American Society of Human Genetics 66th Annual Meeting
October 18–22, 2016 VANCOUVER, CANADA

POSTER ABSTRACTS

Session Topic/Title	Abstract/Poster Board Numbers	
	Start #	End #
Statistical Genetics and Genetic Epidemiology	328W	591F
Cardiovascular Phenotypes	592W	723F
Molecular and Cytogenetic Diagnostics	724W	1032F
Evolution and Population Genetics	1033W	1178T
Complex Traits and Polygenic Disorders	1179F	1649T
Bioinformatics and Computational Approaches	1650F	1956F
Epigenetics and Gene Regulation	1957W	2157F
Developmental Genetics and Gene Function	2158W	2254W
Mendelian Phenotypes	2255T	2661F
Cancer Genetics	2662W	2989W
Genetic Counseling, ELSI, Education, and Health Services Research	2990T	3133W
Omics Technologies	3134T	3227T
Prenatal, Perinatal, and Reproductive Genetics	3228F	3303F
Genome Structure and Function	3304W	3397W

Posters should remain on the board for all three days (Wednesday through Friday)

The program and abstract/poster board number next to each listing is followed by an **W** (Wednesday), **T** (Thursday), or **F** (Friday) to indicate the day on which authors must be present at their poster boards.

328W

Genetic determinants of glycated hemoglobin levels in the Greenlandic Inuit population. *E.V.R. Appel[1], I. Moltke[2], M.E. Jørgensen[3], P. Bjerregaard[4,5], A. Linneberg[6,7,8], O. Pedersen[1], A. Albrechtsen2[2], T. Hansen[1], N. Grarup[1].* 1) NNF-CBMR: Section for Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Copenhagen Ø, Denmark; 2) The Bioinformatics Centre, Department of Biology, University of Copenhagen, 2200 Copenhagen, Denmark; 3) Steno Diabetes Center, 2820 Gentofte, Denmark; 4) National Institute of Public Health, University of Southern Denmark, 1353 Copenhagen, Denmark; 5) Greenland Centre for Health Research, University of Greenland; 6) Research Centre for Prevention and Health, Capital Region of Denmark, Copenhagen, Denmark; 7) Department of Clinical Experimental Research, Rigshospitalet, Glostrup, Denmark; 8) Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark.

We recently showed that a common genetic variant leads to a remarkably increased risk of type 2 diabetes (T2D) in the small and historically isolated Greenlandic population. Motivated by this, we aimed at discovering novel genetic determinants for glycated hemoglobin (HbA$_{1c}$) and at estimating the effect of known HbA$_{1c}$ associated loci in the Greenlandic population. We analyzed genotype data from 4,049 Greenlanders, which have previously been generated using the Illumina Cardio-Metabochip. We performed the discovery association analysis by applying an additive linear mixed model. To estimate the effect of known HbA$_{1c}$ associated loci we modeled the effect in the European and Inuit ancestry proportions of the Greenlandic genome (EPG and IPG). We found no novel significant associations after correcting for multiple testing. When we investigated loci known to associate with HbA$_{1c}$ levels, we found that the lead variant in the *GCK* locus associated significantly with HbA$_{1c}$ levels in the IPG (P$_{IPG}$=4.8·10^{-6}, β$_{IPG}$=0.13 SD). Furthermore, for 10 of 15 known HbA$_{1c}$ loci the effect was similar to previously reported effects. Interestingly, the *ANK1* locus showed a significant ancestral population specific effect, with opposing directions of effect in each ancestral population. We found no evidence of additional independent association signals in the known HbA$_{1c}$ associated loci. In conclusion, we found only 1 of the 15 known HbA$_{1c}$ loci to significant associate within the IPG and that 10 of 15 loci showed similar effects as found in European and East Asian populations. Our results shed light on the genetic effects across ethnicities.

The Type 2 Diabetes Knowledge Portal: A paradigm for the democratization of human genetic information. *M.C. Costanzo, Accelerating Medicines Partnership for Type 2 Diabetes Knowledge Portal.* Medical and Population Genetics, Broad Institute, Cambridge, MA.

Discovery of the association of human genetic variants with diseases and traits can spur novel insights in health and medicine. But most association data are warehoused in disparate silos and are difficult to access. Even in a specific disease area, results from different consortia are often not integrated with each other. Thus it can be prohibitively difficult for researchers even to access the data, let alone use them to generate hypotheses that could catalyze the clinical translation of genetic discoveries. The Accelerating Medicines Partnership in Type 2 Diabetes (AMP T2D) addresses this problem by forging collaboration between the National Institutes of Health and academic, industrial, and nonprofit stakeholders in order to produce and aggregate data, develop analysis methods and tools, and build infrastructure for data storage and presentation. The results of this collaboration are available via the Type 2 Diabetes Knowledge Portal (http://www.type2diabetesgenetics.org), an open-access resource that aggregates genetic and phenotypic data in a framework that facilitates dynamic analysis across disparate data sets while protecting patient privacy. The Portal knowledgebase contains T2D association studies from all the large-scale T2D consortia and projects, covering more than 260,000 individuals, along with harmonized genome-wide association study (GWAS) meta-analysis data from over 600,000 samples for an additional 25 relevant traits. We have recently integrated variant data from 1000 Genomes, 2,500 whole genomes from GoT2D, and 60,000 exome sequences from the Exome Aggregation Consortium. By the end of 2016 we will release results for an additional 9,000 exomes and GWAS data for over 30,000 T2D samples: 4,000 multiethnic samples from a clinical pre-diabetic study (CAMP); 14,000 African-American samples from BioMe; and 11,800 Finnish samples from METSIM and FUSION. Portal data are currently stored in a Data Coordinating Center (DCC) at the Broad Institute. Soon, they will also be stored at connected federated nodes, including the European Bioinformatics Institute, enabling each node to protect patient data in accordance with local regulations while facilitating global access to analyses. To spark insights from these data, we have developed tools for custom analysis of variant associations. Software and methods developed within the AMP T2D project will be publicly available and are generally applicable to variant associations with any disease or trait.

330F

Genotype-by-multivariate dietary environment interaction effects on cardiometabolic risk factors in Mexican American children: The SAFARI study. *V.P. Diego[1], J. Vanamala[3,4], V.S. Farook[2], L. Reddivari[5], S.P. Fowler[6], S. Puppala[7], G. Chittor[8], R.G. Resendez[2], J.C. Alvarenga[2], S. Mummidi[2], L. Almasy[1], J.E. Curran[1], A.G. Comuzzie[7], D.M. Lehman[6,9], C.P. Jenkinson[2], J.L. Lynch[10], R.A. DeFronzo[6], J. Blangero[1], D.E. Hale[10], R. Duggirala[2], R. Arya[2].* 1) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX; 2) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Edinburg, TX; 3) Department of Food Science, Penn State University, University Park, PA; 4) The Pennsylvania State Hershey Cancer Institute, Penn State Milton S Hershey Medical Center, Hershey, PA; 5) Department of Plant Science, Penn State University, University Park, PA; 6) Department of Medicine, University of Texas Health Science Center at San Antonio, San Antonio, TX; 7) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 8) Department of Nutrition and UNC Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC; 9) Department of Cellular & Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX; 10) Department of Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX.

   Obesity, type 2 diabetes (T2D), and the metabolic syndrome (MetSyn)—defined as a cluster of obesity, pre-diabetes, and other cardiometabolic risk factors (CMRFs)—are worldwide epidemics, and are increasingly prevalent in children of minority ethnicity. As part of the San Antonio Family Assessment of Metabolic Risk Indicators in Youth (SAFARI) Study on healthy Mexican American children, we studied genotype-by-environment interaction (GEI) effects on CMRF variation in 216 boys and 208 girls with a mean age of 11.6 years. We studied GEI in relation to dietary multivariate environments (MEs), defined as scores from the first 4 factors of a principal component analysis (PCA) of 15 dietary variables followed by varimax rotation. The 15 dietary variables consist of 13 survey variables—intake of carbohydrate; protein; total, trans-, saturated, monounsaturated, and polyunsaturated fats; cholesterol; sugar; fiber; ω-3 and ω-6 fatty acids; and total kilocalories—and serum α- and β-carotene, measured using an ultra pressure liquid chromatography-photo diode array detector. The first 4 factors, denoted by F1, F2, F3, and F4, explain > 90% of the total system variance. By likelihood ratio tests, we tested the two null hypotheses of GEI effects, namely additive genetic variance homogeneity across a given ME (VH) and an across-ME genetic correlation equal to 1 (GC). Our most interesting results are from analysis of the F2 and F4 MEs, where F2 had significant loadings by protein (0.71), saturated (0.56) and monounsaturated fat (-0.36) intake, and F4 had significant loadings for carbohydrate (0.71), cholesterol (-0.42) and total fat (-0.38) intake. A loading is significant if its absolute value is $\geq$ 0.3. For the F2 ME, we found significant GEI effects for C-peptide (p=0.04 and p<0.01 respectively from the VH and GC tests), and for fasting serum insulin (FSI) (p=0.01), homeostasis model assessment 2 of insulin resistance (p=0.01), HDL cholesterol (p=0.01), % fat mass (%FM) (p<0.001), and waist circumference (p=0.02) from the GC test. For the F4 ME, we found significant GEI effects for C-reactive protein (p=0.03) from the VH test, and for FSI (p<0.001), %FM (p=0.01), and a MetSyn variable (p=0.01) from the GC test. Our results show that dietary variables play critical roles in influencing the genetic determinants of obesity, T2D, and the MetSyn, and are novel in that they show an improved efficacy in detecting GEI effects by multivariate modeling of the environment.

331W

Type 2 diabetes and risk of stroke subtypes: A Mendelian randomization analysis based on individual participant data of 105,000 Chinese adults from the China Kadoorie Biobank. *W. Gan[1,2], M. Holmes[3], R. Walters[3], I. Millwood[3], F. Bragg[3], Y. Guo[4], J. Vaucher[3], Z. Bian[4], A. Mahaja[1,2], R. Clarke[3], L. Lee[4,5], M. McCarthy[1,2,6], Z. Chen[3].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology, and Metabolism (OCDEM), University of Oxford, Oxford, United Kingdom; 3) Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU),Nuffield Department of Population Health, University of Oxford, Oxford, United Kingdom; 4) Chinese Academy of Medical Sciences, Dong Cheng District, Beijing, China; 5) School of Public Health, Peking University Health Sciences Center, Beijing, China; 6) National Institute of Health Research, Oxford Biomedical Research Centre, Oxford, United Kingdom.

   Background: Observational studies report that type 2 diabetes (T2D) is associated with increased risk of both ischaemic and haemorrhagic stroke, but the underlying causal relationships are unclear. Given the increasing prevalence of T2D, clarifying the nature of these relationships could have important repercussions for stroke incidence and highlight potential opportunities for prevention. **Method:** We developed genetic risk scores (GRSs) based on 49 established T2D risk variants, weighting individual genetic variants using the most recent effect size estimates (Gan et al). We used data on 105,696 participants from the population-based China Kadoorie Biobank (CKB) prospective study, 93,119 randomly-selected subjects supplemented with 12,580 from a nested stroke case-control study (n= 8,284 combined prevalent/incident T2D cases and 12,122 stroke cases). We conducted Mendelian randomization (MR) analyses of individual participant data, using the GRS as an instrumental variable to investigate the causal role of T2D for overall stroke and stroke subtypes. Both observational and MR analyses were adjusted for age, sex, geographic region, BMI, smoking, alcohol intake, educational level and household income. **Results:** In observational analyses of the CKB study (512,891 participants), individuals with T2D had higher risks of total stroke (OR [95% CI] = 1.78 [1.72 - 1.84]), ischaemic stroke 1.88 (1.81 - 1.95) and haemorrhagic stroke 1.21 (1.10 - 1.32). In MR analysis, genetically-instrumented T2D was causally associated with an increased risk of stroke (OR = 1.81 [1.25 - 2.46], P = 3.31 × 10^{-3}), mainly with ischaemic stroke (n=6,859 cases; OR = 2.20 [1.50-3.04], P = 3.56 × 10^{-4}) but not haemorrhagic stroke (n=4,733 cases; OR = 1.00 [0.24 - 2.0], P = 0.40). For both stroke subtypes, the observational and causal estimates were similar ($P_{heterogeneity}$ > 0.46). No differences in risks of total or ischaemic stroke were identified when restricting the GRS to T2D genetic variants related primarily to either beta cell function or insulin sensitivity ($P_{heterogeneity}$ > 0.33). **Conclusions:** This MR study supports the causal relationship between T2D and risk of ischaemic stroke and highlights the potential importance of targeting diabetes for prevention of stroke.

Genome-wide interaction with the insulin secretion locus *MTNR1B* reveals *CMIP*, a novel type 2 diabetes susceptibility gene in African Americans. *J.M. Keaton[1,2,3], C. Gao[1,2,3], J.N. Hellwege[2,3], N.D. Palmer[2,3,4,5], J.S. Pankow[6], M. Fornage[7], J.G. Wilson[8], A. Correa[8], L.J. Rasmussen-Torvik[9], J.I. Rotter[10], Y.D.I. Chen[10], K.D. Taylor[10], S.S. Rich[11], L.E. Wagenknecht[5,12], B.I. Freedman[3,5,13], M.C.Y. Ng[2,3], D.W. Bowden[2,3,4].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 6) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 7) Institute of Molecular Medicine and Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 8) University of Mississippi Medical Center, Jackson, MS; 9) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 10) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute, Harbor-UCLA Medical Center, Torrance, CA; 11) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 12) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 13) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) is the result of metabolic defects in insulin secretion and insulin sensitivity, yet most of the T2D loci identified to date are related to insulin secretion. We hypothesize that T2D loci, particularly those impacting insulin sensitivity, can be identified through interaction with insulin secretion loci. To test this hypothesis, an intronic SNP, rs10830963, in *MTNR1B* associated with acute insulin response to glucose (AIR_g; P=1.2x10^{-5}), a dynamic measure of first-phase insulin secretion, was identified in African Americans (AfA) from the Insulin Resistance Atherosclerosis Family Study (IRASFS). rs10830963 was tested for interaction and joint (main + interaction) effects in AfA from five cohorts (ARIC, CARDIA, JHS, MESA, WFSM) comprising 2,452 cases and 3,772 controls. Genome-wide genotype data was derived from the Affymetrix HumanGenome 6.0 array imputed to a 1000 Genomes reference panel. Logistic regression with T2D as the outcome was modeled including rs10830963 dosage, age, sex, and principal component covariates. Joint effects were captured using the Kraft 2 degree of freedom test. Genome-wide significant (P<5x10^{-8}) interaction and joint effects were detected for the intronic SNP rs17197883 in *CMIP* ($P_{interaction}$=1.43x10^{-8}; P_{joint}=4.70x10^{-8}). *CMIP* variants have previously been nominally associated with T2D, fasting glucose, and adiponectin in individuals of East Asian (EAS) ancestry, and with waist-to-hip ratio adjusted for body mass index (BMI) in Europeans (EUR). In follow up cross-ethnic analysis, 54 SNPs in linkage disequilibrium (r^2>0.3) with 7 CMIP SNPs from the AfA interaction analysis (P_{joint}<10^{-6}) were tested for association with AIRg and BMI-adjusted insulin sensitivity (SI) in IRASFS Hispanic subjects (n=1,016). One SNP (rs880795) was nominally associated with SI (P=0.02), while none were associated with AIR_g. These data support the hypothesis that additional genetic factors contributing to T2D risk, including insulin sensitivity loci, can be identified by interactions with insulin secretion loci.

333F

Deep whole genome sequencing empowers and refines traditional eQTL studies. *A. Liu[1], H.M. Kang[1], M. Kretzler[1], V. Nair[1], R. Nelson[2].* 1) Biostatistics, University of Michigan, 1415 Washington Heights, ANN ARBOR, MI; 2) NIDDK, Phoenix Indian Medical Center, 4212 North 16th Street, Phoenix, AZ 85016.

Traditional expression quantitative trait loci (eQTL) studies based on microarrays have successfully identified tremendous numbers of cis-acting associations between genetic variants and expression levels. However, because microarrays estimate gene expression levels from a limited number of exon-overlapping probes, it is well known that reference bias in probe sequences containing genetic variants create false positive cis-eQTLs. However, it is impossible to distinguish such false positive cis-eQTLs completely without knowing all genetic variants polymorphic in the samples. This has been a challenge in our eQTL studies of Pima diabetic nephropathy cohorts with renal expression data from glomerular and tubular tissues collected at two time-points over 8 years. Because Pima Native Americans are genetically distant from populations with European and African ancestry, there are many population-specific variants that would not have been discovered without deep genome sequencing. Recently we deeply sequenced 97 subjects to perform a comprehensive cis-eQTL association analysis across nearly all genetic variants. Here we demonstrate that the availability of deep genome sequence data empowers and refines existing eQTL studies, allowing for correction of reference-bias in variant-overlapping probes. With over 10 million variants genotyped from 97 deeply sequenced genomes, we comprehensively identified a subset of probes overlapping with variants that are polymorphic in the Pima study cohort, and re-normalized the expression data excluding 26,743 probes across 12,970 genes and performed eQTL studies. Surprisingly, we observed that even recent Affymetrix Expression (HuGene 2.1 ST) array platforms have substantial overlap (12.4%) between probe sequences and variants polymorphic in the Pima cohort which is more than the overlap (6.1%/7.7%) of earlier-generation arrays (HG-U133A/HG-U133 Plus 2.0). When performing eQTL studies excluding these probes, we were able to eliminate 63 potentially spurious cis-eQTL genes affected by variants-in-probe effect, confirmed by heavily imbalanced direction of effect sizes consistent to reference bias. Moreover, we were able to identify additional 67 cis-eQTL genes that are largely tissue-specific. As the cost of deep sequencing rapidly decreases, re-visiting microarray-based eQTL studies with deeply sequenced genomes will refine our understanding of the shared and tissue-specific architecture of eQTLs in more population-specific manner.

334W

A T2D case-control study in Africans of Zulu origin. *M. Sun[1], J. Chen[2], A. Morris[1], F. Pirie[3], A. Motala[3], M. Sandhu[3], M. McCarthy[1], I. Barroso[2], A. Mahajan[1], E. Wheeler[2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 3) University of KwaZulu-Natal, Nelson R Mandela School of Medicine, 419 Umbilo Road, Congella, Durban 4001, South Africa.

Genome-wide association studies (GWAS) and follow up meta-analyses have identified nearly 100 susceptibility loci that show robust evidence of association with type 2 diabetes mellitus (T2D). However, these studies are predominantly in samples of European or Asian ancestries. African ancestry populations are still under-studied and need more representation (i) to find variants specifically associated with African populations; and (ii) to facilitate fine mapping of the causal variant(s). To support these aims, we conducted a GWAS of 1602 T2D cases and 976 controls (Durban diabetes case control study) in African subjects of Zulu origin collected in Durban, South Africa. Samples were genotyped using a customized Illumina Multi-Ethnic Genotyping Array which leverages content discovered in several sequencing consortia and databases e.g. the 1000 Genomes Project, CAAPA Consortium, PAGE, and includes European, Asian, Hispanic, African and multiethnic exome content. Samples were imputed up to the 1000 Genomes phase 3 reference panel (October 2014 release). We tested variants for association with T2D using a linear mixed model to account for cryptic relatedness and population structure. We found two loci reaching conventional genome-wide significance ($p < 5x10^{-8}$) and a further four loci with $p<5x10^{-7}$. One genome-wide significant locus mapped to a region outside an established T2D loci [rs79276081 intergenic variant, $p=2.5x10^{-8}$, minor allele frequency (MAF) =1.4% in our data]. The other mapped to the *INS-IGF2* region for which previous association has been seen in African-Americans: the lead variant in our analysis, rs6578990 ($p=2.5x10^{-8}$, MAF=39%) was located 8.4kb from the previously-reported T2D GWAS index SNP rs3842770 (p= 0.01, MAF=29% in our data). In African individuals, the two variants are in weak LD ($r^2<0.2$), indicating either multiple signals or refined localization of the causal variant by our study. Both variants in are rarer (MAF<2.0%) in non-African populations. In addition, seven lead GWAS variants from established T2D susceptibility loci were associated with T2D (p<0.05) and show directionally consistent effects, the strongest signal being observed at *TCF7L2* ($p=1.0x10^{-6}$). Despite the modest sample size of this study, our results highlight the importance of performing GWAS in African ancestry populations which have not been widely studied to date. However, further expansion of sample sets is needed to support replication and meta-analyses.

335T

Estimation of the prevalence of classic galactosemia based on the gene frequency in next-generation sequencing data. *D. Wang[1], J. Johnston[2], A. Cashion[1], L. Biesecker[2].* 1) NINR/NIH, Bethesda, MD; 2) NHGRI/NIH, Bethesda, MD.

Purpose Classic galactosemia is a rare autosomal recessive disorder caused by deficiency of galactose-1-phosphate uridyltransferase (GALT), due to mutations in the *GALT* gene. To date, more than 300 mutations in *GALT* have been associated with GALT deficiency. In US, the incidence of classic galactosemia determined by newborn screening is about 1/50,000, though the exact prevalence is unknown. We analyzed the *GALT* variants in three cohorts of exome sequence data to estimate the prevalence of the disorder. Methods We evaluated the *GALT* variants from the ClinSeq cohort (n=1001) and the NHLBI GO Exome Sequencing Project (ESP) cohort (n= 6,503) or the Exome Aggregation Consortium (ExAC) cohort (n= 60,706). Pathogenicity of each variant was determined based on the latest ACMG Variant-Interpretation Guidelines (2015). The disease prevalence was estimated based on the frequency of the pathogenic/likely pathogenic variants using Hardy-Weinberg equilibrium. A second method was based on the allele frequency of the p.Q188R variant which accounts for 62.8% of all disease-causing alleles in European Americans (EA) patients. Results We identified 16 pathogenic/likely pathogenic variants in the ClinSeq and the GO ESP cohorts. The disease prevalence was estimated to be 1/ 53,120 (95% CI 1/29,901-1/99,012) in EA and 1/59,896 (95% CI 1/24,044 – 1/170,330) in African Americans (AA). Based on the allele frequency of the p.Q188R variant in the two cohorts, the prevalence in EA was estimated to be 1/60,790 (95% CI 1/33,556 -1/115,929). A total of 47 pathogenic/likely pathogenic variants were identified in the ExAC cohort and the majority of the variants were population-specific. The estimated disease prevalence varies greatly in different populations with the highest in AA (1/33,057, 95% CI 1/19,837-1/56,689) and the lowest in East Asian Americans (1/2,993,259, 95% CI 1/550,326-1/28,293,345). Based on the allele frequency of the p.Q188R variant in the cohort, the prevalence in EA was estimated to be 1/92,018 (95% CI 1/70,695 – 1/120,898). Our results suggest that analysis of gene frequency using next generation sequencing data is a powerful and unbiased approach to estimate prevalence of autosomal recessive diseases based on precise categorization of variants. The data also provide an explanation for the widely varied incidences of classic galactosemia in different countries, suggesting that different mutations are mainly responsible for GALT deficiency in different populations.

336F

Detecting differences in longitudinal gene expression profiles in Cesarean section in the first year of life. *M. Laimighofer[1,2], R. Puff[4], R. Fürst[4], F. Theis[1,2], A. Ziegler[4], J. Krumsiek[1,3].* 1) Institute of Computational Biology, Helmholtz Zentrum München, Munich, Bavaria, Germany; 2) Department of Mathematics, TU Munchen, Garching, Germany; 3) German Center for Diabetes Research (DZD), Munchen-Neuherberg, Germany; 4) Institute of Diabetes Research, Helmholtz Zentrum Munchen and Forschergruppe Diabetes, Klinikum rechts der Isar, Technische Universitat, Munchen, Germany.

   Background: Cesarean section (CS) is a surgical procedure that was originally introduced to diminish maternal and fetal birth complications. However, changes in the social, demographic, and economic characteristics of pregnant women as well as alterations in the health care systems have led to a continuous increase of CS over the last two decades. As previously reviewed, the mode of delivery affects the developing immune system by influencing the perinatal programming, thereby causing short- and long-term effects on the offsprings' health. In line with these immunological alterations, CS is associated with a higher risk for autoimmune disorders such as type 1 diabetes (T1D). We are interested in the difference between gene expression profiles during the first year of life after CS or vaginal delivery. **Data:** Peripheral blood mononuclear cell (PBMC) gene expression profiles were measured using microarrays in 108 children, 62 of them born by vaginal delivery and 46 by CS. These measurements were repeated in time and resulted in overall 450 genome-wide transcriptome samples. Restricting to the first year of life, 154 samples were used for this analysis. **Methods**: In order to investigate time-resolved gene expression differences after CS, the following generalized mixed model was fitted per gene: A time correction was performed by adding a spline effect for sample age, a random effect was introduced to account for repeated measurements per child, and a group term for CS versus vaginal delivery was added to capture the effect of interest. Including functional knowledge about genes, we performed a gene set enrichment analysis to identify CS-affected pathways. **Results:** At global transcriptome level and univariate gene level, we could not identify significant effects of CS. However, at pathway level, we obtained a series of significant associations. Pathway enrichment was performed on KEGG pathways and GO slim biological processes. We found significant associations with CS for the pentose phosphate pathway, pyrimidine metabolism and the generation of precursor metabolites. **Conclusion:** Our study shows that there is a systematic impact of CS on the early PBMC transcriptome. Future work should attempt to delineate how these molecular changes translate to an increased risk of autoimmune diseases such as T1D.

337W

Detection and correction of pleiotropic bias in multivariable Mendelian randomization. *C. Chen[1,2,3], M. Verbanck[4], R. Do[4], B. Neale[1,2,3].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 4) Icahn School of Medicine, Mount Sinai Hospital, New York, NY.

   Inferring the causal relationships between a disease outcome and associated traits is essential to understanding disease etiology and the development of treatments. Mendelian randomization (MR) is a widely used method that uses genetic variants as instruments to obtain estimates of causal effects. With the increasing number of disease-associated loci identified by genome-wide association and sequencing studies, methods have been developed to aggregate causal effect estimates from multiple MR analyses, such as Multivariable MR (Do et al. 2013 Nat. Genet.) and MR-Egger regression (Bowden et al. 2015 Int. J. Epidemiol.).   A key assumption of MR analysis is exclusion restriction, which states that the genetic instrument solely acts on the disease outcome through the risk factor. However, pleiotropy is a pervasive phenomenon in human genetics. Consequently, Multivariable MR approaches are increasingly subject to violations of the exclusion restriction assumption. We propose a diagnostic test for detecting unaccounted pleiotropic effects across the set of genetic variants that are included in a Multivariable MR analysis. Specifically, we test for excess variance in the residuals of the Multivariable MR regression analysis. To evaluate the sensitivity of this approach, we performed a series of simulations with and without pleiotropic effects of the genetic variants. Our simulations showed that inverse-variance weighted meta-analysis, which assumes all genetic variants have no pleiotropic effect, gives biased results. Both MR-Egger regression and Multivariable MR showed similar ability to control for pleiotropic bias. These simulations also demonstrated that our method can identify the presence of SNPs with pleiotropic effects. The key parameters that drive the power to detect such pleiotropy are number of instruments, variance explained of the intermediate risk factor and the degree of pleiotropy. Following the detection of pleiotropic variants, outlier identification and robust regression were performed to correct for pleiotropic bias. We applied our method to a multivariable MR analysis of the causal effects of plasma lipids on coronary artery disease and type 2 diabetes, and found no significant pleiotropic bias. Our method improves on existing approaches to multivariable MR analysis by reducing the chance of incurring pleiotropic bias.

Genome-wide association study of quantitative liver fat from the UK Biobank identifies loci that may contribute to fatty liver disease. *M.R. Miller[1], T. Tuthill[1], K.A. Loomis[1], O. Dahlqvist Leinhard[2,3], C.L. Hyde[1].* 1) Human Genetics and Computational Biomedicine, Pfizer, Inc, Cambridge, MA; 2) Linköping University, Sweden; 3) Advanced MR Analytics AB, Linköping, Sweden.

  Introduction: The UK Biobank is a large population based resource with clinical information, medical records and genotype information on 500,000 subjects. Whole body magnetic resonance (MR) images have been collected on ~9000 subjects, and measurements of adiposity, liver fat and muscle volume have been quantified. The imaging data, in conjunction with clinical data and medical records can help to better define obesity-related phenotypes, such as non-alcoholic fatty liver disease (NAFLD) and to identify genetic loci that may contribute to these phenotypes. NAFLD is associated with liver fat accumulation, and can lead to inflammation and fibrosis (non-alcoholic steatohepatitis; NASH). Both NAFLD and NASH have a high burden of disease and no approved treatments. Because of the difficulty in obtaining liver fat biopsies or quantitative measures of liver fat, very few GWAS of liver fat or NAFLD have been performed. Identification of new loci for liver fat based on MR imaging may point to mechanisms of disease.   **Methods**: A genome-wide association study of quantitative liver fat was performed via linear regression on 1467 European subjects from the UK Biobank with MRI and genotyping data available. The model was adjusted for age, sex, BMI, type 2 diabetes status, and daily alcohol consumption.   **Results:** We confirmed GWAS associations of liver with *PNPLA3* (rs738409; $p = 6.31 \times 10^{-15}$) and *TM6SF2* (rs58542926; $p = 3.71 \times 10^{-10}$), both established liver fat/NAFLD genes. While no additional genome-wide signals were identified, one suggestive signals was also identified on chr10 in the region of EMX2 and EMX20S (rs74743905, $p = 6.213 \times 10^{-07}$).   **Conclusions**: A genome-wide association study on a relatively small sample of subjects was able to confirm two previously identified GWAS loci for liver fat, demonstrating that MR imaging of liver fat can be used to identify genetic loci that may contribute to metabolic diseases. As the size of the imaging cohort in the UK biobank increases, the UK Biobank will be a valuable resource to identify additional genetic targets for liver fat. In addition, the UK Biobank will continue to be a valuable resource for scientific discovery and precision medicine by enabling integration of individual level genetic and multi-dimensional phenotypic data.

Association study of rare variants on serum urate level by using whole genome cohort study samples. *K. Misawa[1], T. Hasegawa[1,2], K. Kojima[1], Y. Kawai[1], A. Hozawa[1], T. Takai[1], N. Fuse[1], N. Minegishi[1], J. Yasuda[1], S. Ogishima[1], S. Kure[1], K. Kinoshita[1], M. Yamamoto[1], M. Nagasaki[1].* 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Health Intelligence Center, Institute of Medical Science, University of Tokyo, Minato-ku, Tokyo, Japan.

  Gout is one of the most common inflammatory arthritides, and is caused by hyperuricemia. A twin study showed that the heritability of serum uric acid levels (SUL) and gout are approximately 50 %. However, only 6 % of genetic factors for SUL and gout can be explained by known genetic variation. Unknown low-frequency and rare variants msut contribute to the missing heritability. The Tohoku Medical Megabank Organization (ToMMo) has sequenced 1,070 whole genomes of Community Resident Cohort participants. To identify low-frequency and rare variants that affect SUL, we utilized this data. A linear regression model as well as a sequence kernel association test (SKAT) was used to analyze the associations between serum uric acid levels and SNP genotypes by incorporating age, sex, and body mass index (BMI). We identified novel rare variants with genome-wide significance associated with SUL. Fifteen percent of genetic variation in SUL was explained by these novel and known variants.

340W

Integration of whole genome sequence and epigenomic data highlights regulatory activity in the genomic architecture of glycemic traits. *A. Manning[1], S. Lent[2], M. Jones[3], CHARGE, GoT2D/T2D-GENES.* 1) Center for Human Genetics Research, Massachusetts General Hospital, Boston, MA; 2) School of Public Health, Boston University, Boston, MA; 3) Cedars-Sinai Medical Center, Los Angeles, CA.

Studies of common genetic variants have identified many loci associated with type 2 diabetes (T2D) and glycemic traits that fall outside of protein-coding regions, implicating gene regulation as the causal mechanism. We hypothesize that by integrating diabetes physiology in appropriately designed association tests for whole genome sequence (WGS) data, we will reveal novel underlying molecular mechanisms pointing to new therapies for T2D and insulin resistance. We analyzed WGS data (6-fold average depth) from 2,854 European, non-diabetic individuals from 3 CHARGE cohorts (FHS, CHS and ARIC). With the hypothesis generating nature of the approach in mind, we limited analysis to 69 loci previously associated with glycemic trait levels. We performed targeted replication of CHARGE findings in WGS data with 1,400 non-diabetic individuals from GoT2D. Our genetic association models accounted for family structure and used inverse-normalized covariate-adjusted fasting glucose (FG) and log-transformed fasting insulin (FI) levels, with additional refinement to account for possible interaction by obesity. We aimed to (1) fine-map common variant associations, (2) discover independent common (minor allele frequency [MAF]>5%), low-frequency (0.5%<MAF<5%) and rare (MAF<0.5%) genetic associations in these regions, and (3) using publicly available data from the Roadmap Epigenomics Project, perform rare variant associations using SKAT of active regulatory elements in pancreas, liver, adipose and skeletal muscle tissue. We found 267 loci with nominal (P<0.0001) single variant associations with FG and/or FI levels, within which 34 independent variant associations were observed (14 common, 6 low-frequency and 14 rare). Only 2 of the common variants replicated with P<0.01 in GoT2D. In rare variant tests of active transcription marks (H3K27ac, H3K4me1 and H3K4me3), 25 loci showed nominal (P<0.001) associations with either the same trait as previously reported for the locus or both FG and FI. Replication in GoT2D showed rare variant associations of non-coding variants (SKAT P<0.01) at the *SLC10A6*, *ADCY5* and *PCSK1* loci (with epigenomic peaks observed in multiple tissues). Although sample sizes are small in the current analysis, we have increased our understanding of the genomic architecture of glycemic traits and demonstrated the validity of performing rare variant tests for FG and FI in the non-coding genome using epigenomics data in tissues implicated in T2D and insulin resistance.

341T

Analysis of population specific pharmacogenomic variants using next generation sequencing data. *T. Park[1], E. Ahn[2], Y. Kim[2,3], B-J. Kim[3], T2D Genes Consortium.* 1) Department of Statistics, Seoul National University, Seoul, South Korea; 2) Interdisciplinary Program of Bioinformatics, Seoul National University, Seoul, South Korea; 3) Division of Structural and Functional Genomics, Center for Genome Science, Korean National Institute of Health, Osong, Chungchungbuk-do, South Korea.

The analysis of population differentiation (PD) in pharmacogenomic variants provides an insight on the ethnic sensitivity of drug responses. The analysis of PD for common variants has been successfully performed by using Fst or chi-square test. However, the analysis of PD for rare/less-common variants has rarely been performed. In this study, we aim to perform PD analysis of rare variants to identify the drug-related genes (pharmacogenes). We first show that Fst and chi-square test used for common variants are not suitable for rare variants. We then suggest a new gene-based PD method for handling rare variants inspired by the Generalized Cochran-Mantel-Haenszel statistics. Through simulation studies, we reveal that the proposed PD method adequately summarizes the rare and common variants for PD over a gene. We also apply the proposed method to the real whole exome sequencing dataset which consists of 10K data from Type 2 Diabetes Genetic Exploration by Next-generation sequencing in multi-Ethnic Samples (T2D-GENES) and 3K data from Genetics of Type 2 diabetes (Go-T2D) samples. Among the 48 genes that are annotated with very important pharmacogene summary in PharmGKB database, our PD method identified 7 novel candidate genes including CYP2B6, ACE, and SCN5A. These three genes were previously reported as being highly differentiated in expression levels, but PD of them has not been identified via Fst, which supports the validity of our proposed method through literature review.

342F

Genome-wide association analysis identifies multiple loci associated with kidney function-related traits in Korean populations. *N. Heo[1], Y. Lee[1], J.E. Lee[2], E.S. Shin[2], M.S. Jang[2].* 1) Healthcare System Gangnam Center, Seoul National University Hospital , Seoul, South Korea; 2) DNA Link, Inc., Seoul, South Korea.

   Background/Aims: Chronic kidney disease is a significant public health problem, and the assessment of genetic factors influencing kidney function has substantial clinical relevance. Here, we report an analysis of genome-wide association studies for kidney function–related traits in Korean. **Methods:** We performed a genome-wide association study for kidney function–related traits in large Korean population based samples of 7,999 subjects. We investigated SNPs that are associated with kidney function–related traits, including the concentrations of blood urea nitrogen and estimated glomerular filtration rate based on serum creatinine level. **Results:** We identified 5 previously known loci and 6 new loci associated with kidney function–related traits at the genome-wide significance level (P<10[-7]). After adjusting for age, sex, hypertension and diabetes, four loci, Rs12702509 (UNCX), rs12776722 (METTL10), rs10175462 (PAX8), and rs 9687753 (ANKHD1) were newly identified as loci associated with blood urea nitrogen. And our analysis identified three loci, Rs2390793 (LRP2), rs12702509 (UNCX), and rs144503008 (SSBP3) which were newly associated with glomerular filtration rate after adjusting for age, sex, hypertension and diabetes. Rs12702509 is associated with both blood urea nitrogen and estimated glomerular filtration rate. **Conclusions:** We identified associations among these loci with kidney function–related traits. These findings provide new insights into the susceptibility to CKD and genetics of kidney function. In future studies, we will further examine the association of these loci with CKD trait in the other cohort for validation.

343W

Increased power for sequence-based case-control genome-wide association studies by including external controls. *D. Ray, P. Yajnik, M. Boehnke.* Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

   Genome-wide association studies (GWAS) routinely employ the case-control study design for binary traits like disease status. For diseases with low/moderate prevalence, perfectly ascertained controls may be replaced or supplemented with publicly available datasets that have dense genotype measurements but no (or poor) information about disease status. Inclusion of external controls increases sample size but may misclassify some affected individuals as controls. Edwards et al (2005) determined power for association analytically when such misclassification is present. As publicly available datasets become larger, inclusion of external controls matched for ancestry and genotyping quality may substantially increase power without affecting type I error (Ho et al, 2010). Keeping the financial cost fixed at the cost of a case-control study with perfectly ascertained n cases and n controls (reference design), we consider two study designs that make use of N external controls in addition to either (i) n cases and n controls (design A) or (ii) $2n$ cases and 0 controls (design B). We make the simplifying assumptions that the external controls were sampled randomly from the same population as the study individuals (so that they have the same genetic ancestry, and the proportion of external controls who are truly affected equals the disease prevalence) and that there are no systematic differences in batch genotype effects. We evaluated the performance of these study designs compared to the reference design. For our simulations, we fixed $n=2500$, the odds-ratio to 1.15, the minor allele frequency to 0.2, and varied N to be 2500, 3500, 5000 or 7000 and prevalence to be 0.1, 0.2, 0.3 or 0.4. Our initial results focus on power; eventually we plan to focus on effective sample size. In general, for a fixed N, powers of the studies decrease with increasing disease prevalence (equivalently, increasing mislabeling). For prevalence 0.2 or less, design A is more powerful than the reference design regardless of the value of N, and greater power gain is possible by sequencing more cases. Greatest power gain is achieved using design B if N is at least as large as the number of study individuals. In summary, we show that one can substantially increase power for association by including external controls when disease prevalence is not too large. The choice of the external control size is governed by disease prevalence and the number of available internal and external study individuals.

iFunMed: Integrative functional mediation analysis of GWAS and eQTL.
C. Rojo[1], Q. Zhang[3], S. Keles[1,2]. 1) Department of Statistics, University of Wisconsin-Madison, Madison, WI; 2) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI; 3) Department of Statistics, University of Nebraska-Lincoln, Lincoln, NE.

Genome wide association studies (GWAS) are widely used to elucidate genetic variation associated with disease and traits. When combined with genome-wide expression quantitative loci analysis (eQTL), these studies have the potential to identify genetic variants that modulate disease or trait phenotypes through their impact on expression of specific genes. Two challenging aspects of these studies are: high dimensionality of the variant space and that most candidate genetic variants are in non-coding regions making their interpretation challenging, if not impossible. We develop a novel mediation analysis framework, named iFunMed, to integrate genome-wide association studies and the expression quantitative loci (eQTL) studies with the effective utilization of publicly available functional annotation data.   iFunMed extends the scope of standard mediation analysis framework by incorporating information from multiple genetic variants at a time by utilizing variant-level summary statistics. Furthermore, this integrative framework incorporates the regulatory information encoded in functional annotation data to elucidate how top-ranking association SNPs might be modulating gene expression. A key aspect of iFunMed is its ability to select annotations that are most relevant to the data and cluster them appropriately into a reduced number of groups with a more homogenous biological context . iFunMed has the power to identify mediation potential of genes, estimate direct and indirect effect of each SNP for the trait, and identify relevant functional annotations impacting direct and indirect effects of the SNPs.   We applied our method to Framingham Heart Study data of diabetes for 1,663 subjects focusing on regions with 153 known GWAS hits and within 1MB from each transcript resulting in a total of 525,168 SNPs and 17,873 transcripts from whole genome sequencing. We used 642 epigenomic annotations from the ROADMAP Epigenomics Project and 10 annotations derived in a gene-centric way using GENCODE data. This large scale analysis identified many genes with significant mediator effects. Among these is *PPT1* which is highly expressed in mouse pancreatic islets.

345F

Empirical heritability estimates for body mass index in American Indian sibships. *R.L. Hanson, W.C. Hsueh, S. Kobes, W.C. Knowler, L.J. Baier.* DECRS, NIDDK, Phoenix, AZ.

Genome-wide association studies (GWAS) have identified numerous variants associated with body mass index (BMI), but these associations only explain a small fraction of the currently estimated genetic heritability. One potential explanation is that classical heritability estimates, which are based on expected allele sharing in relatives, can be confounded by shared environmental factors, whereas estimates which employ empirically observed measures of the proportion of alleles shared identical by descent (IBD) within sibships are robust to such confounding. We employed this empirical approach to estimate heritability for BMI in 4462 American Indians, constituting 1508 sibships and 5855 sibling pairs, who had participated in a longitudinal study. A GWAS was performed using a custom Axiom array and IBD allele sharing was estimated for 506,627 autosomal SNPs using the program IBDLD. Actual IBD allele sharing in sibling pairs was taken as the average of observed IBD allele sharing across all SNPs. The maximum age-sex standardized BMI Z-score observed in the longitudinal study was analyzed with adjustment for age at maximum score, sex, birth year and the 1st 5 principal components from the GWAS. Variance components methods were used to obtain the classic heritability estimate (h^2, based on expected IBD sharing), and to further partition familial resemblance into a genetic component (a^2 reflecting actual IBD sharing) and a common sibling component (c^2, presumably reflecting shared environment). Mean IBD allele sharing among all sibling pairs was 0.50 with SD=0.04. BMI was highly familial with h^2=0.68 (P=2.0×10[-106]) by the classic estimate; when this familial resemblance was partitioned by analyzing actual IBD sharing, the genetic component was significant (a^2=0.49, P=0.027) while the common sibship effect was not (c^2=0.09, P=0.24). When analysis was restricted to individuals who had been examined when they were not diabetic (n=4183), similar results were obtained: h^2=0.71 (P=1.2×10[-103]), a^2=0.56 (P=0.015), c^2=0.07 (P=0.31). These analyses are consistent with the hypothesis that familial resemblance of BMI largely reflects the effect of genetic factors; the fact that established variants account for little of the heritability may be indicative of the polygenic nature of obesity.

Multiple lysosomal storage disease newborn screening in a Mexican cohort of patients: Results and follow-up from the Pemex Health System Newborn Screening Program. *J. Navarrete[1], D. Cervantes[1], A. Limon[2], G. Wakida[2], R. Delgado[3], C. Cantu[4], H. Cruz[4], M. Gaytan[1].* 1) Dept Gen, Hosp Sur PEMEX, Mexico City, Distrito Federal, Mexico; 2) Dept Pediatrics, Hosp Sur PEMEX, Mexico City, Distrito Federal, Mexico; 3) Dept Pediatrics, Hosp Reg Villahermosa, Tabasco, Mexico; 4) Dept Gen, Genomi-K Laboratories, Monterrey, Mex.

Lysosomal storage disorders (LSDs) are a diverse group of over 50 inherited metabolic disorderes, that result in cellular disfunction and multiple organ damage due to a progressive accumulation of metabolic precursors within the lysosomes, secondary to reduced or lack of a lysosomal enzyme. The prevalence of these conditions had been shown to be more frequent than previously expected. With a collective estimated incidence of 1 in 7,000 to 9,000 live births, pilot newborn screening studies revealed unexpected LSD higher frequencies. Petroleos Mexicanos is a big governmental institution with approximately ten thousand workers and their families. Since 2005 a larger screening test has been done to all newborns in this institution through all the country. We test for most aminoacidpathies including acidurias, hemoglobinopathies, G6PD deficiency, adrenal hyperplasia, cystic fibrosis and biotinidase deficiency; since August 2 012 we included one immunodeficiency and 6 lysosomal storage diseases, Gaucher, Pompe, Fabry, Hurler, Niemann-Pick type A and B and Krabbe diasease. We analyzed our results from August 2012 to May 2015, we have found 5 newborns wtih Fabry disease, 5 patients with Pompe disease, 1 with Krabbe disease and 2 with Hurler disease. We describe our findings and compared with other populations, and we make a close follow up of all newborns with pathological mutations. and study and analize their families. We also look for biomarkers of the disease so we can start treatment depending of the mutation and the course of the disease as soon as possible. We present all our LSD patients, their mutations found and their families. We also present the patients that have started ERT and their follow up status.

347T

Population-level variability in adipose tissue cell-type composition and its link to obesity. *C.A. Glastonbury[1], K.S. Small[1], M. Civelek[2], A.J. Lusis[3].* 1) Twins Research & Genetic Epidemiology, King's College London, United Kingdom; 2) University of Virginia, United States; 3) UCLA School of Medicine, United States.

Adipose tissue biology impacts multiple complex traits, particularly those associated to obesity. Adipose tissue is a complex mixture of adipocytes, immune and non-immune cells. Obesity affects the cellular composition and inflammation of adipose tissue but due to the difficultly of flow-sorting adipose tissue, adipose cellular makeup and its relationship to phentoypic traits has been poorly explored. We sought to address this by computationally deconvolving the cell-fractions of primary adipose tissue biopsies from 766 healthy TwinsUK females using RNA-seq. First, we constructed a basis matrix from 7 purified adipose resident cells. Top basis matrix marker genes recapitulate well-known cell-specific genes such as *ADIPOQ*-Adipocytes, *VWF*-endothelial and *CXCR4*-Macrophages. We then estimated the proportion of these 7 cell types in the 766 biopsies using support vector regression. The dominant cell proportions were Adipocytes (μ=0.46, σ=0.09), Fibroblasts (μ=0.35, σ=0.07), Mesenchymal stem cells (μ=0.08, σ=0.01), Endothelial cells (μ=0.04, σ=0.01), M2 macrophages (μ=0.03, σ=0.01) CD4+ T-cells (μ=0.02, σ=0.006) and M1 macrophages (μ=0.007, σ=0.009). We derived cell-type estimates in two independent adipose expression datasets. METSIM samples from healthy Finns (N=200) recapitulated the cell-proportion distributions of TwinsUK but post-mortem GTEX samples (N=230) had poor deconvolution accuracy and highly variable cell-type prediction, potentially reflecting tissue fibrosis and prolonged ischemia. Macrophage infiltration into adipose tissue is known to correlate with obesity. We confirm this finding, showing that BMI and DXA derived visceral fat measurements correlate with M2 macrophages (r = 0.30, P = 2.2 x 10^{-16}) and the overall immune fraction (r = 0.29, P = 2.2 x 10^{-16}). Previous work has shown BMI has a large effect on the adipose transcriptome. To assess mechanistically BMI's association to gene expression, we ran a transcriptome-wide association study for BMI, with and without correcting for macrophage proportion. Without adjustment, 85% of genes are associated to BMI (FDR 5%), but 40% of expression associated with BMI is lost after correcting for Macrophage proportion, and those genes are enriched for the immune response (P=2.4 x 10^{-4}). Finally, we uncover 134 additional *cis*-eQTLs after correcting for macrophage estimates (FDR5%), showing that power to detect local genetic effects can be enhanced by accounting for cellular heterogeneity in tissues.

348F

Genetic and environmental overlap between uncontrolled eating and obesity. *U. Vainik[1,2], R. Mõttus[3,2], C. Kandler[4], A. Dagher[1].* 1) Neurology & Neurosurgery, Montreal Neurological Institute, Montreal, Quebec, Canada; 2) Institute of Psychology, University of Tartu, Tartu, Estonia; 3) Department of Psychology, University of Edinburgh, UK; 4) Department of Psychology and Sports Sciences Bielefeld University, Bielefeld, Germany.

Uncontrolled Eating (UE) is a core component in many obesity-related psychological traits. Longitudinal data has shown that increases or decreases in weight are often mirrored by concurrent changes in UE, and targeting UE with cognitive interventions might reduce BMI. Given this covariation, we assessed the genetic and environmental overlap between UE and obesity in the Bielefeld Longitudinal Study of Adult Twins (975 monozygotic and 493 dizygotic twins) using twin ACE models (A = additive genetic effects, C = shared environment effects, E = unshared environment effects). UE was assessed by a single question "I tend to eat too much of my favorite food."; this question has been previously shown to relate strongly to other measures of UE. Heritability was high for obesity (A=0.83 [0.81, 0.85], C=0 [0.13, 0.13], E=0.18 [0.19, 0.15]) and considerably lower for UE (A=0.25 [0.14, 0.4], C= 0.07 [0, 0.3], E=0.69 [0.61, 0.76]). Still, there was a large genetic correlation between UE and BMI (r= 0.81 [0.71, 0.91]). Therefore, UE does seem to share considerable genetic component with obesity. As a next step, other methods, such as narrow sense heritability should be used to clarify the extent of overlap between UE and obesity.

349W

Multi-association analysis identifies T2D variants in the Korean population-based cohort. *J. Lee, M. Go, Y. Lee, B. Kim.* Structural & Genomics, Centers Disease Control, Osong, South Korea.

Type 2 diabetes mellitus (T2D) is a multi-factorial polygenic disease. To date, T2D Genome-wide association studies (GWAS) and meta analysis loci (~ 80) are insufficient to dissect the complex genetic structure underlying etiological heterogeneity. Epistasis has long been suggested to be important to understanding of the missing heritability problem. To identify epistatic effects on T2D, we conducted a multi-association analysis as complementary to the current single SNP-based GWAS. By using community-based cohort, we selected several variables for examining multi traits-unit SNP association; glycated hemoglobin (HbA1C), Fasting plasma glucose (GLU0), plasma glucose 2-hour after ingestion of 75g oral glucose (GLU120). We composed trait set and examined multi traits-unit SNP association with age and sex as the covariates. Our study confirmed previously reported T2D loci (CDKAL1, C2CD4A etc). These results could provide additional insight into the genetic regulation of T2D but require further replicative efforts to confirm the findings.

