes Project as well as Native Americans from the Human Genome Diversity Project. Ancestry percentages at each locus will be compared, between individuals affected with MS and controls for samples of both European and Hispanic descent in order to better characterize the local ancestry of these confirmed loci both in the population in which they were discovered and a genetically admixed population.

1901S

Linear Mixed Model-Based Admixture Mapping. *L. Brown, T. Thornton.* Biostatistics, University of Washington, Seattle, WA.

Genetic studies in recently admixed populations can provide invaluable insight into novel risk factors contributing to disease. Population admixture results in combined genomes from previously isolated ancestral populations that may have discernible allele frequency differences due to natural selection and genetic drift. Genes that underlie ethnic differences in traits and that show differential risk by ancestry can be identified using admixture mapping. Compared to studies carried out in more ethnically homogenous populations, admixture mapping has potentially greater power to detect certain genetic variants. Linear mixed models have gained traction as a tool for genome-wide association studies. Mixed model methods have been shown to protect against spurious associations in structured samples, a common pitfall in genetic association studies, by directly accounting for sources of dependence including cryptic relatedness and population stratification. We present a linear mixed model approach for admixture mapping in the presence of population structure and hidden relatedness. We implement this method using local ancestry estimates based on genome-wide SNP data. We apply the method to analyze genetic associations with white blood cell count and C-reactive protein phenotypes in the African American cohort of the Women's Health Initiative study. We demonstrate that our proposed linear mixed model method for admixture mapping provides a substantial improvement over widely used admixture mapping approaches.

1902M

Genetic evidence of archaic admixture in India. *A. Basu, D. Das, S. Das, N. Biswas.* National Institute of BioMedical Genomics, Kalyani, India.

Comparing high-coverage Denisova and Neanderthal whole-genome sequences has revealed significant admixture with all present day non-African populations. Microblade tool usage from central-India has been reported, yet no genetic-study examined archaic admixture in present day South-Asians. We report the first evidence of archaic admixture from whole genome sequence data of 4 present-day Indians. Four individuals, who are at the extremities of a two-dimensional Principal-Component plot summarizing the extant of genomic variance in 237 Indians belonging to 20 linguistically, ethnically diverse populations sampled from different geographic locations in India; were sequenced. Their population identities are Onge, Jamatia, Panniya and Birhore. All individuals showed slight excess of Denisova admixture (D-Statistic 1.6-1.99) when compared with Eurasians, with admixture evidence increasing from Jamatia(1.6) to Onge(1.99). Similar pattern was also observed when compared with Neanderthal. Our findings show evidence of archaic admixture in different present-day populations, not restricted to proximity of archaeological evidence, indicating wide spread admixture.

Latin America is a vast geographic region that is home to more than 600 million people. To a large extent, the current Latin American population reflects a complex history of admixture between people with ancestral roots in the Americas, Europe and Africa. Studies for pharmacogenomics-related traits are increasingly being performed to identify loci that affect either drug response or susceptibility to adverse drug reactions. However, the effect of a polymorphism can differ in magnitude or be absent depending on the population being assessed. In this work we present the potential impact of admixture on the distribution of genetic markers of pharmacogenetic and pharmacogenomics (PGx) relevance. Differences in admixture history may have an important impact in the distribution of allele and genotype frequencies at population level. Therefore we aim at characterizing the distribution of polymorphisms of PGx relevance of two of the most populous Latin American countries: Brazil and Mexico. The Brazilian sample includes 268 individuals stratified into census categories Branco (White), Pardo (Brown) and Preto (Black). The Mexican sample comprises 45 Native American Zapotecos and 224 self-identified Mestizo individuals located in geographically distant regions. Both samples were genotyped using Affymetrix Drug Metabolizing Enzymes and Transporters (DMET) Plus array. This platform includes 1936 variants, rare and common, in 231 genes involved in drug pharmacokinetics. Our results highlight the complex population history of these two countries. We observed differences in admixture proportions according to geography (Mexico) and census categories (Brazil). Although the overall genetic differentiation of the markers interrogated in the DMET Plus array is low, there are many loci that show high levels of genetic differentiation between the parental populations relevant for contemporary Brazilians and Mexicans. The *VKORC1* rs9923231, a major determinant of warfarin dose in CPIC guidelines, is an excellent example of the practical PGx implications of admixture history. The frequency of the rs9923231A allele, which associates with high warfarin sensitivity, varies 13-fold (52.2% frequency in Africa and 4.1% in Zapotecos) among proxy parental populations of Brazilians and Mexicans. Differences in admixture history among Latin American populations may have an important impact in allele frequency distribution and therefore also in haplotypes associated to drug metabolism.

1904M

The genetic ancestry of African, Latino, and European Americans across the United States. *K. Bryc[1], E. Durand[1], D. Reich[2,3,4], J. Mountain[1].* 1) 23andMe, Inc., Mountain View, CA; 2) Harvard Medical School, Department of Genetics, Boston, MA, USA; 3) Howard Hughes Medical Institute, Boston, MA, USA; 4) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Within the past 500 years, North America has been the site of a dynamic mixing of people from populations that were previously separated by oceans and other geographic features. The interactions between Native Americans, European settlers, and Africans brought to the New World via the Trans-Atlantic slave trade shaped the early history of what became the United States. We studied the genetic ancestry of 5,269 self-reported African Americans, 8,633 Latinos, and 148,789 European Americans who are 23andMe customers living in the US and show that the legacy of these interactions is visible in the genetically-inferred ancestry of modern Americans.

We shed light on the unique regional differences in genetic ancestry within and across the United States. In addition to well-established variability in individual ancestry proportions, we detect systematic clines in the amount of African and European ancestry in African Americans from different states. We demonstrate that the pervasive mixed ancestry in modern Americans and the relationship between self-reported identity and genetic ancestry reflect regional social and political history. We find that levels of Native American and African ancestry in European Americans, Latinos, and African Americans are highly correlated with the population density of African Americans and Latinos in each state with one notable exception.