350T

Genetic variation underlying self-reported weight-loss success in the presence of a dietary intervention. *J.F. Shelton, N.A Furlotte, R. Smith, C. Wheldon, M.N. Johnson, C. Wilson, G. Benton, R. Gentleman. 23andMe, Mountain View, CA.*

   Genetic variation underlying obesity and adiposity are well established, but recent studies have also identified variants that confer different response to diet and exercise. For example, variants in the FTO and MTIF3 genes are associated with differential weight loss in response to caloric restrictions, but variants in the ADRB [2 and 3], FABP2, PPARG, and APOA [2 and 5] genes may be associated with differential weight loss in response to reductions in macronutrients such as fat and carbohydrates. Using a web-based question-naire, we asked 100,000 23andMe consented research participants to detail their dieting (lifetime and past-year) experience. Participants answered questions on restriction of certain food and beverage groups, exercise frequency, duration of diet, adherence to diet, and dietary outcomes based on self-report-ed goals achieved and weight lost. Participants were selected without regard to previously reported body mass index. Of those who responded (n=9,858), 85 percent reported that they had dieted, and 62 percent reported dieting in the past year. Of those who had ever dieted, 12 percent reported never being able to lose weight. Among those who had dieted in the past year, 66 percent reported not being able to achieve their weight-loss goals. Using nine SNPs (rs801282, rs1799883, rs1885988, rs662799, rs9939609, rs5082, rs4994, rs1042713, and rs1137101) previously identified to have a role in differential response to weight-loss interventions, we evaluated the relationship between genotype and the percentage of body weight lost in the past year. For SNPs associated with carbohydrate or fat metabolism, we built models with interaction terms, controlling for other factors affecting the percent of weight lost from baseline. Stricter adherence and longer duration of the diet were predictive of greater weight loss. Preliminary findings show that among people with strict adherence to their diet — and controlling for exercise, duration of the diet, age, sex, and population stratification variables — the GG variant of rs662799 (APOA5) was associated with a five percent greater weight loss in the presence of a fat restriction among women but not men. An internal replication study will be conducted prior to publication of findings. These results indicate that while behavioral changes are the main drivers of weight loss, genetic variation may explain some differences across individuals.

351F

Whole genome sequencing identifies functional founder effect variants associated with CVD traits in the Norfolk Island isolate. *L.R. Griffiths[1], M.B. Benton[1], H.G. Sutherland[1], D.E. Eccles[1], L.M. Haupt[1], S. Stuart[1], J. Blangero[2], J. Curran[2], R.A. Lea[1]. 1) Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Queensland, Australia; 2) The University of Texas Rio Grande Valley, Harlingen, Tx.*

   Background: Genetic isolates have distinct advantages for mapping gene variants that influence complex traits. Founder effects in particular can amplify the frequency of ancestrally rare variants, which in turn, can contribute to an increased prevalence of disease in the isolated population. The Norfolk Island (NI) population is a genetic isolate located off the east coast of Australia. Founded by 11 British mutineers of the HMS Bounty and 6 Polynesian women in the late 1700s the NI population is comprised of a unique 6000-member pedigree spanning 11 generations. We have previously shown that the existing NI population exhibits higher rates of several cardiovascular disease risk traits compared to mainland Australia. In this study we aimed to identify functional founder effect variants associated with CVD traits in the NI isolate.   **Methods:** We performed whole genome sequencing (WGS) of 108 individuals selected from the core founder pedigree using the Illumina HiSeq X10. We first parsed the sequence data through an in-house pipeline using BOWTIE2, SAMTOOLS, VCF, VEP. Secondly we prioritised variants based on being a) probably damaging according to 5 in-silico functional tests b) founder effect variants based on MAF >5% in NI and MAF <1% in the 1000G cohort c) associated with CVD traits.   **Results:** WGS analysis showed an average of >25X coverage. In total we identified 13.4M variants of which 96% are SNVs and ~5.3M variants are unique to NI. Variant prioritisation identified 11 functional founder effect variants. The top ranked variant was rs77408762 that codes a TYR-to-ASN change in the Acyl-CoA Thioesterase 4 (*ACOT4*) gene. The ASN variant was present at 26% in the NI cohort but was rare or absent in the ancestral cohorts European (0.9%) and East Asian/Polynesian (0%). This suggests that this founder effect allele originated specifically from England and was transferred to NI via the Bounty Mutineers. Interestingly *ACOT4* is involved in lipid metabolism and we found evidence that the *ACOT4*-ASN variant is significantly associated with altered HDL, LDL levels as well as body fat indices in the NI cohort.   **Conclusions:** This study has used a customised WGS approach to identify a panel of functional founder effect variants in the NI isolate. Furthermore, we provide evidence for a novel association between *ACOT* and CVD risk traits in NI highlighting the potential of this genetic isolate for uncovering previously undetected variants for CVD using this approach.

A novel mutation in *HEXB* that causing Infantil Sandhoff Disease. *N.H. Akcakaya[1], O. Ozdemir[1], S.A. Ugur-Iseri[1], E. Yucesan[1], P. Tekturk[2], G. Gokcay[3], U. Ozbek[1], Z. Yapici[2].* 1) Istanbul University, Aziz Sancar Institute of Experimental Medicine, Department of Genetics, Istanbul, Turkey; 2) Istanbul University, Istanbul Medical Faculty, Department of Neurology, Division of Child Neurology, Istanbul, Turkey; 3) Istanbul University, Istanbul Medical Faculty, Department of Pediatrics, Division of Metabolic Disorders, Istanbul/Turkey.

   Introduction: Hexosaminidase beta subunit (*HEXB*) gene encodes a lysosomal enzyme. The mutations in *HEXB* leads neuronal damage due to the accumulation of GM2 ganglioside. This lysosomal storage disease named Sandhoff disease (SD) and has three forms (infantile, juvenile, and adult forms). Infantile SD starts between 3-6 months of life and causes death within a few years. In the course of SD developmental delay, progressive decline of motor functions, hearing loss, cherry red spots, macrocephaly, and seizures observed.Methods and Results: Eighteen month of age male patient was admitted to neurology clinic with developmental delay, progressive decline of motor functions, and seizures. He had consanguineous parents. He was hypotonic since birth. He wasn't able to sit until six months of age and within two months mental and motor deterioration starts. Seizures was added at 15 month of age. He had doll-like face, cherry red spots, and macrocephaly. Brain MRI revealed low signal intensity symmetrical at bilateral thalamus in FLAIR and T2-weighted images and high signal intensity at white matter. Total hexosaminidase activity was very low but hexosaminidase A activity was normal.Whole exome sequencing revealed novel homozygous c.1538T>C; p.Leu513Pro (RefSeq. NM_000521) *HEXB* mutation. We confirmed the mutation by Sanger sequencing. Healthy parents were heterozygous carriers. The variant was absent in 350 unrelated healthy individuals from Turkey, who were exome- sequenced by TUBITAK-BILGEM. In silico tools were used and the amino acid substitution was predicted to have a damaging effect on the structure and function of the protein.Discussion: SD has enzymatic diagnostic test, usually genetic testing is not performed and so there are few known mutations. The *GM2A, GNPTG, GNPTAB, HEXA* genes are the related genes with Sandhoff phenotype but these genes did not carry any additional pathogenic variant in our patient. Our patients mutation was in one of the HEXB alpha helix structure that plays an active role in enzymatic function. It has been shown to be compatible with early involvement of radiological and clinical rapid progression. Identifying genetic variations that causes SD could enable to made genotype-phenotype correlation.This work was supported by the grant of Scientific Research Projects Coordination Unit of Istanbul University, Project Number: 51985 & Istanbul Development Agency, Project Number: TR10/15/YNK/0093. .

Multi-ethnic 1000G analysis of TG:HDL ratio in over 78,000 individuals from the CHARGE Consortium. *J.E. Huffman, The Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Lipids Working Group.* The Framingham Heart Study, NHLBI Population Sciences Branch, Framingham, MA.

   The ratio of triglyceride (TG) to high density lipoprotein (HDL) cholesterol has been shown to be highly correlated with insulin resistance and a strong predictor of type 2 diabetes. A glucose clamp procedure or frequently sampled intravenous glucose tolerance test provide a measurement of insulin resistance but are not routinely done in large numbers of subjects due to invasiveness, time and cost of these tests. TG:HDL ratio is calculated based on values from routine lipid profiles and can be readily measured in a large number of individuals. The goal of this study is to perform a genome-wide association study (GWAS) of TG:HDL ratio in order to identify novel genetic regions associated with insulin resistance. The largest previous GWAS of this trait was completed in 2009 using HapMap imputed genotypes, was half the sample size, and identified 2 loci, *APOA1* & *CETP*, both of which were also associated with classical lipids. Meta-analysis was performed for 22 cohorts contributing data from 78,382 individuals, including 54,586 of European ancestry, 8,637 of African ancestry, 1,016 East Asians, and 14,143 Hispanics. Individual cohorts performed a GWAS of TG:HDL ratio using 1000Genomes imputed dosages. The outcome was fasting, natural log-transformed TG:HDL ratio adjusted for sex, age, age^2 and cohort-specific covariates. Inverse variance weighted meta-analysis was performed in METAL within each ethnicity and then combined for a trans-ethnic meta-analysis. Significant associations (p<5E-08) were found at 36 loci in regions previously associated with classical lipids. All have been associated with TG and/or HDL. Both hits from the previous TG:HDL ratio GWAS were replicated. In addition, 4 novel loci were discovered. The first was located at 5q31.1 with the lead SNP found ~2kb 3' of *HSPA4* and the majority of the association peak spanned this gene. The second was found at 8p23.1 with the top SNP mapping ~2kb 3' of *DEFB136*, in a region with extended LD in Europeans. A novel intronic variant within *PRR25* at 16p13.3 reached significance. The final novel association was at 19p13.11 ~5kb 5' of *JUND*. We are undertaking replication of our results in independent samples using TG:HDL ratio as well as in samples with measures of insulin-sensitivity. In conclusion, TG:HDL ratio can be measured in large numbers of individuals and thus may provide a surrogate marker of insulin resistance for potential discovery of novel contributing regions of the genome.

Identification of important genes associated with high-density lipoprotein cholesterol using bioinformatics analysis. *X. Mo[1,2,3], H. Zhang[1,2], S. Lei[1,3], Y. Zhang[1,2].* 1) Jiangsu Key Laboratory of Preventive and Translational Medicine for Geriatric Diseases, Suzhou University, Suzhou, China; 2) Department of Epidemiology, School of Public Health, Medical College of Soochow University, Suzhou, China; 3) Center for Genetic Epidemiology and Genomics, School of Public Health, Medical College of Soochow University, Suzhou, China.

Background: High-density lipoprotein cholesterol (HDL-C) concentration is affected by both lifestyle and genetic factors. The aim of this study was to identify more related genes for HDL-C and evaluate the functional relevance to provide evidences for prioritizing these genes by integrating different types of data. **Methods:** We performed an initial gene-based association study in about 188,578 individuals (a publicly available data from the Global Lipids Genetics Consortium). Furthermore, we performed Gene Relationships Across Implicated Loci (GRAIL), differential expression, protein-protein interaction, coronary artery disease association analysis and other bioinformatics analyses to support the significance of the identified genes. **Results:** About 22,096 genes on the human genome were analyzed for HDL-C levels in gene-based association analysis. A total of 331 genes were found to be statistically significant after Bonferroni correction ($P < 2.3 \times 10^{-6}$). The evidence obtained from the analyses of this study suggested the importance of some well-known genes, e.g. *LPL*, *ABCA1*, *SCARB1*, *LCAT*, *APOE*, *VEGFA*, *LIPC*, *CETP* and *HNF4A*, as well as some unreported genes such as *TGOLN2* at 2p11.2, *TP53INP2* at 20q11.22, *RAC1* at 7p22.1, *IKZF3* at 17q12, *NR1I2* at 3q12-q13.3, *NR1H3* at 11p11.2, *ERBB2* at 17q12, *BCL3* at 19q13.1, *NOTCH4* at 6p21.3, *PACSIN1* at 6p21.3, *MMP9* at 20q13.12 and *BAZ1B* at 7q11.23, and so on. These genes involved in important lipid related pathways or have been reported to be associated with many related diseases or traits, and should be suggested as important candidates for further studies. **Conclusion:** The present study found some important HDL-C-associated genes and the findings might provide more insights into the genetic basis of lipid metabolism.

355W

Association analyses of up to 72,043 East Asian individuals and trans-ancestry analyses with up to 186,265 European individuals reveal new loci associated with cholesterol and triglyceride levels. *C.N. Large-scale meta-analyses of genome-wide association studies (GWAS) have identified >180 loci associated with fasting lipid levels, including total cholesterol (TC), HDL-C, LDL-C, and triglycerides (TG). With differences in linkage disequilibrium (LD) structure and allele frequencies among ancestry groups, genetic studies in additional large samples may detect additional loci. We conducted two GWA meta-analyses in up to 72,043 East Asian individuals from 24 studies performed in Japan, the Philippines, Korea, China, Singapore, and Taiwan, and a third trans-ethnic meta-analysis in up to 211,678 East Asian and European individuals. Included studies were genotyped and imputed to the HapMap Phase 2 reference panel (~2.4 million SNPs). Lipid levels were adjusted for age, age[2], sex, BMI, and other study-specific covariates, and the residuals were then inverse normalized. In the first and second meta-analyses, summary statistics of ~2.4 million study-specific lipid-SNP association analyses were combined using a fixed effects sample-size weighted meta-analysis approach assuming an additive genetic model. In the first meta-analysis, lead signals from the discovery phase (11 studies) were meta-analyzed with 5 *in silico* and 6 *de novo* genotyping studies of selected variants. In the second meta-analysis, results from the discovery phase were meta-analyzed with 2 additional genome-wide studies. With these analyses, we validated ($P<5\times10^{-8}$) 50 known lipid loci and identified 3 novel loci associated with HDL-C near *CD163* ($P=7.4\times10^{-9}$), *NCOA2* ($P=1.6\times10^{-8}$), and *NID2-PTGDR* ($P=4.2\times10^{-8}$), and 1 novel locus associated with TG near *WDR11* ($P=2.7\times10^{-10}$). Additionally, we identified 3 novel lipid associations at loci previously associated with a different lipid trait; HDL-C (*KLHL8*, *GPAM*) and TC (*METAP1*). In the trans-ethnic meta-analysis, summary association statistics from the East Asians were combined with data from 186,265 European individuals from the Global Lipids Genetics Consortium using MANTRA. In this analysis, we identified (logBF >6.1) 30 additional novel lipid loci. Lead signals for each trait were found at *FOLH1* (HDL-C), *MICA* (LDL-C), *KLF12* (TG), and *HLA-B* (TC). The novel HDL locus *NID2-PTGDR* could prove clinically useful, as *PTGDR* is a G protein coupled receptor, a common drug target. Taken together, in the largest East Asian genome-wide analysis of lipids to date, we identified multiple novel lipid loci, indicating new potential therapeutic targets.

Genome-wide association study of abdominal fat depots in the UK Biobank identifies adiponectin as a candidate gene for visceral fat distribution. *A.M. Yiorkas[1], E.L. Thomas[7], M. Borga[4,5,6], J.D. Bell[7], O. Dahlqvist Leinhard[3,5,6], A.I. Blakemore[1,2].* 1) Section of Investigative Medicine, Imperial College London, London, United Kingdom; 2) Department of Life Sciences, Brunel University, London, United Kingdom; 3) Department of Medical and Health Sciences, Linköping University, Sweden; 4) Department of Biomedical Engineering, Linköping University, Sweden; 5) Center for Medical Image Science and Visualization (CMIV), Linköping University, Sweden; 6) Advanced MR Analytics AB, Linköping, Sweden; 7) Department of Life Sciences, University of Westminster, London, United Kingdom.

Introduction: Abdominal fat distribution has been recognized as a major determinant of metabolic health. In particular, visceral adipose tissue (VAT) is associated with increased risk of type 2 diabetes and cardiovascular disease, independently of BMI. It is also appreciated that the pattern of fat distribution is influenced by genetic factors, generally, to a larger extent than overall body adiposity. Whole-body magnetic resonance imaging (MRI) was used to measure abdominal fat depots on ~9000 UK Biobank (UKBB) participants. To our knowledge, this is the first GWAS using MRI measurements to identify genetic loci associated with abdominal adipose tissue distribution. **Methods**: A genome-wide association study of VAT, abdominal subcutaneous adipose tissue (ASAT) and visceral-to-subcutaneous ratio (VSR) was performed on European UKBB participants with available genotyping and MRI data (n = 1,493). An additive genetic model was considered, adjusting for age, gender, BMI, type 2 diabetes and the first five principal components. **Results:** We identified a novel locus (chr3; rs182052) in *ADIPOQ* (adiponectin) associated with VAT at the genome-wide significance level (p = 5.00×10^{-8}). The lead SNP was previously associated with circulating adiponectin levels and metabolic phenotypes. While no SNPs reached genome-wide significance in ASAT and VSR analyses, rs117388882 (p = 1.50×10^{-7}) in *CAV1* (caveolin 1) and rs74393452 (p = 1.54×10^{-6}) in *SCTR* (secretin receptor) were the lead SNPs respectively. These potential contributors to fat distribution are important key players since *ADIPOQ* is related to T2D and metabolism, *CAV1* is linked to lipodystrophy and *SCTR* knock-out mice (SctR$^{-/-}$) have decreased lipolysis. **Conclusions**: A genome-wide association study using MRI data on abdominal fat depots in UKBB participants has identified adiponectin SNPs as a contributor to VAT levels. Although replication is required to validate the suggestive hits for SAT and VSR, there is compelling biological evidence to support their involvement in abdominal adipose tissue homeostasis.

357F

Detecting and prioritizing triglycerides-associated genes by using gene-based method and bioinformatics analysis. *H. Zhang[1,2], X. Mo[1,2,3], S. Lei[1,2,3], Y. Zhang[1,2].* 1) Jiangsu Key Laboratory of Preventive and Translational Medicine for Geriatric Diseases, Soochow University, University, Suzhou, China; 2) Department of Epidemiology, School of Public Health, Medical College of Soochow University, 199 Renai Road, Suzhou, China; 3) Center for Genetic Epidemiology and Genomics, School of Public Health, Medical College of Soochow University, 199 Renai Road, Suzhou, China.

Background: Plasma concentration of triglycerides (TG) is reemerging as an important cardiovascular disease risk factor. The aim of this study was to identify more related genes for TG and evaluate the functional relevance to provide evidences for prioritizing these genes. Methods: We performed an initial gene-based association study in about 188,578 individuals (a publicly available data from the Global Lipids Genetics Consortium). Further, we performed Gene Relationships Across Implicated Loci (GRAIL), protein-protein interaction, coronary artery disease association analysis and other bioinformatics analyses to support the significance of the identified genes. Results: About 22,084 genes on the human genome were analyzed for TG levels in gene-based association analysis. A total of 298 genes were found to be statistically significant after Bonferroni correction ($P < 2.3 \times 10^{-6}$). These genes involved in important lipid related pathways or have been reported to be associated with many related diseases or traits. The evidence obtained from the analyses of this study signified the importance of many genes, e.g., *APOB*, *LPL*, *NR1H3*, *PLA2G6*, *TNF*, *VEGFA*, *APOA5*, *CETP*, *LIPC*, *MET*, *PEPD*, *PLTP*, *TNXB*, *LACTB*, *PARP6*, *BPTF*, and so on. These genes should be suggested as important candidates for further studies. Conclusion: Taken together, the present study found some important TG-associated genes and the findings might provide more insights into the genetic basis of lipid metabolism.

358W

Meta-analysis of quantitative pleiotropic traits at gene level with multivariate functional linear models. *C. Chiu[1], J. Jung[2], W. Chen[3], D. Weeks[3], H. Ren[4], J. Mills[1], M. Ting Lee[5], M. Xiong[6], R. Fan[1].* 1) Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD 20892; 2) National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Bethesda, MD 20892; 3) The University of Pittsburgh Medical Center, Pittsburgh, PA 15224; 4) DataParadise Inc., Belle Mead, NJ 08502; 5) University of Maryland, College Park, MD 20740; 6) University of Texas School of Public Health Houston, Texas 77225.

For a meta-analysis of multiple studies, multivariate functional linear models are developed to connect genetic variant data to multiple quantitative traits adjusting for covariates. The goal is to take the advantage of both meta-analysis and pleiotropy analysis in order to improve power and to carry out a uni ed association analysis of multiple studies and multiple traits of complex disorders. Three types of approximate F-distributions based on Pillai-Bartlett trace, Hotelling-Lawley trace, and Wilks's Lambda are introduced to test association between multiple quantitative traits and multiple genetic variants. Simulation analysis is performed to evaluate the false positive rates and power performance of the proposed models and tests. The proposed methods were applied to analyze lipid traits in eight European cohorts.

359T

Bi-ethnic GWAS refines genetic architecture of membranous nephropathy. *N. Mladkova[1], J. Xie[2], C. Sidore[3], M. Zoledziewska[3], R. LeDesma[1], J. D'Addario[1], N. Lester[1], M. Bodria[1], F. Scolari[4], A. Pani[5], F. Cucca[3], N. Chen[2], K. Kiryluk[1].* 1) Dept of Medicine, Columbia University , NYC, NY; 2) Institute of Nephrology, Department of Nephrology, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 3) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche (CNR), Monserrato, Cagliari, Italy; 4) Division of Nephrology, Azienda Ospedaliera Spedali Civili di Brescia, Montichiari Hospital, University of Brescia, Brescia, Italy; 5) Department of Nephrology and Dialysis, G. Brotzu Hospital, Cagliari, Italy.

   Background: Idiopathic membranous nephropathy (iMN) represents the leading cause of nephrotic syndrome worldwide. iMN is characterized by autoimmune deposits in the glomerular basement membrane. The clinical course of iMN is highly variable, but up to one third of cases progress to end stage renal failure. Common variants at *PLA2R1* and *HLA* loci have previously been associated with iMN in Europeans, but these signals have not yet been fine-mapped. Notably, PLA$_2$R (encoded by *PLA2R1*) represents a known target of pathogenic antibodies in up to 70% of iMN cases. **Methods**: We performed a new GWAS discovery in 1,465 East Asians and 1,685 Sardinians (654 biopsy-diagnosed iMN cases and 2,496 ethnically-matched controls). The Asian cohort was genotyped with the HumanOmniZhongHua-8 chip while the Sardinian cohort with Illumina OmniExpress. Following stringent QC, genotype data were imputed using 1000-G reference (Minimac3). Association testing was performed using a dosage method in PLINK with adjustment for significant PCs of ancestry. Imputation of classical HLA alleles was performed with SNP2HLA. Ethnicity-specific results were meta-analyzed using METAL. **Results**: We replicated strong signals within the *HLA* region on chr.6p21 (OR=5.56, P=9.6E-65) and *PLA2R1* locus on chr.2q23 (OR=3.23, P=2.1E-24). We also confirmed a significant genetic interaction between these two loci (P=0.0014). We next performed conditional haplotype analyses to define at least 3 independently associated HLA signals and a single genome-wide significant *PLA2R1* haplotype. The analysis of classical HLA alleles revealed that the HLA signal is explained by *HLA-DRB1*1501* (OR=5.34, P=7.3E-47), as well as Arg at position 233 of *DRB1* (OR= 5.24, P=1.6E-07) and Arg at position 74 of *DRB1* (OR= 9.0, P= 2.2E-19). After conditioning on the *HLA* and *PLA2R1* loci, we identified a number of new suggestive loci across the genome. These are presently being tested for replication in >1,200 additional cases. **Conclusions**: In our bi-ethnic GWAS for iMN, we confirmed the previously implicated common variants with large effects, fine-mapped the MHC signal to a single gene, demonstrated that the association at the *PLA2R1* locus can be explained by a single risk haplotype, and identified several novel suggestive signals. Our genetic results confirm that the interaction between the antigen (PLA$_2$R) and *HLA-DRB1* is critical for the development of iMN, confirming strong autoimmune component to the disease pathogenesis.

360F

Dosage contribution of a non-classical HLA gene, *HLA-DOA***, to the risk of rheumatoid arthritis.** *Y. Okada[1,2,3], A. Suzuki[2], K. Ikari[4], C. Terao[5,6], Y. Kochi[2], K. Ohmura[6], M. Akiyama[2], K. Ashikawa[2], M. Kanai[2], J. Hirata[1,3], N. Suita[1], Y.Y. Teo[7], H. Xu[8], S.C. Bae[9], A. Takahashi[2], Y. Momozawa[2], K. Matsuda[10], S. Momohara[4], A. Taniguchi[4], R. Yamada[6], T. Mimori[6], M. Kubo[2], M. Brown[11], S. Raychaudhuri[5], F. Matsuda[6], H. Yamanaka[4], Y. Kamatani[2], K. Yamamoto[2,12].* 1) Osaka University Graduate School of Medicine, Osaka, Japan; 2) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 3) Tokyo Medical and Dental University, Tokyo, Japan; 4) Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Japan; 5) Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 6) Kyoto University Graduate School of Medicine, Kyoto, Japan; 7) National University of Singapore, Singapore; 8) The Second Military Medical University, Shanghai, China; 9) Hanyang University Hospital for Rheumatic Diseases, Seoul, South Korea; 10) Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 11) University of Queensland Diamantina Institutem, Brisbane, Queensland, Australia; 12) Graduate School of Medicine, the University of Tokyo, Tokyo, Japan.

   Despite the progress in human leukocyte antigen (HLA) causal variant mapping, independent localization of major histocompatibility complex (MHC) risk from classical HLA genes is challenging. Here, we conducted a large-scale MHC fine-mapping analysis of rheumatoid arthritis (RA), an autoimmune disease with chronic destruction of synovial joints, in Japanese (6,244 RA cases and 23,731 controls) using the HLA imputation method. We further conducted a multi-ethnic validation study by including east Asians and Europeans (*n* = 7,097 and 23,149, respectively). Our study identified a risk of a synonymous mutation at *HLA-DOA*, a non-classical HLA gene, on anti-citrullinated-protein-autoantibody (ACPA)-positive RA risk (*P* = 1.4 × 10^{-9}), independently from the classical HLA genes (*HLA-DRB1*, *HLA-DPB1*, and *HLA-B*). The *HLA-DOA* risk variant demonstrated a cis-expression quantitative trait loci (cis-eQTL) effect on *HLA-DOA* expression levels, demonstrating its dosage expression effect on RA risk. Trans-ethnic comparison revealed different linkage disequilibrium (LD) patterns between *HLA-DOA* and *HLA-DRB1*, which explains the observed *HLA-DOA* variant risk heterogeneity among ethnicities; which was most evident in Japanese but not in Europeans. Whilst the previous HLA fine-mapping studies have identified amino acid polymorphisms of the classical HLA genes as driving genetic susceptibility of the diseases, our study additionally identifies the dosage contribution of a non-classical HLA gene to disease etiology. Our study contributes to understanding of HLA immunology in human diseases, and suggests the value of incorporating additional ancestry in MHC fine-mapping.

361W

Genotypic variability based association of seronegative rheumatoid arthritis identifies *DHCR7* **as a key non-additive locus without significant additive effects.** *W. Wei[1,2], S. Viatte[1], A. Barton[1,3], S. Robertson[2], J. Worthington[1,3].* 1) Arthritis Research UK Centre for Genetics and Genomics, Institute of Inflammation and Repair, Faculty of Medical and Human Sciences, Manchester Academic Health Science Centre, University of Manchester, Oxford Road, Manchester M13 9PT, UK; 2) Department of Women's and Children's Health, Dunedin School of Medicine, University of Otago, Dunedin 9016, New Zealand; 3) NIHR Manchester Musculoskeletal Biomedical Research Unit, Central Manchester NHS Foundation Trust, Manchester Academic Health Science Centre, Manchester, UK.

Seronegative rheumatoid arthritis [MIM 180300] is a complex and heterogeneous disorder where patients have no antibodies against citrullinated peptides (RA[-]). Genome-wide association studies (GWAS) of RA[-] have identified only two genome-wide significant loci *HLA-DRB1* [MIM 142857] and *ANKRD55* [MIM 615189]. It is therefore of interest to examine if there are any non-additive signals. We recently adapted genotypic variability based genome-wide association study (vGWAS) to dichotomous disease phenotypes, to allow identification of potentially interacting loci without prior knowledge of the interacting factors in two steps: using a mixed model approach to partition dichotomous phenotypes into additive risk and non-additive environmental residuals on the liability scale and then the Levene's (Brown-Forsythe) test to assess equality of the residual variances across three genotype groups per marker. We performed a vGWAS of a combined population of six RA[-] cohorts recruited from the UK, US, Sweden (2), Netherland and Spain, respectively, all genotyped with Immunochip. After quality control and the mixed model step, 19,108 unrelated samples (3323 cases and 15,785 controls) and 107,144 autosomal SNPs were used in the analyses, with an estimate of polygenic heritability of 0.045. At the genome-wide cutoff of 5.0e-08, vGWAS identified *HLA-DRB1* (lead SNP rs9275428, P = 2.0e-12) and *DHCR7* [MIM 602858] (lead SNP rs2852853, P = 1.3e-08). In contrast, the GWAS P values of the lead SNPs rs9275428 and rs2852853 were 1.5e-24 and 5.1e-05 respectively, suggesting *HLA-DRB1* can be detected from both analyses but *DHCR7* only from vGWAS. We further performed cross-validation iteratively by randomly splitting the combined population into two halves without changing any phenotypes, doing vGWAS in both sub-populations, and recording any discovery and/or replication successes. In a total of 10 iterations, *HLA-DRB1* was discovered and replicated every time whereas *DHCR7* narrowly missed discovery only once (P = 8.2e-08) but was replicated in all instances. *DHCR7* has an important role in vitamin D metabolism and *DHCR7* mutations could have been adaptive for habitation of early humans at Northern latitudes (e.g. Sweden) with insufficient sunlight and hence risk of vitamin D deficiency. Indeed we detected a significant (P = 0.005) interaction between the *DHCR7* lead SNP and cohorts fitted as an environmental factor. We conclude vGWAS is useful to discover novel non-additive signals.

362T

Joint prediction of gene expression using multimodal functional genomic readouts. *D. Lituiev, J. Ye.* Institute for Human Genetics, University of California, San Francisco, San Francisco, CA.

Although there has been much success in mapping genetic determinants of complex human traits, the prediction of traits using genetic data alone has proved challenging. One way to better understand the predictive capacity of genetic variation is by studying intermediate phenotypes such as gene expression and chromatin states. The advantage of this approach is that gene expression is less likely to be confounded by environmental factors than disease state. Here we explore several models incorporating multimodal genomic and genetic data to predict gene expression. In the first analysis, we develop a sparse generalized regression approach to jointly predict gene expression (GE) from genetic data and chromatin accessibility data. We use elastic net regression with distinct penalty for chromatin accessibility (CA) and genotype (GT) features. We apply our model to CD4+ T cells, where we have obtained ATAC-seq (CA) and RNA-seq (GE) data, and lymphoblastoid cell lines (LCLs), where published DNase-seq (CA) and RNA-seq (GE) data is readily available. Using an unbiased estimate of out-of-sample prediction performance, we estimated an average R^2 of 10% and 2% for those genes with positive R^2 (440/19518 in CD4s) and (199/12213 in LCLs) using GT alone. Including both GT and CA features increased the number of genes with expression predictable at a positive R^2 by 6% and 7% respectively, raising mean out-of-sample R2 by 3.6% and 9.1% respectively. These results suggest that although chromatin accessibility data carries predictive information about gene expression, the experimental noise and cost-limited cohort sizes (N~100 in both datasets) restricts its predictive potential. In the second analysis, we model interactions of *cis* and *trans* elements by utilizing transcription factor expression and genotypes to predict gene expression in ImmVar Nanostring data from dendritic cells. Including expression of 39 transcription factors as covariates raised the number of genes predictable with positive R^2 by 10% (58 to 64/405), improving out-of-sample prediction R^2 on average by 9% for genes with positive R^2. Additionally, we discovered 335 novel transcription factor — genotype interaction using linear regression at FDR < 0.01. Thus we demonstrate that sparse regression models involving genetic and functional genomic inputs can lead to improvements in prediction of gene expression.

Common *HLA* alleles in patients candidates for hematopoietic stem cell transplant in western Mexico. *C. Ortega-de-la-Torre[1], H.J. Pimentel-Gutiérrez[1], A. Corona-Rivera[1,3], A. Márquez-Mora[1], F. Sánchez-Zubieta[2], S.A. Brukman-Jiménez[3], J.R. Corona-Rivera[4], L. Bobadilla-Morales[1,3].* 1) CYTOGENETICS UNIT, HOSPITAL CIVIL DE GUADALAJARA "DR. jUAN I MENCHACA", Guadalajara, Jalisco, Mexico; 2) PEDIATRIC HEMATO-ONCOLOGY SERVICE, PEDIATRICS DIVISION, HOSPITAL CIVIL DE GUADALAJARA "DR. JUAN I MENCHACA", Guadalajara, Jalisco, México; 3) cYTOGENETICS, GENOTOXICITY AND BIOMONITORING lAB, INSTITUTO DE GENETCA HUMANA "DR. ENRIQUE CORONA RIVERA", UNIVERSITY OF GUADALAJARA, Guadalajara, Jalisco, México; 4) PEDIATRICS DIVISION, HOSPITAL CIVIL DE GUADALAJARA "DR. J MENCHACA", Guadalajara, Jalisco, México.

INTRODUCTION. Human leukocyte antigens (HLA) genes are the most polymorphic in the genome and they are in the Major Histocompatibility Complex (MHC) located in 6p21.3 locus. For choosing hematopoietic progenitors (HP) donor should be considered HLA genes. PURPOSE. To determine the most common allele frequencies of HLA genes class I and class II in DNA samples of HP transplant candidates and their potential donors. MATERIAL AND METHODS. This is a descriptive, retrospective and transversal study. 134 transplant candidates and 411 potential donors, collected between 2012 and 2015 in the New Civil Hospital of Guadalajara were included in this study. DNA extraction was performed using purification columns (Qiagen) and analysis of HLA class I (A , B , and C) and class II (DQB1 and DRB1) was performed by PCR-SSO (One Lambda), and / or SSP (One Lambda), and / or SBT (Protrans) . RESULTS AND CONCLUSIONS. Here are mentioned the most common three alleles for each locus and their frequency and percentage. HLA-A: *02 with 311(29%), *24 with 171(15.9%) and *68 with 136 (12.7%); HLA-B: *35 with 197(18.8%), *40 with 102 (9.7%), and *44 with 99 (9.4%); HLA-C: *04 with 229 (21.7%), *07 with 225 (21.3%) and *03 with 150 (14.2%); HLA-DQB1: *03 with 510 (47.8%), *04 with 149(14%), and *06 with 134 (12.6%). HLA-DRB1 *04 with 310 (29%), *08 with 149 (14%) and *07 with 92 (8.6%). In this study was determined the HLA alleles frequency for this population of patients eligible for stem cell transplantation and their potential donors, they correspond to population of western Mexico. The three most common alleles for each locus were identified. The distribution of HLA alleles varies according to the population, so it is necessary to know the allelic frequencies in populations .

Novel shared genomic segment analysis identifies *PARK2* and *ARID1A* as potential risk genes for myeloma. *R.G. Waller[1], T. Darlington[2], K. Curtin[3], D. Atanackovic[3,4], N.J. Camp[1,3,4].* 1) Biomedical Informatics, University of Utah, Salt Lake City, UT; 2) Psychiatry, University of Utah, Salt Lake City, UT; 3) Internal Medicine, University of Utah, Salt Lake City, UT; 4) Hematology, University of Utah, Salt Lake City, UT.

Identifying genetic variants involved in common disease remains a challenge due to multiple genes and sources of heterogeneity, reduced penetrance and sporadic cases. Variant prioritization often relies heavily on rarity and functional impact. Few studies have integrated formal statistical evidence for familial segregation, which could be especially useful in non-coding regions. Shared Genome Segment Analysis (SGS) provides statistical evidence that a genomic region is segregating in a high-risk pedigree (HRP) and indicates regions involved in disease risk. In SGS, chromosomal segments shared longer than expected by HRP cases are likely inherited from a common founder. Here, we use a modified heterogeneity-SGS algorithm that specifically assesses shared segments for all possible subsets of HRP cases. Thresholds, fully-corrected for multiple testing, were determined by optimizing over subsets with the Generalized Extreme Value distribution, accounting for genome-wide (GW) scan with the law of large deviations and correcting for the number of HRPs. We performed SGS using high-density SNP array data on 7 Myeloma (MM) HRPs, a highly heritable cancer of plasma cells. Each pedigree had at ≥ 3 genotyped MM cases with 16-23 meioses between cases. Six regions were identified with statistical evidence at the fully-corrected, GW suggestive level (Table 1). Three overlapped (24-855kb) with regions identified in a 2nd MM HRP. Of note, the overlapping chr18 region is within *PARK2*, a gene previously shown to harbor germline risk for lung cancer (shown to cluster in MM HRPs). To discover additional regions with multiple pedigree support, we added 3 smaller HRPs (13 meioses between 3 cases each) and considered regions that were pedigree-specific, GW suggestive. Four regions overlapped in ≥ 2 HRPs (Table 2). Of note, the chr1 region contains *ARID1A*, a gene somatically mutated in many cancers and associated with accelerated tumor growth. In sum, this study illustrates SGS can direct the search for the genetic basis of complex traits.

A novel statistical framework for meta-analyzing overlapping samples prevents a striking phenomenon that gold standard approach severely loses power when a subset of controls are shared. *E. Kim[1,2], B. Han[3]. 1)* Asan Institute for Life Sciences, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Republic of Korea; 2) Seoul National University, Seoul, South Korea; 3) Department of Convergence Medicine, University of Ulsan College of Medicine and Asan Institute for Life.

   In order to maximize statistical power of genome-wide association studies (GWAS), current studies frequently augment control samples from public database or other GWAS. As a result, many different studies contain shared control samples in their analysis, which makes the samples of these studies dependent to each other. This dependency can cause problems in meta-analysis where we combine multiple independent studies into one. To solve this challenge of overlapping samples in meta-analysis, Lin and Sullivan proposed a novel strategy that calculates and accounts for the correlation between statistics induced by overlapping samples (AJHG 2009), which has become the gold standard (LS method). Here, we report a striking phenomenon regarding the power of this gold standard approach. We observed that when not all but a subset of controls are shared between studies, the gold standard approach shows severe power drop compared to splitting, where splitting refers to a strategy that splits genotype data of overlapping samples into individual studies. For example, in simulations performing meta-analysis of ten studies that share a half of controls, LS strikingly showed 10% power while splitting achieved 91% power (simulation codes available at the web address below). Intuitively, the power drop is caused by heterogeneity of information that each sample contains; it can be shown that shared samples have less information than study-specific samples towards the final summary statistic. Inspired by this phenomenon, we propose a novel power-preserving meta-analysis framework for overlapping samples, called FOLD (Fully-powered method for Over-Lapping Data). To prevent power drop, we obtain a set of summary statistics from each study where each statistic is calculated using a subset of controls that is homogeneous in terms of their information, and combine them into one final statistic. FOLD does not suffer from the power loss phenomenon of LS and achieves similarly higher power to splitting in all conducted simulations. We applied our method to the Wellcome Trust Case Control Consortium data. In the analysis combining three autoimmune diseases with partially overlapping shared controls, LS attenuated the statistical significances of previously reported loci compared to splitting, while FOLD preserved the significances. FOLD and our simulation codes are publicly available at http://software.buhm-han.com/FOLD.

Efficient exact tests for longitudinal microbiome studies with application to HIV lung microbiome studies. *J. Zhou[1], J. Zhai[1], T. Hu[3], H. Zhou[2]. 1)* University of Arizona, Tucson, AZ; 2) University of California, Los Angeles, CA; 3) North Carolina State University, NC.

   Recent improvements in high-throughput sequencing make the longitudinal sampling of a relatively large number of individuals possible. Longitudinal studies that record the temporal variation of microbial communities in a wide range of environments allow us to observe temporal dynamics and its links to changes in human health status. For cross-sectional designs, many statistical methods and softwares analyzing association between microbiome and clinical outcomes have beed developed recently in addition to the traditional distance-based analysis. Among them, versatile regression based methods that directly regresses the outcome on the microbiome profiles while allowing for easy covariate adjustment enjoys great popularity. However, methods and softwares for longitudinal micriobiome studies that can deal with temporal variability are limited. In this paper, we propose efficient exact tests (score, likelihood ratio, and restricted likelihood ratio) for longitudinal microbiome studies (exVCLong). Our method is based on linear mixed effect models and combine with semi-parametric kernel association test to test the association of overall longitudinal microbiome profile and outcome. Additionally, our methods can also be used to detect association of one specific microbiome cluster while adjusting for the effects from related clusters. This can be particularly useful to find causal micribiome clusters. Longitudinal studies tend to have smaller sample sizes. Our 'exVCLong' method does not rely on asymptotic theory of large samples, which can significantly improve power to detect association for sample sample microbiome studies. Our simulation studies present correctly controlled type I error and superior power in detecting association in longitudinal studies. Finally, we applied our method to a longitudinal pulmonary microbiome datasets of Human Immunodeficiency Virus (HIV) patients. We identified two interesting genera Prevotella and Veillonella associated with force vital capacity, which shed lights on biological mechanisms. The software package is implemented in the open source, high-performance technical computing language Julia and is freely available at https://github.com/Tao-Hu/VarianceComponentTest.jl.

A profound effect of common *HLA* polymorphisms on the survival of the patients with HIV infection in the pre-antiviral era in Thailand. *M. Yasunami[1,2], N. Wichukchinda[3], R. Miyahara[2], N. Tsuchiya[2], H. Nakamura[2], M. Mori[2], A. Rojanawiwat[3], P. Pathipvanic[4], P. Sawanpanyalert[3], K. Ariyoshi[2].* 1) Medical Genomics, Life Science Institute, Saga-ken Medical Centre Koseikan, Saga, Japan; 2) Department of Clinical Medicine, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 3) Department of Medical Sciences, Ministry of Public Health, Nonthaburi, Thailand; 4) Day Care Center, Lampang Hospital, Lampang, Thailand.

   Background: *HLA class I* polymorphisms are known to play a crucial role in the control of HIV and progression to AIDS. We previously reported that *HLA-B*35:05* and *B*57:01* were associated with lower viral load in the patients with chronic HIV infection who were enrolled to a longitudinal observational study in Lampang Hospital, a government referral hospital in Lampang, Thailand. In addition to the *HLA class I*-mediated cytotoxic T lymphocytes, a variety of immune/inflammatory responses are regulated by the genes in the *HLA* region of human chromosome 6, so that the other *HLA* polymorphisms may associate with disease outcomes of the patients with HIV infection. **Methods:** A total of 556 HIV-1 CRF01_AE infected individuals were recruited from July 2000 to October 2002, and census data of survival was obtained on October 15, 2004 before the national program of antiviral treatment was introduced. CD4 count, viral RNA load and other information on clinical status were collected upon enrollment. Genotypes of *HLA-A, -B, -C, -DRB1* and *TNF* were determined. **Results:** Unlike *class I HLA* alleles, no effect of *TNF* polymorphisms on chronic phase viral load was detected. *TNF -308A* allele exhibited dominant unfavorable effect on the survival (*TNF -308AA+AG* vs *-308GG*, Cox hazard ratio: 1.46, p=0.034), and the effect was strengthened in HIV-1 positive patients with low CD4 count at enrollment (Cox HR: 1.52, p=0.024). Similar dominant unfavorable effect on the survival in the patients with low CD4 count was observed with *DRB1*03:01* (*DRB1*03:01*-positive vs *DRB1*03:01*-negative, Cox HR: 1.55, p=0.018) The effect of *TNF -308A* was enhanced by co-existence of *DRB1*03:01* allele (Cox HR: 1.65, p=0.010), suggesting a haplotype effect. Because of tight linkage between *TNF -308A* and *DRB1*03:01* alleles forming ancestral haplotype *AH58.1* commonly found in Asian population, it could not be distinguished whether the effects of *TNF/ HLA-DRB1* polymorphisms are primary or secondary to other genetic factor(s) carried by *AH58.1*. Interestingly, *AH58.1* shares the same alleles in *TNF-HLA-DRB1* interval with *AH8.1* which carries a *complement factor 4 null allele*. Shorter survival of *AH58.1*-positive patients might be elucidated by defective complement functions which are important to cope with opportunistic infectious agents such as *Pneumocystis*, etc. **Conclusion:** Unfavorable effect on the survival of the patients with chronic HIV infection in pre-ART era was associated with a common *HLA* haplotype *AH58.1*.

   Most genetic analyses and twin studies published to date support a genetic component to the inflammatory bowel disease (IBD). The most recent genome-wide scan identified a total of 163 loci associated with IBD phenotypes. The identification of these loci has enhanced our understanding of the pathogenesis of IBD, providing perspective on key pathways, and highlighting an essential role for host defense against infection. In parallel, recent work pointed out a potential role of the intestinal microbiota in initiating and maintaining IBD-related phenotypes. While it is generally accepted that the commensal microbiota can induce inappropriate activation of intestinal mucosal immunity, the precise role of the microbiota in the etiology of IBD in regards of the host genetic susceptibility remains unclear. In this study we used 182 well phenotyped IBD cases to explore the relationship between the intestinal microbiota and genetic variants from five of the most established IBD-associated genes (*NOD2, CARD9, LRRK2, ATG16L1* and *IL23R*). We performed a systematic screening for association between the four IBD-increasing genetic variants and bacterial quantification using a novel multivariate approach we recently developed. We identified 7 significant associations, 6 involving *NOD2*, and 1 involving *CARD9*. This includes in particular a negative association between *F. prausnitzii* and a genetic risk score for *NOD2*. *F. prausnitzii* is of particular interest in this context as we previously demonstrated its anti-inflammatory effect on cellular and colitis models. Focusing on this result, we first replicated the *NOD2-F. prausnitzii* association using an independent cohort of 474 IBD cases. We then demonstrated that this association remains after controlling for the established effect of *F. prausnitzii* and *NOD2* variants on IBD. Finally, using theory on causal inference and simulation, we showed that the increased IBD risk associated with *NOD2* is likely mediated through a decrease of *F. prausnitzii* in the gatstro-intestinal tract, showing for the first time an a three-way interdependency between bacteria, human genes and IBD. These results are of major importance for the understanding of IBD pathogenesis and for the discovery or new therapeutic targets on both host and microbiota sides. Moreover, this work has general implications as the concepts pointed out here could be applied to the growing number of other human diseases in which both microbiota and genetics are involved.

Genome-wide analysis of vitamin D response elements implicates vitamin D regulation of antigen presentation in multiple sclerosis risk: Results from the Kaiser Permanente MS Research Program. *A. Mok[1,2], X. Shao[2], B. Rhead[1,2], L. Shen[3], H. Quach[2], C. Schaefer[3,4], T. Olsson[5], I. Kockum[5], L. Alfredsson[6,7], L.F. Barcellos[1,2,3,4].* 1) Computational Biology Graduate Group, UC Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genetics Laboratory, UC Berkeley, Berkeley, CA; 3) Kaiser Permanente Division of Research, Oakland, CA; 4) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA; 5) Department of Clinical Neuroscience and Center for Molecular Medicine, Karolinska Institutet at Karolinska University Hospital, Stockholm, Sweden; 6) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 7) Centre for Occupational and Environmental Medicine, Stockholm County Council, Stockholm, Sweden.

   Recent studies have demonstrated a causal role of vitamin D serum levels in multiple sclerosis (MS [MIM 126200]); however, the mechanisms underlying this association are not yet known. The vitamin D receptor is expressed in nearly all tissue types, but its target genes are specific to cell type and function. Thus, genome-wide analysis of vitamin D signaling may elucidate the downstream factors driving MS pathogenesis. We investigated whether genetic variants in putative vitamin D response elements (VDREs) are associated with MS in non-Hispanic White members of Kaiser Permanente Northern California (1,098 cases; 10,329 controls). Genotypes were obtained through whole-genome profiling and imputation. We identified 6,250 SNPs within 4,764 VDREs from six ChIP-seq datasets for analysis. To detect the effect of VDRE variants on MS susceptibility independent of well-established risk factors, we performed logistic regression for each SNP and controlled for sex, genetic ancestry, a weighted genetic risk score for 110 non-HLA risk alleles, and four independent SNPs in the MHC, the region with the strongest genetic contribution to MS risk. Results show significant disease associations for 19 SNPs in 16 VDREs (FDR q<0.05), including rs2213584 (OR=1.34, p=5.34e-07) and rs2395182 (OR=1.47, p=1.38e-06) in a VDRE 5kb downstream of *HLA-DRA*. We additionally restricted analyses to VDRE SNPs within 10kb of genes established through recent MS GWAS and found significant associations for rs1335532 (OR=0.83, p=1.97e-04) in *CD58* and rs9831894 (OR=0.76, p=5.96e-04) in *CD86*. As HLA-DRA, CD58, and CD86 are all cell surface proteins involved in antigen presentation, findings suggest that vitamin D regulation of antigen presentation may mediate MS risk. A majority (82%) of the MS-associated VDREs demonstrated specificity to B-lymphocytes, and none of the identified VDREs contained the canonical DR3 binding motif. Replication in an independent dataset of Swedish individuals (6,335 cases; 5,762 controls) is underway. We are performing high-throughput sequencing of each VDRE in a subset of samples to confirm findings, and conducting ChIP-seq analysis to identify candidate VDREs specific to T-lymphocytes for further study. We describe the first results from a comprehensive genomics approach to characterizing the contribution of vitamin D metabolism in MS. Our findings also have important implications for cancer and other autoimmune conditions more broadly, for which vitamin D plays a role.

370W

Shared effect modeling reveals that a fraction of autoimmune disease associations are consistent with eQTLs in three immune cell types. *S. Chun[1,2,3], A. Casparino[4], N.A. Patsopoulos[3,5,6], D. Croteau-Chonka[2,7], B.A. Raby[2,7], P.L. De Jager[2,3,5,6], S.R. Sunyaev[1,2,3], C. Cotsapas[3,4,8].* 1) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Neurology, Yale School of Medicine, New Haven, CT; 5) Department of Neurology, Brigham and Women's Hospital, Boston, MA; 6) Ann Romney Center for Neurological Diseases, Brigham and Women's Hospital, Boston, MA; 7) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 8) Department of Genetics, Yale School of Medicine, New Haven, CT.

   The majority of autoimmune disease risk effects identified by genome-wide association studies (GWAS) localize to open chromatin with gene regulatory activity. GWAS loci are also enriched for expression quantitative trait loci (eQTLs), suggesting that most disease risk variants exert their pathological effects by altering gene expression. However, because causal variants are difficult to identify and *cis*-eQTLs occur frequently, it remains challenging to translate this bulk observation into specific instances of a disease risk variant driving changes to gene regulation. We developed a new method, JLIM, to directly evaluate the joint likelihood that a disease association and an eQTL are due to the same underlying causal variant. We assess its performance by benchmarking it on simulated data against *coloc*, a well-calibrated Bayesian framework that considers spatial similarities of association data across windows of markers. Both methods have excellent performance when two distinct causal variants are not in LD (AUC=0.99 for both when $r^2 < 0.5$), but JLIM maintains higher specificity as LD between distinct causal variants increases (AUC = 0.92 vs 0.70 for *coloc* when $0.7 < r^2 < 0.8$). We next compared association signals to six autoimmune diseases in 188 loci densely genotyped on the ImmunoChip to eQTLs from LCLs, CD4+ T cells and CD14+ macrophages. All but 11 loci had at least one eQTL (p < 0.05) in at least one of the three cell types, with most found in all three tissues. We tested 9,268 pairs of disease and eQTL associations with JLIM and find evidence for shared effects for only 57/9,268 pairs (FDR < 0.05), with 43/57 surviving Bonferroni correction. Rather, JLIM strongly supports the alternative hypothesis for distinct effects for the other trait pairs. Overall, we find that only a fraction of disease-eQTL pairs in the same locus are due to the same underlying variant, whereas >75% are associated to distinct variants in the same locus. Thus, we uncover a fraction of gene regulatory changes as strong mechanistic hypotheses for disease risk, but conclude that most risk mechanisms do not involve changes to basal gene expression.

371T

Identifying substructure in genetic risk sharing between diseases. *L. Jostins, G. McVean.* Statistical Genetics, Wellcome Trust Centre Human Genetics, Oxford, Oxfordshire, United Kingdom.

While genetic risks for complex human diseases are often shared across multiple phenotypes, such as disorders of the immune system, this risk sharing shows complicated substructure. Risk alleles can be associated with multiple diseases with similar effect sizes or with smaller or opposite effects, or uniquely with one or a few diseases. Such complexity, along with incomplete power, makes inferring the exact sharing model for any given locus, and hence structure in sharing between loci, difficult.To address these problems we present a statistical approach which models the underlying biology driving genetic risk substructure across multiple loci and phenotypes. Motivated by a network model of shared and potentially pleiotropic risk components, we use a reduced rank representation of genetic covariance in which each risk allele belongs to one of a small number of pathways, where each pathway varies in complexity from simple perfectly correlated effects to more complex covariance models. The method adjusts the number and rank of pathways to infer the simplest model that explains observed association summary statistics. Individual loci are probabilistically assigned to inferred pathways, allowing us to examine the genes and functions associated with each pathway.Using simulations, we show the power and accuracy of the method to estimate underlying parameters and choose the correct pathway structure using the Bayesian information criterion. For example, we have high power to recover the structure of a 3-pathway model under realistic scenarios (100 loci, 5 diseases, 10000 total samples). We apply the method to association data for LDL cholesterol and cardiovascular disease (CVD), where we expect a direct causal relationship. We recover two pathways, a low rank pathway of loci that act on CVD via LDL, and a pleiotropic pathway that acts on CVD in an LDL-independent fashion. The genes in these two pathways are overrepresented in differing tissues (liver for the first, adipose and muscle for the second). We also apply the method to autoimmune diseases associations to recover significant substructure, including a low-rank pathway with opposite effects on type 1 diabetes and multiple sclerosis.The difficulties of cross-disease analysis scale exponentially with the number of diseases. In contrast, by providing simplified, biologically interpretable models of genetic risk sharing, our method could potentially analyse shared pathways across hundreds of diseases. .

372F

Trait agnostic identification of candidate genes associated with noncoding variation. *A. Wuster, D. Chang, T. Bhangale.* Genentech Inc., South San Francisco, CA.

The majority of variants identified by genome-wide association studies are located in noncoding regions and likely act by affecting gene expression. Variants typically contain multiple genes in the region of linkage disequilibrium and identifying the causative one is challenging. Many studies assume that the gene closest to the risk variant is the best candidate, which may often not be the case. Another approach is to look for associations between the variant of interest and the expression of nearby genes (eQTLs). In isolation, this has limitations too as eQTLs are not available for many tissues and disease states and as most variants are not strongly associated with gene expression. We have therefore developed a method that identifies the most likely gene or genes through which variation at a given locus acts. Using a Bayesian approach, our method integrates eQTL data from the Genome-Tissue Expression Project (GTEx), recombination data from the HapMap project, and published Hi-C genome conformation data. For any given locus, our method returns a list of likely candidate genes together with their relative probabilities. We compare our method to a previously published approach that made use of a variety of trait-specific data types to identify candidate genes at 101 rheumatoid arthritis risk loci (Okada et al. 2013, Nature 506, 376). Even though our method is trait agnostic, it identifies the same candidate gene for 84% of loci for which such a determination is possible. We also apply our method to 13,000 loci in the NCBI/EBI GWAS catalog and find that the resulting candidate gene probabilities closely reflect the probability that a gene has been annotated as a candidate gene in the catalog. This suggests that our method can accurately identify candidate genes in the majority of cases. While it is not a substitute for in-depth experimental validation, it can quickly suggest candidate genes without the need to first collect trait or disease specific data. In addition to returning candidate gene probabilities for single variants, our method can identify candidate genes for sets of variants that are in linkage disequilibrium by integrating the individual probabilities of those variants, thus making the identification of the most likely causative variant less of a priority.

373W

KING 2.0: Relationship inference and integrated analysis in one million samples. *W.-M. Chen[1,2], A. Manichaikul[1,2], S.S. Rich[1,2].* 1) Center for Pubic Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, VA.

The kinship coefficient between a pair of individuals can be accurately estimated using their genome-wide SNP data, without estimating the allele frequencies at each SNP in the whole dataset. Together with implementation of bit-wise operations that are applied directly on binary coded genotype data, relationship inference in the first generation of KING has been fast for genetic datasets consisting of 100,000 or fewer individuals. In order to infer related-ness and further to provide integrated genetic analyses in the latest genetic data where the number of individuals can be beyond 1 million, we develop the second-generation of KING. Three levels of computational speed-up are implemented in KING 2.0, including: 1) bit-level parallelism; 2) multiple-core parallelism using OpenMP; and 3) faster algorithms involving a multi-stage procedure to eliminate unrelated or distantly related pairs of individuals, in which we first select a subset of highly informative SNPs to obtain first-pass relationship estimates for all pairs of individuals, and then follow-up using all SNPs on a small subset of pairs identified in the first stage analysis. One particular computing technique for further speed-up is to propose computationally simpler estimators that are upper bounds of the KING estimator. The efficient implementation in KING 2.0 performs relationship inference in a matter of seconds in a typical dataset (with 10,000 or fewer samples), or a few hours in very large data consisting of ~1 million samples. This computational efficiency also applies to integrated genetic analyses that are available in KING 2.0, including automated pedigree reconstruction, extraction of subset of unrelated individuals, family-based Q/C without relying on reported pedigree data, as well as association scans for a massive number of phenotypes (*e.g., trans-* eQTL analysis). Lastly, we implement a new relationship inference algorithm that has a similar performance as PC-Relate (AJHG 98:127-148) while still feasible for very large data. To demonstrate the performance of KING 2.0, we applied relationship inference on a dataset consisting of 1,002,375 samples (generated by duplicating a real dataset consisting of 30,375 samples 33 times) each typed at 168,749 autosome SNPs. It took 2 hour and 13 minutes to identify all 16,090,272 pairs of duplicates, and 6 hours and 16 minutes to identify all 36,151,830 pairs of first-degree relative and duplicates, using 19 CPU cores.

374T

Mapping abundance of 1,129 serum proteins provides functional insights for disease risk alleles. *J. Maranville, Y. Huang, J. McElwee, U-BIOPRED Consortium.* Genetics and Pharmacogenomics, Merck Research Laboratories, Boston, MA.

Although disease GWAS have successfully identified thousands of loci associated with multiple diseases, the molecular mechanisms that underlie these associations are often unclear. Genetic association studies of molecular traits, such as protein abundance, complement genetic studies of disease risk to provide valuable insights into pathobiology. To expand our understanding of allelic effects on protein abundance traits, we mapped protein quantitative trait loci (pQTL) using 414 individuals collected as a part of the UBIOPRED study. SomaLogic assays were used to measure the abundance of 1,129 proteins in serum samples from each participant. This was combined with Axiom array and imputed genotype data to perform pQTL mapping in cis (defined as variants <1MB from encoding gene) and in trans (defined as variants >1MB from encoding gene). We found 269 proteins had at least one significant cis pQTL at a threshold of FDR<10^{-4}. At a Bonferroni-corrected threshold of 5x10^{-11}, we found that 55 proteins had at least one significant trans pQTL. These included multiple previously described QTL for protein abundance traits assayed using other technologies (e.g. ELISA). Additionally, pQTLs overlapped with GWAS signals for asthma and related phenotypes (e.g. allergy). For example, we replicated a cis-pQTL for the soluble IL-6 receptor that also shows a genome-wide significant association with asthma. Specifically, asthma risk alleles were associated with higher levels of soluble IL-6 receptor. This provides additional support to previous suggestions that inhibitors of the IL-6 receptor would be effective in treating asthma. Our study also highlighted novel protein-disease connections. For example, we found a cis-pQTL for the soluble IL-18 receptor α that overlaps a GWAS signal for asthma risk, with disease risk alleles also associated with higher levels of this protein. This suggests that inhibition of IL-18 receptor α could be a promising strategy for the development of novel asthma therapeutics. Overall, our results massively expand on previous studies by identifying QTL for hundreds of proteins and provide important insights into proteomic effects of disease risk alleles.

375F

Identification of SLE-associated risk variants in the *STAT1-STAT4* locus and their effect on differential transcription factor binding. *Z.H. Patel[1], X. Lu[2], D. Miller[3], E. Zoller[3], M. Weirauch[3,4], K. Kaufman[3,4,5], J.B. Harley[3,5], L.C. Kottyan[3,5], SLEGEN Consoritum & Collaborators.* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Immunology Graduate Program, College of Medicine, University of Cincinnati, Cincinnati, OH; 3) Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Department of Biomedical Informatics, College of Medicine, University of Cincinnati, Cincinnati, OH; 5) Department of Veterans Affairs, Veterans Affairs Medical Center – Cincinnati, Cincinnati, OH, USA.

   Systemic Lupus Erythematosus (SLE or lupus) is a chronic autoimmune disease with debilitating inflammation that affects multiple organ systems. The *STAT1-STAT4* locus is one of the first and most highly replicated genetic loci associated with SLE risk. In this study, we aimed to identify all the SLE-associated common variants at this locus most likely to be causal and to further identify the biological mechanism mediating the increased disease risk. We genotyped 328 SNPs spanning the *STAT1-STAT4* locus in 13,581 subjects representing four ancestral groups. We performed imputation and applied frequentist and Bayesian statistical analyses to identify the individual variants statistically most likely to causally increase lupus risk. We further used a separate larger African-American study to generate an Ancestry Informed Credible Set (AICS) of four variants. We computationally predicted differential transcription factor (TF) binding of AICS variants and identified the AT-hook family of TFs as a strong candidate for three of the four AICS variants. After identifying AT-hook family member HMGA1 as binding to rs11889341 through DNA Affinity Precipitation Assay (DAPA) followed by mass spectrometry, we confirmed binding of HMGA1 to two of four AICS variants with genotype-dependent binding by DAPA and Electrophoretic Mobility Shift Assay. In summary, we used large genetic datasets to identify a set of variants that are most likely to be causal for the *STAT1-STAT4* association with increased lupus risk and identified a potential disease-risk mechanism in which HMGA1 differentially binds three genetic variants in a lupus-risk haplotype.

376W

Quantifying directional effects of transcription factor binding on polygenic disease risk using GWAS summary statistics. *Y. Reshef[1], H. Finucane[3], A. Gusev[2], J. Ulirsch[4], B. van de Geijn[2], S. Grossman[4], P. Loh[2], G. Bhatia[2], S. Gazal[2], P. Palamara[2], N. Patterson[4], L. Dicker[5], L. Pinello[6], R. Adams[1], A. Price[2].* 1) Computer Science, Harvard University, Cambridge, MA; 2) Epidemiology, Harvard School of Public Health, Boston, MA; 3) Mathematics, Massachusetts Institute of Technology, Cambridge, MA; 4) Broad Institute of MIT and Harvard, Cambridge, MA; 5) Statistics and Biostatistics, Rutgers University, New Brunswick, NJ; 6) Biostatistics and Computational Biology, Dana-Farber Cancer Institute and Harvard School of Public Health, Boston, MA.

   Connecting complex traits to specific transcription factors (TFs) represents an important path toward better mechanistic understanding of human disease. Existing genetic approaches to this problem focus on functional enrichment, e.g. evaluating whether SNPs in or around binding sites of a TF are enriched for heritability of a trait or over-represented among top GWAS SNPs. However, these approaches a) have limited power to detect enrichment at the resolution required for TF binding sites, and b) have limited mechanistic interpretability because TF binding may simply mark areas of the genome, such as certain enhancers or gene sets, whose importance for the trait is not directly related to the TF in question. To overcome these limitations we define a signed population quantity, *functional correlation*, which quantifies the extent to which the signed effect of SNPs on disease risk is correlated with their signed effect on TF binding. We introduce a method, FCor, that estimates functional correlation from GWAS summary statistics and provides closed-form standard errors for assessing significance. FCor can be viewed as a maximum-likelihood estimate of the genetic correlation between total TF binding and the phenotype in question, in a model in which SNP effects are fixed rather than random. Our simulations show that FCor attains higher power than unsigned functional enrichment approaches given accurate information about the direction of SNP effects on TF binding, and that FCor provides unbiased estimates of functional correlation and controls type I error.   We applied FCor to analyze the relationship of the transcription factor NFκB to rheumatoid arthritis (RA). Using RA summary statistics (N=38,242) together with an annotation of 4,805 NFκB occupancy-modifying SNPs, we found that the polygenic burden of alleles increasing NFκB occupancy is positively correlated with RA risk ($p < 7.9 \times 10^{-4}$). This finding translates into a genetic correlation of 3.2% (s.e. 0.97%) between total NFκB binding and RA, and is consistent with biomedical literature suggesting that increased NFκB activity is a component of RA pathogenesis. To our knowledge this has not previously been demonstrated using GWAS data and so our result constitutes new evidence for a mechanistic link between NFκB and RA. Our work illustrates the potential of functional correlation for improving understanding of human disease, and we plan to apply this framework to tens of phenotypes and TFs.

377T

Effect of some genetic variants changes over time post transplant on tacrolimus concentrations. *B. Wu[1], W. Guan[1], D. Schladt[2], K. Sanghavi[3], C. Dorr[2], A. Muthuswamy[2], R. Remmel[3], R. Mannon[4], A. Matas[5], A. Israni[2], W. Oetting[3], P. Jacobson[3], DeKAF Genomics Investigators.* 1) Division of Biostatistics, University of Minnesota, Minneapolis, MN; 2) Minneapolis Medical Research Foundation, Minneapolis, MN; 3) Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, MN; 4) Division of Nephrology, University of Alabama, Birmingham, AL; 5) Department of Surgery, University of Minnesota, Minneapolis, MN.

Previously we identified three genome-wide significant CYP3A5 variants (*3, *6, and *7) associated with the tacrolimus troughs (TT) in a GWAS of African American (AA) kidney transplant (tx) recipients (Oetting et al., Am J Transplant, 2016). When we estimated the regression coefficients of genotype at each time point posttx for these three variants, overall we found that the variants have non-constant effects on the TT over time posttx. We observed the largest changes of effects in the early days (day 1 to around week 3). Therefore we analyzed in detail our GWAS data with a new statistical model allowing for potentially non-constant variant effects. We evaluated dose-normalized TT and 426,960 common variants (MAF>0.05) genotyped using an Affymetrix TxArray, adjusting for age, gender, study center, top four ancestry principal components, and a set of previously identified important clinical variables. TT from 318 AA kidney tx recipients from three study centers in the DeKAF Genomics study were in the discovery cohort. Each recipient had multiple TT measurements (range 1-24, median 18) posttx from week 1 to month 6. We then validated the variants in a cohort of 35 AA samples from another two study centers. We identified 23 variants that passed genome-wide significance ($P<5x10^{-8}$) in the discovery cohort, and had test p-values $P<0.01$ in the validation cohort. When assuming constant genotype effects, we only identified 3 (located in CYP3A5 on chromosome 7) of the 23 significant variants. We identified variants that have varying effects over time on TT in AA recipients. Understanding and accounting for variants with changing effect sizes over time will allow for more precise tacrolimus dosing.

378F

Integrative whole genome sequencing and metabolomics networks in asthmatics identifies sphingolipid metabolites, genes, and networks associated with asthma severity. *J. Lasky-Su[1], R. Kelly[1], J. Hecker[2], H. Fier[2], D. Prokopenko[2], J. Celedon[3], C. Lange[4], S. Weiss[1,5], IMPACT consortium.* 1) Channing Division of Network Medicine, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Institute of Genomic Mathematics, University of Bonn, Bonn, Germany; 3) Children's Hospital of Pittsburgh and University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Harvard School of Public Health, Boston, MA; 5) Partner's Healthcare Personalized Medicine, Brigham and Women's Hospital, Boston, MA.

In the U.S., asthma affects 26 million people and leads to estimated annual costs exceeding $12.7 billion. Given its strong public health impact, identifying key molecular determinants of asthma remains an important priority in translational science. The genetic determinants identified for asthma to date explain only a fraction of the estimated heritability. Metabolomic profiling enables a functionally relevant exploration of the relationships between the underlying genetic and environmental disease risk factors. We studied a cohort of children with asthma from Costa Rica (CR), which is rich in environmental and clinical measurements relevant to asthma. We generated comprehensive metabolomic profiling in 381 asthmatic children and whole- genome sequence (WGS) data on 1100 individuals from these CR families. For the WGS family data, novel family-based analytic methods that incorporate both individual variant and "region-based tests" , identifying several asthma-associated regions that met genome-wide significance. The most significant finding is in the 5' region of *PDE4DIP* on chromosome 1, the interacting protein for *PDE4D*, one of the first validated genes for asthma ($p=5.9x10^{-8}$). A total of 8185 metabolite features that covered a broad range of the metabolome were measured and passed QC in the 381 plasma samples. A total of 583 (7%) of features, most of which were free fatty acids and bile acids, were associated with asthma severity, defined by airway hyper-responsiveness to methacholine ($p<0.01$). The inclusion of a summary score based on these features (AUC: 0.685 (95%CI 0.625, 0.747)) significantly outperformed a baseline model in discriminating asthma cases by their degree of severity ($p=0.004$). This profile was enriched for metabolites of the sphingolipid, linoleic acid, arginine and proline metabolism and fatty acid biosynthesis pathways. To assess the interrelationships between genes and metabolites, we used a systems biology approach to integrate WGS and metabolomic data, both on an individual variant and pathway levels to identify a set of metabolites and genes that influence asthma. Findings in the aforementioned metabolites, genes, and pathways were validated using 3 populations, including 2 asthma birth cohorts and an asthma clinical trial. Taken together, these findings demonstrate the power of integrating WGS and metabolomics data together in the development of biomarkers of asthma severity and in the understanding of disease pathogenesis.

379W

Admixture mapping of kidney traits in the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). *L. Brown[1], T. Thornton[1], N. Franceschini[2]*. 1) Biostatistics, University of Washington, Seattle, WA; 2) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Chronic Kidney Disease (CKD) affects approximately 14.5% of the adult U.S. population, with a high burden occurring among racial/ethnic minorities, including Hispanics. Albumin–creatinine ratio (ACR) is a quantitative measure of kidney function. Admixture mapping is a method for disease gene mapping in admixed populations that leverages allele frequency differences in ancestral reference populations to identify an association with locus-specific local ancestry. We implement a linear mixed model framework to perform admixture mapping of ACR in subjects from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). We identify a strong Amerindian ancestry driven association on chromosome 2 spanning q11.2-14.1, that is not found by GWAS. Our findings suggest the presence of ancestry-specific variants influencing the variation of urine albumin in admixed populations such as Hispanics.

380T

Genetic polymorphisms of *PNPLA3* and *SAMM50* gene are associated with severity of nonalcoholic fatty liver disease in Koreans. *G. Chung[1], Y. Lee[1], J. Yim[1], M. Kwak[1], C. Lee[1], E. Choe[1], J. Lee[2], J. Kim[2], H. Jang[2]*. 1) Seoul National University Hospital Gangnam Healthcare Center, Seoul, South Korea; 2) DNA Link, Inc., Seoul, Korea.

Background/Aims: Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease. The development of NAFLD is associated with multiple genetic factors, environmental factors and lifestyle. **Methods:** We performed a genome-wide association study to identify genetic factors related to NAFLD in large Korean population based samples of 1,593 subjects with NAFLD and 2,816 controls using the Affymetrix Axiom® Customized Biobank Genotyping Arrays. We replicated the data in another sample including 744 subjects with NAFLD and 1,137 controls. In addition, we investigated SNPs related to severity of ultrasonography-diagnosed fatty liver and NAFLD with increased levels of alanine aminotransferase (ALT). **Results:** After adjusting for age, sex and body mass index, rs738409 located in the *PNPLA3* gene, a locus previously reported, was validated in our population (p=1.7 x 10^{-15}; OR, 1.54 in the discovery set and p=2.6 x 10^{-8}; OR, 1.54 in the replication set). Rs12483959 and rs2281135 were in strong linkage disequilibrium (LD) (r2=0.978 and 0.936) and showed significant associations (p=5.8 x 10^{-15}; OR, 1.53 and p=9.7 x 10^{-15}; OR, 1.52, in the discovery set and p=1.3 x 10^{-8}; OR, 1.56 and p=1.3 x 10^{-8}; OR, 1.51, in the replication set). Rs2143571, rs3761472 and rs2073080 in the SAMM50 gene were in strong LD (r2=0.932 and 0.996) and also showed significant associations with NAFLD (p=1.9 x 10^{-11}; OR, 1.43; p=2.2 x 10^{-11}; OR, 1.43; and p=2.7 x 10^{-11}; OR, 1.43, respectively in the discovery set and p=5.9 x 10^{-7}; OR, 1.48; p=3.3 x 10^{-7}; OR, 1.49; and p=7.8 x 10^{-7}; OR, 1.47, respectively in the replication set). Additionally, these six SNPs showed significant associations with severity of fatty liver (p=2.9 x 10^{-20}; p=2.0 x 10^{-19}; p=3.3 x 10^{-19}; p=1.8 x 10^{-15}; p=1.6 x 10^{-15} and p=3.8 x 10^{-15}, respectively in the discovery set p=1.3 x 10^{-8}; p=3.7 x 10^{-9}; p=3.2 x 10^{-8}; p=5.7 x 10^{-7}; p=1.3 x 10^{-7} and p=6.1 x 10^{-7}, respectively in the replication set) and NAFLD with elevated levels of ALT (p=8.4 x 10^{-17}; p=3.3 x 10^{-16}; p=5.9 x 10^{-16}; p=1.7 x 10^{-12}; p=9.7 x 10^{-13} and p=2.3 x 10^{-12}, respectively in the discovery set p=1.4 x 10^{-7}; p=7.8 x 10^{-8}; p=1.1 x 10^{-6}; p=1.7 x 10^{-6}; p=1.1 x 10^{-6} and p=1.5 x 10^{-6}, respectively in the replication set). **Conclusions:** We demonstrated that the PNPLA3 gene and SAMM50 gene are strongly associated with the presence and severity of NAFLD in Korean population. These findings confirm important roles of genetic factors in the pathogenesis of NAFLD.

Genome-wide SNP interaction analysis suggests polygenic regulatory effects on bone density among adult survivors of childhood cancer. *C. Im[1], C.L. Wilson[2], K.K. Ness[2], W. Moon[2], S.C. Kaste[3,4], W. Chemaitilly[5], M.M. Hudson[2,4], L.L. Robison[2], Y. Yasui[1,2].* 1) School of Public Health, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Epidemiology and Cancer Control, St. Jude Children's Research Hospital, Memphis, TN; 3) Department of Radiological Sciences, St. Jude Children's Research Hospital, Memphis, TN; 4) Department of Oncology, St. Jude Children's Research Hospital, Memphis, TN; 5) Division of Endocrinology, Department of Pediatric Medicine, St. Jude Children's Research Hospital, Memphis, TN.

Interaction between genetic regulatory elements that modulate gene expression may explain some of the heritability that remains uncharacterized for many complex diseases and traits. We explored this hypothesis among childhood acute lymphoblastic leukemia (ALL) survivors for whom bone mineral density (BMD) may be reduced following cancer treatments received in childhood. We analyzed genotype data from 856 adult survivors of ALL (≥10 years from cancer diagnosis) to find SNP interaction patterns associated with age- and sex-standardized lumbar spine BMD Z-scores measured via quantitative computed tomography. After restricting SNPs to exclusively retain those in the regions of promoters and enhancers using ChromHMM regulatory states, our final genome-wide SNP set included 115,793 SNPs. We used a novel algorithm for chromosome-wide learning based on logic regression, an adaptive regression methodology that stochastically searches the space of fixed size interactions, to select the best 3-SNP interaction patterns. These interaction patterns, or 3-SNP Boolean logic trees, represent biologically plausible necessary or sufficient interaction conditions linked to BMD levels, accounting for sex, ancestry, and cumulative cancer treatment dosages. Our algorithm was applied to each chromosome, sequentially selecting 3-SNP Boolean logic trees conditioned on previously selected trees. We used 1,000 permutations to assess the statistical significance of each tree considering its selection order. This algorithm yielded eight 3-SNP trees with permutation-based p-values<0.05, of which five trees were validated in an independent sample of 1,428 non-ALL childhood cancer survivors, either as main or treatment interaction effects. All validated trees featured enhancer and promoter SNPs, none of which achieved genome-wide significance as single SNPs. The validated tree with the strongest statistical evidence of interaction was on chromosome 12 (mean BMD deviation, conditioned on first tree=1.72 SD, P=2.87x10[-13]). This tree may modify methotrexate-related effects on BMD (P=0.02, non-ALL) and implicates interactions between regions regulating the activities of *PFDN5* (repressor of c-Myc), *ANO2* (encodes CaCCs), and *DYRK4* (dual specificity kinase family member) to jointly affect BMD. In summary, our study demonstrates the utility of interaction association analyses in revealing new regulatory-element/gene-gene interaction mechanisms associated with complex traits.

382W

Two amino acids in HLA-B explain majority of the associations between HLA and cutaneous adverse drug reactions induced by phenobarbital and phenytoin in Japanese population. *T. Ozeki[1], T. Mushiroda[1], A. Takahashi[2], M. Kubo[3].* 1) Laboratory for Parmacogenomics, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 2) Laboratory for Stastical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 3) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan.

Anticonvulsants phenobarbital (PB) and phenytoin (PHT) are known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). To identify a gene(s) susceptible to PHT and PB-induced cADRs, we conducted a genome-wide association study (GWAS) and subsequent HLA typing in 22 cases of PB and PHT-induced cADRs (consist of 10 PB, 10 PHT and 2 PB / PHT treated patients) and 880 subjects of a general population in Japanese (GWAS) or 751 subjects of PB/PHT tolerant (HLA typing). Among the SNPs analyzed in the GWAS followed by imputation, 5 SNPs showed significant association with PB and PHT-induced cADRs, and rs34341880 showed the smallest *P*-value for association with PB and PHT-induced cADRs (additive model, $P = 3.7 \times 10^{-11}$; dominant model, $P = 4.8 \times 10^{-10}$). These SNPs were located in the *HLA-B* loci. Thus, we genotyped the individual *HLA-B* alleles and found that HLA-B*13:01 was present in 31.8% (7/22) of the cADR cases, but in 2.0% (15/751) of the tolerant controls (OR = 22.9, 95% CI = 8.2-64.3, $P = 7.0 \times 10^{-7}$). By the conditional analysis for the HLA-B amino-acid sequences, the most significant association was observed at a haplotype Leu145-Ala158 (corresponding to HLA-B*13:01 and B*13:02; OR = 19.9, 95% CI = 7.5-52.5, $P = 3.2 \times 10^{-7}$), followed by another haplotype Arg145-Thr158 (corresponding to HLA-B*38:01, B*38:02, B*39:01, B*39:02, B*39:04 and B*67:01; OR = 6.2, 95% CI = 2.6-15.1, $P = 2.1 \times 10^{-4}$). These two haplotypes showed the independent associations with PB and PHT-induced cADRs and the sum of them possessed the largest effect size (OR = 14.8, 95% CI = 5.9-37.2, $P = 6.0 \times 10^{-9}$). Comparison of genotypes of the *HLA-B* and the marker SNP rs34341880 in all subjects revealed that the sum of these two haplotypes (corresponding to the 8 *HLA-B* alleles) was in strong linkage disequilibrium (LD) with the T allele of rs34341880 ($r^2 = 0.95$, $D' = 1.00$). This work was supported by JSPS Core-to-Core Program, A. Advanced Research Networks.

GRIP1 and *SRGAP1* **as top candidate loci in extended multiplex autism families.** *P.L. Whitehead[1], S. Luzi[1], L. Gomez[1], A.J. Griswold[1], H.N. Cukier[1], J. Jaworski[1], S. Slifer[1], J.R. Gilbert[1,2], M.L. Cuccaro[1,2], E.R. Martin[1,2], J.I. Haines[3], M.A. Pericak-Vance[1,2].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) John T. MacDonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, OH.

Autism spectrum disorder (ASD) is a highly heritable and prevalent neurodevelopmental condition with a demonstrated high heritability but with a complex genetic architecture. While genetic studies to date, including common variant genome wide association studies and rare variant identification with whole exome sequencing, have identified more than 100 candidate genes and genomic loci, they have failed to explain all of the underlying genetic risk for ASD. In order to more fully investigate the genetic etiology of ASD, we have ascertained a unique resource of 86 families of European ancestry with multiple avuncular pairs of individuals with ASD across well characterized extended pedigrees. We hypothesize that in families of this type linkage studies will be a powerful tool to identify genomic risk loci. All individuals were genotyped on either the Illumina HumanHap550 or Illumina Human1M genome-wide genotyping platforms. Extensive parametric 2-point and parametric multipoint linkage was performed using MERLIN software followed by extensive data cleaning (Merlin and Pedwipe), LD pruning (r2=0.16), and manual inspection of potential double recombinants using the Progeny software. The two point parametric analysis indicated linkage at 31 autosomal loci with HLOD >3.3. Of these, highest significance was found at 12q14 and 15q21 loci with HLOD>5.4 and HLOD>3.5, respectively. Multipoint parametric analysis supported these findings. A 3Mb region of 12q14 showed an HLOD>2.5 and covers 26 genes[Office1] . A 1Mb region on 15q21 showed an HLOD>2.2 and covers eight genes. In order to refine these results, we used identity by descent sharing to narrow the linkage peaks to ~400kb on each chromosome. Among the genes contained in the linkage peaks are ASD candidate genes *GRIP1* and *SRGAP1* on chromosome 12 and a neuronal specific glycosidase enzyme *LCTL* on chromosome 15. Examination of existing whole exome sequencing data of both ASD and non-ASD individuals in these families did not reveal segregating coding variants that could explain the linkage signals. Therefore, follow-up custom targeted sequencing covering noncoding regions in the genome to identify segregating nonconding, regulatory variants is underway and will be presented[Office2] . Overall, this approach demonstrates the power of linkage in unique, extended ASD pedigrees and suggests a role for regulatory variants on chromosome 12 and 15 in the genetic etiology of ASD. .

Predicting age of onset in multiple sclerosis patients: *RGS14*, *CD40*, **and** *HLA-DRB1*15:01* **carriers are four years younger.** *M.F. George[1], Y. Natanzon[2], F.B.S. Briggs[2].* 1) Public Health, Dominican University of California, San Rafael, CA; 2) Institute of Computational Biology and the Department of Epidemiology and Biostatistics, School of Medicine, CWRU, Cleveland OH.

Epidemiologic evidence suggests a genetic component to multiple sclerosis (MS) clinical presentation. Previous research shows *HLA-DRB1*15:01* (DR2), the primary MS risk allele, is associated with earlier onset age. However, other genetic determinants of MS onset may also determine age of onset; therefore we hypothesize that increasing copies of the *established* risk alleles for genic MS variants predict earlier age of onset. There were 1,113 non-Hispanic white participants in the Accelerated Cure Project for Multiple Sclerosis with a comprehensive medical history and genotypic data. After removing genetic outliers and related individuals, 1,088 were available for analyses; all of whom had adult onset MS with mean onset age 33.4 yrs (SD=9.8). The sample was 78% females, 11% with a family history of MS, 94% relapsing presentation, and 33% ever smokers before onset. There was ≥80% power to detect 1.75 year change for MAF≥10% and 1.25 years for MAF≥25%. Therefore 49 of the 63 known non-MHC SNPs (MAF≥10%) were tested. Given the hypothesis, we imposed a Bonferroni corrected 1-sided α (p≤0.002). Disease course and smoking history were associated with onset age, thus all models were adjusted for these variables and ancestry. Consistent with prior findings, DR2 (rs3135388A) was significantly associated with onset age (p=0.0055); cases were 1.8 years younger per risk allele. Cases were 1.3 years younger per *CD40* (p=0.0009) and *RGS14* (p=0.002) risk allele. A score summing DR2, *CD40* and *RGS14* significantly predicted earlier onset (p=9.6x10[-7]). Individuals were on average 1.3 years younger per risk allele. Those with at least one risk allele (89%) were four years younger than cases with zero copies (p=2x10[-5]; 33 vs 37 years). Genetic risk score of all 50 or the remaining 47 variants were not associated with onset age. Genotyping of 250 white and 100 African American ACP participants are underway for replication analyses. These results are intriguing, suggesting specific MS risk variants may be associated with earlier onset age. *CD40* is a costimulatory protein found on antigen presenting cells and is required for their activation. Conversely *RGS14* is enriched in CA2 pyramidal neurons and suppresses synaptic plasticity. The findings suggest both inflammatory and neurodegenerative processes may contribute to earlier onset of MS. Replication is warranted, however if these findings are confirmed, the SNPs may contribute to the development of MS diagnostic tools. .

Analysis of large-scale whole exome sequencing data to determine the prevalence of genetically-distinct forms of neuronal ceroid lipofuscinosis. *J. Xing[1], E. Gedvilaite[1], Y. Zhang[1], P. Lobel[2], D. Sleat[2].* 1) Department of Genetics, Rutgers Univ, Piscataway, NJ; 2) Center for Advanced Biotechnology and Medicine and Department of Biochemistry and Molecular Biology, Rutgers Univ, Piscataway, NJ.

The neuronal ceroid lipofuscinoses (NCLs) are a group of fatal neurodegenerative lysosomal storage diseases. While clinically similar, they are genetically distinct and result from mutations in at least twelve different genes. Estimates of NCL incidence range from 0.6 to 14 per 100,000 live births but vary widely between populations and are influenced by whether patients are classified based upon clinical or genetic criteria. We investigated mutations in twelve NCL genes in ~61,000 individuals represented in the Exome Aggregation Consortium (ExAC) whole exome sequencing database. Variants were extracted from ExAC and pathogenic alleles differentiated from neutral polymorphisms using annotated variant databases and missense mutation prediction tools. Carrier frequency was dependent on ethnicity, with the highest (1/75) observed for *PPT1* in the Finnish. When data are adjusted for ethnic diversity within the USA, *PPT1*, *TPP1* and *CLN3* carrier frequencies were found to be the highest of the NCLs, each at ~ 1/400. Carrier frequencies calculated from ExAC correlated well with incidence estimated from numbers of living NCL patients in the US. In addition, the analysis identified numerous variants that are annotated as pathogenic in public repositories but have a predicted frequency that is not consistent with patient studies. These variants appear to be neutral polymorphisms that are reported as pathogenic without validation. Based upon literature reports, such alleles may be annotated in public databases as pathogenic and this propagates errors that can have clinical consequences.

386T

Epigenome-wide association study of delayed cerebral ischemia in stroke patients. *A. Arockiaraj, T.A. Koleck, J.R. Shaffer, P.R. Sherwood, E.A. Crago, S.M. Poloyac, D.E. Weeks, Y.P. Conley.* University of Pittsburgh , Pittsburgh, PA.

Aneurysmal subarachnoid hemorrhage (aSAH) is a form of stroke leading to severe patient outcomes including morality, cognitive impairment, functional disability, and emotional dysfunction. Variability in recovery and development of chronic complications is thought to be negatively impacted by delayed cerebral ischemia (DCI; insufficient blood flow to the brain), which may occur in patients 4 to 10 days following aSAH. Though little is known about the pathophysiology of DCI and its role in the development of chronic complications, dynamic methylomic changes occur during the period following brain injury, and DNA methylation is associated with ischemic tolerance in brain tissue. We hypothesize that epigenetic changes post-injury lead to differences in methylomic profiles between patients that go on to develop DCI and those that do not. Moreover, we hypothesize that these epigenetic changes occur in key genes and/or biological pathways related to recovery and chronic complications. To investigate these hypotheses, we performed parallel epigenome-wide association studies for DCI in 86 blood samples (from 43 DCI cases and 43 controls) and 66 cerebrospinal fluid samples (from 28 DCI cases and 38 controls) collected from patients 1 day after aSAH. Whole-genome methylation data were collected using the Illumina HumanMethylation450K BeadChip. Surrogate variable analysis was used to remove variation due to unknown confounding factors (e.g., distributions of cell types and batch effects). After correction for multiple testing, no significant results were obtained in the CpG site-specific tests for differential methylation in either of the two samples, suggesting that soon after aSAH, methylation differences may not be associated with future DCI events. Results of bump-hunting for differentially methylated regions spanning multiple CpG sites, which may be more powerful, will be presented. In conclusion, this study provides preliminary characterization of the methylomic profiles of cerebrospinal fluid in aSAH patients. Additional work is needed to understand how these methylomic profiles change across time post-injury, which specific regions are associated with DCI, and whether DNA methylation biomarkers may ultimately be useful for predicting aSAH recovery outcomes. 387F

Whole exome sequencing of early-onset Alzheimer disease highlights candidate risk genes involved in endocytosis. *B.W. Kunkle[1], B.N. Vardarajan[2], A.C. Naj[3], P.L. Whitehead[1], S. Rolati[1], S. Slifer[1], E.R. Martin[1], J.R. Gilbert[1], C. Reitz[2], J.L Haines[4], G.W. Beecham[1], G.D. Schellenberg[3], R.P. Mayeux[2], M.A. Pericak-Vance[1], The Alzheimer's Disease Genetics Consortium.* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Taub Institute of Research on Alzheimer's Disease, Columbia University, New York, NY; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

Introduction. Mutations in *APP*, *PSEN1* and *PSEN2* lead to early-onset Alzheimer disease (EOAD). These mutations account for only ~11% of EOAD overall, leaving the majority of genetic risk for the most severe form of Alzheimer disease (AD) unexplained. This extreme phenotype likely harbors highly penetrant risk variants however, and thus represents an excellent resource for discovery of novel risk genes and pathways for AD. **Methods.** We performed Whole-Exome Sequencing (WES) in 53 Non-Hispanic White (NHW) EOAD cases (Age-at-onset (AAO) < 65) previously screened negative for *APP*, *PSEN1*, and *PSEN2* to search for rare variants contributing to risk for EOAD. Variant filtering for rare, damaging (CADD Phred Score ≥ 15) nonsynonymous or loss-of-function (LOF) variants (MAF<0.1%) was performed, using familial segregation data if available. Followup of a) variants in two or more NHW cases, b) genes with variants in the same gene for two or more NHW cases and c) candidate variants and genes present in 19 Hispanic EOAD WES families, was conducted in an Alzheimer's Disease Genetics Consortium (ADGC) cohort of 1,292 EOAD cases (AAO <= 65), 7,087 late-onset AD (LOAD) cases (AAO > 65) and 6,889 controls (Age-at-exam ≥ 65) genotyped with the Illumina exome chip. **Results.** We identified 108 rare, damaging nonsynonymous or LOF variants in two or more EOAD cases, of which 43 were available on the exome chip. Among these, we found a missense variant in the endosomal trafficking gene *RUFY1* associated with EOAD (P=0.0038). Gene-based testing (SKAT-O) revealed several genes associated with EOAD including *PSD2* (P=0.001), which was also associated with risk of LOAD in the ADGC cohort (P=6.2x10^{-6}). Additionally, a damaging missense variant in the gene *TCIRG1* was present in both NHW and Hispanic EOAD WES cohorts, was more frequent in cases than controls (MAF = 0.0032 and 0.0014, respectively) in the ADGC EOAD cohort (P=0.059), and was significant in the ADGC LOAD cohort (P=0.0065). *PSD2* and *TCIRG1* are also involved in endocytosis, a process known to be important to development of AD through the gene *SORL1*. Multiple brain expression datasets show all three genes to be differentially expressed in AD. **Conclusions.** WES of EOAD identified novel candidate endocytic genes for EOAD, two of which are shared risk genes between EOAD and LOAD, a phenomena previously discovered for genes such as *SORL1*, *PSEN2* and *TREM2*.

High-resolution imputation of rare variants identifies novel rare variant candidate loci in late-onset Alzheimer's disease: The Alzheimer's Disease Genetics Consortium. *A.C. Naj[1], Y. Zhao[2], L. Qu[2], S.J. van der Lee[3], K.L. Hamilton-Nelson[4], B.W. Kunkle[4], A. Kuzma[2], O. Valladares[2], C. Reitz[5], G.W. Beecham[3], E.R. Martin[3], L.-S. Wang[2], J.L. Haines[6], R. Mayeux[5], L.A. Farrer[7], M.A. Pericak-Vance[4], G.D. Schellenberg[2], Alzheimer's Disease Genetics Consortium.* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Department of Epidemiology, Erasmus University Medical Centre, Rotterdam, Netherlands; 4) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 5) Gertrude H. Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 6) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 7) Departments of Medicine, Neurology, Ophthalmology, Genetics & Genomics, Epidemiology, and Biostatistics, School of Medicine, Boston University, Boston, MA, USA.

The largest genome-wide association study (GWAS) to date for late-onset Alzheimer Disease (LOAD) identified 19 susceptibility loci in addition to *APOE*, the majority of which were common variant associations (minor allele frequency (MAF)>0.05). The Haplotype Reference Consortium (HRC) recently released a reference panel of 64,976 haplotypes with 39,235,157 SNPs allowing imputation down to an unprecedented MAF=0.00008 to test association of very low frequency variants. To identify novel rare variant associations, ADGC imputed 33 case-control, family, and prospective datasets including 14,743 cases and 15,871 non-cases to the HRC reference panel (8/15 release) using Minimac3 on the University of Michigan Imputation Server, with an average 39,216,773 genotyped or imputed SNVs per dataset. Logistic regression on common variants (MAF>0.01) was performed using imputed genotype probabilities in PLINKv1.9 (generalized linear mixed model in R were used for family-based datasets) and meta-analyzed in METAL, while rare variants (MAF≤0.01) were analyzed using score-based tests and meta-analysis in the SeqMeta/R package; both analyses adjusted for age, sex, and population substructure. Preliminary analyses identified five loci with P<5×10^{-8} in known GWAS candidate loci (*APOE*, *BIN1*, the *MS4A* region, *PICALM*, and *CR1*), consistent with previous associations in these data. An additional 13 loci demonstrated multiple single variant associations with P<10^{-5}, including variants at two prior GWAS loci, rs13155750 in *MEF2C* (OR(95% CI): 1.13(1.08,1.20); P=5.09×10^{-6}) and rs755951 in *PTK2B* (OR(95% CI): 1.11(1.06,1.16); P=5.61×10^{-6}). Novel associations observed include signals at *LILRA5* (19:54821819; OR(95% CI): 1.14(1.08,1.20); P=4.84×10^{-7}), known to be involved in innate immunity pathways; and at *SMOX* (rs1884732; OR(95% CI): 1.11(1.06,1.17); P=5.17×10^{-6}), which is involved in the catabolism of polyamines, levels of which are altered in AD brains. Score test analyses of rare variants identified a novel association at *CUTC* (chr10:101510468, MAF=0.002; OR(95% CI): 0.27(0.17,0.43); P=4.57×10^{-8}), a chromosome 10 copper homeostasis gene proximal to the AD-implicated gene *DNMBP*. Replication analyses and functional follow-up are underway; results will be presented. Several novel candidate loci for LOAD were identified using high-quality imputation of rare variants in the ADGC, demonstrating the utility of rare variant imputation using dense haplotype reference panels for gene discovery.

Dissecting the shared genetic architecture of human communication: Insights into speech, language and reading. *H. Voss-Hoynes[1], C.M. Stein[1,5], B. Truitt[1], J. Tag[2], L. Freebairn[2], J. Vick[2], H.G. Taylor[3], B.A. Lewis[2], S.K. Iyengar[1,4].* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Communication Sciences, Case Western Reserve University, Cleveland, Ohio; 3) Pediatrics, Case Western Reserve University, Cleveland, Ohio; 4) Genetics and Genome Sciences, Case Western Reserve University, Cleveland, Ohio; 5) Center for Proteomics & Bioinformatics, Case Western Reserve University, Cleveland, Ohio.

Purpose. Speech sound disorders (SSD) are communication disorders that occur in 16% of three-year-olds. These disorders affect sound patterns (phonology) and sound production (articulation), and can be comorbid with impairments in language (LI) and reading (RD) likely due to shared genetic architecture. We aimed to explore the shared architecture through genome-wide association study of reading ability and to determine if the genetic-quantitative trait relationships are affected by RD and LI. **Methods**. Using a mixed linear model, we performed a family-based, genome-wide association study in 318 Caucasian individuals over 5 years old with Omni 2.5 Exome chip data imputed to Phase 3 of the 1000 Genome Project. The outcome was scores on the Woodcock Word Identification (WRID) test, a known word reading test. **Results**. We report evidence of the shared genetic architecture between LI, RD, and SSD. The most significant marker, rs193704, B_{unadj}=2.47 ± 0.44, p=3.63x10^{-7}, is a protective locus within *ATP2C2*, a gene previously associated with phonological processing in individuals with LI. Phonological processing, the ability to fraction words into component sounds, is the most common link between SSD, LI, and RD and is positively correlated with reading ability (R^2=0.40). The strength of the relationship between markers in *ATP2C2* and reading scores is slightly reduced when accounting for LI (B_{unadj}=2.47 ± 0.44 vs. $B_{adjlang}$=2.17 ± 0.45, Δ= -12%) and RD affection status ($B_{adjread}$=2.22 ± 0.44, Δ= -10%), but the marker remains genome wide suggestive (p_{lang}= 1.91x10^{-6}, p_{read}=4.46x10^{-6}). Our next most significant signal was a novel locus in *IQCE* (rs4721874,-2.09±0.44, p=3.12x10^{-6}). IQCE is expressed in the hippocampus and is involved in cilia mediated Shh signaling, a process which mediates adult neurogenesis in the same region. Because the hippocampus plays a role in learning, memory, and visual processing, aberrant neurogenesis could result in reading deficits. Accounting for LI and RD attenuates the relationship between rs4721874 and WRID (B_{lang}= -1.6 ±0.42, p_{lang}=1x10^{-4}; B_{read}=-1.4 ±0.4, p_{read}=3x10^{-4}). While IQCE may influence reading, it does not do so independently of LI and RD status. **Conclusions**. Our findings suggest that speech, language, and reading are intricately connected by pleiotropic gene networks. Perturbations in these networks and genes provide insights into how modern human communication has evolved. DC00528, DC012380, T32-HL007567.

Deep genomic analysis of complex diseases and its potential application to precision medicine. *M. Xiong[1], P. Wang[4], N. Lin[1], Y. Zhu[2], J. Zhao[2], L. Jin[4], D. Bennett[3].* 1) Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX; 2) The Tulane University , New Orleans, LA; 3) Rush University Medical Center, Chicago, IL; 4) Fudan University, Shanghai, China.

Next-generation sequencing, imaging and sensing technologies will generate deeper genomic and phenotypic data with millions of features. There are multiple steps between genes and phenotypes. Each step may be influenced by genomic variation and can weaken links between genes and phenotypes. As a consequence, this will obscure the causal mechanism of the phenotype. Integrated and deep analysis of such increasingly larger and deeper biomedical datasets will provide invaluable information for holistic discovery of complicated genetic structures underlying human complex diseases. Precision medicine demands deep, systematic, comprehensive and precise analysis of genotype-phenotype – "and the deeper you go, the more you know". But, standard genetic analysis is to test the association of single variants with a single trait. However, these traditional approaches are less efficient in analyzing high-dimensional, heterogeneous types of correlated genomic and multiple phenotype data, and thus unable to reveal the deep causal structures underlying human complex disorders. Therefore, there is urgent need to develop novel statistical methods and computational algorithms for big and deep genomic analysis of complex diseases and precision medicine. To break the current impasse in progress to precision medicine, we use causal inference theory and chain graph models to develop an innovative analytic platform for deep and precise multilevel hybrid causal genotype-disease network analysis to increase breadth (the number of phenotypes which the genetic variants affect) and (2) depth (the number of steps which are taken by the genetic variants to reach the clinical outcomes). The proposed methods have been applied to Alzheimer Disease (AD) dataset with 53295 genes typed in 1,708 individuals. We identified 387 genes associated with AD, and 20 AD related traits including 7 cognitive function traits, 7 lipoprotein metabolism traits) and 5 environments. We also identified a genotype-disease network consisting genotype subnetwork, phenotype subnetwork and environment subnetwork. The network consists of 37 nodes and 139 edges. All phenotypes in the network were clustered into two groups: cognitive trait group and lipid metabolism trait group. Two groups were connected via MMSE and SBP connection. Five genes were directly connected with AD. Eight genes have > 9 connections. Most genes included in this network are involved in neurological and neuropsychiatric disorders.

Heteroscedastic pleiotropy mapping on the biomedical image data of multiethnic schizophrenia patients. *H. Qin[1], W. Ouyang[1], Y.P. Wang[2].* 1) Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Biomedical Engineering, New Orleans, LA 70118, USA.

Heteroscedasticity (aka, dispersion heterogeneity of trait residuals) is a common phenomenon in biomedical image data mining. It is especially significant when massive clinical traits are involved. As a cause for cross-trait association, pleiotropy occurs when a genetic locus truly affects two or more distinct clinical disorders. Detection and interpretability of complex SNP(s)-trait(s) associations are complicated due to LD patterns between SNPs and correlations between traits. Background confounders, especially in multiethnic imaging studies, may have impact both mean and higher-order heterogeneities of clinical traits. However, existent multivariate methods neglect all the dispersion effects of both test biomarkers and background confounders. After calibrating confounding effects, leveraging dispersion effects of multiple genetically correlated traits is expected to localize not only trait-specific causal loci and genes but also those pleiotropic ones shared between the traits. Herein, we describe a double generalized heteroscedastic linear-mixed model based procedure for heteroscedastic pleiotropy mapping (HPM). In this multi-trait gene-wise association method, we scale the importance of individual traits by the *p*-values of marker-wise heteroscedastic effects. For each trait, causative SNPs and the flanking random markers are up-weighted, and others, down-weighted. By extensive simulations under published designs, the proposed method properly controlled type I error rates and appeared strikingly more powerful than existent prominent multivariate sequence association methods. The HPM is computationally efficient, integrates informative heterogeneities and diverse genetic effects while simultaneously adjusting for arbitrary background covariates and cryptic relatedness. It displayed particular utility in analyzing the biomedical image data of multiethnic schizophrenia patients. In summary, we have paved an effective avenue to integrate high-order informative heterogeneities while adjusting for heteroscedastic background confounders. Our results have demonstrated the tremendous potential gain of explicitly handling higher-order heterogeneities in big multiethnic image data. This work was supported by Innovative Programs Hub (I2PH) Grants Award of Tulane (632037) and Tulane's Committee on Research fellowship (600890).

Novel genetic loci associated with relapse rate in multiple sclerosis. *Y. Zhou[1], S. Simpson,Jr.[1], J. Charlesworth[1], I. van der Mei[1], R. Lucas[2], A.L. Ponsonby[3], B.V. Taylor[1].* 1) Menzies Institute for Medical Research, Hobart, TAS, Australia; 2) National Centre for Epidemiology and Population Health, Canberra, Australia; 3) Murdoch Children's Research Institute, University of Melbourne, Melbourne, Australia.

Background: Due to the gradual accumulation of multiple sclerosis (MS) progression and the high cost of follow-up, no study has ever tried to identify genetic factors that predict relapse rate at a genome wide scale. **Material and Methods:** In the discovery stage, the genome wide association analysis for predicting relapse rate was done using the Southern Tasmania MS Longitudinal Study with 141 participants followed for 2.5 years. In the validation stage, SNPs with P<0.05 from discovery stage were further validated using another independent longitudinal study (the Ausimmune Longitudinal Study) with 279 participants followed for 5 years. Predictors of time to relapse were evaluated by Cox proportional hazards regression models. **Results:** We discovered one novel loci (*LRP2*) with multiple variations with genome wide significance that predict relapse (HR=2.25, P=4.02×10^{-8}). LRP2 is critical for the reuptake of ligands, including lipoproteins, sterols, vitamin-binding proteins and hormones. LRP2 is expressed on the surface of many CNS cells including neurons and oligodendrocytes and is a critical receptor in axonal guidance. Another loci (*N4BP2*) showed suggestive association with relapse (HR=2.31, P=8.82×10^{-8}). **Conclusion:** Our results provided novel insights into the genetic drivers of variation in risk of relapse rate in MS. The finding of a genome wide significant loci that has extensive effects on neuronal development and repair is of significant interest.