We provide evidence that a minor, but measurable, proportion of self-reported European Americans carry African ancestry. Likewise, we demonstrate that an appreciable fraction of European Americans carry Native American ancestry. In European Americans, we find strong differences in European subpopulation ancestry across the US, which are consistent with known major historical migrations from different regions of Europe. The genetic diversity within each identity, combined with significant overlap of ancestry profiles between identities, highlights the complexity of using self-reported or physician-inferred ancestry in a biomedical context, since the genetic ancestry of individuals within each identity is widely variable. Our results inform the geography of historical admixture in the US, have sociological implications for self-identity, and inform the use of self-reported race and ethnicity in a medical setting.

1905S

The Brazilian EPIGEN Initiative: admixture, history and epidemiology at high resolution. *F. Kehdy[1], M. Barreto[2], B. Horta[3], M.F. Lima-Costa[4], A. Horimoto[5], N. Esteban[5], W. Magalhães[1], M.R. Rodrigues[1], G.B. Souza[1], F. Soares[1], G.S Araújo[1], T.P. Leal[1], M. Machado[1], R. Moreira[1], J.M. Sanches[5], H.C. Santos[5], M. Gouveia[1], A. Pereira[5], E. Tarazona-Santos[1], The Brazilian EPIGEN Consortium.* 1) Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Universidade Federal da Bahia, Brazil; 3) Universidade Federal de Pelotas, Brazil; 4) Fundação Oswaldo Cruz, Centro de Pesquiça René Rachou, MG, Brazil; 5) Instituto do Coração, Universidade de São Paulo, Brazil.

Brazil is the largest and most populous Latin-American country, and received the largest proportion of the African slave trade along the last five centuries (approximately 4 million of slaves vs. 700 000 in the United States). We studied three Brazilian longitudinal populational cohorts from the three most populated regions of Brazil: Salvador-Bahia (n=1309), Bambui (n= 1442) and Pelotas (n=3736) from Northeast, Southeast and Southern Brazil respectively. We genotyped the Omni2.5M-Illumina for the 6487 individuals, the Omni5.0M-Illumina for 265 individuals and sequenced 30 genomes (average coverage: 42X). While Amerindian ancestry was low (5-7% at population level, with no individual with > 30% of this ancestry), the three populations showed individuals with all possible combinations of African and European ancestry. At population level, African ancestry ranged from 14-15% in Pelotas and Bambui to 51% in Salvador. The EPIGEN cohorts also exemplify how kinship and inbreeding coefficients may be differently structured in small (Bambuí), medium-size (Pelotas) and large (Salvador) admixed Latin American populations. Model-based ADMIXTURE analysis revealed an unknown cluster of African ancestry, likely Bantu or Eastern Africa-associated more common in Southern Brazil that in any other Latin America population, probably related with slave trade from regions such as Angola-Mozambique. Genetic diversity of European origin in Brazil recapitulates a considerable portion of the whole diversity of this continent, not being restricted to the Iberian Peninsula. The distribution of chromosomal segments of distinct ancestry do show evidence of very recent European admixture into the South East and Southern Brazil but not in the Salvador cohort (NE), while African admixture into admixed populations fits a model of continuous gene flow across the three cohorts. By the genome sequencing we identified between 3.6 M and 4.4 M of autosomal SNPs per each individual, and the high levels of admixture of Brazilians allowed us to identify ~1.4 M of new autosomal SNPs. The EPIGEN Initiative is also performing several GWAS and admixture mapping studies on different complex traits, including longitudinal data. Funding: Brazilian Ministry of Health/FINEP.

Inferring patterns of demography and assortative mating in the Thousand Genomes Project admixed populations from the Americas. *E.E. Kenny[1,5,6,7], C. Gignoux[2], S. Baharian[3], S. Musharoff[2], B. Maples[2], S. Shingarpure[2], A. Auton[4], C.D. Bustamante[2], S. Gravel[3], A.R. Martin[2], The 1000 Genomes Consortium.* 1) Department of Genetics, Icahn School of Medicine Mount Sinai, New York, NY; 2) Department of Genetics, School of Medicine, Stanford University, California, CA; 3) Department of Human Genetics, McGill University, Montreal, Canada; 4) Department of Genetics,Albert Einstein College of Medicine, New York, NY; 5) Institute of Personalized Medicine, Icahn School of Medicine Mount Sinai, New York, NY; 6) Center of Statistical Genetics, Icahn School of Medicine Mount Sinai, New York, NY; 7) Institute of Genomics and Multiscale Biology, Icahn School of Medicine Mount Sinai, New York, NY.

The phase 3 release of the 1000 Genomes project includes genotype and sequence data for 2,535 individuals from 26 populations around the globe. These include six populations from the Americas with mixed Native American, European and West African ancestry. We have identified admixture proportions in these six populations, which, include African Caribbean's from Barbados (ACB), African American's from south-west USA (ASW), Colombians from Medellin (CLM), Peruvians from Lima (PEL), Mexican-American from Los Angeles (MXL), and Puerto Ricans from Puerto Rico (PUR). We show presence of Native American, European and African ancestry in all six populations, in particular, we identify six ASW individuals with > 20% Native American ancestry. The European component of these individuals looks most similar to Nordic ancestry, rather than Spanish ancestry often seen in Hispanic/Latino individuals. Among the ACB, PEL, PUR, CLM and MXL populations, we find an excess of Native American and dearth of European ancestry on chromosome X compared to the autosomes, indicating a history of non-random mating in these populations. We have also inferred local ancestry tracts (LAT), identifying haplotype specific segments of ancestry across chromosomes. We assessed the accuracy of our tract calls and demonstrated accuracies >0.99, >0.98 and >0.97 in African, European and Native American tracts across all populations. By modeling the distribution of ancestral tract lengths, we inferred the timings of migration in the two populations from the America's that are new to phase 3, ACB and PEL. We estimated the PEL have had more recent admixture with European and African individuals than other Hispanic/Latino groups in the Caribbean and throughout northern South America, consistent with known migration patterns. These analyses have given us an insight into the demographic history and migration patterns among admixed populations in the 1000 Genomes Project.

1907S

Genotype and allele frequencies of *RETN* -420 C/G polymorphism in three Mexican native populations. *A. López Quintero[1,2], AG. García Zapién[1], SE. Flores Martínez[1], S. Islas Andrade[3], MC. Revilla Monsalve[3], J. Sánchez Corona[1].* 1) Centro de Investigación Biomédica de Occidente (CIBO), División de Medicina Molecular, Sierra Mojada 800, GDL, Jal; Méx; 2) Universidad de Guadalajara, Centro Universitario de Ciencias de la Salud (CUCS), Doctorado en Genética Humana, Sierra Mojada 950, GDL, Jal; Méx; 3) Unidad de Investigación en Enfermedades Metabólicas, Centro Médico Nacional Siglo XXI, IMSS, Belisario Domínguez 1000, Cd. Mex; Méx.

Introduction. The adipokine resistin plays a significant role in glucose and energy homeostasis, it is also known that resistin increases insulin resistance. The polymorphism -420 C/G in *RETN* gene is associated with increased resistin levels and type 2 Diabetes Mellitus. Objective. To determine genotypic and allelic frequencies of *RETN* -420 C/G polymorphism in individuals from three Mexican native populations: Lacandones (Lacanjá, Ocosingo, Bethel, Nahá), Yaquis and Tepehuanos. Material and methods. The present study included 419 DNA samples of individuals from three Mexican indigenous populations. The *RETN* -420 C/G polymorphism was analyzed by PCR-RFLP. After a 331 bp fragment amplification by PCR, the products were digested with the *BbsI* enzyme restriction to identify the genotypes. The digested products were separated by electrophoresis in 6 % polyacrylamide gels and identified by silver staining. Differences between genotype (GF) and allele frequencies (AF) among the three populations were assessed by using a $\chi 2$ test with the RXC program and 10000 iterations. Results. There were statistically significant differences among the Lacandones community when assessed by genotype and allele frequencies; Lacanjá vs Ocosingo, Bethel and Nahá (p=0.0003, 0.0000 and 0.0004 for GF and p=0.001, p<0.001 and p<0.001 in case of AF). The Tepehuanos population was statistically different when compared the GF (p=0.0005), and AF (p=.0006) with Bethel community. The Yaqui population displayed differences when compared with Lacanjá, and Bethel communities (p= 0.0066 and 0.0015 for GF p=0.0023 and 0.0072 in case of AF respectively). Conclusion. The genotypic and allelic distribution of the *RETN* -420 C/G polymorphism is different among the analyzed populations. Furthermore, it is not possible to consider the four Lacandones communities as one group, and this must be considered in further association studies for the Lacandones community.

1908M

Sub-continental local ancestry inference in U.S. individual. *B.K. Maples[1,2], J.K. Byrnes[3], J.M. Granka[3], K. Noto[3], S. Shringarpure[1], M.L. Carpenter[1], M.J. Barber[3], R.E. Curtis[4], N.M. Myres[4], C.A. Ball[3], K.G. Chahine[4], C.D. Bustamante[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Biomedical Informatics, Stanford University, Stanford, CA; 3) AncestryDNA L.L.C., San Francisco, CA; 4) AncestryDNA L.L.C., Provo, UT.

The United States was populated through a sequence of migratory waves including immigrants from numerous distinct source populations. This "melting pot" process has led to the majority of current U.S. residents being genetically admixed. Understanding this complex genetic diversity is of great interest to the field of population genetics and accounting for it is critical for medical genetics. Numerous methods have been developed for performing local ancestry inference (LAI) in which the ancestry of each genomic locus is estimated, but the majority of these methods are only accurate at the level of continental admixture (e.g. African Americans with ancestry from Africa and Europe). Sub-continental LAI is often more difficult as neighboring populations typically have reduced differentiation. In this study we apply the LAI method RFMix that has been shown to perform well at a sub-continental level (e.g. mixtures of Northern and Southern European ancestry). RFMix is seeded with a reference panel of samples with known origins, and then iteratively learns from a larger collection of test samples. The performance of this method greatly improves with larger reference panel and test sample sizes. Here we use more than 2,000 single-origin reference samples from Ancestry.com and 1000 Genomes, along with over 100,000 research-consented customer samples with admixed origins to train the model to perform inference on individuals with admixed European ancestry. We compare the genome-wide ancestry estimates from RFMix with pedigrees. Using pedigree data as a truth set, we tune the performance of RFMix. We then compare the performance of RFMix with results from the commonly used ancestry estimation method ADMIXTURE run in supervised mode with the same initial single-origin reference panel provided to RFMix. We also use single-origin samples to create synthetic admixed samples with known local ancestry patterns to assess the accuracy of RFMix to call individual segments in admixed Europeans. Finally, we apply the highly trained version of RFMix to the National Institute on Aging's Health and Retirement Study data. We compare county-level geographic summaries of sub-continental ancestry estimates in this data to recent U.S. census data. We find strong evidence of fine-scale population structure with certain localities showing enrichment for particular ancestries (e.g. Irish ancestry in and around Boston and Scandinavian ancestry in the Midwestern states).

1909S

Drift and selection contribute to elevated susceptibility for childhood acute lymphoblastic leukemia in individuals with Native American ancestry. *P. Nakka[1], V. Perez-Andreu[2], C.R. Najera Villagran[3], F. Antillon Klussmann[3], J.J. Yang[2], S. Ramachandran[1].* 1) Brown University, Providence, RI; 2) St. Jude Children's Research Hospital, Memphis, Tennessee; 3) Unidad Nacional de Oncología Pediátrica, Guatemala City, Guatemala.