Two‑component mixture modelling approach integrating genetic and clinical variables in analysis of time to remission in epilepsy. *B. Francis[1], A. Jorgensen[1], A. Morris[1], A. Ingasson[2], A. Marson[1], M. Johnson[3], G. Sills[1], EpiPGX.* 1) University of Liverpool, Liverpool, Merseyside, United Kingdom; 2) deCODE, Iceland; 3) Imperial College London, United Kingdom.

Time to twelve months seizure freedom (remission) after randomisation to an antiepileptic drug (AED) is an important outcome in the treatment of epilepsy with an established genetic component to variable response. A collaborative dataset of 1,706 patients of European ancestry has been assembled via the EpiPGX Consortium to investigate genetic risk factors for remission and other epilepsy-related outcomes. Genotype data were subject to quality control and individuals with <90% match with European reference data were removed from downstream association analyses. The cleaned data was then imputed up to the 1000 Genome reference panel (March 2012 release , all ancestries) using IMPUTE2. Two sub-populations exist for time to remission; those who enter remission and those not susceptible to remission. A traditional survival analysis approach was therefore inappropriate, as the assumption of a homogenous population is violated, and may lack power to detect SNP associations. To consider these two sub-populations, mixture modelling with cure fraction was implemented in a two component model. The two component model is computationally expensive and cannot be applied on the scale of the whole genome. Therefore, to test association, deviance residuals for susceptibility to remission and survival were derived, after adjustment for relevant clinical covariates. We performed multivariate association analysis of SNPs with "reverse regression" modelling in the PLEIOTROPY software. No SNP associations attained the threshold of genome-wide significance ($p < 5 \times 10^{-8}$). However, lead SNPs in several loci attained nominal significance ($p < 1 \times 10^{-5}$), including: IQCK (rs724614, $p = 9.36 \times 10^{-7}$) and PDE3A (rs7484691, $p = 7.62 \times 10^{-7}$). Further investigation of these loci will be undertaken by performing computationally expensive two component survival modelling, including SNP genotypes in the model alongside clinical covariates.

Case-only investigation confirms multiple sclerosis risk conferred by tobacco smoke is modified by *NAT1.* *F.B.S. Briggs[1,2].* 1) Department of Epidemiology and Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH; 2) Institute of Computational Biology, Case Western Reserve University, Cleveland, OH.

Background: Multiple sclerosis (MS) is a multi-factorial autoimmune and neurodegenerative disease of the central nervous system, with genetic and exogenous risk components. Of the exogenous risk factors, tobacco smoke confers the largest risk (OR~1.5). Unfortunately the underlying processes mediating MS risk in smokers remain unknown. A prior case-control study identified a gene-environment interaction between *NAT1* and tobacco smoke (Briggs *et al* 2014), suggesting tobacco smoke metabolism is relevant. MS risk among smokers was significantly increased among carriers of a rs7388368A-rs4921877T-rs6586711C haplotype. **Methods:** 1,088 non-Hispanic white MS participants in the Accelerated Cure Project for MS (ACP) with epidemiologic and genetic data were available for analyses. All participants had an age of onset ≥18 years. Participants reported detailed smoking history; they were classified as a smoker if they were an active smoker within 5 years prior onset. Participants were genotyped using a Human Illumina Custom BeadChip, including >200,000 exonic variants. 80 *NAT1* variants with MAF≥0.01 and genotype rate≥99% were available. Given the prior finding, this investigation focused specifically on variation within the respective haplotype block, defined similarly using solid spline (extend where D'>0.8). There were 4 haplotype blocks across the gene; the second block consisted of 6 SNPs including rs4921877 and rs6586711 (rs7388368 was not available) and spanned 13kb. Case-only analyses were conducted using smoking status before onset as the outcome for the individual SNP and haplotype analyses. All models were adjusted for gender, birth year, disease course, age of onset, and ancestry. A 1-sided Bonferroni-corrected (6 SNPs) alpha of 0.0083 determined significance. **Results:** *NAT1* rs56261729A, which alters a SRF motif, was significantly associated with smoking status (OR=3.3, p=0.0067; MAF=0.03). Smokers were more likey to have rs4921877T and rs6586711C (OR~1.3), but associations were not significant (p>0.1). There were 6 haplotypes, only one carried rs56261729A, and it was significantly associated with smoking status in MS cases (OR=2, p=0.0055). Both the haplotype and the SNP had the same frequency: 4.2% in smokers and 2.3% in non-smokers. **Conclusions:** This case-only analysis confirms a previously identified *NAT1* haplotype block locus as modifying MS risk conferred by tobacco smoke. Further analyses are needed to further characterize this *NAT1* haplotype block.

Using LASSO regression to identify gene-gene and gene-environment interactions influencing cognitive function in a sample at increased risk for Alzheimer's disease. *B. Darst[1], M. Bilgel[2,3], R. Koscik[4], B. Hermann[4,5,6], B. Jedynak[7], S. Johnson[4,5,8], C. Engelman[1,4,8].* 1) Department of Population Health Sciences, University of Wisconsin, Madison, Madison, WI; 2) Department of Biomedical Engineering, Johns Hopkins University School of Engineering, Baltimore, MD, USA; 3) Laboratory of Behavioral Neuroscience, National Institute on Aging, NIH, Baltimore, MD, USA; 4) Wisconsin Alzheimer's Institute, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA; 5) Geriatric Research Education and Clinical Center, Wm. S. Middleton Memorial VA Hospital, Madison, WI, USA; 6) Department of Neurology, University of Wisconsin School of Medicine and Public Health, WI, USA; 7) Department of Applied Mathematics and Statistics, Portland State University, Portland, OR, USA; 8) Alzheimer's Diseases Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI, USA.

Alzheimer's disease (AD) is the 6th leading cause of death in the US and the only leading cause that cannot be prevented, cured, or treated. Although the heritability of AD is estimated to be 58%, most known genetic variants only account for 8% of the phenotypic variance of AD. Expanding investigations to include complex nonlinear relationships between genetic and environmental factors may explain some of this missing heritability. In this analysis, we explore gene-gene and gene-environment interactions that may be influencing cognitive function using participants from the Wisconsin Registry for Alzheimer's Prevention, a longitudinal family-based cohort of initially cognitively healthy adults (N=1,293) enriched for a parental history of AD. This analysis included 19 genetic variants indicated to be associated with AD by the International Genomics of Alzheimer's Project, plus *APOE* ε2 and ε4, and eight environmental factors that have been previously associated with AD: age, gender, education, physical activity, waist-hip ratio, total cholesterol, insulin resistance, and inflammation as measured by interleukin 6 (IL6). We performed variable selection using least absolute shrinkage and selection operator (LASSO) regression, inputting all possible pairwise interaction terms into the model and using the value of the parameter λ that gave the minimum mean cross-validation error. Potential interactions identified by LASSO were tested for significance in mixed linear models. Of the 14 gene-gene or gene-environment terms identified by LASSO, two were statistically significant. An interaction between rs6656401 (*CR1*) and rs9271192 (*HLA-DRB1*) (*P*=.004) suggested that being a carrier of either of these variants was associated with poorer cognitive function, whereas being a carrier of both of these variants was associated with better cognitive function. Evidence of this relationship was also provided by three of six other independent cognitive measures (all with *P*<.004). This suggests that while these variants are independently detrimental, collectively they may have a protective effect. The second interaction was between rs190982 (*MEF2C*) and IL6 (*P*=.006); however, we did not see evidence for this relationship in other cognitive measures. All three of these genes have been reported to be in the immune system pathway and are associated with several other autoimmune diseases. These findings support the early involvement of the immune system in AD.

396F

Mendelian randomization identifies ACE, APOC-1, APOE, clusterin, and GDF-15 as causal serum biomarkers of Alzheimer disease risk. *D. Carere[1,2,3], J. Sjaarda[1,2,4], S. Hess[5], H. Gerstein[1,6,7], G. Pare[1,2,3].* 1) Population Health Research Institute, David Braley Cardiac, Vascular and Stroke Research Institute, 237 Barton Street East, Hamilton, Ontario, Canada; 2) Thrombosis and Atherosclerosis Research Institute, David Braley Cardiac, Vascular and Stroke Research Institute, Hamilton, Ontario, Canada; 3) Department of Pathology and Molecular Medicine, McMaster University, Michael G. DeGroote School of Medicine, Hamilton, Ontario, Canada; 4) Department of Medical Sciences, McMaster University, Hamilton, Ontario, Canada; 5) Sanofi Aventis Deutschland GmbH R&D Division Diabetes, Frankfurt, Germany; 6) Department of Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, Ontario, Canada; 7) Department of Medicine, McMaster University, Hamilton, Ontario, Canada.

Background: Dozens of blood-based biomarkers have been linked to Alzheimer disease (AD), but findings are inconsistent, and likely biased by unmeasured confounding and reverse causation. We combined biomarker data from the Outcome Reduction within Initial Glargine Intervention (ORIGIN) trial with AD data from the International Genomics of Alzheimer's Project (IGAP), and used Mendelian randomization (MR) to identify blood serum biomarkers with a causal role in AD. **Methods:** Genotyping data and baseline serum measurements of 237 biomarkers were available from 5,078 ORIGIN trial participants. Summary statistics from a genome-wide association study of AD (17,008 cases and 37,154 controls) were obtained from IGAP. MR analyses were restricted to biomarkers directly encoded by an autosomal gene and SNPs within 300Kb of a biomarker's corresponding gene. MR associations were computed by regressing SNP-AD effect estimates on SNP-biomarker effect estimates. Conditional MR was used to evaluate independence of effect of proximally encoded biomarkers. **Results:** After quality control, 1,731 non-redundant SNPs associated with 203 biomarkers were available for MR. Five biomarkers were associated with AD, after adjusting for multiple hypothesis testing (α = 0.05/203). MR predicted a deleterious effect of apolipoprotein C-1 (APOC-1, 11 SNPs; OR=1.89 (1.65-2.16)) and growth differentiation factor 15 (GDF-15, 9 SNPs; OR=1.24 (1.14-1.35)); and a protective effect of angiotensin-converting enzyme (ACE, 15 SNPs; OR=0.91 (0.87-0.95)), apolipoprotein E (APOE, 20 SNPs; OR=0.33 (0.32-0.35)), and clusterin (4 SNPs; OR=0.67 (0.56-0.80)). In an adjusted analysis of APOE and APOC-1 (27 SNPs total), each biomarker remained significantly associated with AD. When we further removed from the joint analysis the *APOE* SNPs which determine epsilon allele status (rs7412, rs429358), and all SNPs in LD with these, the effects persisted: APOC-1 OR = 4.09 (3.48-4.81); APOE OR = 0.20 (0.18-0.23). **Conclusion:** Mendelian randomization suggests a causal role for serum ACE, APOC-1, APOE, Clusterin, and GDF-15 concentration in AD risk. The risk effects of increased serum APOC-1 and decreased serum APOE concentration appear to be independent of each other, and of *APOE* epsilon allele status. Our study takes advantage of the largest AD genetics dataset available, and in combination with data on hundreds of serum biomarkers, represents the first investigation of multiple blood biomarkers for a causal role in AD.

397W

Adaptive testing for multiple traits with applications to detect SNP-brain network associations. *J. Kim, W. Pan.* Division of Biostatistics, University of Minnesota, Minneapolis, MN.

There has been increasing interest in developing more powerful and flexible statistical tests to detect genetic associations with multiple traits, as arising from neuroimaging genetic studies. Most of existing methods treat a single trait or multiple traits as response while treating an SNP as a predictor coded under an additive inheritance mode. In this paper we follow an earlier approach in treating an SNP as an ordinal response while treating traits as predictors in a proportional odds model (POM). In this way, it is not only easier to handle mixed types of multiple traits, e.g. some quantitative and some binary, but it is also more robust to the common assumption of an additive inheritance mode. More importantly, we develop an adaptive test in a POM so that it can maintain high power across many possible situations. Contrary to the existing methods treating multiple traits as responses, e.g. in a generalized estimating equation (GEE) framework, the proposed method can be applied to a high dimensional setting where the number of phenotypes (p) can be larger than the sample size (n), in addition to a usual small p setting. The promising performance of the proposed method was demonstrated with applications to the Alzheimer's Disease Neuroimaging Initiative (ADNI) data, in which either structural MRI driven phenotypes or resting-state functional MRI (rs-fMRI) derived brain functional connectivity were used as multiple phenotypes. The applications led to the identification of several top SNPs of biological interest. Furthermore, a simulation study showed competitive performance of the new method compared to several existing methods, including potential power gain of the new method in cases with a dominant inheritance mode.

The rare variant generalized disequilibrium test for association analysis of nuclear and extended pedigrees. *S.M. Leal, Z. He, D. Zhang, B. Li, G.T. Wang.* Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX.

Whole genome and exome sequence data can now be cost effectively generated for families in order to perform rare variant (RV) association analysis. An advantage of analyzing families is that causal variants that aggregate in families usually have larger effect sizes than those found in the general population, thus increasing the power of family-based association studies. Population-based RV association studies can also suffer from the inflated false-positive rates due to population admixture/substructure which family-based analysis can avoid. We developed RV extensions of the Generalized Disequilibrium Test (GDT; Chen et al 2009) to analyze nuclear and extended families. The GDT utilizes the genotype differences of all discordant relative pairs to assess association within a family, and the RV extension of GDT (RV-GDT) is combination of the single variant GDT statistic over a genomic region of interest. The GDT has increased power by efficiently incorporating information beyond first-degree relatives and can be applied when there is missing genotype, e.g. parental data is missing. Using simulated genetic data, we demonstrate that the RV-GDT method has well-controlled type I error rates, even when applied to admixed populations. We also extended the Pedigree Disequilibrium Test (PDT; Martin et al. 2000) to analyzed RVs but the RV-GDT has higher power. The RV-GDT is also more powerful than the RV Affected Sibpair (Epstein et al. 2015) and Family Based Association Test (FBAT, De et al. 2013). The additional advantage of the RV-GDT over these methods is that it can be utilized to analyze extended families and also allows for missing genotype data. Using the RV-GDT publically available user-friendly software we analyzed the exome sequence data from 2,377 nuclear families with autism spectrum disorder (ASD) from Simons Simplex Collection and whole genome sequence data from 81 nuclear and extended Alzheimer's disease (AD) pedigrees. We identified several genes associated with ASD: *ACSBG2*, *C17orf50* and *SGCA* and AD: *TNK1*. Additional results from these analyses as well as extensive simulation studies will be used to demonstrate the power and capabilities of RV-GDT to identify genes involved in the etiology of complex familial diseases.

399F

Coding and non-coding variants in known Alzheimer's candidate genes co-segregate with Late-Onset Alzheimer's disease (LOAD) in the Alzheimer Disease Sequencing Project genome sequence data. *J. Jaworski[1], G. Beecham[1], B. Vardarajan[2,3,4], E. Blue[5], S. Barral[2,3,4], J. Haines[6], W. Bush[6], C.M. Van Duijn[7], E. Martin[1], G. Schellenberg[8], R. Mayeux[2,3,4], E. Wijsman[5], M. Pericak-Vance[1].* 1) John P. Hussman Institute of Human Genomics, Miller School of Medicine, Universi, Miami, FL; 2) The Taub Institute of Research on Alzheimer□s Disease, Columbia University, New York, NY, USA; 3) The Gertrude H. Sergievsky Center, Columbia University, New York, NY, USA; 4) The Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY, USA; 5) Department of Medicine, University of Washington, Seattle, WA, USA; 6) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 7) Erasmus MC, Epidemiologie, Rotterdam, The Netherlands; 8)) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

   Background: The Alzheimer's disease Sequencing Project (ADSP) is an initiative to identify genetic variation influencing LOAD risk. To accomplish this we performed whole-genome sequencing (WGS) on 44 non-Hispanic white (NHW) extended families affected by LOAD and investigate whether variation in known candidate genes co-segregated with LOAD in these families. **Methods**: WGS data were generated for 229 subjects from 44 NHW families at the NHGRI sequencing centers, including both affected individuals and unaffected, elderly relatives. Sequence alignment was performed using BWA, followed by consensus genotype calling using multiple pipelines. Our candidate genes include known early-onset AD (EOAD) genes, genes known to cause dementia, and LOAD genes implicated by GWAS or resequencing studies. Variants within candidate gene regions were annotated for function, frequency, segregation with disease, and information from the ADSP case-control and other datasets. **Results:** We identified 41 variants across the families that were within a candidate gene and co-segregated in >75% of affected genotyped with disease, had minor allele frequency <5%, and were putatively functional (CADD score > 15). These variants were in 12 of the known EOAD genes or LOAD genes implicated by GWAS, most notably *APP*, *PICALM*, *PSEN1*, and *GRN*. *MS4A6A* had a rare, putatively functional (CADD=23.9) splice donor variant. Two other non-intronic, non-coding variants were 3' UTR variants seen in *PICALM* (CADD=20.4) and *MEF2C* (CADD=16.5). Within genes known to cause dementias that can mimic AD, we find co-segregating missense variants in *CSF1R*, *PDGFRB*, and *NOTCH3*, and non-coding variants in *CSF1R* and *SLC20A2*. Within genes known to cause dementias distinct from AD, we find co-segregating missense variants in *ATP13A2* and *LMNB1*, and non-coding variants in *GALC*, *TARDBP*, and *TBP*. All of these non-coding variants with RSIDs are annotated as having enhancer or promoter histone marks. **Conclusion**: This study suggests that rare variation in previously identified candidate genes may play a role in familial LOAD risk. This role extends to both early-onset genes and genes previously implicated with common variation, and may indicate additional mechanisms for LOAD risk.

400W

Whole genome sequence analysis of brain MRI measures in the Framingham Study. *C. Sarnowski[1], C.L. Satizabal[2,3], C. DeCarli[4], A.N. Pitsillides[2], A. Beiser[1,2,3], A.L. DeStefano[1,2,3], J. Dupuis[1,2], S. Seshadri[2,3].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 3) Department of Neurology, Boston University School of Medicine, Boston, MA; 4) Department of Neurology, University of California at Davis, CA.

   Background: Brain MRI measures such as Total Brain Volume (TBV), Hippocampal Volume (HPV) and White Matter Hyperintensities (WMH) are endophenotypes of Alzheimer disease (AD) and vascular injury. Identifying loci that influence these measures may lead to the discovery of new genes and biological mechanisms underlying these diseases. Genome-Wide Association Studies (GWAS) have identified common genetic variants (Minor Allele Frequency ≥ 5%) with modest effect sizes, and most identified variants reside in non-coding regions. **Aim:** We sought to identify rare variants influencing TBV, HPV and WMH in the Framingham Study by performing Whole Genome Sequence (WGS) analyses within the Trans-Omics for Precision Medicine (TOPMed) Program. **Methods:** A total of 905, 894 and 672 individuals from TOPMed were included in the WGS analyses of TBV, HPV and WMH respectively. Mixed effect linear regression models of brain MRI measures were adjusted for sex, age and total intracranial volume and rank-normalized residuals from these models were tested for association with individual SNPs while taking into account familial relatedness. Gene-based tests were conducted for rare variants with two different methods (SKAT or burden test) using 1) a sliding-window approach or 2) a selection of functional exonic SNPs. Finally, WGS results were compared to GWAS using imputed data from the Haplotype Reference Consortium release 1 (~4,000 genotyped individuals with phenotype data). **Results:** WGS analyses revealed at the genome-wide level (P≤5x10[-8]) a new locus in 3q24 for HPV (P_{WGS}=2.0x10[-9], P_{GWAS}=0.003) and suggestive results (P≤10[-6]) in new regions for HPV (5q35, 8q24, 11p15, 19p13), WMH (11p12) and TBV (4q25). Known associations in 12q24 for HPV (P_{WGS}≤ 2.5x10[-3], P_{GWAS}≤ 4.1x10[-8]) and in 17q25 for WMH (P_{WGS}≤ 2.8x10[-4], P_{GWAS}≤ 4.2x10[-6]) were observed. Gene-based tests using a sliding-window approach detected genome-wide associations (P≤2.5x10[-6]) in new loci for HPV (3q24) and TBV (17p13) with the SKAT method and for HPV (4p15, 12q23, 12q24) and TBV (5q23, 9p21) with the burden test. The 3q24 locus associated with HPV includes *ZIC1,* a transcription factor expressed only in human brain with tumor suppressor function that has an important role in brain development and can transactivate *APOE*, whose ε4 allele is the major known risk-factor for late-onset AD. **Conclusion:** This study reveals intriguing new loci determining brain volumes. Replication is underway to confirm these findings.

401T

Improving pedigree-based genotype imputation with simultaneous use of identity-by-descent and linkage disequilibrium information. *R.A. Nafikov[1], E.M. Wijsman[1,2,3].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA; 2) Department of Biostatistics, University of Washington, Seattle, WA, USA; 3) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Pedigree-based genotype imputation methods rely on identity-by-descent (IBD) information. Genomic regions with IBD originate from the same pedigree founder chromosome, allowing imputation of missing alleles by copying from observed to unobserved alleles that originate from the same inferred founder chromosome. Recent research by our group showed the advantage of also incorporating knowledge about linkage disequilibrium, the main source of information used by population-based imputation methods, to increase the accuracy and completeness of imputed genotypes. Both approaches to imputation start with a haplotype-phasing step, which assigns alleles at different nearby sites to one of the two members of a chromosomal pair in an individual. We are developing an approach that can simultaneously utilize pedigree- and population-based information, with the aim of obtaining improved imputation quality especially in the context of missing founder samples and low-frequency alleles. Missing data is common in family studies, and current models of the genetic architecture of many traits include rare and low-frequency variants. We used our pedigree-based genotype imputation program, GIGI, modified to perform pedigree-based genotype phasing. Each founder chromosome is assigned a unique founder genome label (FGL). We use inheritance vectors based on genome scan markers as represented through the FGLs that are generated with the gl_auto program of the Morgan package. By recording allele assignments to FGL at each marker position, haplotype sequences for each founder chromosome are obtained. In application to a large 5-generation, 189-member pedigree with Alzheimer disease (AD), phasing of 35 rare variants spanning a region-of-interest defined by linkage analysis (LA) identified six potential haplotypes in 10 affected subjects with strong effects on the LA. Of these, four represented >89% of the potential haplotypes. Of course not all FGLs at every marker position get a forced allele assignment, in which case population-based imputation into founder haplotypes is performed with a population-based method such as Beagle, and propagated via the FGLs into family members with missing alleles. We use the phased genotype data from the 1000 Genomes Project as a reference panel. Performance of our joint imputation algorithm is in the process of being evaluated for simulated and real data from AD pedigrees and will be presented.

Whole-genome sequencing in familial late-onset Alzheimer's Disease identifies *TTC3* **and** *FSIP2* **as putative risk loci.** *G.W. Beecham[1], J. Jaworski[1], W. Bush[2], B. Vardarajan[3], E. Blue[4], S. Barral[3], J.L. Haines[2], C.M. van Duijn[5], E.R. Martin[1], G.D. Schellenberg[6], R.P. Mayeux[3], E. Wijsman[4], M.A. Pericak-Vance[1] for the Alzheimer Disease Sequencing Project.* 1) Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst.for Human Genomics, University of Miami, Miami, FL; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 3) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University Medical Center, New York, NY, USA; 4) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA; 5) Department of Epidemiology, Erasmus MC, Rotterdam, Netherlands; 6) Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, USA.

Background: The Alzheimer's Disease Sequencing Project (ADSP) is an initiative to identify genetic variation influencing late-onset Alzheimer's disease (LOAD) risk. As part of the ADSP, we performed linkage analysis in 44 non-Hispanic white (NHW) extended families multiply affected by LOAD, followed by whole-genome sequencing (WGS), segregation analysis, and annotation and filtering of variants. **Methods**: WGS data were generated for 229 subjects from 44 NHW families. Standard bioinformatics protocols were applied, with multiple genotype callers used to develop consensus. Family-specific LOD scores were calculated using array data, and parametric multipoint linkage analyses implemented in the MERLIN software. Single nucleotide variants (SNVs) were filtered to families and genomic regions with family-specific LOD scores greater than 1, then annotated for function, frequency, segregation with disease, and information from additional datasets, such as the ADSP case-control dataset. SNVs were annotated with enhancer and expression-QTL data to identify variants likely to influence expression. **Results:** We identified 33 rare (MAF<0.01) SNVs that were under family-specific LOD regions, segregated with disease, were absent from all unaffecteds in the dataset, and were putatively functional (CADD score > 10). These included a missense SNV in TTC3 (CADD=32) that was absent in reference datasets, and confirmed using orthogonal genotyping technology. The FSIP2 gene harbored a missense SNV that segregated with disease among sequenced affecteds, was rare, and likely functional (CADD=25), and showed nominal association in an ADSP case-control gene analysis (p-value=0.043). Additional SNVs in SLC15A5, COG4, CAPZA3, and CONYL1 showed strong functional evidence, in addition to segregation and low MAF. Analysis of intergenic variation identified 17 SNVs that segregated with disease, were rare, and putatively functional (CADD score > 10). Analysis of enhancer data identified multiple enhancer SNVs that segregate with disease and may influence gene expression, including four in a known chr14 linkage region, and two in a known chr1 linkage region; additional enhancer variants were identified in the family-specific regions. **Conclusion**: These results suggest both intra and intergenic SNVs influence LOAD risk in multiplex families, and show the power of segregation-based family designs in WGS studies of complex diseases like AD, and suggest TTC3 and FSIP2 as AD risk genes.

403W

Genome-wide linkage analysis for Parkinson's disease using high-density SNPs in the Faroese cohort. *L.L. Farrell[1], T. Candido[1], S. Bech[2], I. Guella[1], D. Evans[1], J.O. Aasly[3], M.S. Petersen[2], M.J. Farrer[1].* 1) Centre for Applied Neurogenetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Occupational Medicine and Public Health, The Faroese Hospital System, Sigmundargota 5, FO-100 Torshavn, Faroe Islands; 3) Department of Neurology, St Olav's Hospital, Trondheim, Norway.

In the Faroe Islands, the prevalence of Parkinson's disease (PD) is double that of neighboring countries. Disease is assumed to be multifactorial albeit with unknown etiology. Overall, the relative risk for PD is 2.3 for siblings and 1.4 for first cousins. The Faroese cohort is a family-based study of PD that includes several multi-incident pedigrees with detailed genealogy, clinical information and environmental data. Known mutations underlying Parkinsonism have been excluded. In this cohort prior segregation analysis suggests PD best fits an additive or dominant genetic model (Petersen et al., 2015). A subset of 16 families, a total of 303 individuals (124 with DNA, 54 affected) with an average family size of 18.9 (range 10 to 24) were selected for further genetic analyses. Most of the pedigrees are genealogically extensive but prior generations have sparse clinical data and samples. Hence, comprehensive linkage simulations were performed to maximize information content using non-parametric and model-based methods (setting disease frequency to 1/1000, assuming biallelic SNP allele frequencies (0.5) and various penetrance (0.5-0.9), phenocopy (0.01, 0.05) and age-associated liability parameters). Illumina MEGA SNP array genotyping of 1.8M SNPs was prioritized for families with multi-incident PD. After excluding SNPs with significant deviation from HWE ($p<0.01$), MAF<0.05 and LD ($r^2> 0.8$), genome-wide nonparametric and model-based linkage analyses was performed with MERLIN (Abecasis et al.2002), using high-density SNP sets with ~100 kb spacing throughout the genome (24,679 SNPs). Marker allele frequencies were based on all individuals genotyped within the cohort. To date, under non-parametric models evidence of suggestive linkage (LOD >2) was observed at the 137cM to 139cM region on chromosome 7q33.5-q34.5 and 86cM to 88cM region on chromosome 10q23.1-q.23.2 with a maximum LOD score of 2.19 and 2.16, respectively, which was obtained after controlling for marker-marker linkage disequilibrium (LD) with $r^2>0.2$. Model-based linkage analyses are ongoing. For 31 affected individuals, whole exome sequencing has also been performed, primarily to help improve haplotype informatively in loci shared among family members with PD. Overall, results from pedigree/power simulations, linkage and haplotype analyses, informed by exome variants within shared intervals will be presented.

404T

Mosaic loss of chromosome Y (LOY) in peripheral blood is associated with age, smoking, shorter survival and increased risk of cancer and Alzheimer's disease (AD) in men. *L. Forsberg[1], J.-C. Lambert[2], C. Rasi[1], V. Giedraitis[3], H. Davies[1], B. Grenier-Boley[2], C. Lindgren[4], D. Campion[5], C. Dufouil[6], F. Pasquier[7], P. Amouyel[7], L. Lannfelt[3], M. Ingelsson[3], L. Kilander[3], L. Lind[8], J. Dumanski[1], The European Alzheimer's Disease Initiative Investigators.* 1) Dept. Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala, Sweden; 2) INSERM, U1167, Institut Pasteur de Lille, Université de Lille, Lille, France; 3) Department of Public Health and Caring Sciences, Uppsala University, Uppsala, Sweden; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK and Broad Institute of MIT and Harvard University, Cambridge, Massachusetts, USA; 5) CNR-MAJ, INSERM, U1079, Rouen University Hospital, Rouen, France; 6) INSERM, U708, Victor Segalen University, Bordeaux, France; 7) CNR-MAJ, Université de Lille and Centre Hospitalier Régional Universitaire de Lille, Lille, France; 8) Department of Medical Sciences, Uppsala University, Uppsala, Sweden.

Introduction: In the entire world men live on average 4 years shorter lives compared to women. In the developed countries this difference is even larger and the average life expectancy is more than 6 years shorter in men compared with women. This sex-difference has been known for centuries but the underlying factor(s) have been elusive. Our discoveries show that a male specific genetic risk factor, i.e. LOY (mosaic loss of chromosome Y in blood cells), can help explain this observation. Our previous analysis show that LOY is associated with age, smoking, all-cause mortality and non-hematological tumors (*Nat. Genet.* 2014 PMID:24777449, *Science* 2015 PMID:25477213). We can now demonstrate that in addition to this, LOY in blood is also associated with increased risk for Alzheimer's disease (AD) (*In press AJHG*). Materials and Methods: LOY in blood cells was estimated using SNP-array data from >3200 men from one AD case-control study and two prospective cohorts. Strict QC was applied for included data and whole genome sequencing as well as ddPCR was used for experimental validations. 100% concordance in LOY-scoring was achieved between the different platforms. A set of statistical techniques were used to evaluate association between LOY in blood cells and AD diagnosis. Results: LOY was detected in ~17% of participants (median age=73, range=37-96). We found that men with AD diagnosis had a higher degree of LOY mosaicism in the case-control study (adjusted odds ratio=2.80, AD events=606, p=0.0184). Furthermore, analysis of the two prospective cohorts showed that men with LOY in blood at sampling had an increased risk for incident AD during follow-up time (HR=6.80, 95% CI=2.16-21.43, AD events=140, p=0.0011) (*In press AJHG*). Conclusions: Our results suggest that LOY in blood cells is associated with increased risk for both AD and cancer, suggesting a role of LOY in blood cells on disease processes in other tissues, possibly via defective immunosurveillance functions of immune cells without the Y chromosome. Hence, as a male-specific genetic risk factor, LOY might help explain why males on average live shorter than females. Future and on-going studies will put efforts into understanding what happens in cells with LOY and will thus focus on functional aspects at the cellular as well as the organismal levels.

405F

First study of *C2491T FV* **mutation with ischaemic stroke risk in Morocco.** *B. Diakite[1], K. Hamzi[2], W. Hmimech[2], S. Nadifi[2], GMRAVC.* 1) Genetic and Molecular Pathology, FMOS, USTTB, University of Bamako, 1805; 2) Department of Genetics and Molecular Pathology Laboratory (LGPM), Faculty of Medicine and Pharmacy Hassan II University, 9154 Casablanca, Morocco.

   Ischaemic stroke is is a multifactorial disease. It is known that, individual inherited genetic difference in genes involved in the metabolism of lipid or in the process of inflammation and thrombosis play an important role in the development of stroke. Several previous studies have revealed that the distribution of *FV Leiden* mutation remains low or almost absent in some populations (African population) compared to others. The present study evaluated the association of *C2491T FV* mutation with the risk of ischaemic stroke. Genotyping was performed by High Resonance Melting and PCR-RFLP methods. Carriers of *T* mutated allele was associated with a high risk of ischaemic stroke (OR: 3.77, 95%CI = 2.70-5.25; P <0.0001). But this risk was 8.95 fold when the subject carrying of *TT* genotype (P <0.0001) and 4.08 fold with *CT* genotype. According to the risk factors of ischaemic stroke, a positive correlation was observed only with *C2491T FV* mutation and hypertension (P < 0.001). Thus, we can suggest that *C2491T FV* mutation could be a genetic risk factor for Ischaemic Stroke in Moroccan population.

406W

Phenome-wide association study of 28 variants associated with Parkinson's disease in a web-based cohort. *K. Heilbron, B. Alipanahi, P. Cannon.* 23andMe, Mountain View, CA.

   The phenome-wide association study (PheWAS) is a powerful method for detecting phenotypes that are significantly associated with a genetic variant (or other attribute) of interest. A recent genome-wide association study (GWAS) meta-analysis found 28 genetic variants that were significantly associated with Parkinson's disease (PD). By performing PheWAS on these variants, we set out to find traits that share a common genetic etiology with PD and thereby gain insight into the underlying biology of the disease. We performed a PheWAS on the 26 non-HLA SNPs associated with PD. We tested these SNPs for associations with 1,562 phenotypes derived from survey questions that are available to all 23andMe customers who consented to research. We found ten self-reported phenotypes that were significantly associated with at least two of the 26 SNPs (Bonferroni-corrected $P < 0.05$). For four of these phenotypes, all significant associations had the same direction of effect. Family history of PD and status within one's community exhibited positive associations, while heart or metabolic disease and whether one prefers to talk rather than listen during a conversation exhibited negative associations. Follow-up studies are required to replicate these findings and determine whether any of these candidate phenotypes play a causal role in PD.

407T

Identifying genetic modifiers of age at diagnosis in Parkinson disease – A 23andMe study. *K-D.H. Nguyen[1], N.A. Furlotte[2], L. Yu[2], S. John[1], A. Day-Williams[1].* 1) Computational Biology & Genomics, Biogen, Cambridge, MA; 2) 23andMe, Inc., Mountain View, CA.

Background: Age-at-diagnosis (AAD) varies greatly in both familial and sporadic Parkinson Disease (PD); however, the genetic underpinning (if it exists) has not been determined. Mutations in LRRK2 and GBA have been previously implicated in younger AAD in PD patients. Conversely, smoking has been shown to be correlated with later AAD amongst patients. **Objectives:** We want to identify genetic associations affecting AAD in *LRRK2* PD, *GBA* PD and sporadic PD. Additionally, we want to investigate the interaction between genetic contributions and smoking status. **Methodology:** We performed genome-wide association analyses studies (GWASes) of PD AAD for 3 subgroups of adult PD research participants (age ≥30) from the 23andMe cohort: (1) PD participants with known *LRRK2* mutations (n=153), (2) PD participants with known *GBA* mutations (n=151) and (3) sporadic PD participants with neither *LRRK2* nor *GBA* mutations (n=6,835). To investigate the epidemiological association of AAD with smoking we performed the analyses with and without smoking as a covariate to identify both dependent and independent genetic effects. **Results:** The association landscape changed remarkably upon removing the effect of smoking in identifying smoking-independent signals. By removing the effect of smoking from PD AAD regression analysis, we were able to remove spurious (likely false positive) associations and enhance signals for new loci. Despite limited sample size in the LRRK2 and GBA populations, we identified 1 genome-wide significant signal and ~10 suggestive signals in these 2 populations alone. **Conclusions:** This study comprises one of the largest collections of *LRRK2* and *GBA* carriers (N~150-200) to reveal the genetic effects of PD AAD. In addition, we are performing Mendelian randomization to assess the causality of smoking to PD AAD.

Hereditary Spastic Paraplegia (HSP) is a group of clinically and genetically heterogeneous neurodegenerative disorders. Lower limb spasticity and progressive weakness are manifested in pure HSP patients. In complicated HSP patients, other neurological and nonneurological symptoms can be observed. HSP can be inherited in autosomal dominant, autosomal recessive, or X-linked manner. Forty-nine loci and 43 genes are associated with autosomal recessive form of HSP (ARHSP). Whole exome sequencing data of six ARHSP patients from Turkey were analysed to determine the effect of genetic background on phenoytpic heterogeneity among patients. Filtering was performed to determine rare variants via GEM.app[1]. All rare (MAF<0,01), non-synonymous variants in neurodenegeration/neuropathy related genes were selected. We further filtered the variants that were predicted as 'effective' by *in silico* tools. Forty-two rare variants in six individuals were identified and 35 of those variants were located in the genes related to various neurodenegerative/neuropathic diseases such as HSP, CMT and Usher syndrome. Three variations were in homozygous state underlying the effect of rare variants in ARHSP. When whole genome sequencing data of 15 healthy Turkish individuls from Turkish Genome Project[2] were analyzed with the same criteria, 68 rare variant were identified in total. Since the average of rare variant in patients (7 variant per individual) was higher compared to unaffected individuals (4,5 variant per individual), rare variations observed in these patients are probably effective. These rare variants observed with the variant segregating with the disease require further and detailed analyses because they might explain inter- and intra-familial heterogeneity in phenotype. They might also contribute to fulfill the overall picture of mechanism underlying neurodegeneration. This data might also be important to question the approach to "end the genetic analysis after determining the disease-causing variant" because in this approach other variants that might contribute to disease formation are underestimated. 1.   Objective: Primary intracerebral hemorrhage (ICH) and lacunar stroke are acute manifestations of arteriolar injury. Myeloperoxidase (MPO) plays a central role in the initiation and progression of vascular inflammation. We hypothesized that genetic determinants of MPO levels influence risk of ICH and lacunar stroke.   **Methods:** We used a discovery cohort of 1409 ICH cases and 1624 controls from 3 studies, an extension cohort of 12,577 IS cases and 25,643 controls from NINDS-SiGN, and a validation cohort of 10,307 IS cases and 29,326 controls from METASTROKE. An unweighted MPO-increasing genetic risk score (GRS) was constructed from fifteen single nucleotide polymorphisms (SNPs) arising from prior genome-wide studies of circulating MPO levels ($p < 5 \times 10^{-8}$). We used multivariable regression models for association between the MPO-GRS and ICH and IS subtypes, and fixed-effects meta-analyses to pool estimates across studies. We utilized Cox regression models in a prospective cohort of 174 ICH survivors for association with ICH recurrence. **Results:** Genetic determinants of elevated circulating MPO levels were associated with both ICH risk (odds ratio [OR] 1.07, *p*=0.04) and recurrent ICH risk (hazards ratio [HR] 1.45, *p*=0.006). Analysis of IS subtypes demonstrated association with MPO-GRS in only the lacunar subtype (OR 1.05, *p*=0.0012). **Interpretation:** Genetic variants that increase circulating MPO levels increase risk of ICH and lacunar stroke. Because genetic variants are not influenced by environmental exposures, these results provide new evidence for a causal rather than bystander role for MPO in the progression of cerebrovascular disease. Furthermore, this also suggests that chronic inflammation may be a potential modifiable stroke mechanism, and immune-targeted therapies could be useful for treatment and prevention of cerebrovascular disease.

Identifying high genetic risk groups for personalized medicine in Alzheimer's disease. *S.J. van der Lee[1], F.J. Wolters[1], A. Hofman[1,2], M.A. Ikram[1], N. Amin[1], C.M. van Duijn[1].* 1) Erasmus MC, Rotterdam, Rotterdam, Netherlands; 2) Harvard T.H. Chan School of Public Health, Boston, MA, USA.

  Purpose: The gene encoding the apolipoprotein E protein (APOE) is a major determinant for Alzheimer's disease (AD). While the APOE*4 variant associate with an increased risk of AD, the APOE*2 variant associates with a decreased risk. In the past decade genome wide association and sequencing studies identified 24 other genetic variants reaching genome wide significance. These include rare variants with effects similar to APOE but predominantly common variants with small effects. Until now, it is unclear to what extend these variants jointly modify the risk of AD.   **Methods:** We calculated the lifetime cumulative incidence of AD in the Rotterdam study. This prospective cohort study included 12255 subjects (67.48 ± 8.4 years at inclusion) free of AD at age 60. After 12.9 ± 6.3 years (maximum 24 years) of follow-up, 1262 participants developed AD. All participants were characterized for common and rare variants using direct genotyping and imputation. Most recent published effect sizes of new variants were used to calculate an AD specific genetic risk score (AD-GRS) capturing the joint additive effect of the novel variants. Kaplan-Meier-analyses were used to calculate cumulative risk lifetime by age of 85 years, overall and stratified by APOE genotype.   **Results:** We found that 58.6% of the APOE*44 carriers developed AD prior by age 85 years while the risk of APOE*22/23 carriers by age 85 is as low as 6.2%. Overall, there was a significant effect of the AD-GRS on the risk of AD (low risk tertile to the high risk tertile p-value = 1.0×10^{-12}). For those in the low tertile of the AD-GRS the risk of AD was 8.7% by age 85 while the cumulative for those in the high tertile was 17.7%. The cumulative incidence of the low tertile reached 17.7% by age 88.7, translating into a 3.7 year difference in AD-free survival. Although the AD-GRS differentiates the risk of AD across all APOE genotypes, there was evidence for interaction with APOE genotypes (p = 0.01). APOE*44 carriers in the low tertile of the AD-GRS on average developed AD eight years later than those in the high AD-GRS tertile. Of the APOE*44 carriers in the high risk tertile, 82.9% had developed AD by age 85 years given they survived to this age. **Conclusions:** Combining the effects of multiple low and moderate risk variants can identify those at high life-time risk of AD. The results can be used for clinical counseling and patient selection for clinical intervention trials.

411F

Refining the role of *de novo* **protein truncating variants in neurodevelopmental disorders using population reference samples.** *J.A. Kosmicki[1,2,3], K.E. Samocha[1,2,3], D.P. Howrigan[2,3], D.G. MacArthur[2,3], D.P. Wall[4], E.B. Robinson[2,3], M.J. Daly[1,2,3].* 1) Harvard Medical School, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Stanford University, Palo Alto, CA.

One of the fundamental challenges of human disease genetics is differentiating risk-conferring variants from the overwhelming amount of neutral variation in the genome. *De novo* variants comprise a unique component of the genetic architecture of human disease since, not having yet passed through a single generation, any heterozygous variants with complete or near-complete elimination of reproductive fitness must reside almost exclusively in this category. As such, recent studies found that *de novo* protein truncating variants (PTVs) play a significant role in neurodevelopmental disorders. Despite prior evidence of mutational recurrence (i.e., the same mutation occurring *de novo* multiple times), most studies implicitly assumed each *de novo* variant was novel, in line with Kimura's infinite sites model, and thereafter analyzed *de novo* variants genome-wide without respect to their allele frequency in the population. We examined these assumptions using data from 9477 families with ASD, intellectual disability (ID), or developmental delay (DD), and found that overall ~1/3 of *de novo* variants are independently observed as standing variation in the Exome Aggregation Consortium's (ExAC) cohort of 60,706 adults without severe neurodevelopmental disease. *De novo* PTVs absent from ExAC are more strongly associated with neurodevelopmental risk than those present in ExAC, evidenced by enhanced associations in ASD (rate ratio [RR]=1.8, $P<10^{-12}$) and ID/DD (RR=2.6, $P<10^{-21}$). In contrast, *de novo* PTVs present in ExAC do not exhibit enrichment in ASD (RR=0.67, $P=0.98$) or ID/DD (RR=0.69, $P=0.94$). We further use a loss-of-function intolerance metric derived from ExAC to identify a small subset of genes that contain the entire signal of associated *de novo* PTVs in ASD (RR=3.2, $P<10^{-16}$) and ID/DD (RR=6.7, $P<10^{-38}$). These same genes carry a moderate excess of PTVs inherited by individuals with ASD from their unaffected parents (RR=1.2, $P=0.01$), and a larger excess in 404 ASD cases and 3654 controls (OR=2.7, $P<10^{-19}$), with no association seen outside these genes. Furthermore, of the top 11 genes with ≥3 *de novo* PTVs in ASD, all but 4 (*DSCAM*, *ANK2*, *CHD8*, *ASH1L*) are more significantly enriched in ID/DD (OR=9.3, $P<10^{-6}$), indicating the majority of genes previously implicated in ASD using *de novo* variants are associated with ID/DD, not ASD. Collectively, these findings illustrate the importance of population-based cohorts as reference samples for even *de novo* variation.

From one family to replication in five data sets: Two loci associated with age-at-onset of familial and sporadic Alzheimer disease. *E. Blue[1], E. Wijsman[1,2,3], T. Bird[4,5,6], C-E. Yu[7], T. Thornton[2].* 1) Div Med Gen, Univ. of Washington, Seattle, WA; 2) Dept Biostat, Univ. of Washington, Seattle, WA; 3) Dept Genome Sci, Univ of Washington, Seattle, WA; 4) Dept Medicine, Univ of Washington, Seattle, WA; 5) Dept Neurology, Univ of Washington, Seattle, WA; 6) Dept Psych Behav Sci, Univ of Washington, Seattle, WA; 7) Div Geront Geriatr Med, Univ of Washington, Seattle, WA.

We have fine-mapped a linkage region in a single family, evaluated sequence variants within the region, and replicated association at 2 loci in 5 data sets. These data sets include subjects with early- (EO) and late-onset (LO) Alzheimer disease (AD), with and without family history, and European or Hispanic ancestry. We began with strong linkage signals on chromosomes (chr) 1 and 17 for age-at-onset (AAO) modifiers in a German from Russia (GFR) family with EOAD caused by the *PSEN2* N141I variant. We obtained genome-wide SNP data on 32 members of the family and combined a measured genotype (MG) approach with identity-by-state (IBS) and identity-by-descent estimates to reduce to one tenth the size of the linkage regions in that family. We sequenced the exomes of 6 members of this family, and the genomes of 4 of these, maximizing variant detection and phasing information for the linked haplotypes. We applied bioinformatic and IBS filters as well as the MG approach to derive a short list of candidate variants. We genotyped these 54 variants in 331 subjects of GFR ancestry ascertained from both LO and *PSEN2* N141I families, including the discovery family. We tested for association between the residuals from a Cox proportional hazards analysis with AAO of AD adjusted for both *APOE* and *PSEN2*, incorporating known pedigree information. We found 13 variants that were both nominally significant in the discovery family and in the larger GFR sample. Using a similar model, we tested for association between AAO of AD and these loci (+/-25kb) in exome sequence variants observed in 5,567 cases and 4,961 controls with non-Hispanic European (EUR) ancestry from the Alzheimer's Disease Sequencing Project. We found highly significant ($p<10^{-9}$) association between variants surrounding two GFR loci: a promoter of *NCSTN* (chr1q23.2) and a promoter of *KDM6B* (chr17p13.1). We performed similar analyses of SNP array-focused data in a total of 4,203 EUR and 5,174 Caribbean Hispanic (CH) subjects from 5 different LOAD data sets encompassing both familial and unrelated subjects. We found nominally significant evidence for association between AAO of AD and SNPs surrounding the *NCSTN* locus with SNPs in each of one EUR and one CH sample, and surrounding the *KDM6B* locus in each of 2 CH and 2 EUR data sets. We therefore show that loci associated with phenotypic variation in a Mendelian EO form of AD have similar effects in cases with sporadic or familial LOAD as well as across populations.

413T

Identifying novel genes whose tissue-specific expression level causally influence complex human traits. *E. Porcu[1,2], A. Reymond[1], Z. Kutalik[2,3].* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Institute of Social and Preventive Medicine, CHUV and University of Lausanne, Lausanne, Switzerland.

In the last decade Genome-Wide association studies (GWAS) identified thousands of variants associated with hundreds of complex traits but in many cases the underlying biological reason for such association is unknown. Given that many GWAS loci fall far from coding regions of genes and the importance of regulatory variations in shaping complex phenotypes, we propose to use gene expression quantitative trait loci (eQTLs) to interpret the role of variants in a GWAS region and the complex trait. Recently, a study (Zhu et al. Nature Genetics 48, 481–487 (2016)) applied Mendelian Randomization (MR) approach using a single instrumental variable to search for the most functionally significant genes at the loci associated in GWAS for complex phenotypes by integrating association summary statistics and gene expression eQTL data. Here, we propose an advanced MR approach that uses multiple SNPs jointly as instruments and multiple gene expression traits simultaneously in multiple tissues. Our method is not only more powerful than the previously one, but verifies MR assumptions more rigorously. We applied the method to schizophrenia using summary data from the latest GWAS meta-analyses and various eQTLs datasets and identified more than 200 genes causally implicated in schizophrenia in various tissues. Whereas we replicated 6 out of the 17 signals reported by Zhu and colleagues, for the remaining 11 SNPs we cannot ensure that the MR assumption of absence of pleiotropy holds. Among our results we find examples of genes with a) overestimated effect in single-gene analysis: e.g. *SPCS1*, p=1.2x10^{-34}; b) significant association only in the multiple-gene analysis: e.g. *EFNA1*, p=7.3x10^{-8} ; c) tissue-specific causal effects: e.g. *INPP5B* associated with schizophrenia only using brain eQTLs, p=8.9x10^{-20} ; and d) not significant association in previous GWAS analysis: e.g. *L3HYPDH*, p=1.6x10^{-16}. These results suggest that a multi-SNP and multiple-gene approach verifies MR assumptions more rigorously. It allows unraveling new insights in the tissue-specific transcriptomic regulation of complex traits. Such mechanistic insight should facilitate tissue-specific pathway enrichment analysis. These observations confirm the importance of integrating data from various tissues when trying to interpret GWAS results using gene expression as an intermediate phenotype.

414F

Exploring the genetic architecture of ADHD by assessing the contribution of non-additive genetic effects and the role of rare coding variation. *D.S. Palmer[1,2], A. Bloemendal[1,2], D. Demontis[3,4,5], D.M. Hougaard[3,4,5,6], A.D. Børglum[3,4,5], B.M. Neale[1,2,7], iPSYCH-Broad Consortium.* 1) Broad Institute, Boston, MA, USA; 2) ATGU, Massachusetts General Hospital, Boston, MA, USA; 3) iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Aarhus, Denmark; 4) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 5) iSEQ, Centre for Integrative Sequencing, Aarhus University, Aarhus, Denmark; 6) Center for Neonatal Screening, Department for Congenital Disorders, Statens Serum Institut, Copenhagen, Denmark; 7) Harvard Medical School, Boston, MA, USA.