Acute Lymphoblastic Leukemia (ALL) is the most common childhood cancer and one of the leading causes of death in children and adolescents. ALL is characterized by young age at disease onset (particularly in children between 2-5 years of age), which points to a strong genetic basis of disease susceptibility. In fact, previous genome-wide association studies on multiple ancestral backgrounds have identified multiple common variants predisposing children to ALL with relatively large effect sizes. (Treviño et al. Nat Genet, 2009, Xu et al. JNCI 2013). Interestingly, ALL is more prevalent and carries a poorer prognosis in patients with high genome-wide Native American (NA) ancestry than those of any other ancestry type (Yang et al. Nat Genet 2011). This suggests that the evolutionary history of NAs has played a role in the high incidence and inferior treatment outcome of ALL in these populations. Here we analyze germline genotype data from 233 Guatemalan individuals, many of whom identify as Native American, consisting of children with ALL and their unaffected parents, genotyped with Affymetrix SNP 6.0 and Illumina Exome arrays to better understand the genomic signatures of demographic history and selection on NAs populations ,particularly at loci that contribute to genetic predisposition to ALL. Genome-wide we find that individuals in our sample from Guatemala have 83% NA ancestry on average and 14% European ancestry on average (significantly higher and lower, respectively, compared to the admixed Americans in the 1000 Genomes). Principal component analysis confirms that sampled Guatemalans capture features of NA ancestry not seen in the admixed Americans from the 1000 Genomes. Local ancestry de-convolution of the Guatemalan samples shows that Asians in the 1000 Genomes are poor proxies for NA ancestral haplotypes. Of 6 previously-identified ALL susceptibility loci, we find evidence for adaptive selection at rs4982731 (CEBPE) with a minor allele frequency difference in the top 2% between Guatemalans and Asians and an Integrated Haplotype Score (in the top 5.25% of scores indicating selection for the derived allele). The elevated allele frequencies of other ALL risk alleles in Native Americans, in contrast, may have resulted from genetic drift. Although clinical studies have observed racial differences in the frequency of ALL susceptibility variants , this study presents the first evolutionary analysis of why this is the case.

1910M

Relationship between Glaucoma and Admixture in Postmenopausal African American Women. *R. Nassir[1,3,4], L. Garcia[2], L. Qi[2], R. Kosoy[3,4], N. Fijalkowski[5], M. Haan[6], K. Singh[5], J. Robbins[4], M. Seldin[3,4].* 1) Umm Al-Quraa University, Makkah, Westren, Saudi Arabia; 2) Department of Public Health Sciences, University of California, Davis, CA, USA; 3) Department of Biochemistry and Molecular Medicine, University of California, Davis, CA, USA; 4) Department of Internal Medicine, University of California, Davis, CA, USA; 5) Department of Ophthalmology, Stanford, CA, USA; 6) Department of Epidemiology & Biostatistics, University of California, San Francisco, CA, USA.

Different ethnic groups have different propensities for Glaucoma. To further assess the relationship between ethnicity and this phenotype, we examined whether differences in continental admixture in cross-sectional analysis for both African American and Hispanic American adult women in the Women's Health Initiative were associated with this trait. The proportion of European, Sub-Saharan African and Amerindian admixture was estimated for each individual participant using a Bayesian clustering method (STRUCTURE) and 92 SNP ancestry informative markers (AIMs). In self-identified African American women (n= 11616) there was a significant association between African Admixture and Glaucoma (OR= 1.38; 95% CI= 1.02-1.86) in age-adjusted model. However, this relationship had become not statistically significant after adjusting for socioeconomic status, hypertension, diabetes and BMI (OR= 1.24; 95% CI= 0.91-1.68). In contrast, there was a significant association between diabetes and glaucoma (OR= 1.51; 95% CI= 1.37-1.67) in age-adjusted model. This association persisted after the adjustment for admixture, socioeconomic status, hypertension, and BMI (OR=1.52; 95% CI= 1.37-1.68). In addition, lower socioeconomic status was significantly associated with higher risk of glaucoma (OR=1.07; 95%CI= 1.02-1.12). But, in a fully adjusted model, which included African Admixture, diabetes, hypertension and BMI, the association between socioeconomic status and glaucoma was marginally significant (p=0.04), while hypertension and BMI were not associated with glaucoma. This study shows that, Diabetes and socioeconomic status, but not the African admixture, were found to be independently associated with glaucoma status. These finding suggest that the high frequency of glaucoma in African Americans maybe largely due to factors other than admixture such as diabetes and socioeconomic status.

1911S

Inference of the demographic history of Japan using Approximate Bayesian Computation. *C.D. Quinto[1], K.R. Veeramah[2], A.E. Woerner[3], M.F. Hammer[3].* 1) Graduate Interdisciplinary Program in Genetics, University of Arizona, Tucson, Arizona, USA; 2) Department of Ecology and Evolution, Stony Brook University, Stony Brook, NY, USA; 3) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tucson, Arizona, USA.

The genetic exchange between differentiated populations, termed admixture, has increasingly been shown to be an important process in human history. The formation of Hispanic populations in the Americas is one of the best-known examples of this phenomenon. Another important but less well-known example is the origin of modern Japanese. At least two distinct incoming migrations are known to have occurred during the prehistory of Japan. The first took place at least 10,000 years ago and established the Jōmon culture, which was characterized by a semi-sedentary hunter-gatherer way of life and one of the earliest uses of ceramics. Then, around 2,300 years ago, a second migration to the archipelago brought rice agriculture and iron, and established the Yayoi culture. The mixture of the people belonging to these two cultures is believed to have formed the ancestors of the modern Japanese population. Although archaeological records provide information about the time of arrival of the Yayoi people to Japan, the dynamics of the admixture process are still unclear. Previous genetic studies, focusing on mitochondrial DNA and the Y chromosome, have supported an admixture model for the origin of the modern Japanese population. While genome-wide data have being used to investigate this question, there are currently no studies that infer the parameters describing the dynamics of the admixture process. Part of the reason for this is that explicit population genetic modeling is problematic when utilizing genome-wide arrays because of the underlying ascertainment bias in the choice of SNPs. To address these issues, we genotype 500,000 SNPs in 282 samples from populations across the Japanese archipelago and East Asia. We then attempt to correct for the ascertainment bias by using whole genome sequencing data to approximate the discovery sample used to ascertain SNPs. We utilize the SNP genotypes from the different populations to identify ancestry blocks in Japanese samples. The distribution of these blocks provides insights about the time and proportion of admixture, and this information is used in an Approximate Bayesian Computation analysis to infer other key demographic parameters such as divergence times, migration rates and population sizes.

1912M

A Fine-Scale Comparative Analysis of Population Structure, Divergence and Admixture in in Han Chinese, Japanese and Korean Populations. *S. Xu[1], Y. Wang[1], D. Lu[1], Y. Chung[2].* 1) Population Genomics, CAS-MPG Partner Institute for Computational Biology, Shanghai, Shanghai, China; 2) Integrated Research Center for Genome Polymorphism, Department of Microbiology, The Catholic University Medical College, Socho-gu Seoul 137-701, Korea.

n East Asia, human origins and dispersals remain poorly understood and debatable. As the major ethnicities of East Asia, Han Chinese, Japanese and Korean people share many similarities in characteristics, language and culture. However, the genetic relationships, divergence times and subsequent gene flow among the three populations have not been well studied or quantitatively estimated. Here, we conducted a genome-wide study using over 900,000 single nucleotide polymorphisms (SNPs) and evaluated the population structure of 182 unrelated Han Chinese, 90 Japanese and 100 Korean individuals, and compared with 663 individuals representing 8 worldwide populations. Our analysis revealed that Han Chinese, Japanese and Korean populations have distinct genetic makeup and can be well distinguished based on the genome wide data, or a panel of ancestry informative markers (AIMs) screened from genome-wide SNPs, indicating they have been isolated for substantially long time. Interestingly, population structure is perfectly corresponding to the geographical distribution of the three populations, indicating geography was an important factor resulted in population differentiation. We identified a cline of north/south admixture, which is consistent with either a scenario of isolation by distance (IBD) or that of north/south migrations or both. We theorized that both IBD effect and migrations could have resulted in such a pattern. On the other hand, our analysis revealed patterns of admixture which occurred after initial splits of populations. We further estimated gene flows among the three populations. We concluded that the genetic structure of the present-day Han Chinese, Japanese and Korean people was shaped jointly by common origin, subsequent gene flow and local adaptation. Our results advance the understanding of the genetic relationship and population history in East Asia.

1913S

Analysis of autosomal and Y-chromosomal DNA Suggests West Asian Population Derivation from Northern Middle Eastern Populations in the post-Glacial Period. *P. Zalloua[1,2], F. Utro[3], M. Haber[1], L. Parida[3], E. Matisoo-Smith3[4], D. Platt[3].* 1) Genomics Laboratory, Gradute School, Beirut, Lebanon; 2) Harvard School of Public Health, Boston, MA, USA; 3) I.B.M. T. J. Watson Research Center, Yorktown Hgts, NY; 4) University of Otago, Dunedin 9054, New Zealand.

Analysis of Y DNA J and E haplogroups in West Asians (Georgians, Armenians, Turks, Syrians, Lebanese, Jordanians, Saudi Arabians, Yemenis, Kuwaitis) suggest expansions coming primarily from the north (Turkey, Georgia, Armenia), with an early differentiation between those who headed south along the Tigris-Euphrates, versus those who headed south along the Levantine coast. We sought to resolve whether southern variations represented evolution within separate ice age refugia, or evolved from the same northern refugia as suggested by Y chromosome data by revealing population divergence times between Saudi Arabia and Yemen versus Turkey, Syria, and Armenia that predate the post-glacial expansions. We employed IRIS to compute times for grand most recent common ancestors applied between pairs of subjects drawn from Georgians, Armenians, Turks, Syrians, Lebanese, Jordanians, Saudi Arabians and Yemenis, as well as pair-wise FST's based on the estimated times. We contrasted these results with raw SNP counts and pairwise FST's obtained from those counts. We applied MDS and hierarchic clustering to identify geographically informative relationships, and observed a clear pattern of a north-to-south gradient. Within the western Middle East, our results suggest population differentiation dates consistent with post Last Glacial expansions, with subsequent population constriction into the Fertile Crescent in the presence of admixture. Our estimates show a north-to-south differentiation time of ~24,800-18,200 y.a., well within the Last Glacial Period. However, the time of J1/J2 haplogroups splits that mark this diversion are dated by BATWING well into the Last Glacial Period, around 31kya. These results place the genetic differentiation of the autosomal genome to be a bit more recent than the J1/J2 split. Expansions into Europe show a somewhat more recent record than those into Africa, with signals that show affinities with particular Middle Eastern regions, suggesting more recent trade impacts.

1914M

A method to use control data and exploit the structure of genetic ancestry space to enhance case-control studies. *C. Bodea[1], S. Ripke[2, 3], B. Neale[2, 3], B. Devlin[4], M. Daly[2, 3], K. Roeder[1, 5].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 5) Ray and Stephanie Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA.

In genetic studies of common and rare variants, considerable effort and expense is required to obtain a sample of control subjects matched by genetic ancestry to the case subjects. Repositories like dbGap contain genetic data from tens of thousands of potential control samples, but these data can be accessed only with considerable effort on the part of the research team. We're exploring the use of publicly available collections of control data to create a common genetic ancestry space onto which cases and controls can be mapped independently. We employ spectral clustering to construct ancestry spaces as well as to perform projections. The base space and projected controls are then used to estimate the allele frequency surface over the ancestry space. To identify small-scale frequency variation while also borrowing strength from the entire data set we employ a combination of empirical Bayesian analysis across a hierarchical clustering of the controls and, for localized ancestry regions, a Gaussian process model of the minor allele frequency. We call our approach the Universal Control Repository Network (UNICORN), because it is designed to provide optimally matched allele frequency information for any case sample at hand.

We have performed a small-scale association test on the POPRES data (Nelson et al., Am J Hum Genet, 2008) based on simulated signal of varying risk and allele frequency and found that UNICORN delivers strongly superior results over a traditional matched control setup, even when the matched controls greatly outnumber cases. We have also replicated the results of a large (5956 cases, 14927 controls) GWAS on Crohn's disease (Jostins et al., Nature, 2012) via the UNICORN framework by computing the matched allele frequency estimates from the study's control set. This result highlights that even big studies with ample control collections can benefit from UNICORN.