Attention Deficit Hyperactivity Disorder (ADHD) is a neurodevelopmental disorder characterized by hyperactivity, impulsivity and inattentiveness. Current twin study estimates place heritability at ~0.76 [1], while SNP-based approaches estimate the additive contribution of SNP heritability at ~0.28 [2]. In order to more thoroughly characterize the genetic architecture of ADHD, we examine two additional sources of variance: non-additive genetic effects of common variants and rare coding variation from exome sequencing. SNP-based approaches such as GREML [3] and LD score regression [4] assume a polygenic model, where a large number of small effects combine additively toward a continuous phenotype or case/control status. Here, we extend this 'polygenic model' to allow for dominance effects upon the observed phenotype. Based on the variance decomposition in Fisher's original biometrical model [5], we augment the polygenic model with terms that act orthogonally to the additive genetic effects. We develop an extension of the method of LD score regression to estimate the additional heritability explained, and apply it to genotype data from iPSYCH of 12,000 cases and 20,000 controls. We report on the increase in heritability explained by accounting for dominance effects in our analysis. To further explore the contribution to genetic architecture, we also examine exome sequence data from 3,500 ADHD cases and 6,000 controls. In this study, whole exome data is obtained from stored bloodspots taken from the Danish Neonatal Screening Biobank at Statens Serum Institut, Denmark. Using these data, we find that cases of ADHD show an enriched rate of ultra-rare disruptive and damaging mutations (OR=1.43, p=7e-6) but these mutations explain less than 1% of the variance of ADHD.[1] Faraone et al, 2005. Molecular genetics of attention-deficit/hyperactivity disorder. Biological Psychiatry.[2] Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013. Genetic relationship between five psychiatric disorders estimated from genome-wide SNPs. Nature Genetics.[3] Yang et al, 2010. Common SNPs explain a large proportion of the heritability for human height. Nature Genetics.[4] Bulik-Sullivan et al, 2015. LD score regression distinguishes confounding from polygenicity in genome-wide association studies. Nature Genetics.[5] Fisher, 1918. De novo mutations account for a small fraction of the epidemiologic association between autism and paternal age. *E.B. Robinson[1,2,3], D.J. Weiner[1,2,3], E.M. Wigdor[1,2,3], S. Ripke[1,2,3,4], J.A. Kosmicki[1,2,3,5], K.E. Samocha[1,2,3,6], A. Bloemendal[1,2,3], M.J. Daly[1,2,3].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Boston, MA; 3) Medical and Population Genetics Program, Broad Institute of MIT and Harvard, Boston, MA; 4) Department of Psychiatry and Psychotherapy, Charite, Campus Mitte, Berlin, Germany; 5) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 6) Program in Genetics and Genomics, Biological and Biomedical Sciences, Harvard Medical School, Boston, MA.

Advanced paternal age is consistently linked to risk for autism spectrum disorders (ASDs). For example, one epidemiologic meta-analysis suggested that men above age 50 are approximately 2.5 times as likely as men under 30 to have a child diagnosed with ASD (Hultman et al. 2011). It is commonly assumed that this increase in risk is driven by *de novo* mutations, which also increase with paternal age. However, a recent test of this assumption used simulated data to estimate that *de novo* mutations were not likely to account for more than 20% of the observed risk relationship between paternal age and ASD (Gratten et al. 2016).   Using **empirical** exome sequence and genotype data from over 2500 families from the Simons Simplex Collections (SSC), we aimed to directly estimate the amount of paternal age risk that could be attributable to *de novo* mutations. We also aimed to directly test the hypothesis that men who have children later in life could have greater common, polygenic risk for ASD, an alternate genetic route to advanced paternal age risk.   In the SSC, nonsynonymous *de novo* mutations in the exome are 20% more common in affected probands than in their unaffected siblings (odds ratio (OR)~1.2). Consistent with previous estimates (Kong et al. 2012), we found that nonsynonymous de novo mutations in controls increase at a rate of approximately 3% per year of paternal age. Modeling this observed increase against the empirical OR, we find that less than 10% of the epidemiologic association between paternal age and ASD risk can be explained by *de novo* mutations in the exome.   Most genetic risk for ASDs reflects common, polygenic variation (Gaugler et al. 2014). We estimated the SSC parents' polygenic risk for ASD, as well as for educational attainment and schizophrenia (traits genetically correlated with ASD; Bulik-Sullivan et al. 2015). Increasing paternal age was significantly associated with higher polygenic risk for schizophrenia (p=0.004) and educational attainment (p=0.001), but not ASDs (p=0.98). These analyses suggest that 1) *de novo* mutations in the exome account for a limited component of the epidemiologic association between paternal age and ASD risk, and 2) some of the association is being driven by complex, polygenic variation, an unchanging property of parents that influences timing of childbearing. These findings have significant implications for public health messaging and genetic studies of ASD.

416T

Genetic influence on age of onset of obsessive-compulsive disorder. *H. Qin[1], K. Wen[1], M. Ritter[1], G. Nestadt[2], Y. Yao[1].* 1) National Institute of Mental Health (NIMH/NIH), Bethesda, MD; 2) Johns Hopkins University School of Medicine, Baltimore, MD.

Obsessive-compulsive disorder (OCD) consists of obsession and compulsion domains, characterized by frequent upsetting thoughts and rituals/repeat behaviors that to relieve the anxiety caused by an obsession. The National Comorbidity Survey Replication (NCS-R) estimated in 2005 that 1.0% of the US adult population had been affected by OCD in the past 12 months. Individuals with OCD begin to develop symptoms during childhood or adolescence. Genetic predictors for the young onset OCD are solely needed. In addition, genetic studies of young onset OCDs may lead to understanding of the genetic underpinnings of OCD development. Our OCD Collaborative Genetics Association Study project (OCGAS) recruited families with at least two OCD-affected siblings from outpatient and inpatient clinics. Subjects were diagnosed as "affected" if they had met DSM-IV OCD diagnosis criteria at any point in their lives. Diagnostic assessments were conducted using the OCD Collaborative Genetics Study Assessment Package. Probands were included if age of onset ≤18. We hypothesized that young onset OCDs might be more genetically driven. To take the advantage of the unique characteristics of our samples, we conducted a genetic analysis to explore the potential relationship between age of onset and genetic variants in a sample of OCD patients (n = 1,711). We categorized patients into two groups using the age of onset of 8 as threshold to determine the early onset (≤8 years old) and late onset (>8 years old). We used the PLINK software to analyze genotypic and phenotypic data and tested for potential association. As a result, we found a potential correlation between the SNP rs4656781 and the age of onset of OCD (early vs. late onset), with p-value of 6.58×10^{-7}. The SNP is located in SPON1 gene. A recent study showed that haplotypes on SPON1 were associated with plasma concentrations of Methadone R- and S-enantiomers in heroin-dependent patients. Also, SPON1 is known as a cell adhesion protein contributing to the growth and guidance of axons in both the spinal cord and the peripheral nervous system. However, we need note the limitations of our study, including relatively small sample size, and the self-reported age of onset. To conclude, albeit the fact that our study did not identify a genome-wide level significant SNP, the preliminary results presented gave a suggestive association between genetic variations and age of onset. This potential finding warrant further investigations. .

417F

A semi-supervised learning approach to functional annotations for coding and noncoding variants. *Z. Liu[1], J. Zou[2], I. Ionita-Laza[3].* 1) Department of Biostatistics, Harvard School of Public Health, Boston, MA; 2) Microsoft Research New England and MIT, One Memorial Drive, Cambridge, MA 02142; 3) Department of Biostatistics, Columbia Mailman School of Public Health, NYC, NY.

   Predicting and interpreting the pathogenicity of mutations is a fundamental challenge in human genetics. Great efforts have been devoted to generate functional annotation of variation in the human genome sequence through either high-throughput experiments such as the ENCODE project or computational predictions such as genomic conservation. Such annotations can help identify putatively causal genetic variants obtained from genetic association studies. There has been intense research efforts to develop supervised and unsupervised methods that integrates functional annotations predict the effects of genetic variants. Supervised methods use variants that are known to be pathogenic or benign to train prediction algorithms. The major challenge with this approach that only a small proportion of genetic variants can be labeled reliably with its effects on humans. Methods such as CADD uses evolutionary conservation as a surrogate for true pathogenicity. Recently we have proposed two unsupervised approaches named Eigen and Eigen-PC, that do not make use of any labeled data, and tend to outperform CADD. However, its prediction accuracy can be improved if the information contained in the small proportion of high quality labeled data is properly used. Here, we propose a novel semi-supervised co-training approach to derive an annotation score that, unlike any existing methods, can integrate both the labeled and unlabeled data to increase predictive accuracy. This framework allows us to fully capture the complementary benefits of previous methods. We show that the resulting annotation score has better discriminatory power than Eigen and Eigen-PC on noncoding variants from GWAS and eQTL studies, as well as in coding mutations in Mendelian neuropsychiatric diseases.

418W

Whole genome analysis of the genetic relationship between attention deficit disorder and obsessive compulsive disorder. *M. Ritter[1], G. Nestadt[2], W. Guo[1], H. Qin[1], Y. Yao Shugart[1].* 1) Unit on Statistical Genomics, National Institute of Mental Health, NIH, Bethesda, MD; 2) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD.

   Attention deficit disorder (ADHD) and obsessive compulsive disorder (OCD) are both highly heritable, neurodevelopmental disorders that onset in childhood. The comorbidity of ADHD and OCD has often been observed in pediatric populations, ranging from 10-50%. In this study, we aimed to examine the genetic relationship between ADHD and OCD. In particular, this was done by calculating polygenic risk scores. To take advantage of the publically available data shared by the Broad Institute, we downloaded the summary statistics from the PGC-GWAS analysis and used that dataset to predict the susceptibility of OCD. The OCD dataset includes 2,998 individuals from nuclear families. The ADHD dataset contains 2,960 cases, as well as parental and independent controls. Our meta –analysis did not detect any genome-wide significant signals. However, while conducting protein-protein interaction analyses, several proteins were predicted to play a role in a complex network that may jointly contribute to ADHD and OCD susceptibility. We would like to recognize that the limitations of using polygenic risk scores and meta analyses to predict psychiatric diseases require further work and a larger sample size. This will be done by combining other relevant datasets into the above mentioned ones.

419T

Identification of novel genetic variants of *DSM-5* Nicotine Use disorder: Exome array analysis in National Epidemiology Survey on Alcohol and Related Conditions-III. *J. Jung, H. Zhang, B. Grant.* Laboratory of Epidemiology and Biometry, NIH/NIAAA, Rockville, MD.

DSM-5 nicotine use disorder (NUD) is a complex addictive disorder that affects about 32% of European Americans (EA) and 24% of African Americans (AA). Moderate to severe DSM-5 NUD and DSM-4 nicotine dependence (ND) have a concordance rate of 93% and DSM-4 ND has heritability of 50%-72% based on twin studies. We analyzed data from the National Epidemiologic Survey on Alcohol and Related Condition-III (NESARC-III) to perform an exome array study of nicotine use disorder with moderate to severe symptoms (NUD >=4). EA and AA in NESARC-III samples were genotyped by Affymetrix Axiom Exome Chip 319K and 100K additional customized SNPs. EA samples of 3,470 cases and 4,078 supernormal controls assessed DSM-5 with no identified psychiatric disorders, and AA samples of 733 cases and 1,766 supernormal controls were analyzed. A single SNP based analysis with common variants (minor allele frequency (MAF)>=0.01) was performed to test associations with moderate to severe NUD using an additive model, and a gene (regional) based analysis with rare variants (MAF<0.05) was performed using a Sequence Kernel Association Test (SKAT) after controlling for sex, age, family income, marital status, education, and two population stratification scores. In a gene based analysis using SKAT-OPT method, we found 21 genes with p-value <2.5e-6 of a gene level threshold in EA and 7 of them (*BCAP29, FER1L6, LRRFIP2, MAP4K3, OMD, SPOCK2, SPTBN5*) were detected in AA with p-value <0.005. Based on a single SNP analysis, we identified 12 novel SNPs in EA with p-value <2e-7: *MAP4K3, WDR17, BAZ2B, FOLR2, EIF4E2, ZAK, LRRFIP2, DEPDC5, KIF25, OR5K4, SPTBN5, SLC22A15* and 7 of 12 identified genes in EA were significant in AA with p-value <0.007; *MAP4K3* (rs140914094)*, FOLR2* (rs150788760)*, ZAK*(rs149819262)*, LRRFIP2* (rs144038552)*, DEPDC5* (rs199749859)*, OR5K4* (rs78102601) *, SPTBN5* (rs200664511). Both the gene based approach and the SNP based approach detected associations between *LRRFIP2, MAP4K3,* and *SPTBN5* with NUD in both EA and AA. In addition, we confirmed the previous findings on association of *SPOCK2, MAP4K3* with nicotine-related phenotype such as smoking behavior or lung cancer. Our preliminary data identified novel associations that promises to improve understanding of the etiology of NUD.

Vertex-wise heritability of human brain cortical thickness and surface area using a twin and non-twin siblings design. *S. Patel[1,2], M. Park[3,4], G.A. Devenyi[3], R. Patel[3], J. Knight[1,2,5], M.M. Chakravarty[3,6].* 1) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 3) Cerebral Imaging Centre, Douglas Mental Health University Institute, McGill University, Verdun, QC, Canada; 4) Schulich School of Medicine and Dentistry, Western University, London, ON, Canada; 5) Lancaster Medical School, Faculty of Health and Medicine, Lancaster University, Lancaster, UK; 6) Department of Psychiatry, McGill University, Montreal, QC, Canada.

Introduction Variation in complex phenotypes such as neuroanatomical measurements can be accounted for by three factors: genetics (A), shared (C) and unique environment (E). The genetic component is defined as heritability and can be quantified using twin studies. The volume of the whole brain is highly heritable with a heritability score of 90% [Baare et al., 2001]. Investigating the heritability of vertex based cortical thickness (CTh) and surface area (SA) allows us to explore the genetics influence across brain regions to make inference and interpretation of studies relating behavior and neuropsychiatric disorders to the same structural phenotypes. **Methods Database:** High-resolution 3 Tesla, T1 weighted magnetic resonance images (MRI; 0.7mm isotropic) from the Human Connectome Project (HCP) [Van Essen et al., 2013] were used in this study (542 healthy subjects: 126 monozygotic twins, 144 dizygotic twins and 272 siblings; age range of 22-36 years old). **Image processing**: CIVET 1.1.12 pipeline [Collins et al., 1994, Lyttelton et al, 2007] was used to measure CTh and SA at each vertex (40,962 in each hemisphere). Each voxel is classified into either white matter (WM), gray matter (GM) or cerebrospinal fluid (CSF). CTh is calculated by the distance in millimeters between WM surface (interface between GM and WM) and GM surface (interface between GM and CSF) at each vertex. The middle cortical surface which is at the geometric center between the inner and outer cortical surface is used to measure SA. **Heritability calculations:** Broad-sense heritability of vertex wise CTh and SA was estimated using structural equation modeling implemented with OpenMx package [Neale et al., 2015] within R. A univariate model controlling for sex and age was used to examine the genetics, shared and unique environment. **Results** Preliminary results demonstrate the overall heritability of SA was higher than CTh. The posterior cingulate gyrus had a mean SA heritability score of 69% (SD± 0.07). The highest mean heritability score of CTh was within the paracentral lobule of 49% (SD± 0.11). **Conclusion** A continuous heritability spatial brain map is created from vertex based CTh and SA. The preliminary results suggest that SA and CTh can be partly accounted by genetic variation. Currently we are working with a larger HCP dataset (n=970) to identify potential quantitative phenotypes to be used in neuropsychiatric disorders based on heritability scores of SA and CTh.

421W

Integrative analysis of eQTL and GWAS detects novel genes having pleiotropic effects on schizophrenia and gene regulations. *Q. Wang[1,2,3], J. Gelernter[2,3,4,5], H. Zhao[1,4,6,7].* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT, USA; 2) Department of Psychiatry, Yale University School of Medicine, West Haven, CT, USA; 3) VA CT Healthcare Center, West Haven, CT, USA; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT, USA; 5) Department of Neuroscience, Yale University School of Medicine, New Haven, CT, USA; 6) Department of Biostatistics, Yale University School of Public Health, New Haven, CT, USA; 7) VA Cooperative Studies Program Coordinating Center, West Haven, CT, USA.

Although genome-wide association studies (GWAS) have identified many SNPs associated with psychiatric disorders, some have been difficult to replicate and interpret functionally. This is due in part to polygenicity; therefore, combining signals at the gene level should aid in interpretation and would have the further potential to reveal underlying mechanisms. In search of disease-associated genes, a number of studies aimed to identify differential expression between cases and controls have yielded helpful insights. However, they have frequently suffered from confounding environmental factors; thus the directionality of observed differential expression as consequences of, or causal, genetic factors cannot be interpreted. Therefore, there is need for statistical methods that can identify genes whose expression levels share genetic factors with psychiatric disorders. We developed a novel method that integrates GWAS summary statistics and expression quantitative trait locus (eQTL) summary statistics to identify genes with pleiotropic effects. Observed GWAS signals in genes are combined based on their eQTLs, and linkage disequilibrium (LD) information extracted from 1000 Genomes Project data was used in testing the level of statistical significance. Simulations under multiple settings indicate well-controlled type I error rate and good statistical power for this method. We applied our method to study the genetics of schizophrenia, using GWAS summary statistics from the Psychiatric Genomics Consortium (PGC), *cis*-eQTLs from the Genotype-Tissue Expression Project (GTEx), and *cis-/trans*-eQTLs from the seeQTL database. A list of novel genes that are not significant in VEGAS gene based test were identified by our method, including 108 genes using GTEx eQTLs, 14 genes using seeQTL cis-eQTLs and 9 genes using seeQTL *trans*-eQTLs. For example, a mitochondrial gene, *NDUFC1,* was implicated with combined statistical significance level p<1e-6 using seeQTL *trans*-eQTLs, and has been reported to be differentially expressed in schizophrenia cases vs. controls. We also found that genes prioritized in our method are enriched in the set of differentially expressed genes in a tissue specific manner, using schizophrenia gene expression datasets from brain (GSE17612) and blood (GSE27383). Our results indicate the importance of both *trans*-eQTLs and *cis*-eQTLs in capturing pleiotropic associations, and might lead to further insights in the pathophysiological mechanisms of schizophrenia.

Mediation methods applied to post-traumatic stress disorder to identify genomic effects. *S. Gaynor[1], G. Guffanti[3], T. Jovanovic[2], L. Almli[2], A. Lori[2], A. Wingo[2], E. Binder[2], K. Ressler[2,3].* 1) Harvard University, Boston, MA; 2) Emory University, Atlanta, GA; 3) McLean Hospital, Belmont, MA.

Mediation methods have been developed to characterize causal relationships that decompose a total effect into natural direct and indirect effects. Recent studies have suggested that genomic analyses may be improved by jointly analyzing SNP and gene expression data to analyze phenotypes of complex diseases. We are able to perform such a joint analysis via the mediation framework in order to: (1) elucidate the complete relationship between genomics and diseases, (2) detect biologically important effects from genetic disease-causing mechanisms and (3) better assess contributions by weak genomic effects. Genetics of psychological disorders have been particularly challenged by the weakness of sparse effects across the genome. We apply the mediation approach to the Grady Trauma Project (GTP), a cross-sectional study of post-traumatic stress disorder (PTSD). PTSD is an anxiety disorder that can occur after an individual experiences or witnesses a traumatic event. Individuals respond differently to traumatic stress and it has thus been suggested to have a genetic component. GTP has been collecting genetic, genomic and clinical data on minority individuals in Atlanta, GA that have been highly traumatized. We will leverage the GTP data to identify biological mechanisms and mutations via mediation analysis in order to better biologically characterize PTSD.

423F

Genome-wide polygenic atlas of the phenome in emerging adulthood. *A. Moscati[1], A.R. Docherty[1], D.M. Dick[2], J.E. Savage[1], J. Salvatore[2], M.E. Cooke[2], F. Aliev[2], A.A. Moore[1], A.C. Edwards[1], D.E. Adkins[3], B.P. Riley[1], B.T. Webb[1], S.A. Bacanu[1], K.S. Kendler[1].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Richmond, VA; 2) Virginia Commonwealth University Department of Psychology, Richmond, VA; 3) Virginia Commonwealth University Center for Biomarker Research and Personalized Medicine, Richmond, VA.

Goal: Identifying genetic relationships between complex traits in emerging adulthood can provide useful etiological insights into risk for psychopathology and other adverse outcomes. This study examined genomic and clinical assessment data from a large sample of young adults (The VCU Student Survey, a cohort sequential assessment of behavior and substance use in college undergraduates, N = 5,951) to construct an atlas of polygenic risk that indexed all clinical, health factor, and outcome data. Methods Used: This study used genome-wide association studies of 34 diverse psychiatric phenotypes and health factors as discovery samples to calculate genome-wide polygenic scores (GPS) and used them to predict 55 phenotypes in the sample of undergraduate young adults. A special emphasis was placed on *a priori* testing of previously published phenotypic and genetic relationships. All analyses were tested separately in each ancestry group in the sample (African ancestry, native populations of the Americas, East Asian ancestry, European ancestry and South Asian ancestry) and corrected for multiple testing within group. GPSs were also correlated with one another to examine polygenic relationships between profile scores in the young adult sample Summary of Results: The analyses resulted in over 1,800 associations between GPS and phenotype, with over 80 reaching robust significance. The majority of *a priori* hypotheses were replicated. A number of notable findings emerged beyond the expected within-trait prediction (GPS for height and body mass index predicted phenotypic height and BMI, respectively). The GPS for schizophrenia predicted depressive symptoms, anxiety symptoms, and nicotine use, as well as experiences of interpersonal trauma and family history of mental health problems. Furthermore, significant positive associations were observed between schizophrenia, bipolar disorder, and major depressive disorder GPS. Conversely, the subjective well-being GPS predicted fewer depressive symptoms, fewer anxiety symptoms, less family history of mental health problems, as well as higher social support and relationship satisfaction. Many of these associations were consistent across all ancestry groups. These analyses highlight the power of a careful polygenic modeling framework in younger samples, and provide potential avenues for prediction of risk and resilience in emerging adulthood.

424W

Investigating the inflammatory hypothesis of depression using Mendelian randomization in the Avon Longitudinal Study of Parents and Children. *H.M. Sallis[1,2], L. Paternoster[1], J. Evans[2], G. Davey-Smith[1].* 1) MRC IEU, School of Social and Community Medicine, University of Bristol, Bristol, Bristol, United Kingdom; 2) Centre for Academic Mental Health, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

To date, our understanding of the aetiology of depression and its mechanisms is relatively limited. However, there is currently much interest in the 'inflammatory hypothesis' of depression, which postulates that depressive symptoms could stem from an increase in levels of inflammatory markers such as pro-inflammatory cytokines. Many groups have reported increased levels of inflammatory biomarkers, including tumor necrosis factor (TNF)-α, c-reactive protein (CRP) and interleukin (IL)-6, among patients with a depressive disorder or increased depressive symptoms. However, the majority of these are observational associations from cross-sectional data. It is thus unclear whether these levels of circulating inflammatory markers are a potential cause, or effect, of the mood disorder itself, or simply a chance finding. Using data from the Avon Longitudinal Study of Parents and Children (ALSPAC), we have investigated this hypothesis by looking at the association between depression and a number of exposures with known inflammatory responses and strong genetic instruments, using a combination of Mendelian randomization (MR) approaches. These exposures were interleukin (IL)-6 (a pro-inflammatory cytokine), vitamin D, which is thought to have anti-inflammatory properties, and the chronic, inflammatory skin condition, eczema. For each exposure, we looked at the instrument-outcome association and a 2 stage least squares regression. For the IL-6 analyses, we were also able to incorporate data from 2 independent European cohorts to perform a 2-sample MR. Initial results from our MR analyses suggest some evidence of an association between increased IL-6 levels and depressive symptoms, and between decreased vitamin D and depressive symptoms, while the link between eczema and depression is less clear. Viewed together, these results may provide some support for the inflammatory hypothesis of depression. 1 Maier SF, Watkins LR. *Psychol Rev* 1998; **105**: 83–107. 2 Smith RS. *Med Hypotheses* 1991; **35**: 298–306. 3 Howren MB, Lamkin DM, Suls J. *Psychosom Med* 2009; **71**: 171–86. 4 Dowlati Y, Herrmann N, Swardfager W, Liu H, Sham L, Reim EK *et al. Shared genetic effects between clinical ADHD and smoking, alcohol and breastfeeding in mothers from the general population. *E. Stergiakouli[1,2], J. Martin[3], M. Hamshere[3], B. St Pourcain[4], N. Timpson[1], A. Thapar[3], G. Davey Smith[3].* 1) MRC Integrative Epidemiology Unit (IEU) at the University of Bristol, Bristol, United Kingdom; 2) School of Oral and Dental Sciences, University of Bristol, Bristol, United Kingdom; 3) Institute of Psychological Medicine and Clinical Neurosciences, MRC Centre for Neuropsychiatric Genetics and Genomics, Cardiff University School of Medicine, Cardiff, UK; 4) Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands.

Introduction: Smoking and alcohol consumption during pregnancy have been suggested as possible risk factors for ADHD. Inferring causality has not been possible because the mother provides both the prenatal environment and genetic risk factors for ADHD. We investigated if there are shared genetic effects between ADHD and possible risk factors for ADHD using polygenic risk score analysis in mothers from the general population. Materials and Methods: ADHD polygenic risk scores were calculated for 8340 mothers from the Avon Longitudinal Study of Parents and Children (ALSPAC) based on the results of a genome-wide ADHD case-control study (Stergiakouli et al. 2012). We tested polygenic scores for association with smoking status and alcohol consumption before pregnancy and during the first trimester and with breastfeeding status at 2 months postnatally. Results: Higher genetic risk for ADHD was associated with higher odds of smoking before and during the first trimester of pregnancy and not breastfeeding at 2 months after birth (see Table). However, there was no evidence of association with alcohol consumption. Adjusting for the ADHD polygenic score of the child did not change the association. Conclusions: Our results show for the first time that there are shared genetic effects between ADHD and life style choices in adults from the general population that do not reach diagnostic criteria for the disorder. The mother can not only transmit genetic risk for ADHD to her offspring but also expose the child to risk factors through her life style choices that are in turn influenced by her genetic risk for ADHD.

Outcome	N	OR (95% CIs)	p value
Smoking before pregnancy	7530	1.05 (1.01 to 1.1)	0.03
Smoking at first trimester	7543	1.08 (1.03 to 1.15)	0.002
Alcohol consumption before pregnancy	7530	0.99 (0.91 to 1.08)	0.9
Alcohol consumption at first trimester	7543	0.98 (0.94 to 1.03)	0.5
Breastfeeding	6604	1.06 (1.01 to 1.11)	0.03

Dynamic trajectories of psychiatric hospitalizations in the Danish population for subjects with 22q11.2 deletions and duplications. *W.K. Thompson[1], L. Olsen[1], S. Weinsheimer[1], M. Bertalan[1], W. Mazin[1], J. Grauholm[2], M. Hollegard[2], D. Hougaard[2], C.B. Pedersen[3], P.B. Mortensen[3], T. Werge[1], T. Sparso[1], iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research.* 1) Institute of Biological Psychiatry, Roskilde, Region Sjæland, Denmark; 2) Section of Neonatal Genetics and the Danish Neonatal Screening Biobank, Copenhagen, Denmark; 3) National Centre for Register-based Research, Aarhus, Denmark.

Purpose: Genetic rearrangements in the 22q11.2 region are mediated by LCR. Frequency estimates of the 3Mb deletion has so far been based on hospital recruitments and commonly referred to as 1:4000 newborns. A unique source for population-based studies is provided by the iPSYCH initiative (www.ipsych.au.dk). Dried bloodspots from all newborns have been stored since 1982 and today DNA has been extracted from 76,109 individuals (N=25,703 are random samples). Here, we present the first accurate population-based prevalence of both 22q11.2 deletions and duplications. Using the National Health Registry, we provide population-based incidence rate ratio (IRR) estimates for neurodevelopmental disorders in individuals with the 22q11.2 rearrangement. We used incidence density sampling to calculate incidence rate ratio (IRR) estimates for the psychiatric diagnostic categories (ADHD, autism, schizophrenia, and mental retardation). We also perform dynamic survival analyses showing the pattern of diagnoses as a function of age and 22q11.2 rearrangement type. These estimates are weighted using appropriate case-cohort weights and are therefore interpretable as an unbiased estimated of the effect of 22q11.2 rearrangements on psychiatric hospitalizations in all of Denmark. Results: Among the 25,703 population-based samples we observed a frequency of 0.027% (1:3672) for 22q11.2 deletions and 0.0622% (1:1606) for the reciprocal duplications. In our samples of ADHD (N=16,715), autism spectrum (N=14,333), schizophrenia (N=2,623) and mental retardation (N=4,097), we found a significant increased IRR for individuals carrying the 22q11.2 deletion (ADHD: IRR=5.00 (p=0.0026), autism: IRR=6.00 (p=0.00309), mental retardation: IRR=14.29 (0<0.00001). Carriers of the reciprocal 22q11.2 duplication showed similar increased risk for neurodevelopmental disorders (ADHD: IRR=3.75 (p=0.00053), autism: IRR=2.86 (p=0.018), schizophrenia: IRR=4.29 (p=0.035), and mental retardation: IRR=4.10 (p=0.00398), however, not as profound as for deletion carriers. Conclusion: True population-based frequency of the 22q11.2 deletion is marginally higher than the widely accepted 1:4000. Both the 22q11.2 deletion/duplication confer risk of neurodevelopmental disorders at the population-level.

427W

Gene-based meta-analysis of genome wide association studies uncovers novel genes associated with alcohol use disorder. *H. Zhang, J. Jung, B. Grant.* NIH/NIAAA, Rockville, MD.

Alcohol use disorder (AUD) is widespread around the world. Research shows that genetic factors account for about half of the risk for alcoholism (heritability = 0.49). Previous genome-wide association studies (GWAS) typically focus on single variant analysis, which may not have enough power to detect the majority of truly susceptibility genes. We performed gene based meta-analysis using publicly available data genotyped at the Illumina 1M bead-chip from the Study of Addiction: Genetics and Environment (SAGE; dbGap study Accession: phs000092), which included 1,235 alcohol dependent cases and 1,433 unrelated, alcohol-exposed, nondependent controls in the European ancestry (EA) cohort and 662 alcohol dependent cases and 499 controls in the African American (AA) cohort. The VEGAS (VErsatile Gene-based Association Study) program was used to conduct gene-based association analysis in each cohort separately before gene-based meta-analysis was performed using Fisher's method. Among 38 genes that yielded $P < 10^{-3}$ in the EA discovery cohort, six novel genes (GATAD1, ING3, OR52R1, CTD-2270F17.1, ASB13 and PIWIL4) passed a marginally significant threshold ($P < 0.10$) in the AA replication cohort and generated significant outcomes (combined $P < 10^{-3}$) in meta-analysis. Notably, variants at the GATAD1 locus on 7q21 were associated with alcohol use disorder (discovery $P = 2.8 \times 10^{-4}$, replication $P = 0.022$, combined $P = 7.8 \times 10^{-5}$). Our gene-based meta-analysis of GWAS indicated several novel susceptibility genes are involved in alcohol use disorder. Our results also suggest that gene-based GWAS models may be powerful in identifying and prioritizing candidate loci for association studies.

428T

Evaluating polygenic risk for narcolepsy and essential hypersomnia, including SNP and CNV. *M. Yamasaki[1], T. Miyagawa[1,2], H. Toyoda[1], S.S. Khor[1], X. Liu[3], H. Kuwabara[4], Y. Kano[4], T. Sasaki[16], Y. Honda[17], M. Honda[2,17], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Sleep Control Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 3) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Kanagawa, Japan; 4) Department of Child Psychiatry, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 5) Division for Counseling and Support, The University of Tokyo, Tokyo, Japan; 6) Department of Child and Adolescent Psychiatry, Hamamatsu University School of Medicine, Shizuoka, Japan; 7) Asunaro Hospital for Child and Adolescent Psychiatiry, Mie, Japan; 8) Department of Epidemiology and Public Health, Yokohama City University Graduate school of Medicine, Kanagawa, Japan; 9) Department of Neuropsychiatry, Teikyo University Hospital, Tokyo, Japan; 10) Department of Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 11) Tokyo Metropolitan Matsuzawa Hospital, Tokyo, Japan; 12) Panic Disorder Research Center, Warakukai Med. Corp., Tokyo, Japan; 13) Department of Psychiatry, Shonan Kamakura General Hospital, Kanagawa, Japan; 14) Department of Molecular Genetics, Bioresource Science Branch, Center for Bioresources, Brain Research Institute, Niigata University, Niigata, Japan; 15) Department of Psychiatry, Institute of Medical Life Science, Graduate School of Medicine, Mie University, Japan; 16) Department of Physical and Health Education, Graduate School of Education, The University of Tokyo, Tokyo, Japan; 17) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan.

In humans, narcolepsy is a sleep disorder that is characterized by sleepiness, cataplexy, and rapid eye movement (REM) sleep abnormalities. Essential hypersomnia (EHS) is another type of sleep disorder that is characterized by excessive daytime sleepiness without cataplexy. A human leukocyte antigen (HLA) class II allele, *HLA-DQB1*06:02*, is a major genetic factor for narcolepsy. Almost all narcoleptic patients are carriers of this *HLA* allele, while 30% to 50% of EHS patients and 12% of all healthy individuals in Japan carry this allele. The pathogenesis of narcolepsy and EHS are thought to be partially shared. In order to evaluate the contribution of common SNP to narcolepsy onset and to assess the common genetic background of narcolepsy and EHS, we conducted a polygenic analysis that included 393 narcoleptic patients, 38 EHS patients with *HLA-DQB1*06:02*, 119 EHS patients without *HLA-DQB1*06:02,* and 1,582 healthy individuals. We also included 376 individuals with panic disorder and 213 individuals with autism to confirm whether the results were biased. Polygenic risks in narcolepsy were estimated to explain 58.1% ($P_{\text{HLA-DQB1*06:02}} = 2.30 \times 10^{-48}$, $P_{\text{whole genome without HLA-DQB1*06:02}} = 6.73 \times 10^{-2}$) including *HLA-DQB1*06:02* effects and 1.3% ($P_{\text{whole genome without HLA-DQB1*06:02}} = 2.43 \times 10^{-2}$) excluding *HLA-DQB1*06:02* effects. The results also indicated that small-effect SNPs contributed to the development of narcolepsy. Reported susceptibility SNPs for narcolepsy in the Japanese population, *CPT1B*, *TRA@*, and *P2RY11*, were found to explain 0.8% of narcolepsy onset ($P_{\text{whole genome without HLA-DQB1*06:02}} = 9.74 \times 10^{-2}$). EHS patients with *HLA-DQB1*06:02* were estimated to have higher shared genetic background to narcoleptic patients than EHS patients without *HLA-DQB1*06:02* even when the effects of *HLA-DQB1*06:02* were excluded (EHS with *HLA-DQB1*06:02*: 40.4%, $P_{\text{HLA-DQB1*06:02}} = 7.02 \times 10^{-14}$, $P_{\text{whole genome without HLA-DQB1*06:02}} = 1.34 \times 10^{-1}$, EHS without *HLA-DQB1*06:02*: 0.4%, $P_{\text{whole genome without HLA-DQB1*06:02}} = 3.06 \times 10^{-1}$). Meanwhile, the polygenic risks for narcolepsy could not explain the onset of panic disorder and autism, suggesting that our results were reasonable. In addition to SNP-based polygenic analysis, we evaluated polygenic risks including not only SNP but also CNV, so that we can get more integrated genetic background.

429F

Pleiotropic effects of CSF levels of Alzheimer's disease proteins. *O. Vsevolozhskaya[1], D. Zaykin[2], D. Fardo[1].* 1) Biostatistics, University of Kentucky, Lexington, KY; 2) Biostatistics & Computational Biology Branch, National Institute of Environmental Health Sciences, Cary, NC.

Cerebrospinal fluid (CSF) analytes harbor potential as diagnostic biomarkers for Alzheimer's Disease (AD). Quantitative measures of CSF proteins comprise a set of often highly correlated endophenotypes that have previously shown promise in genetic analyses (Cruchaga et al., 2013; Kauwe et al., 2014). Pleiotropic impact of genetic variations on this set may provide additional insights into AD pathology at its earliest stages. To determine which specific endophenotypes are pleiotropic, one can employ methods based on the reverse regression of genotype on phenotypes. Recently, we proposed a method based functional linear models (Vsevolozhskaya et al, 2016) that utilizes reverse regression and simultaneously evaluates all variants within a genetic region for an association with multiple correlated phenotypes. Here we apply our novel methodology to explore pleiotropic effects of CSF analtyes using Alzheimer's Disease Neuroimaging Initiative (ADNI) data.

430W

GWASs of ability to carry a musical tune and mathematical educational attainment. *R. Bell, D. Hinds, C. Tian.* 23andMe Inc., Mountain View, CA.

We describe the results of large-scale GWAS of two interesting cognitive traits in the 23andMe cohort — the self-reported ability to carry a musical tune and the highest level of mathematics classes completed. Our musical tune analysis included 130,673 cases and 85,081 controls of European ancestry and revealed twenty-five novel associations that exceed the genome-wide significance threshold. These included a noncoding variant rs6882046 upstream of MEF2C (p=1.3e-23), which is in the MEF2 family of proteins that play a role in myogenesis and muscle differentiation and also play a role in brain development, learning and memory. The musical tune trait is genetically correlated in the 23andMe cohort with other music-related phenotypes such as the ability to clap to a beat (LD score rg=.75), perfect pitch (LD score rg=.88), and the ability to sing back musical notes (LD score rg=.97). It also shares significant associations with several other music-related phenotypes. The math analysis included 210,135 research participants of European ancestry and revealed twenty-nine associations that exceeded the genome-wide significance level. Associations included a loss of function variant rs10555297 in GIGYF2 (p=2.5e-13), which is involved in tyrosine kinase regulation, and rs4500960 in SLC4A10 (p=1.5e-11), a sodium coupled bicarbonate transporter that regulates intracellular pH of neurons. The trait is genetically correlated in the 23andMe cohort with other academic achievement traits such as having completed college, years of education (both LD score rg=.80), and other phenotypes relating to math ability such as working in a technical occupation (LD score rg=.74). It also shares significant associations with many of those phenotypes. We found that the math class and carry a tune phenotypes are not significantly correlated (LD score rg=-.05, p=.08) but they do share several significant associations both with the same effect direction and opposite effect direction. This data suggests there may be both synergy in the underlying mechanisms in some cases versus a tradeoff in other cases. Overall the analysis suggested that the complex phenotypes included in our study are highly polygenic, share common factors with related phenotypes, but are nonetheless quite distinct.

431T

A genome-wide association study of mitochondrial DNA copy number in mothers and children from the Avon Longitudinal Study of Parents and Children (ALSPAC). *A.L. Guyatt[1,2], K. Burrows[1,2], P.A.I. Guthrie[2], T.R. Gaunt[1,2], S. Rodriguez[1,2].* 1) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 2) School of Social & Community Medicine, University of Bristol, Bristol, United Kingdom.

Background: The mitochondrial genome (MtDNA) is expressed at variable copy number between cell populations and individuals. Since rare mutations in nuclear genes lead to a reduction in MtDNA copy number (the 'mitochondrial depletion syndromes'), we hypothesised that smaller, population-level differences in MtDNA copy number might be attributable to common, nuclear DNA polymorphisms. **Methods:** We performed a genome-wide association study (GWAS) in the ALSPAC study. For the main analysis, 2805 mothers (mean age 28 years), 3712 children (mean age 8 years) and 2164 neonates were studied (these participants were unrelated). Since cell populations vary in their mitochondrial content, we undertook additional analyses in which we controlled for white cell proportions, as estimated previously from methylation data by the Houseman method. **Results:** rs57968500 (*PSMD3* intron) on chr17 was associated with a -0.16 (S.E. 0.027, p=3.98e-09) change in SD units of log MtDNA copy number, in mothers. In unrelated neonates, but not children, this association was also present (beta [SE]=-0.13 [0.031], p=3.49e-05, beta [SE]=-0.02 [0.024], p=0.525, respectively). In addition, to assess the effects of cell proportions on the rs57968500 chr17 association (a known GWAS white cell count locus), a larger population of mothers was used. In order to maximise power, it was necessary to include some who were related to the offspring: beta (unadjusted) [SE]=-0.12 [0.019], p=1.26e-09, N=5431; beta (cell-proportion adjusted) [SE]=-0.04 [0.060], p=0.516, N=642. In neonates, an association at rs10424198 (chr19, *ABHD8* intron) was observed (beta [SE]=-0.26 [0.034], p=3.84e-14). *ABHD8* is in head-to-head orientation with the mitochondrial ribosomal protein L34: a SNP in *MRPL34* rs11548548 [synonymous]) was in LD (r2=0.27, D'=0.89) with rs10424198, and neared genome-wide significance (beta [SE]=-0.25 [0.047], p=2.43e-07). However, the rs10424198 association was not replicated in mothers or children. **Conclusion:** We observed associations between MtDNA copy number and a white cell count locus. Although this association diminished after controlling for cell proportions, this analysis had limited power, and replication in larger cohorts is warranted. A chr19 locus was associated with MtDNA copy number in neonates: given its location in proximity to a mitochondrial ribosomal protein implicated in organelle biogenesis, it will be important to see whether this locus replicates in other neonatal populations.

Mitochondrial haplogroup backgrounds modify the phenotypic impact of SNPs in genes relevant to mitochondrial function. *R.T. Levinson[1], D.C. Samuels[1,2].* 1) Vanderbilt Genetics Institute, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN.

Mitochondrial haplogroups are patterns of genetic variation that are maternally inherited and are specific to continental ancestry. Mitochondrial haplogroups have been associated with neurological and immune function phenotypes, among others. Despite having their own genomes, mitochondria are still dependent on ~1000 proteins encoded in the nucleus for proper function. Using BioVU, a biobank linked to de-identified EHRs, we explored the relationship between nuclear and mitochondrial genetic variation in humans. We determined the mitochondrial haplogroup of 20,064 White individuals randomly split into discovery (n=13391) and replication (n= 6673) sets. Common nonsynonymous SNPs in genes on the MitoCarta2 list of genes relevant to mitochondria and present on the Illumina Human Exome BeadChip were obtained for these individuals. We performed a phenome-wide association study (PheWAS) to evaluate whether the presence of a SNP in individuals of a given mitochondrial haplogroup increased the likelihood of a medically relevant phenotype compared to individuals without the SNP or the haplogroup. ICD.9 codes aggregated into groups of similar phenotypes were used as our outcomes, and all regressions were adjusted for age at last record and gender. Several different nuclear SNPs in combination with the common mitochondrial haplogroup H increased the risk of cancer phenotypes. In contrast, on the background of haplogroup IWX, the SNPs tested were more likely to increase the risk for immune phenotypes. Overall, we noticed that different haplogroup backgrounds had different general areas of significant phenotypes. In conclusion, our study provides evidence that mitochondrial haplogroup backgrounds may impact the phenotypic effect of SNPs in genes relevant to mitochondrial function.

Comparison of mitochondrial DNA copy number estimation techniques from multiple platforms. *R.J. Longchamps[1], R.N. Eggebeen[1], J.A. Lane[2], F.N. Ashar[1], T.M. Bartz[3], N. Pankratz[2], D.E. Arking[1].* 1) Mckusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Laboratory Medicine and Pathology, University of Minnesota School of Medicine, Minneapolis, MN; 3) Department of Biostatistics, University of Washington, Seattle, WA.

Mitochondrial DNA copy number (mtDNA-CN) declines with age and is associated with frailty, cardiovascular disease, and overall mortality. The gold standard for determining mtDNA-CN is qPCR; however this method is cost prohibitive for large scale association studies. We have recently developed several methods (available in Genvisis) to overcome this issue by leveraging preexisting data in the forms of microarray raw probe intensities and next generation sequencing read counts. Here, we compare mtDNA estimated from qPCR, the Affymetrix 6.0, the Illumina Exome Chip, Whole Exome Sequencing (WES) data and Whole Genome Sequencing (WGS) data to highlight the best technique for accurately quantifying mtDNA-CN. White blood cell (WBC) count is known to be negatively associated with mtDNA-CN. SNPs associated with WBC count were used as proxies to evaluate how well each platform accurately measured mtDNA-CN. Data from 29,273 individuals (22.3% African American [AA]) across four independent cohorts (ARIC, MESA, CHS, and LLFS) were used to evaluate effect size (beta) concordance with known WBC count SNPs (n = 13) to determine which method maximized known association signals. Initial analysis for AA in MESA determined Affymetrix optimally maximized signal from rs2814778, the top Duffy locus SNP, a well-established WBC count locus in African Americans. The effect size estimate for Affymetrix was -0.29 standard deviation units (SE = 0.043) compared to -0.16 and -0.17 (SE = 0.044 and 0.044) for the Exome chip and qPCR metrics, respectively. A similar analysis within the ARIC cohort revealed WES to perform similarly to the Exome chip. In a further comparison of effect size estimates, a GWAS for WBC count was compared to a GWAS for mtDNA-CN within ARIC for all SNPs p < 0.0001. The highest correlation belonged to the Affymetrix array with a correlation coefficient of -0.579 compared to -0.228 for the Exome Chip, -0.262 for WES and -0.128 for WGS. Here we illustrate the ability to use WBC as a proxy for evaluating mtDNA-CN estimates derived from five separate platforms. With the ability to collect information from hundreds of mitochondrial probes, estimates from microarrays appeared to maximize signal relative to qPCR. Interestingly, our metric derived from sequencing read count data does not appear to outperform mtDNA-CN calculated from microarray data. However, our results show that despite the poor signal, mtDNA-CN can still be derived from the Exome Chip, WGS and WES data.

Exfoliation syndrome (XFS), involving the deposition of proteinaceous fibers on ocular tissues, is a major cause of glaucoma, cataract and other eye diseases. The *LOXL1* gene is the only well-characterized risk locus for XFS with strong effect, and while *CACNA1A* has recently been implicated as a causal locus with small effect from a Japanese sample (Aung et al., 2015, *Nat Genet* **47,** 387), there still remain undiscovered genetic determinants of XFS. We conducted a genomewide association study (GWAS) on a sample of 1,124 XFS cases and 4,894 controls of European ancestry, using the Illumina OmniExpress panel (532,011 common variants with minor allele frequency ³ 0.01 after quality control). Association analysis for single common variants was carried out by means of logistic regression, adjusting for sex and six principal components for population structure, using an additive genetic model. Consistent with previous studies, we observed an exceedingly strong association signal at *LOXL1*, with numerous genomewide significant markers with odds ratios near 4.0 for the common alleles (most significant marker: rs2165241, OR = 4.11 for the A allele, 95% CI = (3.65, 4.62), $p = 4.0E-121$). In addition, suggestive association results ($1E-07 < p < 1E-06$) appeared on chromosome 3q (rs7629566, intronic to *CEP19* and *PIGX*) and on chromosome 6p (rs2763122, within pseudogene *HNRNPLP1*). We did not, however, observe strong association in or near previously reported XFS loci *CACNA1A* or *CLU* (best $p > 0.001$ within 100 kilobasepairs of gene). Moreover, our chromosome 3q and 6p findings were not strongly supported by results from three previous EXF GWAS on cohorts of European ancestry. Overall, these results support *LOXL1* as a major risk factor for XFS in this European Caucasian population, and suggest that there are no other common genetic risk factors in this sample with moderate to large effects. Grant support: NIH/NEI R01 EY020928.

Common and rare variants of congenital cataract genes and age-related nuclear cataract: International Cataract Genetics Consortium. *E. Yonova[1], W. Zhao[2], R.P. Igo Jr[3], P. Sundaresan[4], A. Fletcher[5], C.C. Klaver[6], B.E. Klein[7], J.J. Wang[8], S.K. Iyengar[3], C.J. Hammond[1,9], C.Y. Cheng[2,10], International Cataract Genetics Consortium.* 1) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 2) Singapore Eye Research Institute, Singapore National Eye Center, SG; 3) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, USA; 4) Department of Genetics, Aravind Medical Research Foundation, #1, Anna Nagar, Madurai¬ 625020, Tamilnadu, IN; 5) Department of Epidemiology & Population Health, London School of Hygiene & Tropical Medicine, London, UK; 6) Department of Epidemiology, Erasmus Medical Centre, Rotterdam, NL; 7) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, USA; 8) Centre for Vision Research, Westmead Institute for Medical Research, University of Sydney, Sydney, AU; 9) Department of Ophthalmology, King's College London, London, UK; 10) Duke-NUS Medical School, National University of Singapore, SG.

   Purpose: A recent genome wide association study (GWAS) in Asian populations identified common variants within *CRYAA* to be associated with age-related nuclear cataract. Mutations in *CRYAA* are the most common cause of congenital cataracts. As part of the International Cataract Genetics Consortium (ICGC), we performed GWAS meta-analysis of 14,151 individuals from European and Asian ancestry and found variants in three additional congenital cataract genes to be associated ($p<1\times10^{-5}$) with age-related nuclear cataract, two at genome-wide significance (GJA3 and SOX2-OT/SOX2). The aim of this study was to explore whether common and rare genetic variants in other congenital cataract genes were also associated with age-related nuclear cataract.   **Methods:** 95 congenital cataract genes (longest transcript +/- 100kb), selected from 3 publicly available databases (OMIM, CatMap and ClinVar) and an in-house database, were tested for single-variant association with nuclear cataract using common variants from the ICGC GWAS meta-analysis. We also performed a burden test for rare variants (SKAT) in those genes using whole-genome sequencing data from 905 unrelated individuals from the TwinsUK cohort. Finally we performed a gene-set enrichment test (DAVID) to explore whether any of the associated congenital cataract genes belonged to the same pathways.   **Results:** Common variants in 47 congenital cataract genes (50%) were associated with age-related nuclear cataract ($p<0.05$). The most strongly associated variants belonged to the following genes: *BFSP1* ($p=3.5\times10^{-5}$), *LIM2* (1.4×10^{-4}), *MIP* (3.4×10^{-4}) and *CHMP4B* (3.8×10^{-4}). *BFSP1* encodes for a filament-like protein that is part of a structure (the beaded element) that is unique to the differentiated lens fibers. *LIM2* encodes for another lens specific structural protein found at lens fiber junctions. *MIP* encodes for an aquaporin that plays a role in cell communication while *CHMP4B* encodes for a part of a complex which functions in the sorting of endocytosed cell-surface receptors. Rare variant (MAF<0.05) burden test analysis showed only two genes to be associated with nuclear cataract: *POMT2* ($p=1.5\times10^{-3}$) and *CRYBA4* ($p=0.02$), although sample size was smaller, limiting power to find associations. Only one pathway – focal adhesion was enriched ($p=0.004$). **Conclusions**: These results suggest that common polymorphisms within genes where coding mutations cause congenital cataract may be important contributors to age-related nuclear cataract.

Marital status, marriage patterns and fertility of deaf people in the Tyva Republic (South Siberia, Russia). *O.L. Posukh[1,2], M.S. Bady-Khoo[1,3], V.Yu. Mikhalskaia[1,2], M.V. Zytsar[1,2], N.A. Barashkov[4,5], G.P. Romanov[5], S.A. Lashin[1,2].* 1) Federal Research Center Institute of Cytology and Genetics, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation; 2) Novosibirsk State University, Novosibirsk, Russian Federation; 3) Perinatal Center of the Tuva Republic, Kyzyl, Russian Federation; 4) Laboratory of Molecular Genetics, Yakut Scientific Center of Complex Medical Problems, Yakutsk, Sakha Republic, Russian Federation; 5) Laboratory of Molecular Biology, Institute of Natural Sciences, M.K. Ammosov North-Eastern Federal University, Yakutsk, Sakha Republic, Russian Federation.

   High frequency of deafness caused by mutations in the *GJB2* (Cx26) gene might be the consequence of combined effects of high rate of assortative mating among deaf individuals and the relaxed selection against deafness (Nance et al., 2000). Our previous studies revealed that 18.9% of deafness in the Tyva Republic (South Siberia, Russia) were caused by *GJB2* mutations. This study aims to evaluate marital status, marriage patterns and fertility of deaf persons (n=456) at the age of 19 to 86 years (mean 39.6±0.7) living in the Tyva Republic. Most of them have congenital or early onset severe-profound deafness. Deaf individuals indicated sign language as a common communication mode with other deaf persons, whereas in communication with hearing people they use lip-reading, writing, and oral language skills, if any. 329 (72.1%) deaf individuals are married and the data on 200 marriages were available for analysis. We revealed assortative mating rate of 0.65 in total sample of married deaf people with significant differences in urban (0.71) and rural (0.58) groups (p=0.036). Fertility of married deaf individuals is slightly lower compared with their hearing siblings (2.22 vs. 2.40). We also found tendency to decreasing fertility in assortative marriages (2.14±0.08) compared with marriages in which only one of spouses was deaf (2.50±0.16) although the differences were not significant. This study provides insight to social aspects of deafness in the Tyva Republic and our data are relevant for predicting the prevalence of inherited deafness in studied region. Work is supported by the RFBR grant #15-04-04860_a.