1915S

Population Genomics of the South American Andean Region. *J.R. Homburger[1], A. Moreno-Estrada[1], C.R. Gignoux[1], E. Sanchez-Rodriguez[2], B.A. Pons-Estel[3], E. Acevedo[4], J.M. Cucho[4], P. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA, USA; 2) Centre for Genomics and Oncological Research (GENYO), University of Granada, Granada, Spain; 3) Sanatorio Parque, Rosario, Argentina; 4) Hospital Nacional Guillermo Almenara Irigoyen, Lima, Peru; 5) Facultad Medicina Occidente, Universidad de Chile, Santiago de Chile, Chile; 6) Hospital Italiano de Buenos Aires, Argentina; 7) H.I.G.A. General San Martin, La Plata, Argentina; 8) Hospital Eva Peron, Granadero Baigorria, Argentina; 9) Hospital Italiano de Córdoba, Córdoba, Argentina; 10) H.I.G.A. Oscar E. Alende, Mar del Plata, Argentina; 11) Hospital Interzonal San Juan Bautista, Catamarca, Argentina.

The South American continent has experienced multiple migration and admixture events. Here, we examine the genetic history of the Andean region using 551 individuals from Colombia, Ecuador, Peru, Chile, and Argentina genotyped on Illumina SNP arrays. Combining these data with individuals from the 1000 Genomes Project and the Population Reference Panel (POPRES), we show that the admixed individuals have varying degrees of Native American and European ancestry. We use ADMIXTURE and principal component analysis (PCA) to study the genetic ancestry of the admixed South American individuals. We show that on average the Peruvian individuals have a higher amount of Native American ancestry while the Argentinian individuals had on average the highest amount of European ancestry when compared with the other admixed South American samples. We also find that Andean indigenous groups account for the largest proportion of Native American ancestry in the South American individuals. On the other hand, the largest proportion of European ancestry in admixed individuals is from Southern Europe and the Iberian Peninsula. We aim to estimate the specific timing and the subcontinental origin of ancestral components involved in South American admixture by applying ancestry-specific PCA and tract length analysis to admixed genomes.

1916M

Fast individual ancestry inference from DNA sequence data leveraging allele frequencies from multiple populations. *O. Libiger[1,3], V. Bansal[1,2].* 1) Scripps Translational Science Institute, La Jolla, CA; 2) Department of Pediatrics, University of California San Diego, La Jolla CA; 3) MD Revolution, San Diego, CA.

Estimation of individual ancestry from genetic data is useful for the analysis of disease association studies, understanding human population history and interpreting personal genomic variation. We describe a fast method for estimating the relative contribution of known reference populations to an individual's genetic ancestry. Our method utilizes allele frequencies from the reference populations and individual genotype or sequence data to obtain a maximum likelihood estimate of the global admixture proportions using the BFGS optimization algorithm. It accounts for the uncertainty in genotypes present in sequence data by using genotype likelihoods instead of genotypes. Unlike previous methods, our method does not require individual genotype data from external reference panels and can utilize allele frequencies estimated from the analysis of homogeneous as well as admixed human populations. Simulation studies and application of the method to real datasets demonstrate that our method is 8-10 times faster than ADMIXTURE and has comparable accuracy. Using data from the 1000 Genomes project, we show that our method can estimate genome-wide average ancestry of admixed individuals using exome or low-coverage sequence data. Finally, we demonstrate that our method can be used to estimate admixture proportions using pooled sequence data making it a valuable tool for controlling for population stratication in sequencing based association studies that utilize DNA pooling.

1917S

Molecular and cytogenetic analysis of inversions in human and Great Apes. *M. Miroballo, A. De Magis, F. Antonacci.* Department of Biology, University of Bari, Bari, Italy.

In the last few years the burst of whole genome techniques allowed the detection of all kinds of unbalanced structural variations, while balanced rearrangements, such as inversions, are still hardly discovered. Several studies described inversions as a very frequent interspecific rearrangement and for their high potential power in suppressing recombination they are generally considered as one of the main genomic driving forces among evolutionary mechanisms. The prominent role of inversions coupled with the lack of high-throughput techniques for their detection, force research to take advantage of prediction methods that may imply the possibility to obtain false positives that must undergo experimental validation. In the present work-in-progress we resume a previously published study (Feuk et al., 2005) about the prediction and validation of inversions in human and chimpanzee genomes extending the analysis to the rest of the Great apes. First, we investigated by PCR and FISH a total of 19 predicted inversions in a panel of 16 samples, four per each species. For those regions showing both direct and inverted orientations in one species, we enlarged the investigations to more individuals in order to evaluate their occurrence and stratification in the different geographical areas of origin. 11 out of 19 regions were confirmed as previously published: three inversions occurred in the chimpanzee lineage, six inversions occurred in the human lineage (with one region confirmed as polymorphic) and two were false positives, showing the same orientation in the two species. One of the three previously validated inverted regions in PTR (7q21.3), was found to be polymorphic among the chimpanzee subspecies: in western chimpanzees the region was found to be inverted with a 67% allele frequency, while the eastern chimpanzees uniquely showed the direct orientation. We also characterized seven predicted inversions found to be false positives, mainly due to the presence of inverted duplications at the breakpoints of the predicted rearrangements. Further analysis will include at least three steps: (i) selection and validation of additional predicted inversion regions to increase the reliability of the predictive method; (ii) sequence analysis of the inversion breakpoints to investigate the molecular mechanisms of inversions; and (iii) study of genes mapping in the inverted regions to investigate their role in the recent evolutionary history of Great apes.

1918M

Identification of pleiotropic association signals in multiple autoimmune diseases at 2q24. *J.E. Molineros, C. Sun, S.K. Nath.* Oklahoma Medical Research Foundation, Oklahoma City, OK.