Identifying rare and low-frequency variants associated with axial length in the Beaver Dam Eye Study (BDES). *S.M. Bomotti[1], P. Duggal[1], F. Chen[1], B.E.K. Klein[2], K.E. Lee[2], B. Truitt[3], R. Klein[2], S.K. Iyengar[3], A.P. Klein[1,4,5].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA; 2) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin, USA; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio, USA; 4) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland, USA; 5) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, Maryland, USA.

Refractive errors, myopia and hyperopia, are the most common causes of visual impairment in the US and the world. Although studies suggest a strong genetic component, only ~3.4% of the genetic variation in refractive errors has been explained to date. The primary determinant of refractive errors is ocular axial length. The goal of this analysis is to identify rare and low-frequency variants (minor allele frequency (MAF) ≤ 5%) associated with axial length. A subset of 1,908 individuals aged 58-94 years from the population-based Beaver Dam Eye Study (BDES) cohort were successfully genotyped using the Illumina exome array. Following standard quality control procedures, 10,397 autosomal genes and 34,981 single variants from 874 individuals were available for analysis. Axial length measurements were obtained from the fourth follow-up visit of the BDES using partial coherence laser interferometry (IOL Master, Carl Zeiss, Jena, Germany). We conducted a gene-based analysis using SKAT-O to increase our power to detect the effects of rare and low-frequency variants on axial length variation. A single variant analysis was then conducted in PLINK under an additive model. All analyses were adjusted for age, sex, height, and education, and were conducted in the right eye followed by the left eye to ensure consistency of results. The Bonferroni-corrected threshold for significance was $P < 4.81 \times 10^{-6}$ for the gene-based analysis and $P < 1.84 \times 10^{-6}$ for the single variant analysis. In the gene-based test, the *RAD17* checkpoint clamp loader component gene (MIM 603139) on chromosome 5q13.2 was significantly associated ($P = 3.44 \times 10^{-6}$) with axial length. The single variant test supported this finding with a suggestively associated missense variant (rs35440980, c.1778G>A [MAF = 0.76%], p.R593K) in *RAD17* in the right ($P = 7.48 \times 10^{-6}$) and left ($P = 1.65 \times 10^{-5}$) eyes. The adhesion G protein-coupled receptor G7 gene (*ADGRG7* [MIM 612307]) on chromosome 3q12.3 was also significantly associated with axial length ($P = 1.56 \times 10^{-6}$). A missense variant (rs61742836, c.187G>A [MAF = 0.68%], p.D63N) in *ADGRG7* was suggestively associated in the right eye ($P = 8.18 \times 10^{-5}$) and significantly associated ($P = 1.26 \times 10^{-6}$) with axial length in the left eye. These results suggest that rare and low-frequency variants within the *RAD17* and *ADGRG7* genes are associated with variation in axial length. These results may help to elucidate the biological mechanism underlying ocular refraction.

438F

Variation in *RNF149* associated with nuclear lens opacity. *S.J. Loomis[1], A.P. Klein[1,2,3], B.E.K. Klein[4], R. Klein[4], K.E. Lee[4], B. Truitt[5], S.K. Iyengar[5], P. Duggal[1].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland; 3) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, Maryland; 4) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin; 5) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, Ohio.

PURPOSE: Nuclear sclerotic cataract (NSC; MIM 601371) is the most common form of age-related cataract and is one of the leading causes of blindness worldwide. NSC is severe nuclear sclerosis, or opacity of the nucleus (center) of the optic lens. NSC is multifactorial, with evidence for both genetic and environmental risk factors, such as smoking. We sought to better understand the genetic factors associated with increasing nuclear lens opacity through interrogation of rare and low frequency coding variants using exome array data. **METHODS:** We analyzed genotype data from the Illumina Human Exome Array for 1489 participants in the Beaver Dam Eye Study for association with nuclear sclerosis grade. All individuals were of European ancestry and had not undergone cataract surgery. We conducted analysis using highest nuclear sclerosis grade in either eye prior to lens replacement surgery or loss to follow up after regressing off the effects of age and sex as outcome. We then performed single-variant regression analysis for 32,138 variants with MAF≥0.003. We used 11,844 genes with at least two variants with MAF<0.05 (N=63,598 SNPs) to perform a gene-based unified burden and non-burden sequence kernel association test (SKAT-O) using Madsen-Browning weights. We analyzed the data overall and stratified by smoking status (never vs. past or current smokers). **RESULTS:** None of the single variant tests were statistically significant after controlling for multiple tests (p<1.6 x 10^{-6}; top SNP: rs144458991, p=2.83 x 10^{-5}). Gene-based tests showed suggestive evidence of association for the gene *RNF149* (p=8.25 x 10^{-6}) in the overall analysis. This finding reached genome-wide significance (p<4.2 x 10^{-6}) when the analysis was limited to never smokers (N=790, p=2.67 x 10^{-6}), but not when limited to past or current smokers (N=698, p=0.07). *RNF149* codes the ring finger 149 protein, involved in ligase and protein ubiquitination activity. **CONCLUSIONS:** Our study suggests exonic changes in the *RNF149* gene may affect risk of nuclear lens opacity, Further research is necessary to fully understand the genetic architecture of nuclear sclerosis. .

Age-related macular degeneration (AMD) is a leading cause of visual impairment among people age 50 and older. Previous AMD genetics studies have focused on subsets of the genome accessible via genotyping arrays or targeted sequencing. While this approach is affordable and accurate, it limits the number and types of variants that can be discovered. We therefore conducted whole genome sequencing (WGS) to assess the contribution of the full spectrum of genetic variants to AMD pathogenesis.We sequenced, at 6x coverage, 4,806 samples (2,413 cases and 2,393 controls, age- and sex-matched) of European ancestry, from the University of Michigan Kellogg Eye Center, the National Eye Institute, the University of Pennsylvania, and the Michigan Biobank. Our cases consist of subjects with large drusen (intermediate AMD), geographic atrophy (GA), choroidal neovascularization (CNV), and mixed GA/CNV. Our WGS analysis discovered over 45 million variants (42 million SNPs and 3 million indels), a majority of which are very rare (>35 million with allele frequency <1%) and previously unreported (>26 million variants not in dbSNP version 138).We rediscovered significant genomewide association signals (P-value <5x10^{-8}) at four loci (*CFH*, *C2/CFB/SKIV2L*, *ARMS2/HTRA1*, and *C3*). In a follow-up association study restricted to advanced AMD (excluding participants withintermediate AMD), we discovered 6 new genomewide significant signals near the known risk loci: an intergenic deletion near *ST3GAL6-AS1* and an intronic deletion in *lnc-GTPBP8-1* on chr 3, an intergenic deletion near *MARCKS* on chr 6, an intronic deletion in *CAMSAP1* on chr 9, an intergenic deletion near *FLJ26245* on chr 16, and an intergenic deletion near *VPREB1* on chr 22. We were also able to better characterize rare variants: for example, the *CFH* R1210C variant was detected in 23 cases vs. 2 controls (P-value = 3.0x10^{-7}).In addition to the GWAS, our study contributes a large catalog of rare variants from a large number of AMD cases, which can be used for AMD-specific reference panel to impute into much larger genotyped panels, potentially increasing both the number of AMD-associated imputed variants and the imputation accuracy of those variants.In summary, our WGS and association study of AMD replicate 4 previously-discovered loci and identified significant signals outside of known loci, providing a more complete list of potentially causal variants genomewide.

440T

Linkage analysis of common myopia using whole exome genotyping in highly aggregated Ashkenazi families finds novel signals and replicates known loci. *C.L. Simpson[1,2], A.M. Musolf[2], L. Portas[2], F. Murgia[2], Q. Li[2], J.E. Bailey-Wilson[2], D. Stambolian[3].* 1) Department of Genetics, Genomics and Informatics, University of Tennessee Health Science Center, Memphis, TN; 2) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland, United States; 3) Ophthalmology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Myopia is a common refractive error which affects at least a third of most populations. Both genetic and environmental factors influence myopic development. It has a significant impact on the lives of affected individuals and carries high economic costs associated with treatment, loss of productivity and co-morbidity from vision impairment. Here we report the results of linkage analyses on highly aggregated Ashkenazi Jewish families with common myopia using an exome-targeted genotyping array. Sixty-four extended Ashkenazi Jewish families previously collected from New Jersey. Myopia defined as mean spherical equivalent (MSE) of -1D or worse and both parametric two-point linkage analyses (using MCLink) and collapsed haplotype pattern linkage using SEQlinkage were performed. Significant evidence of linkage was seen on chromosome 16q22.1 (max two-point LOD=7.28), chromosome 1p36.2 (max two-point LOD=4.47) which had previously been linked to ocular refraction but not myopia in these families (MYP14) and chromosome 8q24.22 (max two-point LOD=3.75). Suggestive evidence of linkage was seen on multiple chromosomes including the 7p14 close to the MYP17 locus and 11p13-p15.4 which overlaps the MYP18 locus and includes a 3' UTR variant in PAX6. Collapsed haplotype pattern linkage analysis of these data identified four genomewide significant loci, including the 16q22.1 locus (max HLOD 7.78, α=0.8) centered on the PDPR gene and 1p36.1 (max HLOD 3.47, α=0.57) centered on LINC00339. There was one signal unique to this analysis from the SSPO gene on chromosome 7q36.1 (max HLOD 4.02, α=1), which does not overlap with the known chromosome 7 myopia locus MYP17. Here we report novel loci and replicated a locus previously reported in refractive error but not myopia in these families. Targeted sequencing in these regions to will be necessary to further find causal variants under these linkage peaks.

441F

Modeling misclassified cases in electronic medical records using genotype information. *X. Zhao[1], E. Schmidt[1], L. Fritsche[2], G. Zajac[1], C. Brummett[3], S. Kheterpal[3], G. Abecasis[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI 48109, USA; 2) K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health, NTNU, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, MI 48109, USA.

Combining the clinical data in electronic medical records (EMR) and genetic data provides us a chance to accelerate the pace of genomic discovery on thousands of traits. One major challenge in using EMR data is the potential misclassification of cases and controls. Previous studies have shown that misclassification of disease can cause biased effect size estimates and misleading association results. Existing methods for correcting misclassification require either knowing the misclassification rate or identifying a gold standard set of sample. We focus on the setting where neither is available. Here, we propose a method that estimates the misclassification rate by examing genotype information of dozens of disease associated loci. Instead of using gold standard samples, we use the odds ratios of known risk loci from previous large-scale genome-wide association studies (GWAS). Assuming that these odds ratios in our study are similar to those in previous GWAS, we are able to construct the likelihood and obtain the MLE of the misclassification rate. Then we can correct biased association statistics using estimated misclassification rate. In a simulation study, we generated phenotypes and genotypes for 5000 samples at 52 variants. The 52 variants were previously reported to be associated with age-related macular degeneration (AMD) by the International AMD Genomics Consortium. The simulation demonstrated that this method accurately estimated misclassification rates for a variety of different misclassification rates (range: 0.1-0.5) and disease prevalence (range: 0.05-0.5). For example, in the setting with disease prevalence 0.05 and misclassification rate 0.3, the mean square error of our estimated misclassification rate was 0.002. We also show that estimates of the misclassification rate are robust to errors in odds ratios. We applied our technique to the data from the Michigan Genomics Initiative (MGI), a collaborative research at the University of Michigan aiming to analyze the patient EMR jointly with genetic data. Using the odds ratios for 52 associated variants of AMD, we found that 36% of cases were likely to be misclassified when using the ICD-9 based classification scheme implemented in the PheWAS R package. Our method enables the evaluation of new EMR-based case definition schemes and provides accurate estimates of disease odds ratios and other association measures when cases are misclassified.

442W

Socioeconomic status, genetic risk, and how their interactions affect risk of oral clefts. *M.M. Jenkins[1], L.M. Almli[2], C.P. Bay[2], P.A. Romitti[3], L.M. Uribe[3], G.L. Wehby[3].* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Carter Consulting, Inc., Atlanta, GA; 3) University of Iowa, Iowa City, IA.

Low socioeconomic status (SES) has been linked to increased risk of oral clefts. However, little is known about how SES interacts with genetic risks for oral clefts. Using data from a population-based, case-control study (National Birth Defects Prevention Study [NBDPS]), we examined whether the association between SES and risk of cleft lip with/without cleft palate (CL/P) was modified by genetic predisposition to CL/P. Our sample included 614 cases with isolated CL/P and 2213 controls without any major birth defect; birth years were between 1997 and 2009. SES was estimated by maternal education (≤high school [HS] vs >HS [reference]) or household income (1st and 2nd tertiles vs 3rd tertile). Genetic risk was estimated by a genetic risk score (GRS) based on a set of top genes and loci associated with CL/P in previous genome-wide association studies; SNPs of interest were assayed using a Fluidigm platform (San Francisco, CA). Logistic regression analyses were used to estimate CL/P risk for cases relative to controls, adjusting for maternal age at conception, NBDPS site, and maternal race/ethnicity. The risk for CL/P was greater for mothers with ≤HS education compared to mothers with >HS education (OR=1.27, 95%CI 1.03-1.58) and for mothers in the lowest income tertile compared to those in the highest tertile (OR=1.35, 95%CI 1.01-1.80). As expected, the GRS was significantly associated with increased risk for CL/P (OR=2.49, 95%CI 2.17-2.85). A significant SES x GRS interaction was observed. Specifically, the risk of CL/P associated with ≤HS education was higher at 1 standard deviation (SD) below the GRS mean (i.e., a low genetic risk profile; OR=2.00, 95%CI 1.43-2.81) than at the mean GRS (OR=1.40, 95%CI 1.11-1.76). Educational status was not associated with CL/P risk at 1 SD above the GRS mean (i.e., a high genetic risk profile; OR=0.98, 95%CI 0.75-1.27). Similarly, comparing the lowest tertile of household income to the highest, the association with CL/P was stronger at 1 SD below the GRS mean (OR=2.13, 95%CI 1.36-3.33) than at the mean GRS (OR=1.47, 95%CI 1.07-2.00). There was no association between household income and risk of CL/P at 1 SD above the GRS mean (OR=1.01, 95%CI 0.71-1.43). Our preliminary results suggest that for individuals with a higher genetic risk profile for CL/P, the influence of lower SES on risk of CL/P is attenuated. Similarly, SES seems to be a more influential risk factor for CL/P among individuals with lower genetic risk scores.

Down syndrome patients are often born with congenital heart defects (CHD). Among those, atrioventricular septal defect (AVSD) is the most frequent and one of the most severe. The incidence of AVSD is 43% in CHD T21 patients (17% in the trisomic population) and almost absent in the general population. The genetic architecture of CHD regarding chromosome 21 variants has been previously studied with SNP arrays and oligonucleotide hybridization. With this approach our group identified two SNPs and three CNVs regions significantly associated with the risk of CHD (Sailani et al., Genome Research, 2013). Here we use targeted chromosome 21 ultradeep sequencing (>120x) using a custom DNA selection design to perform a case-control association study in a trisomic population to identify SNVs, structural variants and CNVs associated with an increased risk of AVSD. The study cohort includes 162 Down syndrome patients with AVSD at birth and 178 Down syndrome patients without detectable cardiac defect as controls. A total of 179931 SNVs has been called through our in-house pipeline implementing BWA, GATK and Annovar. The association study of SNVs and structural variants has been performed with Fisher's exact test and revealed rs1156253 in the MIR99AHG cluster and rs869725 in a regulatory area nearby PDE9A, a gene known to be expressed in heart tissues and upregulated in case of hypertrophy and cardiac failures ($p<10^{-6}$). We performed CNVs detection with CoNIFER and CONTRA. We were able to call in average more than 20 CNVs per sample; the association analysis is ongoing. This study shows that common variants on chromosome 21 contribute to the developmental phenotype of AVSD and might provide insights to the understanding of the biological and genetic mechanisms underlying the development of the disease.

444F

Whole exome association of rare deletions in multiplex oral cleft families. *J. Fu[1], T. Beaty[2], A.F. Scott[3], M. Parker[4], J. Wilson[5], M. Marazita[6], E. Mangold[7], H. Albacha-Hejazi[8], J. Murray[9], A. Bureau[10], J. Carey[2], S. Cristiano[1], I. Ruczinski[1], R. By sequencing the exomes of distantly related individuals in multiplex families, rare mutational and structural changes to coding DNA can be characterized and their relationship to disease risk assessed. Recently, several rare single nucleotide variants (SNVs) were associated with an increased risk of non-syndromic oral cleft, highlighting the importance of rare sequence variants in oral clefts and illustrating the strength of family-based study designs. However, the extent to which rare deletions in coding regions of the genome occur and contribute to risk of non-syndromic oral clefts is not well understood. To identify putative structural variants underlying oral cleft risk, we developed a pipeline for the delineation of rare hemizygous deletions in families from whole exome sequencing and statistical inference based on rare variant sharing. Our method utilizes a read-depth approach, with median centering across samples, and includes adjustments for sequencing artifacts like GC-content and mappability. We further employ the 1000 Genomes database as well as a Bayesian mixture model to filter for the rarity of identified deletions. Among 46 multiplex families, we identified 51 regions with one or more rare hemizygous deletions. We found 43 of the 51 regions contained rare deletions occurring in only one family member. Members of the same family shared a rare deletion in only 8 regions, which included a rare deletion on chr13 at 53,078,416 - 53,158,768bp showing nominal statistical significance (p = 0.004). We also devised a scalable global test for enrichment of rare variant sharing. .

Associated anomalies in cases with anotia and microtia. *C. Stoll, Y. Alembik, B. Dott, M.P. Roth.* genetics , Faculté de Médecine, Strasbourg, France, France.

Infants with anotia and microtia (AM) often have other non-AM associated congenital anomalies. The purpose of this investigation was to assess the prevalence and the types of these associated anomalies in a defined population. The associated anomalies in infants with AM were collected in all livebirths, stillbirths and terminations of pregnancy during 29 years in 387,067 consecutive births in the area covered by our population-based registry of congenital malformations. Of the 146 cases with AM registered during this period, representing a prevalence of 3.77 per 10,000, 49.3% had associated anomalies. There were 14 (9.6%) cases with chromosomal abnormalities including 5 trisomies 18, and 18 (12.3%) nonchromosomal recognized dysmorphic conditions including 6 cases with oculo-auriculo-vertebral spectrum. However, numerous other recognized dysmorphic conditions were registered. Forty (27.4%) of the cases had multiple congenital anomalies (MCA). Anomalies especially in the cardiovascular, the musculoskeletal, the urogenital, the central nervous, and the digestive systems, and facial clefts were the most common other anomalies. This study included special strengths: each affected child was examined by a geneticist, all elective terminations were ascertained, and the surveillance for anomalies was continued until 2 years of age. In conclusion the overall prevalence of associated anomalies, which was one in two cases, emphasizes the need for a thorough investigation of cases with AM. A routine screening for other anomalies may be considered in infants and in fetuses with AM.

Genetic determinants of telomere length in a Bangladeshi cohort. *D. Delgado[1], B. Pierce[1,2,3], C. Zhang[1], J. Farina[1], M. Kibriya[1], H. Ahsan[1,2,3,4].* 1) Department of Public Health Sciences, University of Chicago , Chicago , IL. 60637; 2) Department of Human Genetics, University of Chicago, Chicago, IL 60637; 3) Comprehensive Cancer Center, University of Chicago, Chicago, IL 60637; 4) Department of Medicine and Human Genetics, University of Chicago, Chicago, IL 60637.

Introduction: Attrition of telomere length (TL) occurs with each round of cell division and is associated with aging and increased risk for various age-related chronic diseases. TL has high heritability and shows differences by race/ethnicity. We performed a genome-wide association study (GWAS) to identify genetic determinants of TL in a Bangladeshi cohort. Methods: We measured TL for 5,019 individuals participating in one of two prospective cohort studies in Bangladesh (2.416 men and 2,603 females with a mean age of 39.9 years). TL was measured using one of two technologies: a qPCR-based assay (n=2,203) and a Luminex–based method (n=2.816). All subjects were genotyping using the Illumina HumanCytoSNP array. Prior to analysis, we used mixed effects models to adjust our TL measures for plate, position, and batch effects, and we used the standardized residuals from these regressions as our TL phenotypes for GWAS. We used the Genome-wide Complex Trait Analysis (GCTA) software to identify single nucleotide polymorphisms (SNPs) associated with TL, using a mixed effects model to account for the presence of cryptic relatedness among our participants. Results: After standard quality control procedures, a total of >250,000 genotyped and 8.5M imputed SNPs were included in the analysis. We replicated loci reported in prior GWAS studies of TL in European populations, including the *TERC* region (P = 1.7x10-9), the *TERT* region (P = 4.1x10-7) and *RTEL1* region (P = 9.3x10-7). We identified a suggestive novel association with TL in the *NCR2* region (P = 7.4x10-7). The SNP –based heritability estimate based on all genome-wide SNP was 26.7% (P=4.7x10-10). Conclusion: Our data suggest that the *TERC* region harbors the strongest common genetic determinants of TL in this Bangladeshi cohort. Our results also suggest that several of TL-associated regions identified in GWAS of European ancestry show consistent association with TL among Bangladeshi participants. In addition, we also observe suggestive evidence for a novel association signal for TL in the *NCR2* region.

447F

Simultaneous scan of whole-genome genetic variants in family-based association studies via supervised dimension reduction. *D. Zhang, L. Wang, Q. Wang, M. Zhang.* Depart of Statistics, Purdue Univ, West Lafayette, IN.

Population stratification, family structure and cryptic relatedness are known to produce spurious association if not properly corrected. Recent Study showed that mixed model is an effective way to handle these confounding factors. Most of the current mixed model based methods are typically carried out by testing one or few loci at a time, making these algorithms essentially limited in identifying genetic variants of weak effects. We propose an algorithm that extends penalized orthogonal component regression (POCRE) to family-based association studies (fPOCRE), with the merit of accounting for multiple loci at the same time. Our proposed algorithm is a hybrid of linear mixed model that is well known for handling confounding issue and penalized regression that performs well in large p small n setting. We compared fPOCRE with existing methods, and demonstrated that fPOCRE has promising performance over others in terms of both power and false discover rate. We have applied our method to a genome-wide association study in the Framingham Heart Study.

On predicting tissue specific functional effects of genetic variation with applications to complex diseases. *D. Backenroth[1], B. Xu[1], K. Krzysztof[1], E. Khurana[2], J. Buxbaum[3], I. Ionita-Laza[1].* 1) Columbia University, New York, USA; 2) Weill Medical College, Cornell University, New York, USA; 3) Mount Sinai School of Medicine, New York, USA.

Over the past few years, large scale genomics projects such as the ENCODE and Roadmap Epigenomics have produced genome-wide data on a large number of biochemical assays for a diverse set of human cell types and tissues. Such data can play a critical role in identifying putatively causal variants among the abundant natural variation that occurs at a locus of interest. We will present unsupervised approaches to integrate these diverse sets of annotations for specific tissues and cell types into a single predictor of functional importance. We have calculated such integrative functional scores for every possible position in the human genome for 127 tissues and cell types available in Roadmap Epigenomics. We demonstrate the usefulness of such scores in the context of complex disease genetics, using GTEx data on over 44 tissues, and summary statistics from over 20 GWAS. Specifically we show that tissue specific functional variants are enriched among eQTLs in related tissues in Roadmap. Furthermore, we show how these integrated functional scores can be used to identify the most likely tissue for a complex disease using summary statistics from GWAS, and can shed light on pathways implicated in a disease using existing enhancer-gene target maps.

449T

Modeling prediction error improves power of transcriptome-wide association studies. *K. Bhutani[1], A. Sarkar[2], Y. Park[2], M. Kellis[2], N. Schork[1].* 1) Bioinformatics & Systems Biology, UCSD, La Jolla, CA; 2) CSAIL, MIT, Cambridge, MA.

Thousands of loci associated with hundreds of complex diseases have been reported in the NHGRI catalog of genome-wide association studies (GWASs), but most genome-wide significant loci are devoid of protein-coding alterations and likely instead affect transcriptional regulation. Several studies have directly investigated the role of transcriptional regulation on complex diseases by jointly considering genotype, expression, and phenotype. However, such studies require all data to be measured in all samples, which is still prohibitive at the scale of GWAS. Recent large-scale efforts such as the Gene-Tissue Expression Project (GTEx) have produced reference profiles of transcription, enabling transcriptome-wide association studies (TWASs). TWAS tests for association between gene expression and phenotype by predicting gene expression in GWAS cohorts (where expression is not measured) using models of transcriptional regulation trained on reference transcriptomes. However, current methods for TWAS only use point estimates of imputed expression and ignore uncertainty in the prediction. Here, we develop a method to explicitly model error in imputed expression and propagate this error through TWAS. We demonstrate that imputed expression has high uncertainty, possibly due to genetic factors not included in typical models, environmental factors which vary between reference transcriptome cohorts, and technical biases in training the predictive models. We show through simulation and application to real data that our method improves power to detect genes associated with phenotype.

450F

Exploring the Latino asthma paradox: Significant interactions between genetic ancestry, psycho-social stressors, and environmental exposures on asthma susceptibility in Puerto Rican and Mexican children. *M.G. Contreras[1], M.J. White[2], D. Hu[2], S. Huntsman[2], C. Eng[2], N. Thakur[2], S. Thyne[2], A. Davis[3], K. Meade[3], H.J. Farber[4], P.C. Avila[5], R. Kumar[6], E. Brigino-Buenaventura[6], M.A. LeNoir[7], D. Serebrisky[8], W. Rodriguez-Cintron[9], J.R. Rodriguez-Santana[10], L.N. Borrell[11], E. Burchard[2].* 1) San Francisco State University 1600 Holloway Ave, San Francisco, CA 94132; 2) University of California, San Francisco Departments of Medicine and Bioengineering and Therapeutic Sciences. 1550 4th St. Rm 584D San Francisco, CA 94158; 3) Children's Hospital and Research Center Oakland, Oakland, CA; 4) Department of Pediatrics, Section of Pulmonology, Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 5) Children's Memorial Hospital; Feinberg School of Medicine, Northwestern University, Chicago, IL; 6) Department of Allergy and Immunology, Kaiser Permanente–Vallejo Medical Center, Vallejo, California; 7) Bay Area Pediatrics, Oakland. CA; 8) Pediatric Pulmonary Division, Jacobi Medical Center, Bronx, NY; 9) Veterans Caribbean Health Care System, San Juan, Puerto Rico; 10) Centro de Neumologia Pediatrica, San Juan, Puerto Rico; 11) Department of Health Sciences, Graduate Program in Public Health, Lehman College, City University of New York, Bronx, NY.

Asthma, an inflammatory condition of the airways, is the most common chronic disease among children. In the U.S. Puerto Ricans have the highest asthma prevalence and mortality rates compared to all other racial/ethnic groups; particularly as compared to Mexican Americans who have the lowest asthma prevalence, this phenomenon is known as the Latino Asthma Paradox. Asthma is a complex disease likely affected by genetic and environmental interactions. We used a non-parametric method, VISEN, to identify genetic x environmental interactions, including genetic ancestry, associated with asthma susceptibility in Puerto Rican and Mexican children with and without asthma. Our study population included 1520 participants (Mexican: 525 cases, controls 224; Puerto Rican 651 cases, controls 120) from the Genes, Environment, and Admixture in Latino Americans (GALA II) study. Our environmental variables included evidence of discrimination, sex, BMI, age, genetic ancestry, and prenatal smoking. We identified several interactions associated with asthma in Puerto Rican and Mexican American children. One of the strongest interactions in Mexicans included BMI * Discrimination * Age; interestingly, in Puerto Rican children we discovered a model that included BMI * Discrimination * Native American Ancestry. Our results indicate that interactions play a significant role in asthma susceptibility in these two Latino populations; and the nature of those interactions may be population specific. These results emphasize the need to recognize differences between populations that self-define as Latino.

Bayesian analysis of genetic association across tree-structured routine healthcare data in the UK Biobank. *A. Cortes[1,2], D. Vukcevic[3,4,5], A. Motyer[3,4], L. Jostins[1], C. Dendrou[2], L. Fugger[2], S. Leslie[3,4,5], G. McVean[1].* 1) Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) Nuffield Department of Clinical Neurosciences Weatherall Institute of Molecular Medicine John Radcliffe Hospital University of Oxford, Oxford, UK, OX3 9DU; 3) School of Mathematics and Statistics, University of Melbourne, Parkville, Vic 3010, Australia; 4) School of BioSciences, University of Melbourne, Parkville, Vic 3010, Australia; 5) Data Science, Murdoch Childrens Research Institute, Parkville, Vic 3052, Australia.

The past decade has seen an accelerated rate of discovery of the genetic determinants of complex traits. These discoveries have shed light on the molecular pathways involved in the aetiology of common diseases and have led to new therapeutics. Moreover, there is a growing interest in using genetic associations for assessing the efficacy and safety of therapeutic candidates, and this could be enabled with a better understanding of the spectrum of clinically phenotypes associated to genetic variants. So far, this has been limited by insufficient phenotyping in GWAS cohorts and improper methodological approaches. Cross-sectional cohorts, such as the UK Biobank, provide a resource that aims to overcome this limitation. The UK Biobank has recruited half a million individuals, derived genome-wide genotype data, and collected phenotypic data through questionnaires and linking of national health registries. Such resources require novel analytical strategies to jointly analyse genetic variation in individuals with a wide range of phenotypes collected. These methods must be robust to complexities in the data, with expected correlated effect sizes, abundant missing data and varied sample sizes across different phenotypes. Here we propose a Bayesian analysis framework that uses the hierarchical structure of diagnosis classifications to jointly analyse genetic variants against phenotypes in the UK Biobank Hospitalisation Episode Statistics and the self-reported diagnosis datasets. We validate our method using simulations and the analysis of allelic variation in the MHC. Simulations demonstrated an increase in statistical power when jointly analysing all phenotypes compared to individually analysing each clinical phenotype. The gain in power was quantified as the area under the ROC curve at different allele frequencies. For example, for a genetic variant with population allele frequencies of 1% an improvement from 0.757 to 0.902 was observed. Analysis of MHC allelic variation showed we could identify known associations to common immune-mediated diseases with routine health-care data. Increased evidence in the tree analysis was also notable, with support for HLA-B*27 association to ankylosing spondylitis at log10(BF)=29.96, whilst the evidence with the single phenotype analysis was log10(BF)=20.34. Furthermore, we observe allele associations with secondary outcomes common in disease prognosis, such as HLA-B*27 predisposing to glaucoma, a common complication in AS.

452T

Meta-imputation: A flexible approach to combine genotype data imputed against multiple reference panels. *S. Das, G. Abecasis.* Department of Biostatistics, University of Michigan, Ann Arbor.

Genotype imputation has proven to be an invaluable tool for human genetic studies - increasing power of gene mapping analyses, facilitating combination of results across studies (meta-analyses), and accelerating fine-mapping efforts. Imputation involves an in-silico method in which a reference panel is used to infer genetic variants that were not genotyped in the study sample. In the last few years, reference panels have proliferated - starting with the Hap-Map Consortium and the 1000 Genomes Project, and now including multiple disease specific sequencing efforts. Combining these reference panels for imputation leads to increased imputation accuracy, especially for rare variants. However, constructing a combined (joint) reference panel from these datasets can be quite difficult, and may often be impossible due to data-sharing restrictions. This is especially true when some panels, such as the Haplotype Reference Consortium, are not publicly available but can only be accessed through web imputation services. In this study, we explore the idea of meta-imputation, an approach that combines results from imputation against different reference panels to obtain a consensus imputed genotype. We construct this imputed genotype as a weighted average of individual imputed dosages. The weighing scheme is based on new individual-specific imputation diagnostic metrics, estimated by minimac3, reflecting the combined effects of chip density, probability of template switches, historical recombination events around the site being meta-imputed, and the genetic distance between study samples and the reference panel. We show that meta-imputation performs well compared to more cumbersome joint imputation in terms of imputation accuracy (measured by Pearson R^2). The prime benefit of our our tool (MetaMinimac) is to allow users to combine their imputed data from multiple reference panels in-silico without requiring direct access to individual haplotypes from all potential reference panels. An added bonus is that this method allows imputation analyses to be run in parallel and thus reduces net compute time. In summary, we describe a method that makes it easier for genetic studies to take advantage of the many currently available reference panels and improve imputation accuracy in genetic studies while abiding by data sharing restrictions.

Statistical tests for Hardy-Weinberg equilibrium at X-chromosomal genetic markers. *J. Graffelman[1], B.S. Weir[2].* 1) Department of Statistics and Operations Research, Polytechnic University of Catalonia, Avinguda Diagonal 647, 08028 Barcelona Barcelona, Spain; 2) Department of Biostatistics, University of Washington, Box 359461, Seattle, WA 98195-9461, USA.

In large-scale genotyping studies genetic markers are usually tested for Hardy-Weinberg equilibrium (HWE). Disequilibrium is often related to genotyping error, and tests for HWE form a useful device for detecting genotyping error. It has become computationally feasible to test millions of autosomal genetic markers for HWE using an exact test. For markers on the X chromosome, the same autosomal exact test is typically applied, but using only the females in the database. Hitherto, the hemizygous males were considered to be uninformative with regard to HWE. It is well known that an autosomal marker will achieve HWE in one generation of random mating. However, for a marker on the X chromosome the situation is different. If there is a difference in initial allele frequency between males and females, then it can take several generations before equilibrium is reached. Equilibrium refers to the stability of allele and genotype frequencies over the generations, and this condition will only be attained if male and female allele frequencies are equal. In a recent paper in Heredity, we have therefore argued that males are informative, because a difference in allele frequency between males and females may indicate that equilibrium does not hold. For the X-chromosome, it seems more sensible to jointly test Hardy-Weinberg proportions in females and equality of allele frequencies in males and females in a single omnibus test. We have developed such omnibus tests, specifically tailored to biallelic markers on the X-chromosome, using a classical frequentist approach. We have designed X-chromosomal versions of the chi-square test, the exact test, the likelihood ratio test and the permutation test, and updated our R software (the HardyWeinberg package) implementing these tests. Statistical inference with a test including males can differ considerably from a test that uses females only. In this contribution we address ongoing extensions of our work on HWE for X-chromosomal markers with multiple alleles and present our latest methodological advances. We apply our newly developed methodology to complete X-chromosomes with data from different populations of the 1000 genomes project. We create tracks for HWE test results, and suggest these to be included in genome browsers. We show examples of such tracks where we uncover areas of Hardy-Weinberg disequilibrium on the X-chromosome.

Improved imputation accuracy of rare and low-frequency variants using population-specific imputation reference panel. *R. Magi[1], M. Kals[1,2], K. Parn[1], M. Mitt[1,3], T. Esko[1,4], P. Palta[1,5].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Mathematics and Statistics, University of Tartu, Tartu, Estonia; 3) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 4) Broad Institute, Cambridge, MA, US; 5) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland.

Genetic imputation has shown to be a cost efficient way to improve the power and resolution of GWAS studies. Current large reference panels work well for common variants, but the imputation quality of rare and low-frequency (RLF) variants is rather limited. For better imputation of RLF variants, two approaches could be employed: (i) increase the size of the reference panel; or (ii) use a population-specific reference panel. In the current study we evaluate and compare imputation quality and accuracy among several different panels into individuals from the Estonian population: (a) 1000 Genomes (HRC); (b) Haplotype Reference Consortium (HRC); (c) Estonian-specific whole-genome sequence; and (d) merged panels. As a population-based reference, we used the Estonian Genome Center, University of Tartu (EGCUT) high-coverage (30x) whole-genome sequenced dataset – 2,244 geographically diverse samples from Estonia, selected randomly by county of birth. All reference panels were tested with imputation into 6,400 Estonian samples genotyped on Illumina HumanCoreExome chip. These samples were pre-phased (SHA-PEIT2 software) and imputed (IMPUTE2 software) into each reference panel and two combinations of the EGCUT and 1000G panels (EGCUT+1000G and 1000G+EGCUT). As 500 of these individuals also had whole-exome sequencing (WES) data available, these overlapping samples were used to determine the imputation accuracy. The EGCUT reference panel has less variants than the multi-ethnic 1000G and HRC reference panels, but more than 75% of those are confidently imputed (IMPUTE2 INFO>0.8). The average imputation quality is fairly similar across all reference panels for common variants (MAF>5%), with INFO ranging between 0.93-0.96 and is the most discrepant for the rare variants (MAF<0.5%), where the average imputation quality differs the most between EGCUT (average INFO 0.75) and 1000G panels (average INFO 0.40). When comparing imputed data with available WES data from the same individuals, we were able to test the imputation quality of all references. We observed that the imputed genotypes matched the real genotypes from WES data better in the whole frequency spectrum when using the Estonian population-specific panel alone or merged with 1000G reference. In conclusion, we have shown that population specific imputation reference panels do improve the imputation quality across entire allele frequency spectrum with the greatest improvement in rare variants.

455T

Canonical correlation analysis separates genetic and non-genetic confounders. *R. Schweiger[1], E. Rahmani[1], L. Shenhav[1], E. Halperin[1,2,3].* 1) Computer Science, Tel Aviv University, Tel Aviv, Israel; 2) Molecular Microbiology and Biotechnology Department, Tel Aviv University, Tel Aviv, Israel; 3) International Computer Science Institute, 1947 Center Street, Berkeley, CA 94704, USA.

Estimation of statistical confounders is a necessity in genetic and epigenetic studies in order to control for false discoveries in association testing. However, different confouders, both genetic and non-genetic, may combine in the same dataset and could be difficult to estimate separately. For example, Genome-wide association studies (GWAS) routinely apply principal component analysis (PCA) to infer population structure within a sample to correct for confounding due to ancestry. However, the top PCs do not always reflect population structure: they may reflect family relatedness, long-range LD (for example, due to inversion polymorphisms), or completely non-genetic confounders, such as assay artifacts. Another example is epigenome-wide association studies (EWAS), where different methylation profiles of distinct cell types may lead to false discoveries. Dimensionality reduction techniques, such as PCA and variants thereof, are often used for the correction of cell type heterogeneity, since the first several principal components are correlated with cell type composition. However, EWASs reported thousands of CpG methylation sites to be associated with genetics and ancestry, and applying PCA on a group of genome-wide CpGs correlated with genetics can be used in order to efficiently capture population structure. We show that applying cross decomposition techniques, such as canonical correlation analysis (CCA), on datasets of different measurements of the same individuals separates genetic and non-genetic confounders. These techniques allow for more accurate estimation of various types of confounders, which can then be used as covariates in statistical analyses or studied separately.

456F

A two-stage hidden Markov model design for biomarker detection, with application to microbiome research. *Y. Zhou[1], X. Wang[2].* 1) North Carolina State University, Raleigh, NC; 2) IMEDACS, LLC.

High-throughput genomic and transcriptomic sequencing technologies promise to yield great advances in biomedicine, but the enormous amount of data produced raises statistical challenges. Typical data in a microbiome study consist of the operational taxonomic unit (OTU) counts that have the characteristic of excess zeros. There are few methods which can control false discovery rate as well as increase the power to detect significant associations. For many high-throughput technologies, the cost still limits their application. Two-stage designs are attractive, in which a set of interesting features or biomarkers is identified in a first stage, and then followed up in a second stage. However, the statistical principles of two-stage FDR control with hidden Markov model (HMM)s have not been established. In this paper, we study an efficient HMM-FDR based two-stage design, using a simple integrated analysis procedure across the stages. Numeric studies show its excellent performance when compared to available methods. A power analysis method is also proposed. We use examples from microbiome data to illustrate the methods.

Large scale brain eQTL meta-analysis from multiple RNA-sequencing cohorts. *S.K. Sieberts[1], M. Allen[2], K. Dang[1], J. Calley[3], P.J. Ebert[3], T. Perumal[1], L.M. Mangravite[1], the AMP-AD Consortium eQTL Working Group and the CommonMind Consortium (CMC).* 1) Sage Bionetworks, Seattle, WA; 2) Department of Neuroscience, Mayo Clinic Florida, Jacksonville, FL; 3) Lilly Research Labs, Eli Lilly and Company, Indianapolis, IN.

To date, hundreds of risk loci have been associated with neurodevelopmental, neuropsychiatric and neurodegenerative diseases. When risks are mediated through gene expression, eQTL can implicate the specific genes involved through colocalizing algorithms or global tests of case-control differences in the predicted gene expression. In each case, eQTL from the relevant tissue are necessary to understand the specific expression patterns contributing to disease, which may not be captured in readily available tissue such as blood. Recently, several large initiatives, including the CommonMind Consortium (CMC), the Accelerating Medicines Partnership for Alzheimer's Disease (AMP-AD) and GTEx, have made high-quality data available from the RNA-sequencing and genotyping of post-mortem brain collections representing neurodegenerative and neuropsychiatric cases, and undiseased individuals. Here we generate the best-powered brain eQTL resource to date which spans multiple brain regions and diseases. In total, we have collected 6 cohorts, comprised of tissue from approximately 2400 individuals and representing 4 brain regions, the largest collection of which is from dorsolateral prefrontal cortex comprised of 1800 samples. A common analysis pipeline was applied to each cohort. Samples were imputed to the Haplotype Reference Consortium panel. For each of the AMP-AD cohorts, RNA-seq data was realigned and quantitated using parameters appropriate to specifics in library prep strandedness and paired-end sequencing. Following quality control, quantified expression from each of the 6 cohorts was then normalized via *voom*, adjusting for available known clinical and technical covariates, and hidden confounders, prior to applying a linear model to detect eQTL, adjusting for inferred genetic structure and diagnosis. Meta-analysis across cohorts was then performed. Preliminary analysis of the Caucasian samples from the CMC MSSM-Penn-Pitt cohort (n=467) imputed to 1000 Genomes v1 identified >2.1 million proximal (distance ≤ 1 Mb) eQTL with MAF ≥ 0.05 and FDR ≤ 5%, which is an order of magnitude more than reported in previous expression or exon array cohorts, or in the publically available GTEx PFC (v6) eQTL. Despite this, the replication of GTEx eQTL in CMC is extremely high ($\pi_1 = 0.98$) confirming these experiments are capturing the same information, despite substantially different processing and analysis pipelines, and are appropriate for meta-analysis.

458T

Interactive effect between ATPase-related genes and early-life tobacco smoke exposure on bronchial hyper-responsiveness detected in asthma-ascertained families. *M-H. Dizier[1,2], P. Margaritte-Jeannin[1,2], L. Pain[3], C. Sarnowski[1,2], M. Brossard[1,2], H. Mohamdi[1,2], N. Lavielle[1,2], J. Just[4], M. Lathrop[5], E. Bouzigon[1,2#], C. Laprise[3#], F. Demenais[1,2*], R. Nadif[6,7*], #* contributed equally.* 1) Inserm U946, Paris, France; 2) Univ Paris Diderot, Paris, France; 3) Université du Québec à Chicoutimi, Québec, Canada; 4) Centre de l'Asthme et des Allergies – Inserm, UMR-S 1136, Equipe EPAR, Paris, France; 5) Mc Gill University, Montréal, Canada; 6) Inserm, UMR-S 1168, Villejuif, France; 7) Univ Versailles Saint-Quentin en Yvelines, France.

In a previous positional cloning study of the 17p11 region, we identified genetic variants interacting with exposure to tobacco smoke (ETS) in early life for bronchial hyper-responsiveness (BHR) in the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) (Dizier *et al.*, 2007). These variants were located in Dynein, Axonemal, Heavy Chain 9 gene, *DNAH9* (Dizier *et al.*, 2016), a promising candidate gene, which has a key role in motile cilia function and is associated to primary ciliary dyskinesia, a disease associated with bronchiectasis and abnormalities of pulmonary function. The aim of the present study was to identify other genetic variants interacting with ETS for BHR by investigating genes involved in the "ATPase binding" and the "ATPase activity" pathways. These two pathways were selected because they both include *DNAH9*, are known to be target of cigarette smoke and are involved in the movement of respiratory cilia. Analyses were first conducted in a discovery sample of 388 asthmatic EGEA families, using family-based association test (FBAT). For all SNPs located within 277 genes belonging to the two pathways, we applied FBAT homogeneity test between exposed *vs.* unexposed siblings to detect SNP x ETS interactive effects on BHR. Replication was performed in Saguenay-Lac-Saint-Jean (SLSJ) asthma collection (Laprise 2014), another asthma-ascertained sample of 253 French-Canadian families. In EGEA families, 25 SNPs showed interaction signals ($P \leq 5 \times 10^{-3}$) with ETS among BHR siblings. One SNP on 4p13 region reached the threshold ($P = 2 \times 10^{-5}$) for a significant interaction with ETS when correcting for multiple testing. This result did not quite reach the nominal level for replication in SLSJ families ($P = 0.13$) but there was improvement of evidence for interaction in the meta-analysis of the two samples ($P = 10^{-5}$). Another SNP on 9q31 showed a stronger signal of interaction in the SLSJ study ($P = 0.003$), and a suggestive interaction by meta-analysis ($P = 6 \times 10^{-5}$). Further replication studies are now necessary to confirm these results. This study highlights that incorporating biological knowledge in the selection of genes may identify novel genes potentially interacting with ETS in BHR siblings.

459F

A novel statistical method for genetic pleiotropic analysis of multiple phenotypes. *N. Lin[1], Y. Zhu[2], R. Fan[3], J. Zhao[2], M. Xiong[1]*. 1) University of Texas School of Public Health, Houston, TX; 2) Tulane University, New Orleans, LA; 3) NIH, Washington DC.

   Next-generation sequencing technologies and modern biosensing produce dozens of millions of SNPs and large number of phenotypes. A key issue for learning the intricate structures of genotype-phenotype is how to effectively extract a few informative internal representation and features from extremely high dimensional genotype and phenotype data. Deep learning uses statistical tools to extract information and reduce the size of "Big Data". Both genome and phenotype signals are compositional hierarchies, in which low level features are combined into higher-level features. Deep hierarchical representations of the genome and phenotype data transform the internal representation at one level into a representation at a higher and more abstract level, extract better informative features and capture invariant features that are only sensitive to the phenotype variability. Motivated by deep learning, we develop a novel quadratically regularized functional canonical analysis (QFCCA) for genetic pleiotropic analysis and apply it to UK-10K dataset with 46 traits and 2,240,049 SNPs in 33,746 genes typed in 765 individuals. The number of genes that were significantly associated with 46 traits after Bonferroni corrections(P-value less than 1.5E-6) identified using QFCCA, FCCA, GAMuT, functional MANOVA and USAT were 80, 50, 0, 50, 0, respectively. The 46 phenotypic variables can be classified as 13 sub- groups according to their biological functions. Then by applying the QFCCA statistics to these sub-group phenotype separately, we can identify 8 genes that are significantly associated with 3 sub-group phenotypes and 43 genes were significantly associated with 2 sub-group phenotypes. A total number of identified genes that were significantly associated with at least one of 46 traits using QFCCA, FCCA, functional MANOVA, USAT and GAMuT were 299, 262, 262, 0 and 43, respectively. The results show that the QFCCA substantially outperforms all existing statistics for genetic pleiotropic analysis.

A comparison of methods for genome-wide association mapping in the PAGE study. *R. Tao[1], J. Haessler[2], D.Y. Lin[1], T. Thornton[3], S. Buyske[4,8], Y. Patel[5], C.R. Gignoux[6], E. Stahl[7], T. Matise[8], G.L. Wojcik[6], K.E. North[9], S. Bien[2], C.D. Bustamante[10], L. Hindorf[11], R.J.F. Loos[7], E.E. Kenny[7], C. Carlson[2], C. Kooperberg[2], D.O. Stram[5]*. 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Department of Biostatistics, University of Washington, Seattle, WA; 4) Department of Statistics, Rutgers University, Piscataway, NJ; 5) Keck School of Medicine, University of Southern California, Los Angeles, CA; 6) Department of Genetics, Stanford University, Palo Alto, CA; 7) Department of Genetics and Genome Sciences, Ichan School of Medicine at Mount Sinai, New York, NY; 8) Department of Genetics, Rutgers University, Piscataway, NJ; 9) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 10) Stanford Center for Computational, Human, and Evolutionary Genomics, Palo Alto, CA; 11) Division of Genomic Medicine, NHGRI, NIH, Bethesda, MD.

   Purpose: Recently 53,424 participants in the diverse PAGE study were genotyped for 1.7 million SNPs on the Illumina MEGA array. Genome-wide association studies of the PAGE data require statistical methods to control for hidden population stratification, admixture, and also for a high degree of both known and unknown relatedness. Failure to adjust for population structure and relatedness will lead to high false positive rates in genetic association testing. Two adjustment methods one based on linear mixed models (LMM) and another on generalized estimating equations (GEE) were compared in order to provide guidance to investigators concerning the relative performance of these methods in analysis of the large number of phenotypes available for the consortium. **Methods:** The LMM used is the Genesis program implemented in Bioconductor package for R, while the GEE method considered is the SUGEN program of Lin et al. Markers of frequency of 0.001 or greater in the PAGE genotype data were used in the association tests. All association analyses included principal components and (when appropriate) age and sex, as adjustment variables. **Results:** After examining nearly twenty different phenotypes with up to 49,000 individuals in a given analysis we found relatively few instances where the output from SUGEN and Genesis differed markedly between one another. Overall the genomic control parameters were slightly smaller when using the Genesis program than the SUGEN program, indicating somewhat better control for relatedness using the former. However p-values, effect sizes, and test statistics were generally very highly correlated between the two methods with little reordering of the top associations. The greatest differences in pooled versus stratified analyses were seen for phenotypes showing heterogeneous variances by strata (i.e. by racial/ethnic group). In general the Genesis program was much slower than the SUGEN program for the pooled analyses, for stratified analyses, where there were smaller numbers of subjects per analysis, the run times were much more similar. **Conclusions:** Compared to most GWAS datasets the PAGE samples genotyped on the MEGA-array exhibit an unusual degree of structure especially relatedness. The LMM-based Genesis program theoretically allows for a much more complex relatedness structure than does the GEE-based SUGEN program. However, in these data the results of the two approaches are quite compatible.

461T

Integration of summary data from GWAS and eQTL studies predicts complex trait gene targets. *Z. Zhu[1], F. Zhang[1], H. Hu[2], A. Bakshi[1], M. Robinson[1], J. Powell[1,3], G. Montgomery[4], M. Goddard[5,6], N. Wray[1], P. Visscher[1,7], J. Yang[1,7].* 1) Queensland Brian Institute, University of Queensland, Brisbane, QLD, Australia; 2) State Key Laboratory of Plant Physiology and Biochemistry, College of Life Sciences, Zhejiang University, Hangzhou, China; 3) Institute for Molecular Bioscience, University of Queensland, Brisbane, Queensland, Australia; 4) Molecular Epidemiology, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 5) Faculty of Veterinary and Agricultural Science, University of Melbourne, Parkville, Victoria, Australia; 6) Biosciences Research Division, Department of Economic Development, Jobs, Transport and Resources, Bundoora, Victoria, Australia; 7) University of Queensland Diamantina Institute, Translation Research Institute, Brisbane, Queensland, Australia.

Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with human complex traits. However, the genes or functional DNA elements through which these variants exert their effects on the traits are often unknown. We propose a method (called SMR) that integrates summary-level data from GWAS with data from expression quantitative trait locus (eQTL) studies to identify genes whose expression levels are associated with a complex trait because of pleiotropy. We apply the method to five human complex traits using GWAS data on up to 339,224 individuals and eQTL data on 5,311 individuals, and we prioritize 126 genes (for example, *TRAF1* and *ANKRD55* for rheumatoid arthritis and *SNX19* and *NMRAL1* for schizophrenia), of which 25 genes are new candidates; 77 genes are not the nearest annotated gene to the top associated GWAS SNP. These genes provide important leads to design future functional studies to understand the mechanism whereby DNA variation leads to complex trait variation.

462F

Improving power for rare variant tests by integrating external controls. *S. Lee[1,2], S. Kim[1], C. Fuchsberger[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Due to the drop in sequencing cost, the number of sequenced genomes is increasing rapidly. To improve power of rare variant tests, these sequenced samples could be used as external control samples in addition to control samples from the study itself. However, when using external controls, possible batch effects due to the use of different sequencing platforms or genotype calling pipelines can dramatically increase type I error rates. To address this, we propose novel summary statistics-based single and gene- or region-based rare-variant tests that allow the integration of external controls while controlling for type I error rates. Our approach is based on the insight that batch effects on a given variant can be assessed by comparing allele frequencies between internal and external control samples. Specifically, to mitigate possible batch effects for the single variant test, we propose a shrinkage estimator of a log odds ratio; we then extend the shrinkage estimator to gene- or region-based tests by aggregating single variant log odds ratios. Through extensive simulation experiments, we show that the proposed method can control type I error rates at the exome-wide significant level (alpha=2.5x10^{-6}), and have substantially increased power over an approach using the internal controls only. By using European ESP samples as external controls in the analysis of age-related macular degeneration (AMD) targeted sequencing data, the proposed method can replicate rare-variant associations between AMD and *CFH* (*p*-values=8.27×10^{-6}) and *C3* (*p*-values=1.57×10^{-5}) genes. These genes are not significant when the internal control samples are exclusively used (*p*-values > 0.01). The proposed method is implemented in iECAT R-package.

463W

Adjustment for confounders in random forests analysis. *Y. Zhao, D.F. You, F. Chen, H. Yu.* Department of Biostatistics, Nanjing Medical University, Nanjing, China.

   AIM: Random forest (RF) has been increasingly applied in the analysis of high dimensional genetic data. However, if the confounding effects has not been appropriately removed, RF may produce biased results.**METHODS:** We propose to adjust the confounding effects by a residual-based procedure. Suppose that there are 1 response (Y), p confounders and k predictors. We firstly fit a RF model by using Y as the response and the p confounders as the predictors. We then generated the adjusted response as the difference between Y and the prediction of the RF model. Similar procedures were performed to generate the adjusted predictors. The adjusted response and predictors are then used as the outcome and covariates in the RF analysis.**RESULTS:** Extensive simulations were performed to evaluate the proposed procedure. The proposed procedure has advanced performance when there are one or two confounders. The proposed adjustment can also be used when there are interactions between confounders. We also applied the proposed method in a real GWAS dataset.**CONCLUSIONS:** The proposed adjustment procedure can be used in the RF analysis on high dimensional data when there are potential confounders.

464T

Are population-specific panels of exomes useful to identify disease variants: Insights from the French Exome Project. *E. Genin[1], C. Dina[2], T. Ludwig[1], O. Quenez[3], S. Letort[1], P. Lindenbaum[2], J. Giemza[2], B. Grenier-Boley[4], C. Charbonnier[3], C. Bellenguez[4], D. Bacq[5], D. Lechner[5], A. Boland[5], V. Meyer[5], S. Chatel[2], K. Rouault[1], G. Nicolas[3], C. Férec[1], H. Le Marec[2], L. Letenneur[6], J-F. Dartigues[6], J-C. Lambert[4], D. Campion[3], R. Redon[2], J-F. Deleuze[5].* 1) U1078 Genetics, functional Genomics, Biotechnology, INSERM, CHRU, UBO Brest, France; 2) Inserm UMR-1087 / CNRS UMR 6291, l'institut du thorax, Univ. Nantes, Nantes, France; 3) Inserm UMR-1079, Faculté de Médecine, Univ.    Novel high throughput sequencing technologies enable the characterization of all the genetic variations in the coding sequence (exome) of individuals and the discovery of novel variants involved in monogenic and complex diseases. The study of these two kinds of diseases require different methods and raises specific problems however, in both situations, the major challenge is to understand the functional role of the identified variants to filter out the neutral ones. For this purpose, investigators often rely on the observed frequencies of variants in public databases. In this work, we show that these public databases are not well representatives of the different ancestries in Europe and this is true in particular for France. Indeed, comparing the exomes of 573 individuals sampled in 6 different regions of France to the frequency data available in ExAC, we identified several variants with significant allele frequency differences. We also found that compared to the different public panels, the "French exomes" allow a more efficient filtering of variants leading to a substantial reduction in the number of candidate variants retained for validation. These allele frequency differences are also detected within France between the different geographic regions, pointing out, for example, to some loss-of-function variants that could have been under positive selection. Moreover, at this fine geographical scale, we were able to detect differences in the rare variant burden in several genes that could have consequences for the setting-up of rare variant association studies. Population-specific exome panels such as the one we have developed through the French Exome (FREX) Project are clearly useful to avoid false positives findings due to population structure and to allow a better understanding of genetic diversity at fine geographic scales.

465F

Functional regression method for whole genome epistatic eQTL analysis with sequencing data. *K. Xu[1], L. Jin[1], M. Xiong[2,1].* 1) School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, Shanghai, China; 2) Department of biostatistics, University of Texas School of Public Health, Houston, TX.

Epistasis plays an essential rule in understanding the regulation mechanisms and is an essential component of the genetic architecture of the gene expressions. However, interaction analysis of gene expressions remains fundamentally unexplored due to great computational challenges and data availability. Sparse multivariate regression models (MLMs) are widely used methods for expression epistasis analysis. The current MLMs were designed for microarray gene expression measurements and common variants. They consider a SNP at a time and take one number as a summarized gene expression level. Due to variation in splicing, transcription start sites, polyadenylation sites, post-transcriptional RNA editing across the entire gene, and transcription rates of the cells, RNA-seq measurements generate large expression variability and collectively create the observed position level read count curves. A single number for measuring gene expression which is widely used for microarray measured gene expression analysis is highly unlikely to sufficiently account for large expression variation across the gene. Simultaneously analyzing epistatic architecture using the whole genome RNA-seq and next-generation sequencing (NGS) data poses enormous challenges for methodologies and computations. To meet these challenges, we proposed a functional regression model (FRM) for epistasis analysis of gene expression, which takes a gene as a basic unit and view the RNA-Seq of each gene as a continuous curve. By large-scale simulations, we demonstrate that the proposed method can achieve the correct type 1 error and has higher power to detect the interactions between genes than the existing methods. The proposed methods are applied to the RNA-Seq and next-generation sequencing data from the 1000 Genome Project. The numbers of pairs of significantly interacting genes after Bonferroni correction identified using FRM, RPKM and DESeq were 16,2361, 260 and 51, respectively, from the 350 European samples. The QQ plots for FRM had excellent behavior. In summary, the FRM is a good choice for the whole genome epistatic eQTL analysis. .

466W

X-inclusion: Integrating X chromosome in whole genome association studies of variance heterogeneity. *W.Q. Deng[1], S. Lei[1,2].* 1) Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada.

Genetic variants associated with heterogeneity of quantitative trait variance are considered promising candidates to follow up. Not surprisingly, this approach to discover potentially interacting SNPs has so far been restricted to autosomes as X-chromosomes are often excluded from genome-wide analyses. In this short report, we qualitatively examined three grouping strategies to test variance heterogeneity of X-chromosome SNPs using Levene's test. We showed theoretically, in the context of variance heterogeneity testing, the three-genotype grouping assuming either the presence or absence of X-inactivation could potentially cause spurious variance signals as a result of confounders. For example, an inherent confounder for X-chromosomal SNPs is sex. Since sex necessarily correlates with the the number of minor alleles of X-chromosomal SNPs, and the distribution of certain quantitative traits due to physiological differences between female and male. Simulation studies and empirical analyses using data from Multi-Ethnic Study of Atherosclerosis are provided to show that 1) the extent the confounding depends on the sex-stratified distributions of the quantitative trait, 2) the five-group genotype/allele combined scheme is the most robust strategy for X-chromosome analysis of phenotypic variability, 3) the pattern of variance heterogeneity signals from X-chromosome SNPs also supports the complex genetic architecture of polygenic traits.

Effect of bias and misclassification on gene-environment studies conducted in observational cohort settings: A simulation study. *A.A. Seyerle[1], C.M. Sitlani[2], K.E. North[1], C.R. Lee[3], E.A. Whitsel[1,4], T. Stürmer[1,5], C.L. Avery[1].* 1) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 2) Department of Medicine, University of Washington, Seattle, WA; 3) Division of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, NC; 4) Department of Medicine, University of North Carolina, Chapel Hill, NC; 5) Center for Pharmacotherapy, University of North Carolina, Chapel Hill, NC.

Gene-environment studies represent an increasingly popular avenue to characterize complex traits. Yet few investigations have evaluated the degree to which gene-environment interaction estimates are influenced by sources of bias that affect estimates of the association between the environmental exposure and the outcome. Using pharmacogenomics as our gene-environment model, we therefore simulated three designs (cross-sectional, repeat cross-sectional, incident exposure), two referent groups (whole cohort, alternate exposure), and two scenarios (extreme or modest environmental effects) of N=120,000 participants using 1 million iterations to enable comparisons of 12 studies of the electrocardiographically measured QT interval (QT). For each study, we simulated a causal SNP with minor allele frequency of 25% and an index exposure frequency of 17%, using an $\alpha=5\times10^{-8}$. When selection bias was introduced to the extreme environmental effect scenarios, modest bias in the environment-SNP interaction was observed for all designs and referent groups with the exception of the two incident exposure designs (relative bias range: 2-18%); statistical power also was modestly decreased for these studies (e.g. relative power decrease of 1-37% to detect a simulated 2 ms environment-SNP interaction). However, minimal bias in the environment-SNP interaction effect was observed when selection bias was introduced to the modest effect scenario. When plausible degrees of exposure misclassification (sensitivity=97%, specificity=79%) were introduced, substantial bias towards the null in the environment-SNP interactions was observed across all 12 study settings (relative bias range: 25-51%); statistical power also was substantially decreased (e.g. relative power decrease of 50-99% to detect a simulated 2 ms environment-SNP interaction). In the presence of exposure misclassification, the detection of a simulated 2 ms effect required a repeat cross-sectional design with at least 150,000 participants. Exposure misclassification poses a sizable threat to gene-environment studies, greatly reducing estimated effect sizes, statistical power, and therefore perceived clinical and public health impact. Efforts to reduce the effects of exposure misclassification in gene-environment studies are therefore warranted.

468F

Heritability and ancestry influence the genomic architecture of height in South African KhoeSan populations. *C. Gignoux[1], M. Lin[2], J.M. Granka[1], A.R. Martin[1], J. Myrick[2], E. Atkinson[2], C.J. Werely[3], D. Gurdasani[4], C. Pomilla[4], T. Carstensen[4], B. Scelza[5], M. Moller[3], M. Sandhu[4], C.D. Bustamante[1], E.G. Hoal[3], M.W. Feldman[1], B.M. Henn[2].* 1) Stanford University, Stanford, CA; 2) Stony Brook University, Stony Brook, CA; 3) SA MRC Centre for Tuberculosis Research, DST/NRF Centre of Excellence for Biomedical Tuberculosis Research, Division of Molecular Biology and Human Genetics, Faculty of Medicine and Health Sciences, Stellenbosch University, Cape Town, South Africa; 4) Wellcome Trust Sanger Institute, Cambridge, UK; 5) Department of Anthropology, University of California, Los Angeles, CA.

Height is a standard quantitative trait for genetic associations and has been extensively studied in European populations, however like most complex traits the architecture is less well known in other populations. However even with study sizes in the hundreds of thousands, GWAS hits explain only a limited amount of phenotypic variance relative to the high heritability of the trait. Very little is known about the genetics of height elsewhere, particularly in indigenous populations. To understand shared and unique components of height in a different population we collected DNA from over 400 individuals in extended families from two KhoeSan communities from the Northern Cape in South Africa, the ≠Khomani San and Nama. These groups continue to practice elements of traditional hunter-gatherer or pastoralist subsistence and therefore have the potential for different environmental influences. Pedigree-based heritability estimates of height in the KhoeSan is quite high (h2=0.95), although average height is lower than in other neighboring populations. Estimating heritability via relatedness matrices from SNP array and exome data are similar, likely due to inclusion of close relatives. After imputation we used linear mixed models to control both for population stratification and relatedness in our GWAS. We identified several signals associated with height variation in *VWA8* and *KSR2*, previously associated with BMI and energy regulation. We confirmed the associations at these regions through targeted resequencing in the same cohorts, boosting common variant signals at associated loci (p~5.19[-8] in *VWA8*, p~5.33[-9] in *KSR2*). We were able to replicate our top hits in the GIANT Consortium, primarily using a gene-based test (p=0.01), suggesting a shared influence on height in both KhoeSan and European populations. Interestingly, while both populations identify as KhoeSan, they historically have had different cultural practices and patterns of admixture with neighboring groups, resulting in a significantly different local ancestry patterns. This affects cross-population replicability and places additional importance on understanding fine-scale population structure in these communities. Taken together, these results show that genetically diverse cohorts can be effectively leveraged for characterization of genetic architecture and large effect variants, and contribute to the trans-ethnic basis of height.

Highly differentiated *HLA-DPA1* **variant rs3077 may account for global disparity of hepatitis B virus infection.** *P. An, C.A. Winkler.* Basic Research Laboratory, Center for Cancer Research, National Cancer Institute, Leidos Biomedical Research, Inc., Frederick National Laboratory for Cancer Research, Frederick, MD.

Hepatitis B Virus (HBV) infection is a pandemic global disease. However, HBV prevalence varies greatly in the world populations, with high prevalence in East Asia and Africa and low prevalence in Europe. Recent GWAS and candidate studies have reported that SNP rs3077 in the *HLA-DPA* gene is consistently associated with HBV infection and HBV clearance. The risk C allele of rs3077, located in the 3'UTR, was associated with lower *HLA-DPA1* mRNA expression in normal human liver. To evaluate whether *HLA-DPA1* rs3077 contributes to the global disparity of HBV prevalence, we compared the global distribution of *HLA-DPA1* allele frequencies from HGDP and HapMap data and HBV prevalence in the world populations. We calculated Fixation index (Fst) values reflecting population differentiation of rs3077 among populations. Based on our previous finding (J Infect Dis. 2011;203:943-7), the risk ancestral C allele of rs3077 was associated with higher acquisition risk of HBV infection (Odds ratio [OR] 1.61) and failure to clear HBV infection (OR = 0.42). We calculated population attributable risks of 36% for HBV infection and 56% for failure to clear HBV, respectively, for the risk rs3077 C allele in Han Chinese. The rs3077 C allele frequency was highest in Africa Yoruba (74%) and Han Chinese (63%) and lowest in Europeans (12%). The pairwise Fst values of 0.25 between Asians and Europeans and 0.42 between Africans and Europeans indicate that rs3077 is highly differentiated among populations. In a simple linear regression analysis of 20 populations with both rs3077 allele frequencies and HBsAg (HBV surface antigen) prevalence rates available, the rs3077 C allele frequency was in strong positive correlation with HBsAg prevalence. The correlation between rs3077 and HBV carrier rates was highly correlated (correlation coefficient 0.81, $P < 0.001$). Although a causal relationship remains to be established, the *HLA-DPA1* rs3077, would explain 66% ($r^2=0.66$) of the variance in global HBV prevalence. The highly-stratified distribution of rs3077 across human populations and correlation with HBV prevalence suggest that *HLA-DPA1* rs3077 may account in part for disparate HBV chronic infection rates in human populations. (Funded by the National Cancer Institute under Contract HHSN261200800001E).

Genetic variation and smoking behavior among diverse populations: Multi-Ethnic Genotyping Array (MEGA) analysis in the PAGE Study. *I. Cheng[1], Y. Li[1], S.L. Park[2], K. Young[3], S. Bien[4], C. Schurmann[5], T. Matise[6], L. Hindorff[7], R. James[8], S. Buyske[6], S.P. David[9], N. Zubair[4], C.A. Haiman[2], L.R. Wilkens[10], R. Loos[5], U. Peters[4], C. Kooperberg[4], K. North[3], D.O. Stram[2], L. Le Marchand[10] for the PAGE Study.* 1) Cancer Prevention Institute of California, Fremont, CA; 2) University of Southern California, Los Angeles, CA; 3) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 6) Rutgers University, New Brunswick, NJ; 7) Division of Genomic Medicine, NHGRI, NIH, Bethesda, MD; 8) Clinical and Health Services Research, NIMHD, NIH, Bethesda, MD; 9) Stanford University, Palo Alto, CA; 10) University of Hawaii Cancer Center, Honolulu, HI.

Background: Globally, cigarette smoking accounts for 6.1 million deaths and 143.5 disability adjusted life years and is the primary risk factor for many cancers as well as other common chronic diseases such as cardiovascular disease. Numerous common variants have been associated with various smoking traits. However, many of these variants have been studied in predominately European populations. The objective of this analysis was to identify novel genetic risk variants for smoking behavior, using the Illumina Multiethnic Genotyping Array (MEGA) that was designed specifically to improve variant discovery and fine-mapping for metabolic, anthropometric, and lifestyle loci in non-European populations. Methods: We included 14,785 smokers from the Population Architecture using Genetics and Epidemiology (PAGE) Study that were genotyped using MEGA with information on the number of cigarettes smoked per day. We examined over 1.1 million SNPs with a minor allele frequency (MAF)>0.01. Race/ethnicity-specific ordinary linear regression results for African Americans, Asian Americans, Native Hawaiians, and Native Americans and generalized estimation equation results for Hispanics were meta-analyzed. Results: We confirmed associations for known smoking loci at chromosome 15q25.1 and chromosome 19q13.2. Potential novel associations for the number of cigarettes smoked per day were observed at chromosome 8p23.2 with rs7003625 in *CSMD1* (average MAF= 0.31, beta= 0.040, standard error= 0.008, P= 4.1x10^{-7}) and chromosome 20q11.2 with rs182236729, a missense variant in *MYH7B* (average MAF =0.01, beta= -0.641, standard error= 0.129, P=6.9x10^{-7}). There was no evidence of heterogeneity in associations by race/ethnicity. Conclusions: These preliminary findings suggest novel associations for smoking behavior among diverse racial/ethnic populations. Future work will further examine rare variants, fine-map known smoking risk loci, and incorporate data on imputed genotypes. The discovery of novel risk variants and the genetic characterization of known smoking loci in non-European populations will increase our understanding of the shared and population-specific genetic susceptibility of smoking. Such findings may ultimately guide tailored smoking cessation and screening efforts for tobacco-related diseases.   .

Exposure to polychlorinated biphenyls (PCBs) and uric acid transporter polymorphisms in American Indians: The Strong Heart Family Study. *G. Chittoor[1], K. Haack[2], A. Sjodin[3], S. Laston[4], L.G. Best[5], J.W. MacCluer[2], J.G. Umans[6], S.A. Cole[2], A. Navas-Acien[7,8,9,10], V.S. Voruganti[1].* 1) Department of Nutrition, and Nutrition Research Institute, University of North Carolina at Chapel Hill, NC; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) Centers for Disease Control and Prevention, Atlanta, GA; 4) South Texas Diabetes and Obesity Institute, School of Medicine, University of Texas Rio Grande Valley, Brownsville, TX; 5) Missouri Breaks Industries Research Inc., Timber Lake, SD; 6) Georgetown-Howard Universities Center for Clinical and Translational Science, Washington, DC; 7) Department of Environmental Health Sciences, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 8) Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 9) Welch Center for Prevention, Epidemiology and Clinical Research, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 10) Department of Oncology, Johns Hopkins School of Medicine, Baltimore, MD.

   Background: Polychlorinated biphenyls (PCBs) are among several persistent organic pollutants (POPs) recognized to be toxic to the environment and humans by the United Nations environment program at their Stockholm Convention. Like other POPs, PCBs are highly resistant to biodegradation and tend to accumulate in living organisms, particularly in lipid rich liver and adipose tissues. Studies have shown a positive relationship between exposure to PCBs and metabolic disease risk factors such as hyperuricemia, hypertension, insulin resistance, inflammation, and oxidative stress. Previously we have shown that 25% of American Indians participating in the Strong Heart Family Study (SHFS) had hyperuricemia or elevated serum uric acid (SUA) concentrations and that SUA is strongly influenced by uric acid transporter gene variants. Therefore, our aim in this study was to assess genetic influences on serum PCBs and their relationship with SUA in SHFS.   **Methods**: Serum levels of 24 PCBs were ascertained in a cohort of 169 SHFS participants using GC/HRMS. DNA samples were genotyped using Illumina Vera Code Golden Gate genotyping assay kit for 78 SNPs that were selected for their strong association with SUA concentrations in previous studies. A variance components-based quantitative genetic analysis was performed using SOLAR. The association of serum PCBs with SUA-associated SNPs was estimated using a measured genotype analysis accounting for family relationships.   **Results:** Mean values of serum PCB concentrations ranged from 0.94 to 183.33 pg/g. Serum PCBs showed a positive but non-statistically significant trend of association with SUA concentration. Of the 24 PCBs, 7 analytes (PCB66: 2,3',4,4'-tetraCB; PCB99: 2,2',4,4',5-pentaCB; PCB105: 2,3,3',4,4'-pentaCB; PCB118: 2,3',4,4',5-pentaCB; PCB183: 2,2',3,4,4',5',6-heptaCB; PCB206: 2,2',3,3',4,4',5,5',6-nonaCB; PCB209: decaCB) exhibited moderate-to-high heritabilities (p < 0.03). Significant associations were observed between uric acid transporter SNPs and PCBs, (p < 0.006, MAF between 12 and 42%, effect sizes up to 7%) rs2078267 (*SLC22A11*) with PCB105, rs2242206 (*SLC16A9*) with PCB118 and PCB66, rs1183201 (*SLC17A1*) and rs942379 (*SLC17A3*) with PCB206 and PCB209, and rs2231142 (*ABCG2*) with PCB183. **Conclusions:** Several of the serum PCB measures were heritable and associated with uric acid transporter gene variants suggesting a pleiotropic relationship between serum PCBs and SUA concentrations in SHFS Participants. .

A variance-components approach to identifying causal haplotypes in quantitative-trait linkage. *J.E. Hicks[1,2], M.A. Province[1,2].* 1) Division of Biostatistics, Washington University School of Medicine in Saint Louis, St Louis, MO; 2) Division of Statistical Genomics, Washington University School of Medicine in Saint Louis, St Louis, MO.

   Variance-components (VC) linkage analysis has been an important tool for identification of quantitative trait loci in humans. However, the VC model has some drawbacks. In conventional linkage analysis, pedigrees are assumed to be independent. This assumption may not always hold, as research shows that cryptic relatedness between 'unrelated' individuals is common. Additionally, effect sizes generated only give the amount of variance attributable to a locus, and not which variants are most influential to that variance.   Recent exponential population growth has resulted in an excess of rare variants across the genome. Population genetics theory predicts that these rare variants reside on long haplotypes in the population. Long shared haplotypes between individuals are identifiable from high-density genotype data both within and across pedigrees. Incorporation of haplotype information may increase power to identify rare variants influencing common traits.   We propose a method based on a linear mixed-effects model to find haplotypes responsible for a linkage signal. Phased haplotype data contains much of the information provided by identity-by-descent (IBD) covariance matrices. Instead of an IBD covariance matrix for a locus, we include a random effect indicating an individual's haplotype state alongside a polygenic effect. Statistical significance can be determined by likelihood ratio test. Duing the model fit, best linear unbiased predictions (BLUPs) of the effect of each haplotype are generated.   To test the power of this method we generated simulated data. One hundred replicates were generated for 50 pedigrees with genotypes based on the Affymetrix 6.0 chromosome 12 marker set. P henotypes were generated based on genotypes to have a standard normal distribution and heritability of 50%. Each pedigree had a 50% chance of carrying a 5,000 SNP haplotype containing a rare variant influencing the trait. We fit a model with 8 SNPs per haplotype in a 1Mb region around the rare variant.   This haplotype VC model showed 100% power at α=0.05 to detect a disease haplotype with effect +2σ . Powers for smaller effect sizes were 95%, 70%, and 23% for sizes +1.5σ, +1σ, and +0.5σ, respectively. In null data, the method showed a false positive rate of 3%.   The ability to identify BLUPs for each haplotype makes this a useful method to better understand the results of VC linkage. Additionally, BLUPs can allow more accurate selection of individuals to sequence for further research.

473T

Association analyses of myopia in multiplex African-American families using FBAT and a rare variant FBAT with exome chip data. *C.D. Middlebrooks[1], C.L. Simpson[2], A.M. Musolf[1], L. Portas[3], F. Murgia[4], D. Stambolian[5], J.E. Bailey-Wilson[1]. 1) National Human Genome Research Institute, Baltimore, MD; 2) University of Tennessee Health Science Center, Memphis, TN; 3) Università degli Studi di Verona, Cagliari Area, Italy; 4) Institute of Population Genetics - National Research council of Italy, Cagliari Area, Italy; 5) Scheie Eye Institute - Penn Presbyterian Medical Center, Philadelphia, PA.*

Myopia is an eye condition in which the light entering the eye does not focus on the retina and instead focuses on a point in front of the retina and results in distant objects appearing out of focus. Within recent years, the incidence and prevalence of myopia have increased, reaching epidemic proportions in several Asian countries. Myopia currently affects about 1 in 4 Americans. Research efforts have sought to identify both genetic and environmental causes of this phenomenon. Populations of African descent have lower rates of myopia than Asian populations, but multiplex families from the African-American (AA) population may represent an opportunity to identify unique susceptibility and protective alleles. We have performed an association study examining common and rare variants using Exome Chip genotyping (Illumina HumanExome v1.1 array plus 24,263 custom SNPs) within a family - study framework in 106 African-American families from the Philadelphia area who have multiple individuals affected with myopia (The Penn Family Study). Individuals in the families were defined as myopic if their average refractive error was <= -1 Diopter (D) and were considered unaffected if their average refractive error was > 0.0 D; others were coded as having an unknown phenotype. More stringent rules were used to code children as unaffected since children's eyes are constantly changing during childhood and adolescence. After quality control there were 242,901 SNPs (3300 AIMs, 5300 common SNPs across the genome and 240,000 coding SNPs) available for analysis. Single-variant analyses using FBAT resulted in a suggestive-level association signal in African Americans within the psoriasis susceptibility 1 candidate 3 gene (rs887468 in PSORS1C3) (P=1.2E-05) on chromosome 6. This association signal is intriguing but the analysis of each genetic variant individually does not adequately make use of the many rare variants available in this dataset. To increase power, we are performing gene-based tests using a rare variant analysis approach within the Family Based Association Test (FBAT) software suite. Using this analysis, we expect to increase our power to identify an association by testing for an association at the gene-level which combines the effects of multiple variants within a gene.

474F

The impact of population structure on rare variant association tests. *E. Persyn[1], L. Bellanger[2], R. Redon[1], C. Dina[1]. 1) l'institut du thorax – UMR Inserm 1087 / UMR CNRS 6291, Nantes, France; 2) Laboratoire de Mathématiques Jean Leray – Université de Nantes / UMR CNRS 6629, Nantes, France.*

Rare variant association studies are now enabled with the advances of next-generation sequencing technologies. They aim to identify new genes of susceptibility for complex diseases. Due to the power limitation of single marker tests to detect association signals, a strategy is to test groups of rare variants, commonly defined as genes. Numerous methods have been proposed during the last decade to test heterogeneous groups of rare variants. Population structure is known to be a confounding factor in genome-wide association studies for common variants. However the impact of the genetic stratification was less studied for rare variant association tests. Some authors as Mathieson and McVean (2012) and O'Connor et al. (2013) have shown that population stratification inflated the results of rare variant association tests but this field requires more investigation. Evaluating the effect of this stratification is important as ad hoc controls is a cost-effective option and often adopted by researchers. We aim to better understand the impact of population structure on different rare variant association tests. We conducted genetic simulations based on a coalescent model implemented in the COSI program (Schaffner et al., 2005). We considered in the demographical model several populations whose geographical positions are defined by mutual migration rates. We simulated different scenarios. The varied parameters are the migration rates, the time to the split between populations and the number of controls sampled from each population. Finally we applied ten rare variant association tests with different strategies in order to identify those who are less sensitive to stratification. We observe that some statistical association tests as SKAT (sequence kernel association test) (Wu et al., 2011), SKAT-O (Lee et al., 2012) and KBAC test (kernel-based adaptive cluster) (Liu and Leal, 2010) are more sensitive to population structure than other statistical such as CAST (cohort allelic sum test) (Morgenthaler and Thilly, 2007) and the weighted sum test (Madsen and Browning, 2009). Appropriate correction methods should be considered for various rare variant association strategies.

Local genetic correlation provides insights into shared genetic basis of 30 complex traits. *H. Shi[1], B. Pasaniuc[2,3].* 1) Bioinformatics, University of California Los Angeles, Los Angeles, CA; 2) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, CA; 3) 3Dept of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, CA.

Many complex traits and diseases share a correlation at a phenotypic level. Such correlations can be attributed to shared environmental or similar genetic architectures. Quantifying the correlation in phenotypes that is due to genetic variations is of great interest in understanding the causal relationship between complex traits. Standard approaches to estimate genetic correlation require individual-level genotype data, and are hindered by the availability of such data due to privacy concerns. Cross-trait LD Score regression (Bulik-Sullivan et al., Nat. Genet. 2015) provide the convenience to estimate genome-wide genetic correlation from GWAS summary statistics, but its random-effect assumption renders it less suitable to estimate genetic correlation at a single locus, where few SNPs may be causal. Here, we propose an estimator of genetic correlation between pairs of traits at a single locus in the genome from summary GWAS data while taking LD and overlapping GWAS samples into account. Importantly, our estimator does not make any assumption on the number of causal variants or their effect sizes by treating them as fixed-effects in our model. Through extensive simulations, we show that our estimator is unbiased given in-sample LD, and approximately unbiased given external reference LD. We apply our estimator to GWAS summary data of 30 complex traits spanning 2.4 million phenotype measurements. We observe substantial local genetic correlations among HDL, BMI, and years of education and many other pairs of traits. To gain insights into the causality link among traits, we decompose the genetic correlation across genomic loci, and identify loci that contribute significant amount of genetic covariance.

476T

To ERV is Human: A phenotype-wide scan linking previously unrecognized heterogeneous human endogenous retrovirus insertions to complex diseases. *A. Wallace[1], B. Rhead[2], X. Shao[2], C. Metayer[1], J. Wiemels[3], S. Francis[3,4].* 1) Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genomics Laboratory, University of California, Berkeley, Berkeley, CA; 3) Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 4) Community Health Sciences, University of Nevada, Reno, Reno, NV.

Approximately 8% of the human genome is comprised of ancient retroviral insertions (ERVs), which integrated into germ cells and have been preserved through natural selection. While the function of ERVs as regulators of gene expression and immune modulation is well established, it was assumed until recently that the locations of ERV insertions in the genome were fixed across individuals and so their potential contribution to germ-line genetic risk of complex diseases was largely overlooked. However, studies have shown that the most recent ERV integration, HERV-K, is active in a range of complex conditions from cancer to neurologic diseases. After demonstrating the heterogeneous nature of HERV-K insertion sites genome-wide, our group has associated these heterogeneous insertions with SNPs previously established through GWAS of complex phenotypes using a hypothesis-free approach. Due to the functional nature of ERVs, they serve as excellent candidates for causal variants contributing to the hidden heritability of complex diseases. Previously we used an in-house pipeline, HERVnGoSeq, on the 1000 Genomes Phase 3 whole genome sequencing data (n=2557) to 1) identify novel HERV-K insertion sites not present in the human reference and 2) characterize the heterogeneity of known and novel HERV-K insertion sites within and between populations world-wide. Here, we first tested the association of 1252 potential insertions with 24 million SNPs genome-wide among the 1000 Genomes Phase 3 European population (n=489). Insertion sites that were mappable using SNPs were defined as sites with a single, genome-wide significant peak and were confirmed by visual inspection of Manhattan plots. Among mappable insertion sites, associated SNPs positioned within 10Kb of the SNP with the lowest p-value and with p-value $< 1 \times 10^{-2}$ will next be extracted and the UCSC Genome Browser PubsMarkerSnp table and the NHGRI-EBI GWAS Catalog will be used to identify previously published associations of these SNPs with complex traits. Of the nominated SNPs, we expect to identify associations with phenotypes in previous publications. For phenotypes identified via this method, ERVs may play an etiologic role, warranting further study. Furthermore, this tool can be used in future GWAS to identify ERV variants as risk factors for disease.

Generalized polygenic risk prediction for non-medical traits in a direct-to-consumer setting. *M.L. Multhaup, R.P. Smith, D. Hinds, N.A. Furlotte.* 23andMe, Mountain View, CA.

   The use of genetic risk prediction to classify individuals into disease risk categories based on their genetics has remained a challenging problem despite dramatic growth in the number of disease-associated variants identified by genome-wide association studies (GWAS). For a small number of conditions, GWAS have identified single, large-effect variants that effectively discriminate high-risk individuals. For many common complex traits, however, GWAS have found many small effect variants, and it is less clear how to use these variants to quantify risk. Recent work has shown that polygenic genetic risk scores (GRS) can be used to identify high-risk individuals. However, most work has been conducted on a limited set of well-studied phenotypes within clinically ascertained cohorts. The generalizability of these methods has yet to be determined. Furthermore, few studies have examined how GRS results could be communicated to at-risk individuals. These issues are important for the future of personalized medicine, which hinges on the ability to accurately quantify and communicate risk to clinicians and the public. In this study, we developed a generalized system for building polygenic risk prediction models and used it to systematically evaluate the utility of GRS using the cohorts at 23andMe. 23andMe has one of the largest databases of genetic and phenotypic information with over 1.2 million customers, 80% of whom have consented to participate in research and contributed more than 345 million points of phenotypic data. Using these data, we created polygenic risk models for dozens of non-medical traits and validated model performance using multiple metrics and separate testing cohorts. In addition, we have implemented a system for translating model output into easily-understandable consumer reports. We present accuracy metrics for over a dozen GRS models created with cohorts of 50-140,000 individuals and Area-Under-Receiver-Operator-Curves (AUROCs) ranging from 0.55 to 0.737. We discuss how AUROCs, despite being a common one-number summary metric, do not capture relevant model features necessary for evaluating the accuracy of information returned to recipients. To our knowledge, this study is one of the first to evaluate the applicability of GRS methods over multiple traits using information derived from a large database of self-reported phenotypes. Our results provide a blueprint for developing complex genetic risk estimates in a direct-to-consumer setting.

478W

Inheritance modes specific pathogenicity prioritization (ISPP) for human protein coding genes. *J. Hsu[1], J. Kwan[1], Z. Pan[1], M. Garcia-Barcelo[2], P. Sham[1,3], M. Li[1,3].* 1) Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HK; 2) Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HK; 3) Centre for Genomics Science, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HK.

   Motivation: Exome sequencing studies have facilitated the detection of causal genetic variants in yet-unsolved Mendelian diseases. However, the identification of disease causal genes among a list of candidates in an exome sequencing study is still not fully settled, and it is often difficult to prioritize candidate genes for follow-up studies. The inheritance mode provides crucial information for understanding Mendelian diseases, but none of the existing gene prioritization tools fully utilize this information.**Results:** We examined the characteristics of Mendelian diseases genes under different inheritance modes. The results suggest that Mendelian-disease genes with autosomal dominant (AD) inheritance mode are more haploinsufficiency and *de novo* mutation sensitive, whereas those autosomal recessive (AR) genes have significantly more non-synonymous variants and regulatory transcript isoforms. In addition, the X-linked (XL) Mendelian-disease genes have fewer non-synonymous and synonymous variants. As a result, we derived a new scoring system for prioritizing candidate genes for Mendelian diseases according to the inheritance mode. Our scoring system assigned to each annotated protein-coding gene (N=18,859) three pathogenic scores according to the inheritance mode (AD, AR, and XL). This inheritance mode specific framework achieved higher accuracy (AUC=0.84) in XL mode.**Conclusion:** The inheritance mode specific pathogenicity prioritization (ISPP) outperformed other well-known methods including Haploinsufficiency (HI), Recessive (REC), Network centrality (NET), Genic Intolerance (RVIS), Gene Damage Index (GDI) and Gene Constraint (CONS) scores. This systematic study suggests that genes manifesting disease inheritance modes tend to have unique characteristics.**Availability:** ISPP is included in KGGSeq v1.0 (http://grass.cgs.hku.hk/limx/kggseq/), and source code is available from (https://github.com/jacobhsu35/ISPP.git).

GWAS of circulating soluble receptor for advanced glycation end products: Evidence from the Long Life Family Study (LLFS), the Atherosclerosis Risk in Communities Study (ARIC), and the Rotterdam Study (RS). *P. An[1], N.M. Maruthur[2], S. Ligthart[3], M. Li[2], A.T. Kraja[1], M.K. Wojczynski[1], B. Thyagarajan[4], J.H. Lee[5], B.C. Astor[6], I. Miljkovic[7], A. Dehghan[3], K. Christensen[8], T.T. Perls[9], A.B. Newman[7], M.A. Province[1].* 1) Washington University, St Louis, MO; 2) Johns Hopkins University, Baltimore, MD; 3) Erasmus University, Rotterdam, The Netherlands; 4) University of Minnesota, Minneapolis, MN; 5) Columbia University, New York City, NY; 6) University of Wisconsin, Madison, WI; 7) University of Pittsburgh, Pittsburgh, PA; 8) University of Southern Denmark, Odense, Denmark; 9) Boston University, Boston, MA.

The importance of glycation has been highlighted in aging processes and glycosylation related diseases. Advanced glycation end-products (AGEs) and their specific receptor play a central role in vascular outcomes. sRAGE, a soluble form of the AGEs receptor, has been recognized with a counter-regulatory mechanism, identifying it as a biomarker of endothelial function or early stage atherosclerosis. To identify loci associated with circulating sRAGE, we assessed SNPs imputed from the 1000 genome project and conducted GWAS using 6,579 participants of European ancestry in the LLFS (nondiabetic subjects, discovery), ARIC (replication), and RS (nondiabetic subjects, replication). In all three studies, levels of sRAGE were natural log-transformed to approximate normality, and adjusted for age, sex, BMI, and GWAS principal components. sRAGE levels were additionally adjusted for field centers (LLFS), current smoking status (LLFS, RS), and educational level, eGFR, prevalent diabetes and CHD (ARIC), and a kinship model was used to correct for random effects of relatedness (LLFS). A linear mixed effects model, assuming additive genetic effects, was used for testing associations. In the discovery phase, a significant SNP (rs190643062, MAF = 0.011, p = 3e-8, near upstream *CCDC71L* and downstream *PIK3CG*) along with five suggestive loci (p < 1E-6; *ST5*, *TRIM49B*, *LOC646813*, *AGBL1*, *SLC32A1*) were identified in the LLFS. While rs190643062 was not replicated (p = 0.36, ARIC; data not available in the RS), the intergenic locus was supported by a significant (p < 2e-4, simpleM test) and independent SNP near *PIK3CG* (rs73186275, p = 3e-5) in the ARIC (but not in the RS, p = 0.01). Further, rs190643062 is in perfect LD with a ~30 kb upstream SNP rs192033857 at 3'-UTR of *CCDC71L* that is conserved in mammals and is located in the promoter/enhancer histone marks of 7-10 tissues where a DNase and a protein bind; the polymorphism modifies binding motifs of *RXRA* and *SIX5* transcription factors. Interestingly, neighboring intergenic SNPs at this locus (e.g., rs342293, rs17477177, rs4730171) are associated with a broad spectrum of cardiovascular traits including platelet counts, lipids, BP, glucose, IR, atherosclerosis, carotid intima media thickness, presence of atherosclerotic plaque and pulmonary function. In conclusion, we identified a novel locus near *CCDC71L* and *PIK3CG* genes that regulates levels of circulating sRAGE. Further independent replications and function queries are warranted.

480F

Genome-wide association study of *Staphylococcus aureus* **infection and clonal complexes in related samples from Starr County, Texas.** *H. Chen[1], H. Hu[2], L.E. Petty[1], D.A. Robinson[3], H.T. Essigmann[4], R.S. Fischer[4], C.L. Hanis[1], C. Huff[2], E.L. Brown[4], J.E. Below[1].* 1) Human Genetics Center, Division of Epidemiology, Human Genetics, and Environmental Sciences, University of Texas Health Science Center at Houston, Houston, TX, United States of America; 2) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, TX, United States of America; 3) Department of Microbiology, University of Mississippi Medical Center, Jackson, MS, United States of America; 4) Center for Infectious Disease, Division of Epidemiology, Human Genetics, and Environmental Sciences, University of Texas Health Science Center at Houston, Houston, TX, United States of America.

Staphylococcus aureus infections represent a severe public health problem in hospitals and communities. The underlying biology of susceptibility to *S. aureus* has been difficult to unravel due to complex interactions between the microorganism, the environment, and the host. Host genetic susceptibilities have been reported to be associated with malaria, HIV and cholera infections and identification of *S. aureus* susceptibility genes would be helpful in the development of novel intervention strategies. The purpose of this study was to identify genes and variants that are correlated with nasal carriage of *S. aureus,* and to investigate associations between genetic susceptibility and different *S. aureus* clonal complexes. 769 subjects from the Mexican-American community of Starr County, Texas were recruited, including 416 individuals from 176 households. Chip genotyping was conducted on Illumina Expanded Multi-Ethnic Genotyping Array and imputation to 1000 Genomes Project Phase 3 reference data was performed using standard procedures to obtain final genotype data. In addition, the carriage status of *S. aureus*, including clonal complex, was determined based on two nasal swabs collected 11-17 days apart. The sample size of the three different carriage states i.e., persistent, intermittent, and non-carrier was 127, 135, and 507, respectively, and the five major clonal complexes identified were CC5, CC8, CC30, CC45, and CC188. Using Efficient Mixed-Model Association eXpedited (EMMAX) we applied linear mixed models with kinship adjustment to identify variants associated with infection of and clonal complex of *S. aureus*. Furthermore, meta-analysis of current study results and a previous publication was conducted using METAL. In the meta-analysis, two suggestive associations were identified in the comparison between intermittent infection and non-carriers (rs115503846 on chromosome 1, p= 6.9×10[-07]; rs3861635 on chromosome 14, p= 5.8×10[-07]). Although we could not replicate the previously reported significant variants, either through direct replication or meta-analysis, several variants and regions were found significantly associated with carriage and specific clonal complexes of *S. aureus*. The significant association between these variants and infection of *S. aureus* confirmed the interaction of genetic susceptibility and *S. aureus* carriage states.

Winner's curse in quantitative genomics studies. *G. Darnell[1], J. Tung[2], C. Brown[3], S. Muhkerjee[2], B. Engelhardt[1].* 1) Princeton University, Princeton, NJ; 2) Duke University, Durham, NC; 3) University of Pennsylvania, Philadelphia, PA.

Winner's Curse is a phenomenon characterized for common value auctions in economics to describe the winner of the auction tending to overpay for the item, and has been used to explain the overestimation of effect sizes and lack of reproducibility of associations that have plagued genomics studies [Zöllner et al., 2007]. The bias in effect size estimation traces back to agricultural QTL mapping studies as the Beavis effect, but has been widely overlooked in the human genetics community [Göring et. al., 2001]. Standard association mapping techniques in modern eQTL studies are mostly concerned with the trade-off between computational tractability and statistical power. However, little focus has been placed on accurate and reproducible effect size estimates, even when false positives are properly controlled and statistical power is high. A corollary to inflated effect sizes is that the causal association is rarely identified, but, instead, a non-functional genetic variant often has the most significant test statistic value. Even conditioning on detection of an association between the truly causal variant and gene expression level of interest, estimation of the strength of association is almost always inflated. We demonstrate with a suite of previously proposed and novel methods that trade off computational and statistical properties, that each method suffers from one or more of four consequences: (1) increasing false positives and decreasing true positives, (2) enrichment of discoveries at low minor allele frequency, (3) false discoveries that are not in high LD with causal variants, and (4) underestimation of locus heterogeneity. In addition, we show lack of reproducibility and lack of correspondence of effect sizes in real data between gene expression microarrays of the same individuals under baseline conditions and drug responses. We propose new directions for robust and accurate effect size estimates in attempt to increase reproducibility in eQTL studies and mitigate Winner's Curse.

Shared genetic predictors of resting heart rate and all-cause mortality. *R.N. Eppinga[1], Y. Hagemeijer[1], S. Burgess[2], D.J. van Veldhuisen[1], P.B. Munroe[3,4], N. Verweij[1], P. van der Harst[1,5,6].* 1) University of Groningen, University Medical Center Groningen, Department of Cardiology, 9700 RB Groningen, the Netherlands; 2) Department of Public Health and Primary Care, University of Cambridge, Cambridge CB1 8RN, United Kingdom; 3) Department of Clinical Pharmacology, William Harvey Research Institute, Barts and The London, Queen Mary University of London, London, EC1M 6BQ, United Kingdom; 4) NIHR Barts Cardiovascular Biomedical Research Unit, Queen Mary University of London, London EC1M 6BQ, United Kingdom; 5) University of Groningen, University Medical Center Groningen, Department of Genetics, 9700 RB Groningen, the Netherlands; 6) Durrer Center for Cardiogenetic Research, ICIN - Netherlands Heart Institute, 3511GC Utrecht, the Netherlands.

Background Resting heart rate is a heritable trait correlated with lifespan. Little is known about the genetic contribution of resting heart rate and its relationship with mortality. **Methods** We performed a genomewide association analysis of 19.9 million genetic variants in 134,251 individuals from UK Biobank to further our understanding of the genetic basis of resting heart rate. We then used the identified genetic variants as an instrument to study the association between resting heart rate, cardiovascular risk factors and all-cause mortality. **Results** Genomewide association analysis identified 76 loci associated with resting heart rate ($P<5×10^{-8}$), 58 of these were novel. An increase in genetically predicted resting heart rate of 5 beats per minute was associated with a 20% increased mortality risk (hazard ratio 1.20, 95% CI of 1.11-1.28, $P=8.20×10^{-7}$) translating to a 2.9 years reduction in life expectancy for males and 2.6 years for females. Genetically predicted resting heart rate was found to be associated with higher body-mass index and diastolic blood pressure, hypertension, diabetes, smoking, myocardial infarction, heart failure, supraventricular tachycardia, beta-blockers, calcium channel-blockers and device implantation (all $P<0.05$). However, we did not identify such factors as mediators on the causal pathway between resting heart rate and all-cause mortality. Candidate gene and pathway analyses provide strong support for a dominant role of cardiac development and structure. **Conclusion** We discovered 58 novel loci for resting heart rate and provide evidence for shared genetic predictors of resting heart rate and all-cause mortality. Large-scale replication efforts are currently underway.

483F

The susceptibility of genome-wide association studies to recent fine-scale population structure. *J.M. Granka, E. Han, P. Carbonetto, K. Rand, J.K. Byrnes, R.E. Curtis, A. Kermany, Y. Wang, K. Noto, E. Elyashiv, H. Guturu, N.M. Myres, E. Hong, C.A. Ball, K.G. Chahine.* Ancestry.com DNA, LLC, San Francisco, CA.

   Large, heterogeneous genetic datasets have identified associations of thousands of single nucleotide polymorphisms (SNPs), sometimes subtly, with hundreds of human diseases and traits. Numerous methods have been developed to account for confounding effects of population structure unavoidable in such datasets; these include linear mixed models (LMMs) and the inclusion of population-level principal components (PCs) in fixed models. However, the susceptibility of GWAS to subtle, fine-scale population structure unidentifiable from PCs or F_{ST} has not been fully studied. Here, we address whether ultra-fine scale population structure, such as from post-colonial U.S. history or recent British history (Leslie *Nature* 2015), could produce an inflation of false positive GWAS associations, even for common variants. To do so, we use simulated phenotype data and genome-wide SNP data from over 1 million AncestryDNA customers who have consented to research. Among these individuals, we identify very recent fine-scale population structure using community detection algorithms across a network of identity-by-descent (Han *ASHG* 2015). Identified sub-populations, such as individuals of the U.S. Appalachian region, correspond to history within the last several hundred years and are driven by both spatial and cultural factors such as religion. We simulate phenotypes under various null and alternative models, as well as under models where latent environmental variables (such as cultural habits) associated with sub-populations affect the phenotype to varying degrees. Under both balanced and imbalanced sampling across sub-populations, we examine results of GWAS obtained from various methods: from linear fixed models using PCs as covariates to LMMs controlling for cryptic relatedness. The susceptibility of current GWAS approaches to fine-scale structure is dependent upon the degree of genetic differentiation among identified sub-populations, as well as the degree of sampling bias. In cases where latent environmental variables affecting the phenotype are related to fine-scale population structure, accounting for such structure using LMMs markedly improves GWAS accuracy. This highlights that even when underlying confounders are unknown, accounting for fine-scale structure can lessen effects of hidden environmental covariates without compromising power. Furthermore, our results suggest that accounting for fine-scale structure is even more critical when studying rare variant associations.

On testing of gene-gene interaction based on case-control data using genotype similarity between individuals. *P. Mondal, I. Mukhopadhyay.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India.

   Background: Some possible explanations for the limited success of genome wide association study (GWAS) are that the current biostatistical analysis paradigm ignores all prior knowledge about disease pathobiology and/or the linear modeling framework of GWAS considers only one marker at a time thus failing to exploit their full genomic context and giving rise to multiple comparison problems. Also gene–gene (G-G) or marker based interactions might be another cause for this. This led to the development of multilocus association that combines information from multiple markers at a time. In spite of some already available multilocus association methods for testing association, no study is done to see its effectiveness in detecting G-G interaction. **Aims and objectives:** We adopt a more holistic approach that explores G-G interaction, combining information from multiple markers of two genes. This new approach is promising in identifying the variants along with relatively potent causal markers in gene interaction models. It has the flexibility to use knowledge from other sources (biological pathways, databases etc) and helps to prioritize genetic variations to be analyzed for G-G interactions to interpret genetic association studies in a biologically meaningful manner. **Material and Methods:** Our method is based on case-control data and the information contained at each marker is captured through a kernel function based on genotypes of two individuals. We use this genotype similarity score or kernel score to develop a novel statistical method avoiding the huge burden of multiple comparisons to a great extent. The newly proposed statistic for testing any such G-G interaction is easy to compute but the calculation of p-value poses another challenge. However, we are able to derive the asymptotic distribution of the statistic under the null hypothesis of no interaction. **Results:** The asymptotic distribution of the test statistic helps in the fast calculation of p-value even in presence of thousands of markers spread over different genes. Extensive simulations studies show that our method is very powerful in detecting any such interaction under various genetic models and is very robust. **Conclusions:** This method will have immense importance to the geneticists because of its robustness, powerful detection of interaction that may occur with or without main effects, ability to fast calculation of p-value with less multiple comparison burdens.

485T

A robust powerful statistical method to integrate genotype and gene expression data identifies novel associated loci. *I. Mukhopadhyay, S. Das, R. Chatterjee.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India.