Overlapping etiological factors among the autoimmune diseases (ADs) have been suspected owing to shared clinical and immunological characteristics, and familial aggregation of multiple ADs. As a follow up to our previous study of Systemic Lupus Erythematosus (SLE) association on 2q24, where we identified three functional independent variants in IFIH1, we performed association analysis on Six additional autoimmune diseases (type 1 diabetes N=823, celiac disease N=1716, vitiligo N=1089, psoriasis N=919, rheumatoid arthritis, N = 1999 and systemic sclerosis N=833). One common control dataset (N=8833) was used to facilitate comparisons of this study. Given the different SNP densities in each dataset, missing SNPs were imputed using MACH. We focused on the genomic region including genes GCG, GCA, FAP, IFIH1 and KCNH7. We performed conditional logistic regressions to identify which SNPs were statistically independent. We were able to replicate association ($P<0.05$) of our three reported IFIH1 variants (rs1990760, rs10930046 and rs13023380) in all ADs, although not all three in all of them. Surprisingly, we identified stronger association signals originating from potassium channel gene KCNH7, that after conditional analyses explained much of the association in the region for celiac disease (rs867824 P=3.0×10-7), psoriasis (rs2389739 P=6.6×10-10), rheumatoid arthritis (rs12623464 P=9.31×10-17) and type 1 diabetes (rs1352071, P=4.8×10-3), whereas the strongest signal for systemic sclerosis originated at GCA (rs17783344 P =2.8×10-10), and at FAP in the case of vitiligo (rs13422767 P=4.9×10-6). Bioinformatic analysis of these independent variants, identified eQTLs as well as transcriptional regulatory elements. Thus, together with IFIH1, additional evidence from KCNH7 and GCA points towards the involvement of 2q24 in susceptibility for multiples ADs.

Genomic Affinities Among Different Population Groups of Jammu Region of J&K State, India. *R.K. Panjaliya[1], V. Dogra[1], J. Kour[1], D. Gupta[2], P. Kumar[1], S. Gupta[1].* 1) Human Genetic Research cum Counselling, Jammu, J & K, Jammu, India; 2) University of Nottingham, United Kingdom.

Human genomic diversity is the result of differential accumulation of genetic variations in individuals and populations throughout the evolution. The identification of such distinctive characteristics in the DNA represents the basis of human identification, genetic diversity and population genetics. The state of Jammu and Kashmir, India harbors heterogenous population groups inhabiting the different geographical regions. A little work is being carried out regarding the study of genetic diversity of the people of the state. In present study, genomic diversity study in six of the prominent population groups (Brahmins, Rajputs, Bhagats, Chamar, Gujjars and Jatt Sikhs) was carried out using ten autosomal DNA markers belonging to seven Alu insertion/deletion polymorphisms namely Alu ACE, Alu APO, Alu PV-92, Alu PLAT, Alu FXIIIB, Alu D1, Alu CD4; LPL PvuII, ESR PvuII and ESR XbaI polymorphism. Blood samples were collected randomly from 600 unrelated healthy individuals after prior consent. DNA was extracted and amplified by PCR using target specific oligonucleotide primers and finally subjected to agarose gel electrophoresis. Further, for LPL PvuII, ESR XbaI and ESR PvuII, the PCR product was subjected to restriction digestion using PvuII and XbaI restriction enzymes. Allele frequencies were used to calculate average heterozygosity. All the markers except Alu CD4 were found to be highly polymorphic with high heterozygosity values in almost all the population groups of the state. It was observed that most of the genomic diversity was attributed to individuals within the population. The study is a preliminary work on the population groups of the J&K state which may help in future work on the genetic heterogeneity in other population groups of the state which may give a genetic insight and genetic basis underlying the different genetic diseases prevailing in the state.

Acetylation of RNA Polymerase II Evolved in the Early History of Animals. *C. Simonti[1], K.S. Pollard[3], S. Schroeder[3], D. He[3], B.G. Bruneau[3], M. Ott[3], J.A. Capra[1,2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Biological Sciences, Vanderbilt University, Nashville, TN; 3) Gladstone Institutes, University of California, San Francisco, CA.

The evolution and diversification of animals from their unicellular ancestors required the development of novel functional capabilities that enabled the differentiation and coordination of different cell types. We argue that a recently discovered posttranslational modification of RNA polymerase II—acetylation of its RPB1 subunit—arose in the early history of animals and provided a substrate for developing gene regulatory mechanisms, such as polymerase pausing, essential to animal diversification. RPB1 contains a modifiable C-terminal domain (CTD) that consists of variations of a heptad repeat sequence ($Y_1S_2P_3T_4S_5P_6S_7$). Modeling the evolutionary dynamics of CTD repeat count and sequence content across diverse eukaryotes revealed an expansion of the CTD in the ancestors of Metazoa. The new CTD repeats introduced the potential for RPB1 acetylation (acRPB1) due to the appearance of repeats with lysine at position seven. This was followed by an increase in the number of lysine-containing repeats in Deuterostomia. Mouse genes enriched for acRPB1 occupancy at their promoters and genes with significant expression changes when acRPB1 is disrupted are enriched for functions essential to the development and diversification of animals, such as growth factor response, cellular adhesion, and vascular development. Genes sensitive to acRPB1 show significant enrichment for origins near the appearance of lysine-containing repeats, and p300, the acetyltransferase enzyme known to acetylate the CTD, also appeared on the same ancestral lineage. Our combined functional and evolutionary analyses show that RPB1 CTD acetylation specifically regulates processes essential to multicellularity and suggest that this regulatory mechanism was involved in the expansion of animals.

Structural Comparison and Natural Selection of Filaggrin Gene within Primates. *V. Romero, K. Hosomichi, I. Inoue.* National Institute of Genetics, Mishima, Japan.

Human Profilaggrin gene (FLG) is produced in the outer layers of the epidermis and encodes important components of the skin. Mutations in this gene are associated with a variety of skin disorders, such as, atopic dermatitis (atopy). These mutations have a high prevalence in European and Asian population. When this mutations are analysed, a higher frequency of nonsynonymous variation is found, which is indicative of positive selection and may suggest a benefit for the organism. This benefit is described in one hypothesis called “natural vaccination”. This hypothesis suggests a heterozygote advantage in which a higher number of antigens enter through skin - during childhood- and thus serve to strengthen the immune system, as an adult. High prevalence of mutations in different populations, higher nonsynonymous variations and “natural vaccination” hypothesis suggest that filaggrin is evolving under positive selection. The aim of my study is to determine the structure of FLG in Macaque, Orangutan, Gorilla and Chimpanzee, compare it with the one in human and test their sequences for evidence of positive selection. To look for this, phylogenetic analysis; maximum-likelihood tests were used and filaggrin monomers were analysed for either concerted or birth-and-death evolutionary models. Profilaggrin coding sequence consists of a repeat region formed by identical monomers. These monomers are cleaved and function independently. The structure of the repeat region has two partial monomers (not-skin related) flanking the functional ones. This structure was found to be conserved in primates, however the number of functional monomers differs in each species. Phylogenetic analysis indicated monomers of species with long divergence time cluster together and maximum-likelihood tests demonstrated positive selected codons in different branches. Evolution of filaggrin as concerted or birth-and-death has to be evaluated since results are not conclusive.

Population genomics analysis in whole genome sequencing of 152 rhesus macaques. *F. Yu[1], C. Xue[1], M. Raveendran[1], G.L. Fawcett[1], S. White[1], D. Rio Deiros[1], R.A. Harris[1], M. Dahdouli[1], W. Salerno[1], Z. Johnson[2], E. Vallender[3], R. Wiseman[4], H.M. Kubisch[5], L. Cox[6], S. Kanthaswamy[7], D.G. Smith[7], B. Ferguson[8], J. Horvath[9], D. Muzny[1], R.A. Gibbs[1], J. Rogers[1].* 1) Human Genome Sequence Ctr, Baylor College Med, Houston, TX; 2) Yerkes National Primate Research Center, Atlanta, GA; 3) New England NPRC, Southborough, MA; 4) Wisconsin NPRC, Madison, WI, 5Tulane NPRC, Covington, LA; 5) Tulane NPRC, Covington, LA; 6) Southwest NPRC, San Antonio, TX; 7) California NPRC, Davis, CA,; 8) Oregon NPRC, Beaverton, OR; 9) North Carolina Central University, Durham, NC.

Rhesus macaques (Macaca mulatta) are themost widely studied nonhuman primate species in biomedicine. Rhesus share many fundamental biological and physiological processes with humans that make them an ideal model system for vaccine research and studying molecular mechanisms of human diseases. However the patterns of the genetic variation and the evolutionary and population genomics processes that shaped rhesus genomes have not been well studied. We applied next generation whole genome sequencing for 152 unrelated individuals (144 Indian-origin, 8 Chinese-origin) using either deep (30X) or low coverage (6X) strategies. Our analysis using SNPTools identified 51.6 million SNPs. And rigorous quality control procedure was applied, the average transition transversion ratio is ~2.2. We characterized evolutionary and population genomics from five different aspects: (1) characterization of population genetics parameters; (2) detailed demographic modeling; (3) identification of loci affected by Darwinian selection; (4) characterization of the patterns of linkage disequilibrium and recombination hotspots in comparison to human and chimpanzees; and (5) functional annotation of SNPs for prioritization and hypothesis generation. On average, Indian-origin individuals have >9.5 million variants, while Chinese animals have >12 million, representing much higher diversity than humans. Current effective population size (Ne) is estimated at 65,000 for Indian-origin animals, 79,000 for Chinese-origin, substantially higher than values for humans. Analyses also reveal dramatic demographic changes over the past 10 million years. Functional annotation in coding sequences found >250,000 mis-sense variants and >4600 stop-codon-gained mutations. In addition, about 110,000 SNPs mapped to conserved ENCODE transcription factor binding motifs. We used position weight matrices from the JASPAR database to assess these SNPs and found >25,000 candidate variants that may significantly affect TF binding, and thus gene expression. We mapped rhesus SNPs to the 4% of the genome identified as conserved across 29 mammals, and found reduced SNP density and MAF, consistent with negative selection in those regions. We also applied anumber of site frequency spectrum tests and found significant new evidence for both positive and negative selection in both coding and noncoding regions. Analyses of LD and local recombination rates are in progress.

RNA-seq analysis of endogenous retroviral elements in bovine conceptuses during the period of placentation. *S. Nakagawa[1], T. Miyazawa[2], T. Gojobori[3], K. Imakawa[4].* 1) Department of Molecular Life Science, Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2) Department of Cell Biology, Institute for Viral Research, Kyoto University, Kyoto, Japan; 3) Center for Information Biology, National Institute of Genetics, Mishima, Shizuoka, Japan; 4) Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo, Japan.

In evolution of mammals, some of essential genes for placental development are known to be of retroviral origin, as syncytin-1 derived from an envelope (env) gene of an endogenous retrovirus (ERV) aids in the cell fusion of placenta in humans. Although the placenta serves the same function in all placental mammals, env-derived genes responsible for trophoblast cell fusion and maternal immune tolerance differ among species and remain largely unidentified in the bovine species. To examine env-derived genes playing a role in the bovine placental development comprehensively, we determined the transcriptomic profiles of bovine conceptuses during three crucial windows of implantation periods using a high-throughput sequencer. The sequence reads were mapped into the bovine genome, in which ERV candidates were annotated using RetroTector© (7624 and 1542 for ERV-derived and env-derived genes, respectively). The mapped reads showed that about 18 percent (284 genes) of env-derived genes in the genome were expressed during placenta formation, and about four percent (63 genes) were detected for all days examined. We verified three env-derived genes that are expressed in trophoblast cells by polymerase chain reaction. Out of these three, the sequence of env-derived gene with the longest open reading frame (named BERV-P env) was found to show high expression levels in trophoblast cell lines, and to be similar to those of syncytin-Car1 genes found in dogs and cats, despite their disparate origins. These results suggest that placentation depends on various retrovirus-derived genes that could have replaced endogenous predecessors during evolution.

How population growth affects linkage disequilibrium. *A. Rogers.* Anthropology, University of Utah, Salt Lake City, UT.

The`LD curve'' relates the linkage disequilibrium (LD) between pairs of nucleotide sites to the distance that separates them along the chromosome. It is used to map disease genes and to search for adaptive evolution. But it also responds to the history of population size. The present research describes new theoretical results about the effect of population history. When a population expands in size, the LD curve grows steeper, and this effect is especially pronounced following a bottleneck in population size. When a population shrinks, the LD curve rises but remains relatively flat. As LD converges toward a new equilibrium, its time path may not be monotonic. Following an episode of growth, for example, it declines to a low value before rising toward the new equilibrium. These changes happen at different rates for different LD statistics. They are especially slow for estimates of σ_d^2, which therefore allow inferences about ancient population history. For the human population of Europe, these results suggest a history of population growth.