Genome wide association studies (GWAS) identify many SNPs that are associated with disease traits. However, there is always a possibility that underpowered single marker test misses out SNPs with moderate effect sizes and fails to capture information embedded in the rare variants that are believed to explain the missing heritability of polygenic traits. On the other hand, gene expression contains information about the deregulation of genes when compared between cases and controls. Due to multiple testing or other issues some signals may remain unidentified especially when the sample size is not so large. Moreover, RNA being unstable compared to DNA, high cost is involved in RNA analysis which tend researchers to have a large population of genotyped individuals with only few of them having expression. Thus, to unravel the genetic architecture of common or complex disease, it is intuitive to integrate information from various data sources to decode biologically sound interpretation on heritable traits. No standard statistical procedure is available to deal with the complexities of these datasets, which motivated us to propose a novel method that tests for multi-loci association in the existing scenario. Based on a simple consistent two-stage regression method using Least Squares procedure, we develop a statistical method that essentially integrates genotype data and gene expression data to study genetic association at a genome-wide level using case-control data. For a large number of individuals gene expression data are not available whereas genotype data are available for all individuals. We integrate the information contained in both data sources into a latent variable based model. Our simple yet powerful multi-loci association test integrates two databases that broadcasts more of the deep-seated features comprehensively in a single test, which would otherwise be lost when databases are considered in singularity. We have developed asymptotic distribution of our test statistic for fast calculation of p-value for real data set. Extensive simulation confirms that our method is robust to many genetic models and disease models with different types of penetrance. This method is very powerful in detecting some novel markers that might be associated with the disease phenotype and that may go missing by genotype-based test only. We also get promising result when applied this method at a genome-wide level even with a small gene expression dataset related to psoriasis.

Genetic variants associated with C-Reactive protein levels in US minorities from the Population Architecture using Genomics and Epidemiology (PAGE II) Study. *K.K. Nishimura[1], C. Hodonsky[2], J. Haessler[1], C.S. Carlson[1], I. Cheng[3], R. Do[4], L.A. Hindorff[5], R. James[6], R.C. Kaplan[7], J. Kocarnik[1], L. Le Marchand[8], S.L. Park[8], A.P. Reiner[1], B. Thyagarjan[9], M. Verbanck[4], G.L. Wojcik[10], C.L. Avery[2], C.A. Haiman[11], R.J.F. Loos[4], T.C. Matise[12], K.E. North[2], U. Peters[1], C.L. Kooperberg[1] on behalf of the PAGE Study.* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Cancer Prevention Institute of California, Freemont, CA; 4) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Division of Genomic Medicine, NHGRI, NIH, Bethesda, MD; 6) Clinical and Health Services Research, NIMHD, NIH, Bethesda, MD; 7) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 8) Cancer Research Center, University of Hawaii, Honolulu, HI; 9) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 10) Stanford University School of Medicine, Stanford, CA; 11) Department of Preventative Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 12) Department of Genetics, Rutgers University, Piscataway, NJ.

C-reactive protein (CRP) is a general marker of systemic inflammation. Consistent positive associations between CRP and coronary heart disease (CHD) have spurred research into the genetic, environmental, and pathophysiological factors influencing normal and disease-related CRP levels. Most genome-wide association studies (GWAS) have been conducted in European populations. However, variation in CRP values exists between racial/ethnic groups, and GWAS using admixed populations can increase statistical power to identify novel associations and fine-map known loci. In this study, we present preliminary results from a GWAS of 24,830 African Americans, Hispanics, Asians and Native Americans from the Population Architecture using Genomics and Epidemiology (PAGE II) consortium. Participants were genotyped on the Multiethnic Genotyping Array (MEGA), which was designed to improve variant discovery and fine-mapping for metabolic, anthropometric and lifestyle traits in US minorities. All racial/ethnic groups were pooled and analyzed in the R package GENESIS with linear mixed models. CRP values were natural log transformed, and all regressions were adjusted for age at time of CRP measurement, sex, body mass index, current smoking status, study, and the top 8 principal components of genetic ancestry derived from the pooled study. Analyses stratified by race/ethnicity were also performed, with results meta-analyzed using fixed-effect models in METAL. Overall, our study found 11 genome-wide significant loci ($p<5x10^{-8}$), confirming 9 loci previously associated with CRP, and identifying 2 novel loci: *TREM2* (6p21.1, rs2234256) and *CD300LF* (17q25.1, rs1037170). Pooled and race-specific meta-analyses had similar effect sizes and p-values. The 6p21.1 and 17q25.1 associations were strongest in African Americans and Hispanics, respectively, where the minor allele frequencies were highest. Both genes encode proteins involved in regulating the immune response. Imputation of all MEGA genotypes on additional participants to the 1000 Genomes Project and Haplotype Reference Consortium is currently underway for replication efforts. Future plans include burden association tests to identify rare-variant associations, conditional analyses to uncover independent signals within known and new loci, and gene-environment interactions with a CRP genetic risk score. We attribute our success to the inclusion of diverse populations and expect that our study will yield additional novel findings.

487W

Gene- and pathway-based association tests for multiple traits with GWAS summary statistics. *W. Pan, I. Kwak.* Division of Biostatistics, University of Minnesota, Minneapolis, MN.

To identify novel genetic variants associated with complex traits and to shed new insights on underlying biology, in addition to the most popular single SNP-single trait association analysis, it would be useful to exploit multiple correlated (intermediate) traits at the gene- or pathway-level by mining existing single GWAS or meta-analyzed GWAS data. For this purpose, we present an adaptive gene-based test and a pathway-based test for association analysis of multiple traits with GWAS summary statistics. The proposed tests are adaptive at both the SNP- and trait-levels; that is, they account for possibly varying association patterns (e.g. signal sparsity levels) across the SNPs and traits, thus maintaining high power across a wide range of situations. Furthermore, the proposed methods are general: they can be applied to mixed types of traits, and to Z-statistics or p-values as summary statistics obtained from either a single GWAS or a meta-analysis of multiple GWAS. Our numerical studies with simulated and real data demonstrated the promising performance of the proposed methods. In particular, we applied the proposed gene-based test to the summary statistics for sex stratified anthropometrics data from The Genetic Investigation of ANthropometric Traits (GIANT) consortium, identifying more genes with significant sex-specific associations than other existing methods. The proposed methods are implemented in R package aSPU, freely and publicly available at https://cran.rproject.org/web/packages/aSPU/.

488T

Designing of an efficient genotyping chip for discovery and pan-disease screening in the Veterans Administrations Million Veteran Program (MVP). *S. Pyarajan[1,2], T. Webster[3], Y. Shi[1], M. Li[1,5], A. Huda[4], A. Clark[4], J. Moser[8], S. Muralidhar[8], T. O'Leary[8], J. Concato[6,7], J. Gaziano[1,2] for The MVP Genomic Working Group.* 1) VA Boston Healthcare System, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Affymetrix Inc., Santa Clara, CA; 4) Booz Allen Hamilton, McLean, VA; 5) University of Utah, Salt Lake City, UT; 6) VA Connecticut Healthcare System, West Haven, CT; 7) Yale University School of Medicine, New Haven, CT; 8) VA Office of Research and Development, Washington D.C.

The Million Veteran Program (MVP) is a national program initiated by the Veterans Affairs (VA) to collect consented biosamples for personalized medicine research from a million Veterans. MVP has already collected over 470,000 samples and is expected to reach over a million in the next 4-5 years. Proposed initial analysis includes genotyping all the MVP samples. Lower density genotyping chips have recently emerged as a cost-effective means for genotyping a very large number of samples. A custom lower density genotyping chip was designed on the Affymetrix Axiom platform for genotyping the MVP samples. The MVP 1.0 genotyping array was designed to allow for investigation of markers of clinical significance for a wide variety of human conditions and diseases. We started with the Affymetrix Biobank Chip as the backbone and designed a set of custom markers for inclusion on the chip. The MVP 1.0 array includes 723,305 probes investigating about 668,543 markers. Clinically significant SNPs from over 3400 genes including all of the 57 genes recommended for reporting of incidental findings by the ACMG have been included. Over 800 clinical conditions, with an emphasis on conditions of high prevalence in US Veterans, are covered by the markers on the chip. For some of the clinically relevant markers we have included SNPs with allele frequencies as low as 0.005% for some of the ethnicities. We also enriched for HLA and KIR markers for multiple ethnicities. Our design philosophy also incorporated a low-density genotyping approach with ability to imputing to high density for wide coverage across the genome for multiple ethnicities. Markers for genome wide coverage for not only Caucasians but specifically for African-Americans and other ethnicities were selected by an imputation aware algorithm for incorporation. The imputation coverage (Mean r^2) for marker with MAF range of 0.05-0.5 in the CEU population is expected to be 0.909 while in YRI and ASW population it is expected to be 0.814 and 0.799 respectively. Overall, the MVP 1.0 Array is an efficient low cost genotyping array that can be used not only as a pan-disease screening chip to design future more comprehensive and potentially expensive "omic" assays for MVP samples but also for discovery with efficient imputation. .

489F

Mapping variants to amino-acid changes in three-dimensional protein space improves aggregate association test power and suggests mechanisms of action. *M. von Grotthuss[1], J. Florez[1,2,3], J. Flannick[1,2].* 1) The Broad Institute, Cambridge, MA; 2) Massachusetts General Hospital, Cambridge, MA; 3) Harvard Medical School, Cambridge, MA.

To explore rarer variants than those identified by GWAS studies of complex traits such as Type 2 Diabetes (T2D), aggregate tests have been proposed to increase power. As aggregate analysis is negatively impacted by the inclusion of non-functional variants, the majority of aggregate associations identified to date have tested variants that truncate the protein (PTVs), or are functional in cellular assays. However, PTVs exclude the majority of variants in a gene, cellular assays are seldom available, and bioinformatics algorithms have been shown to be poor predictors of cellular function. We hypothesized that three-dimensional (3-D) protein structure maps might enable more accurate groupings of variants for aggregate association tests. We developed a novel method to (a) map all missense mutations to 3-D structures of proteins; (b) identify patterns of amino-acid changes in 3-D space; and (c) cluster variants according to these patterns for use in aggregate association analysis. We applied our methodology to analyze missense variants in TBC1D1 and TBC1D4 as identified from sequence data of 16,857 multi-ethnic T2D cases/controls; we chose these genes because TBC1D4 was recently identified to carry a Greenlandic variant of large effect on T2D risk and has an established role in insulin signaling, while TBC1D1 has a potentially (but unverified in humans) analogous role to TBC1D4 based on animal models. PTVs in TBC1D1 (OR=2.14, p=0.02), as well as combined PTVs and bioinformatically deleterious variants in TBC1D4 (OR=1.2, p=0.03), demonstrated nominally significant aggregate association with increased T2D risk in the heterozygous state. However, bioinformatically deleterious missense variants in TBC1D1 showed no association (OR=1.02, p=0.88). In contrast, our mapping algorithm identified a cluster of mutations localized on the surface of the TBC1D1 Rab-GAP binding site, which in aggregate demonstrated a nominal association with T2D risk (OR=2.7, p=0.038). Rab-GAP plays a known role in localization of the glucose transporter GLUT4 to the plasma membrane in insulin responsive tissues, with TBC1D1 and TBC1D4 binding necessary for activation of Rab. Collectively, our results thus suggest (a) that disruption of TBC1D1 in humans increases risk for T2D; (b) that impaired Rab-GAP binding is responsible for this increase in risk; and (c) that analyzing variants in 3-D protein space can inform aggregate tests of missense variants when cellular assay data is unavailable.

490W

Principal component based adaptive-weight burden test for quantitative trait associations. *X. Wu.* Dept of Statistics, Virginia Tech Univ, Blacksburg, VA.

High-throughput sequencing has often been used to screen samples from pedigrees or with population structure, yielding genotype data with complex correlations attributed to both familial relation and linkage disequilibrium. Accounting for such genotypic correlations can improve power for genetic association testing. However, due to model restrictions, existing methods cannot make efficient use of the correlation information appropriately, especially when assessing the contribution of multiple genomic loci. Recognizing this limitation, we develop PC-ABT, a novel principal-component-based adaptive-weight burden test for gene-based association. This method uses a retrospective score test to incorporate genotypic correlations, and employs "data-driven" weights to obtain maximized test statistic. In addition, by adjusting the number of principal components that make major contributions to genetic association, PC-ABT is able to control the degree of freedom of the null distribution to improve power. Simulation studies show that PC-ABT is generally more powerful than previously proposed burden tests that allow related individuals, while controlling for the type I error rate. We illustrate the application of PC-ABT by an analysis of the systolic blood pressure data from the Framingham Heart study to detect associated genes with common and rare variants.

491T

Meta-GWAS in cystic fibrosis indicates common variation in regulatory regions of modifier genes contributes to meconium ileus. *B. Xiao[1,14], N. Panjwani[1,14], J. Gong[1], G. He[1], K. Keenan[2], F. Lin[1], D. Soave[1,3], M. Drumm[4,5], G. Cutting[6,7], M. Knowles[8], H. Corvol[9,10], L. Sun[3,11], J.M. Rommens[1,12], L.J. Strug[1,3,11,13].* 1) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Program in Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 3) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 4) Department of Pediatrics, Case Western Reserve University, Cleveland, Ohio, USA; 5) Department of Genetics, Case Western Reserve University, Cleveland, Ohio, USA; 6) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 7) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 8) Cystic Fibrosis Pulmonary Research and Treatment Center, University of North Carolina, Chapel Hill, North Carolina, USA; 9) Pediatric Pulmonary Department, Hospital Trousseau, Assistance Publique-Hôpitaux de Paris (AP-HP), Institut National de la Santé et la Recherche Médicale (INSERM), U938, Paris, France; 10) Pierre et Marie Curie University–Paris 6, Paris, France; 11) Department of Statistics, University of Toronto, Toronto, ON, Canada; 12) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 13) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 14) These authors contributed equally to this work.

Genome-wide association studies (GWAS) by the International Cystic Fibrosis (CF) Gene Modifier Consortium (ICFGMC) previously identified SNPs near *SLC26A9* and *SLC6A14,* in addition to genes of the apical plasma membrane that reside alongside the causal CF transmembrane conductance regulator, as contributing to intestinal obstruction at birth (meconium ileus, MI). Here we report on a meta-GWAS for MI in an expanded ICFGMC population. CF patients (N=5,845) from the United States, Canada and France were genotyped genome-wide, and imputed to a common set of >12 million SNPs. Random effects meta-analysis determined association evidence at each SNP. Genome-wide significant findings were assessed in the context of available data from the Roadmap Epigenomics and ENCODE projects. SNPs annotated to genes of the apical plasma membrane as defined by AmiGO were tested as a set (n=157 genes; 4,172 SNPs), and a novel nested subset test was implemented to assess whether association was enriched when restricting to nearby *cis*-regulatory elements of the genes (n=157 genes; 212 SNPs). Five loci had SNPs that reached genome-wide significance, $P < 5*10^{-8}$. These included the previously reported *SLC26A9* and *SLC6A14*, and three novel loci containing *PRSS1*, *ABCG5/ABCG8* and *ATP12A*. *ATP12A* was recently reported to contribute to CF lung disease in animal models, and *PRSS1* encodes cationic trypsinogen, a biomarker of CF in newborns. The top ranked SNP, rs9969188, near the transcription start site (TSS) of *PRSS1* is in high linkage disequilibrium (LD) with a promoter variant associated with pancreatitis, and reported luciferase assays argue decreased PRSS1 levels may increase MI risk. Rs12710568, a SNP in high LD with the top ranked *SLC6A14* variant, falls just 5' of the *SLC6A14* TSS. Analysis of chromatin states, DNase hypersensitivity, phylogenetic conservation and transcription factor binding suggest associated SNPs also influence *SLC26A9* expression levels. In addition, independent of the 5 significant loci, our nested subset test suggests the association of apical constituents is enriched when restricted to nearby *cis*-regulatory regions (-5kb to +2kb of the TSS of each gene; p<0.0001).   The positions of the genome-wide significant SNPs, and of the subset of associated variants from the apical plasma membrane constituents suggest their contributions to MI risk may be through expression regulation. These results may inform a broader mechanism for variation in CF disease severity.

492F

Accounting for population stratification in joint analyses of host and pathogen genomes to control type I and type II error rates. *N. Chaturvedi[1,2], O. Naret[1], J. Fellay[1,2].* 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland.

A joint analysis of host and pathogen genomes (genome-to-genome or G2G analysis) can identify variants in the host genome that put a selective pressure on the pathogen genome. G2G can suffer from inflated type I error rate as well as low power due to systematic differences in host and/or pathogen population. In this work, we show through several simulation studies that correcting for both host and pathogen stratification reduces false positive and false negative results. We used the Balding-Nichols model for generating the host SNPs. Using these simulated host SNPs, the pathogen data was generated from a combination of Balding-Nichols and logistic models. This gave us a binary matrix representing amino acid variations in the pathogen genome. To detect associations, we used logistic regression with dichotomized pathogen data as dependent variables and host SNPs as independent variables. To prevent spurious associations due to host population stratification, we included the top five principal components of the genotyping data as covariates. To correct for pathogen stratification, we included either viral genotypes, or alternatively linear, nonlinear or phylogenetic principal components of viral amino acid variation as covariates. In a scenario where the only observed associations were due to host and pathogen stratification, we observed a better control of type I error rate after adjustment for both host and pathogen genetic structure. For example, the p-value of association between a simulated host SNP and pathogen amino acid (both contributing to stratification, but not associated with each other) was 1.5×10^{-21}; it was still significant after correcting for host or pathogen stratification ($p_{host} = 2.9 \times 10^{-10}$; $p_{pathogen} = 5.2 \times 10^{-9}$), but correcting for both made the association non-significant ($p_{both} = 0.06$). When true associations between host and pathogen variants were simulated, we saw an overall improvement in the strength of associations (example: $p_{nocorrection} = 4.1 \times 10^{-6}$, $p_{host} = 2.3 \times 10^{-8}$, $p_{pathogen} = 3.5 \times 10^{-7}$, $p_{both} = 6.2 \times 10^{-10}$) upon adjustment for stratification from both sides. Furthermore, even when the stratification was only from one side (host or pathogen), adding both as covariates in the model did not over-correct or diluted the true signals. Currently we are applying our method to jointly analyze HIV host and viral genome for detecting potential host genetic effects on the diversity of HIV virus.

Statistical methods for rare variant test for multiple phenotypes. *D. Dutta, S. Lee.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

In genetic association analysis, a joint test of related multiple phenotypes can provide novel insights into the genetic architecture of complex diseases. Although a number of methods have been developed for multiple phenotype tests for common variants, only a few exist for rare variants. Here we present two broad strategies to combine multiple phenotypes, nonparametric PCA-based and parametric regression-based approaches, and incorporate them into gene or region-based rare variant tests. The PCA-based approach performs a variance component test for associations using the principal components of the phenotypes, with no assumption on the effect sizes of the variants, and aggregates association signals across multiple PCs with leveraging on their orthogonality. The regression-model-based approach models the distribution of the effect sizes of the variants to multiple phenotypes through a correlation structure in mixed models and conducts a variance component test for associations. In addition, we combine the results of these different approaches through various aggregating strategies such as the minimum p-value and the weighted sum of test statistics. Furthermore, using Copula, we propose a resampling-based fast computation method to obtain a p-value of the minimum p-value-based combined test. From extensive simulation studies, we show that the proposed tests can improve power over a standard approach of aggregating single-phenotype test p-values, while maintaining type-1 error rate. The relative performance of these tests depends on the number of associated phenotypes and correlation patterns. The combined tests had robust power regardless of the genetic model. From the analysis of a real data example, we also show the superior performance of our methods.

494T

Assessing phenome-wide consequences of gene regulation using 40 human tissue expression prediction models. *H.K. Im[1], A. Barbeira[1], J. Zheng[1], E.S. Tortensen[2], J.M. Torres[1], S.P. Dickinson[1], K.P. Shah[2], H.E. Wheeler[3], T.L. Edwards[2], G.I. Bell[1], D.L. Nicolae[2], N.J. Cox[2].* 1) The University of Chicago, Chicago, IL; 2) Vanderbilt University, Nashville, TN; 3) Loyola University Chicago, Chicago, IL.

GWAS and sequencing studies have yielded thousands of genetic variants robustly associated with complex traits. However, the underlying biology of those associations needs to be further elucidated. To address this issue we have proposed a method called PrediXcan that links these genetic variants with likely causal genes using the correlations between genetically predicted expression levels and phenotypes. Our method tests whether the transcript-level consequences of genetic variation have an effect on a specific phenotype and is similar in some respect with Mendelian randomization-based approaches. Recently, we have developed an extension called MetaXcan, which can infer PrediXcan results using only summary results from GWAS. Among the advantages of our approach are that it a) directly tests a biological mechanism, b) provides gene level results, c) provides directions of effect (which can be used to prioritize drug targets since positively correlated genes have the potential to reduce disease risk when knocked down), d) the multiple testing burden is reduced, and e) provides tissue specific results. To implement our approach we have developed prediction models for gene expression in 40 tissues using the GTEx Consortium and Depression Genes Network data and applied it to 117 phenotypes with publicly available GWAS meta analysis results. These include results from large consortia such as DIAGRAM, MAGIC, PGC, among others. We validate our approach by re-identifying many established genes but in many cases, we find evidence that genes in the vicinity of reported ones are more likely mediators of the phenotype. These results, software, and all prediction models necessary to reproduce them or apply to new datasets are made publicly available on https://github.com/hakyimlab/PrediXcan.

Efficient phenome-wide analyses of large-scale sequencing data. *X. Zhan[1], B. Li[2], G. Abecasis[3], D. Liu[4].* 1) University of Texas Southwestern Medical Center, Dallas, TX; 2) Vanderbilt University; 3) University of Michigan; 4) Pennsylvania State University.

The advancement of technology has enabled medical researchers to collect an unprecedented amount of big data that are represented in three dimensions: the growing number of phenotypes (e.g., thousands of phenotypes via Electronic Medical Records or biobanks), the increasing sample sizes in large studies (e.g., the UK10K and UK Biobank projects), and the millions of genetic markers (e.g., imputation outcomes). Traditional analytical approaches can take months or years, which is computationally inhibitive. Thus there is an emerging need to efficiently analyze these big datasets in order to gain scientific insights. In order to solve this problem, we developed a new computationally efficient model and improved computational speed suited for phenome-wide analysis. The software implementation (RVTESTS) can be readily applied. It is benchmarked on the UK10K dataset, which includes 1854 samples, along with their 46 phenotypes and 43 million variants, and can be analyzed within one day. Further evaluated in a larger simulated dataset (100,000 individuals and 50 phenotypes), RVTESTS can analyze half a million variants per day. Our software can also be easily improved using parallel computations. We conclude that the computational speed and memory consumption of this tool outperform other popular approaches. In all, we have proposed a useful and efficient approach to tackle the needs of performing phenome-wide analysis of large-scale data sets.

496W

Efficient calculation of genetic correlations across 700,000 pairs of diverse phenotypes. *A. Kleinman, N. Furlotte, A. Auton, D. Hinds.* 23andMe, Inc., 899 W. Evelyn Ave., Mountain View, CA 94041.

The genetic correlation between a pair of traits is the proportion of phenotypic variance attributable to shared genetics. Specifically, assuming an infinitesimal model, two traits are said to be genetically correlated if effect sizes of SNPs associated with the traits are themselves correlated. This is not necessarily the same as phenotypic correlation, as two traits can be highly correlated in phenotypic space but not in genetic space if their correlation is solely induced by shared environmental factors. We used LD Score Correlation, a recently developed method that calculates genetic correlation from genome-wide association study (GWAS) summary statistics, to compute genetic correlations across more than half a million pairs of self-reported phenotypes. We replicated dozens of published correlations and found tens of thousands more across a diverse array of traits, including autoimmune, cardiovascular, infection, lifestyle, morphological, neurological, sleep, personality and reproductive phenotypes. Given the direct availability of phenotypic data, we showcased situations in which high phenotypic correlation is observed in the absence of high genetic correlation, and vice versa. Collectively, these correlations paint both a broad and detailed portrait of shared genetics across the spectrum of human traits and diseases.

497T

Multiple HCV amino acid variants associate with interferon lambda polymorphism in genotype 1a, 1b and 3a infections. *J. Fellay[1], N. Chaturvedi[1], K. Chodavarapu[2], M. Lin[2], A. Osinusi[2], E. Svarovskaia[2], H. Mo[2], D. Brainard[2], M. Subramanian[2], J. McHutchison[2], S. Zeuzem[3].* 1) School of Life Science, EPFL, Lausanne, VD, Switzerland; 2) Gilead Sciences, Foster City, USA; 3) Department of Medicine I, J.W. Goethe University Hospital, Frankfurt, Germany.

   A specific human genetic polymorphism in the interferon lambda (IFN-λ) region, tagged by SNP rs12979860, is associated with spontaneous clearance of HCV infection and with response to interferon-based antiviral treatment. A recent report also showed a higher prevalence of pretreatment NS5A variant Y93H in genotype (GT) 1b patients homozygous for the C allele at rs12979860. Here, we evaluate the associations between HCV amino acid variants and IFN-λ polymorphism in >7000 patients from various geographical regions and ethnicities, infected with HCV genotype 1a, 1b or 3a. We used logistic regression to search for associations between rs12979860 and amino acid variation in NS3, NS4A, NS5A and NS5B in a total of 7131 chronically infected HCV patients (GT1a, n=3623; GT1b, n=2010; GT3a, n=1498). HCV consensus sequences were obtained by next generation of sequencing on Illumina MiSeq, and binary variables were created for each non-conserved amino acid present in at least 0.3% of samples. We ran the analyses on all samples and in subgroups defined by HCV genotypes. To prevent spurious associations due to host and viral stratification, we included the following covariates in all regression models: gender, country of origin, self-reported ethnicity, cirrhosis status, prior treatment experience, SVR12 information and viral genotype. Associations with a p-value lower than the Bonferroni adjusted threshold ($p < 3.6 \times 10^{-5}$) were considered significant. A total of 73 HCV amino acids were significantly associated with rs12979860 (8 in NS3, 3 in NS4A, 44 in NS5A and 18 in NS5B). The strongest associations were observed in and around the highly variable interferon sensitivity-determining region of NS5A (top associated variant: I280V, $p = 2.8 \times 10^{-23}$). We also confirmed the association between the NS5A variant Y93H and IFN-λ polymorphism ($p = 5.4 \times 10^{-15}$). In the genotype-specific models, we detected 68, 38 and 26 significant associations for genotype 1a, 1b and 3a, respectively. The difference in the number of significant associations between subgroups most likely reflects an effect of sample size on statistical power. We also observed that patients with the rs12979860 CC genotype have a higher prevalence of multiple amino acid changes, including Y93H, a naturally occurring NS5A inhibitor resistance-associated mutation. This study provides strong evidence of pervasive viral adaptation to innate immune pressure from the host during chronic HCV infection.

498F

Frequency of arylsulfatase A pseudodeficiency in healthy Mexican individuals, haplotypes construction and enzyme activity determination. *A. Juárez[1], S. Mendoza[2], T. Da Silva[1,2], A. Porras[1,2], E. García[2].* 1) Instituto de Genética Humana "Enrique Corona Rivera" , Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Bioquímica IB, División de Genética, Centro de Investigación Biomédica de Occidente, Guadalajara, Jalisco, México.

   Introduction. One of every 50 healthy individuals has a substantial deficiency of arylsulfatase A (ASA, EC 3.1.6.8). These individuals express even a tenth of the normal enzyme activity without developing the disease. The ASA pseudodeficiency (PD-ASA) is mainly associated to the presence of two alleles: the first; c.1055A> G (p.N352S; rs2071421), causes the loss of one of the three N-glycosylation sites in ASA, while the second; c. * 96A> G (rs6151429), leads to the loss of polyadenylation signal in exon 8, both in *ARSA* gene. This work was performed in order to determine the frequency of PD-ASA in Mexico. Material and methods. Samples of 200 healthy mexican individuals were included in the study. The determination of enzyme activity of ASA in leukocytes was accomplished by a modification of the Percy assay and 4-nitrocatechol sulfate substrate (Sigma® LifeScience). The polymorphisms analysis was performed by RFLPs, with *Dde*I and *Bsr*I (Time-SaverTM New England BioLabs® Inc.). The genotypes were confirmed by Sanger sequencing with Big Dye Primer Kit (Applied Biosystems) and ABI Prism 310 (Applied BioSystems). Finally, through Arlequin v.10.04 haplotypes were constructed and the analysis of linkage disequilibrium was performed with X Cube. Results and discusion. The results of enzyme activity of the total population showed a 95% CI of 1.74-2.09 nmol / mg protein / min. Allele, genotype and haplotype frequencies of c.1055A> G and c.*96 A> G polymorphisms were obtained, the mutated allele (G) was observed in 21% (86 of 400 alleles) for the first polymorphism and 4% (16 of 400 alleles) for the second one. 15 individuals were positive for GG haplotype (frequency 0.04, 4%) with ASA activity of 0.53-0.95 nmol / mg protein / min and no AG haplotype was found. The linkage disequilibrium statistics were: D '= 1, r2 = 0.1477. Conclusion. For the first time in Mexico, the presence of the alleles of PD-ASA is demostrated, the frequencies were in Hardy-Weinberg equilibrium. Alleles are found in linkage disequilibrium. The GG haplotype was found in 15 individuals, so the frequency of PD-ASA in Mexico is 7.5%, corresponding to the observed in other populations. No AG haplotype was observed. One individual has an ASA activity of 13%, that individual was homozygous for the G allele of both polymorphisms.

Modeling the covariance of effect sizes in a meta-analysis. *D. Duong[1], S. Snir[2], E. Kang[1], B. Han[3], E. Eskin[1].* 1) Computer Science, UCLA, Los Angeles, CA. USA; 2) Evolutionary & Environmental Biology, University of Haifa, Israel; 3) Department of Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center. Seoul. Republic of Korea.

Meta-analysis can be traced back to the 17th century studies of astronomy, and over the years, meta-analysis has become one of the most widely used method in many fields of research including medical, social, and biological sciences. Meta-analysis is a method that pools results from different studies on the same topic in order to infer a general conclusion and to measure the consistency among study findings. Two most popular meta-analysis paradigms are the fixed and random effects models. The fixed effect model assumes that all studies share a true underlying mean effects, whereas the random effect model allows for heterogeneity among the true effect sizes of the studies. The shortcoming of the classical random effects model is that it models heterogeneity assuming independent and identically distributed (i.i.d.) effect sizes. A more realistic scenario happens when some studies have samples that share certain characteristics so that the effect sizes of the studies tend to be more similar than usual. For example, consider several studies in a meta-analysis that target a disease with some treatment where half of the studies contain only male individuals and the other half contain only female individuals. Study findings using only male (or female) participants would be more similar among themselves; more precisely, the effects of the treatment among these studies are more correlated than effects between a male-only and a female-only study. In this paper, we introduce a meta-analysis method that models the covariance of the effect sizes among the studies in a meta-analysis. Our method extends a likelihood ratio procedure in a meta-analysis so that the covariance among the effect sizes can be easily accounted for. We use our new method to analyze 17 mouse High-density lipoprotein (HDL) studies containing 4,965 distinct animals. Our method attains better statistical power than previous methods and identifies more significant loci.

500T

Phenotype similarity regression for identifying the genetic determinants of rare diseases. *E. Turro[1], D. Greene[1], S. Richardson[2], NIHR BioResource.* 1) University of Cambridge, Cambridge, United Kingdom; 2) MRC Biostatistics Unit, Cambridge, United Kingdom.

Rare genetic disorders, which can now be studied systematically with affordable genome sequencing, are often caused by high-penetrance rare variants. Such disorders are often heterogeneous and characterized by abnormalities spanning multiple organ systems ascertained with variable clinical precision. Existing methods for identifying genes with variants responsible for rare diseases summarize phenotypes with unstructured binary or quantitative variables. The Human Phenotype Ontology (HPO) allows composite phenotypes to be repre- sented systematically but association methods accounting for the ontological relationship between HPO terms do not exist. We present a Bayesian method to model the association between an HPO-coded patient phenotype and genotype. Our method estimates the proba- bility of an association together with an HPO-coded phenotype characteristic of the disease. We thus formalize a clinical approach to phenotyping that is lacking in standard regression techniques for rare disease research. We demonstrate the power of our method by uncovering a number of true associations in a large collection of genome-sequenced and HPO-coded cases with rare diseases.

SMART: Statistical Metabolomics Analysis – An R Tool. *Y.-J. Liang[1,2], Y.-T. Lin[2], C.-W. Chen[2], C.-W. Lin[2], K.-M. Chao[1,3], W.-H. Pan[4], H.-C. Yang[2,5,6,7,8].*
1) Graduate Institute of Biomedical Electronics and Bioinformatics, National Taiwan University, Taipei 10617, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei 115, Taiwan; 3) Department of Computer Science and Information Engineering, National Taiwan University, Taipei 10617, Taiwan; 4) Institute of Biomedical Sciences, Academia Sinica, Taipei 115, Taiwan; 5) Institute of Public Health, National Yang Ming University, Taipei 11221, Taiwan; 6) Department of Statistics, National Cheng Kung University, Tainan 701, Taiwan; 7) Institute of Statistics, National Tsing Hua University, Hsinchu 30013, Taiwan; 8) School of Public Health, National Defense Medical Center, Taipei 114, Taiwan.

Metabolomics data provide unprecedented opportunities to decipher metabolic mechanisms by analyzing hundreds to thousands of metabolites. Data quality concerns and complex batch effects in metabolomics must be appropriately addressed through statistical analysis. This study developed an integrated analysis tool for metabolomics studies to streamline the complete analysis flow from initial data preprocessing to downstream association analysis. We developed Statistical Metabolomics Analysis – An R Tool (SMART), which can analyze input files with different formats, visually represent various types of data features, implement peak alignment and annotation, conduct quality control for samples and peaks, explore batch effects, and perform association analysis. A pharmacometabolomics study of antihypertensive medication was conducted and data were analyzed using SMART. Neuromedin N was identified as a metabolite significantly associated with angiotensin-converting-enzyme inhibitors in our metabolome-wide association analysis ($p = 1.56 \times 10^{-4}$ in an analysis of covariance (ANCOVA) with an adjustment for unknown latent groups and $p = 1.02 \times 10^{-4}$ in an ANCOVA with an adjustment for hidden substructures). This endogenous neuropeptide is highly related to neurotensin and neuromedin U, which are involved in blood pressure regulation and smooth muscle contraction. The SMART software, a user guide, and example data can be downloaded from http://www.stat.sinica.edu.tw/hsinchou/metabolomics/SMART.htm.

Incorporate technical variation to assess reproducibility of genome-wide methylation data. *W. Guan[1], Y. Bai[1], J.S. Pankow[2], E.W. Demerath[2], J. Bressler[3], M. Fornage[3], M.L. Grove[3], M.Y. Tsai[4].*
1) Division of Biostatistics, School of Public Health, University of Minnesota, Minneapolis, MN; 2) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, MN; 3) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 4) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN.

Genome-wide DNA methylation measures are now routinely used to investigate their association with various outcomes of interest. Inherent to the array-based DNA methylation measures, e.g., Illumina HumanMethylation450 (HM450) or Infinium MethylationEPIC chips, is the associated technical variation of non-biological interest. A commonly adopted strategy is to remove non-biological variation through preprocessing or normalization procedures. The processed data are then treated as the raw data (with only biological variation) and used in any downstream analysis. Intuitively downstream analysis can have improved statistical power and better accuracy of parameter estimates by accounting for technical variation. We have proposed a mixed effects model framework to incorporate technical variation, and developed an expectation–maximization (EM) algorithm to estimate the model parameters. We applied our proposed methods to the Atherosclerosis Risk in Communities (ARIC) methylation study. Specifically, we considered the bead-to-bead variation in the HM450 data. We calculated the intraclass correlation coefficients (ICC) for each CpG probe to evaluate reliability of the Illumina HM450 chip after accounting for the bead-to-bead variation, an extension of a previous study (Bose et al., 2014). We observed that the ICCs were improved by a median of 0.04, and ~6,000 probes have the updated ICCs close to 1, suggesting that most of the technical variation could be explained by the bead-to-bead variation at these sites. We think that accounting for bead-to-bead varation can improve power of association tests for future epigenome-wide association studies (EWASs) using methylation arrays.

503T

Multi-marker methylation predictors of clinical biomarkers. *M.W. Hattab[1], G.v. Grootheest[2], R.F. Chan[1], R. Jansen[2], A.A. Shabalin[1], L.Y. Xie[1], M. Zhao[1], S.L. Clark[1], B.W. Penninx[2], K.A. Aberg[1], E. J.C.G. van den Oord[1].* 1) Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, Richmond, VA, USA; 2) Department of Psychiatry, VU university Medical Center / GGZ ingest, Amsterdam, the Netherlands.

Biomarkers have become a standard approach to predict the risk of disease, diagnose patients, and monitor response to treatment. Their measurement typically involves collecting multiple biological samples (blood, saliva, urine and/or hair) and the use of a wide variety of laboratory assays or clinical tests. This makes the use of biomarkers typically time consuming, complex, and expensive. In this study we examine whether commonly used biomarkers have specific DNA methylation signatures in blood that could be used as alternative indicators. Methylation marks are potentially ideal as they involve the stable methyl-cytosine bond that can be measured in easy to collect genomic (histone-free) DNA. Furthermore, as different biomarkers may be captured by a single methylation assay, they could potentially provide a convenient and cost-effective one-stop alternative. To test our hypothesis we generated methylome-wide data in 1,159 samples using an optimized methyl-CG binding domain sequencing (MBD-seq) protocol that provide a cost-effective approach for assaying methylation status of almost all CpGs in the human genome. Rather than using individual sites, we use a method that combines all associated individual methylation markers into multi-marker predictors. Regularization regression methods such as elastic nets will be main tools for this purpose. Such methodologies enable the user to fit a model where the number of predictors exceed by far the number of observations. Coupled with a screening rule that eliminates sites that most likely have little or no effect, we have successfully applied them to millions of sites. To obtain an unbiased assessment of the overall predictive power, a nested *10*-fold cross validation is implemented. To provide proof of concept, we first show that MBD-seq leads to a considerably more precise, likely because it assays many more sites, prediction of biological aging compared to common used methylation arrays. Next we study an extensive battery of biomarkers including blood lipids (e.g., total cholesterol), inflammation and immune response markers (e.g., absCRP), hormonal function (e.g., parathyroid hormone, vitamin D25, testosterone, and insulin-like growth factor-1) as well as measures of oxidative stress (e.g., 8-OHdG). In addition to study correlations of multi-marker predictors and the biomarkers they intend to measure, comparisons are made in term of their ability to predict short and long term clinical outcomes. .

504F

Association of chromosome 15q25 (CHRNA5/A3/B4) with smoking behavior generalizes to a Hispanic/Latino cohort. *L.S. Emery[1], T. Sofer[1], A.M. Stilp[1], S.M. Gogarten[1], M.P. Conomos[1], T. Louie[1], E. Perez-Stable[2], K.D. Taylor[3], C.C. Laurie[1], L. Bierut[4], N.L. Saccone[5], R.C. Kaplan[6].* 1) Biostatistics, University of Washington, Seattle, WA; 2) National Institute on Minority Health and Health Disparities, National Institutes of Health, Bethesda, MD; 3) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute, Torrance, CA; 4) Psychiatry, School of Medicine, Washington University in St. Louis, St. Louis, MO; 5) Genetics, Human genetics, Washington University in St. Louis, St. Louis, MO; 6) Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY.

Genetic variants associated with nicotine dependence have previously been identified and characterized, primarily in populations of European ancestry. In particular, variants in the chromosome 15 gene *CHRNA5* (encoding the α5 cholinergic nicotinic receptor subunit) have been unequivocally associated with nicotine dependence and heavy smoking in European, African, and Asian ancestry cohorts. However, no large-scale genome-wide study has examined the genetics of smoking behaviors in Hispanic/Latino populations. We examined genetic associations with smoking behaviors in participants from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). HCHS/SOL participants were recruited from four U.S. field centers (Miami, San Diego, Bronx NY, and Chicago). Consented individuals were genotyped at ~2.3 million SNPs, and imputed to the 1,000 Genomes Project phase 3 reference panel (~49 million imputed variants). Current smokers reported the average number of cigarettes smoked per day (CPD) in structured questionnaires. We performed GWAS of heavy (CPD > 10) versus light (CPD ≤ 10) smokers in 5,085 current smokers from the HCHS/SOL. We used a mixed logistic regression model that accounted for population structure, sampling design, shared household, relatedness, sex, and age. Heavy smoking varies substantially among HCHS/SOL participants, and rates of non-daily smoking are particularly high as compared to other U.S. populations. The known association of the CHRNA5 region with smoking generalized to the HCHS/SOL, with multiple correlated SNPs reaching genome-wide significance ($p \leq 5 \times 10^{-8}$). The known functional SNP, rs16969968, had a p-value of 2.20×10^{-7} with minor allele frequency (MAF) of 0.22 and an odds ratio of 1.32 for the minor allele (A). In groups based on self-reported country of origin, the minor allele frequencies for rs16969968 were: Central American = 0.18; South American = 0.19; Mexican = 0.18; Puerto Rican = 0.25; Dominican = 0.22. Conclusion: The association of variants in a nicotine receptor gene with smoking behavior, previously reported in Europeans, generalized to Hispanics/Latinos despite different patterns of smoking behavior. The generalization of the functional SNP rs16969968 to an additional population may provide further insight into its mechanism of function.

505W

A quasi-likelihood approach for transmission-based association mapping using sibship data. *H. Kulkarni, S. Ghosh.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India.

The classical transmission disequilibrium test (TDT) [Spielman et al. 1993] based on thetrio design is an alternative to the population based case-control design to detect geneticassociation as it protects against population stratification. Most of the complex diseases are governed by quantitative precursor and hence, it may be more prudent to analyze these quantitative traits rather than converting them in to endpoint traits. The test for transmission disequilibrium based on logistic regression [Waldman et al. 1999, Haldar and Ghosh 2015] use the same approach as the classical TDT that is based on allelic transmission from heterozygous parents. However, in the presence of the sibship data,the marginal effect of linkage can result in transmission bias of parental alleles and hence,the test is valid only for linkage. We modify the classical TDT procedure using quasi likelihood [Wedderbur 1974] based on Generalized Linear Regression model [McCullagh and Neldar 1989] using a logit link. Parameters of the models are estimated using the Generalized Estimating Equation (GEE) [Gourieroux, Monfort, and Trognon 1984; Liang and Zeger 1986] but this method is highly influenced by the outliers. We use a modifiedResistance Generalized Estimating Equation approach (RGEE) [Preisser and Qaqish1999, Preisser and Qaqish, 1996; Hall, Zeger, and Bandeen-Roche,1996] to down weight the outliers. Moreover, information on genetic association is contained not only on the allele transmitted by a heterozygous parent, but also the allele transmitted by the other parent. We modify the quasi likelihood approach by including the transmission information from both parents. Based on extensive simulations under different genetic models as well as for different probability models for trait value we compute the type-I errors and the powers of the proposed test procedures and compare the powers with FBAT [Lake et. al.2000]. We observe that the powers of the tests are comparable across different distributions of trait values. The simulations also indicate that the quasi likelihood approach is more powerful than FBAT and inclusion of transmission information from both parents increases the powers of the test procedures. The proposed approach can be easily extended for multivariate phenotypes comprising a mixture of the categorical, count and continuous phenotypes.

Clustering RNA-seq expression data using grade of membership models. *K.K. Dey, C.J. Hsiao, M. Stephens.* University of Chicago, Chicago, IL.

Grade of membership models, also known as admixture models, topic models or Latent Dirichlet Allocation, are a generalization of cluster models that allow each sample to have memberships in multiple clusters. These models are widely used in population genetics to model admixed individuals who have ancestry from multiple populations, and in natural language processing to model documents having words from multiple topics. Here we illustrate the potential for these models to cluster samples of RNA-seq gene expression data, measured on either bulk samples or single cells. Traditional clustering methods for this problem attempt to partition samples into distinct groups of similar expression patterns. However, it seems likely that oftentimes the structure of a typical gene expression data set will be too complex to be fully captured by such a partitioning. Motivated by this, here we analyse expression data using grade of membership (GoM) models, which generalize clustering models to allow each sample to have partial membership in multiple clusters. Our model allows that each sample has a proportion, or grade of membership in each cluster. We suggest the use of a "Structure" plot visualization, which represents the estimated membership proportions of each sample as a stacked bar-chart, with bars of different colors representing different clusters. Additionally, we also discuss ways to interpret the clusters by identifying the genes that are most distinctively expressed in each cluster. We applied these methods to several example RNA-seq applications to demonstrate its utility in identifying and summarizing structure and heterogeneity. Our applications include the GTEx V6 bulk RNA seq data and a couple of single cell RNA-seq data. Applied to the GTEx project data on 51 human tissues, the approach highlights similarities among biologically-related tissues and identifies distinctively-expressed genes that recapitulate known biology. Applied to single-cell expression data from mouse preimplantation embryos, the approach highlights both discrete and continuous variation through early embryonic development stages, and highlights genes involved in a variety of relevant processes from germ cell development, through compaction and morula formation, to the formation of inner cell mass and trophoblast at the blastocyte stage. The methods are implemented in the Bioconductor package **CountClust**.

Novel genomic predictor of bleeding risk in African Americans treated with warfarin. *T. De[1], W. Hernandez[1], N. Nwanze[1], E. Smithberger[1], T. O'Brien[2], M. Tuck[3], J. Duarte[4], S. Bourgeois[5], R. Kittles[6], M. Perera[1].* 1) Department of Medicine, The University of Chicago, Chicago, IL; 2) The George Washington University, Department of Pharmacology and Physiology, Washington, DC; 3) Veterans Affairs Medical Center, Washington, DC; 4) University of Florida, Gainesville, FL; 5) Queen Mary University, William Harvey Research Institute, Clinical Pharmacology - Heart Centre, London; 6) University of Arizona, Tucson, AZ.

   Hemorrhage is the major concern for patients treated with warfarin. The relative risk of major bleeding from warfarin is 44% higher in patients of African descent than of other ethnicities. The commonly studied genetic variants associated with bleeding explain substantially less variability in African Americans (AAs). Uncovering the causal variants is critical for safer use of the drug and drug selection. We conducted the first genome-wide association study in 546 AAs to identify the genetic predictors of warfarin induced bleeding requiring hospitalization at International Normalized Ratio (INR) <4, a range when most physicians do not consider warfarin reversal. To determine if clinical factors could further help to predict bleeding risk, the predictive performance of HAS-BLED (hypertension, abnormal renal/liver function, stroke, bleeding history, labile INR, elderly, drugs/alcohol) scheme was evaluated by Cox proportional hazards analysis and C-statistics. Genome-wide significant signal was observed for rs62420645 on chromosome 6 (OR=4.43, p=2.20x10^{-08}). Validation in 201 AAs confirmed this association (p=0.002, combined p=3.456x10^{-10}). A HAS-BLED score of ≥3 was associated with 2-fold risk of major bleeding (*p*=0.02). rs62420645 inclusion to HAS-BLED improved major bleeding risk prediction by correctly reclassifying 12.5% of major bleeding, thereby increasing sensitivity of prediction from 77.5% to 90% (C-indices: 0.70 vs. 0.65 for HAS-BLED+rs.62420645 vs. HAS-BLED respectively). The number needed to genotype to prevent one bleeding event was 8. *CYP2C9* star alleles showed no significant association with warfarin related bleeds. Our findings can help to predict clinically avoidable bleeding events and improve the safety of anticoagulation therapy in AAs.

Genetic variation and pulmonary tuberculosis susceptibility in Guinea-Bissau and The Gambia. *G. Tavera[1], A. Tacconelli[2], G. Morris[3], M. White[8], L. Sausville[8], C. Wejse[4], C. Ciccacci[7], P. Hill[5], C. Bisseye[3], W. Scott[6], G. Sirugo[2], S. Williams[1].* 1) Case Western Reserve University, Cleveland, OH, USA; 2) Unità di Genetica Medica, Ospedale San Pietro FBF, Rome, Italy; 3) MRC Laboratories, Fajara, The Gambia, West Africa; 4) Department of Infectious Diseases, Aarhus University Hospital, Skejby, Denmark; 5) Centre for International Health, University of Otago School of Medicine, New Zealand; 6) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Florida, USA; 7) Tor Vergata University, Rome, Italy; 8) Department of Genetics, Dartmouth College, Hanover, NH 03755, USA.

   The burden of tuberculosis (TB) in West Africa is responsible for more years of healthy life lost than any other infectious disease, apart from AIDS and malaria and is second only to AIDS in mortality. Treatment for TB is poor, with few novel therapies developed in the last 50 years. We analyzed two West African samples (Guinea-Bissau: n=289 cases and 322 controls; The Gambia: n=240 cases and 248 controls) to evaluate 60 single-nucleotide polymorphisms (SNPs) in 12 candidate genes that may be implicated pulmonary TB pathogenesis. Chi squared analysis identified rs10841847 in the C-Type Lectin Domain Family 4, Member E (*CLEC4E*) gene as significant after Bonferroni correction in the Guinea Bissau population (p=0.0008644). It was not significant in the Gambian population. *CLEC4E* is involved in diverse functions, including cell adhesion, cell-cell signaling and inflammation and immune responses. Although they did not pass Bonferroni correction, other SNPs reached significance in The Gambia samples alone (rs1800896, *IL10*, p= 0.0305 and rs163790, *CTSZ*, p=0.02166) and the Guinea Bisseau samples Analysis for epistasis using MDR and ViSEN software revealed weak epistatic interactions between the assayed SNPs. Further analysis of the ethnic backgrounds of study participants may clarify the significance of these SNPs.

509T

Utility and biases of multiple whole genome methods to estimate heritability and examine genetic architecture of complex traits. *L.M. Evans[1], R. Tahmasbi[1], P. Visscher[2], J. Yang[2], S. Vrieze[1], B. Neale[3], D. Bjelland[1], T. DeCandia[1], G. Abecasis[4], S. Das[4], M. Keller[1], Haplotype Reference Consortium.* 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Queensland Brain Institute, University of Queensland, Brisbane, Queensland, Australia; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 4) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA.

Statement of Purpose: Complex trait genetic architecture has important implications for disease genetics as well as providing fundamental understanding of human evolutionary genetics. Narrow-sense heritability (h^2) is a central concept to this, yet the h^2 estimated from family studies of most complex traits cannot be explained by significant genome-wide associated genetic markers— the so-called missing h^2 problem. Recently, a number of methods—GREML, LD score regression, LDAK, treelets, etc.—have begun to examine the source of this missing h^2 using genome-wide markers in unrelated individuals. We compared these methods to understand their performance across different genetic architectures, levels of stratification, and marker type (common SNPs from arrays vs. sequence data) using simulated phenotypes in real whole-genome sequence data. Methods Used: We used a subset of ~21K whole genome sequences from the Haplotype Reference Consortium to generate phenotypes (h^2=0.5) from 1K causal variants (CVs) chosen randomly from different minor allele frequency (MAF) categories from common to very rare. We then used either the whole genome sequence data or positions found on common SNP arrays to estimate h^2 and examine genomic architecture in mixed effects models (GREML) using genetic relationship matrices (GRMs) estimated from 12 different methods across levels of stratification. Summary of Results: Using SNP array genotypes, most methods estimated common CV phenotype h^2 well, but progressively underestimated h^2 for rarer CV phenotypes. Furthermore, with array SNPs, most methods cannot accurately estimate the variance explained by rare CVs when the phenotype is derived from a mix of common and rare CVs. In contrast, using whole genome sequence data, the use of multiple, MAF-stratified GRMs in the GREML model accurately estimated total h^2 and partitioned the variance between rare and common CVs. This was true regardless of sample stratification. When using a single GRM, even if adjusted to better estimate relatedness such as with Treelet Covariance Smoothing, estimates were highly dependent on both the genetic architecture and the degree of sample stratification and could be strongly biased. Thresholded GRMs also produced highly variable biases. Finally, GREML estimates based on GRMs from identical-by-descent segments detected from SNP array data in unstructured populations appeared to provide better estimation of both rare and common causal variants.

510F

A phenome-wide gene burden analysis to identify DrugBank genes associated with patient diagnoses. *S.A. Pendergrass[1], S.S. Verma[1], N. Josyula[1], D. Hartzel[1,2], D. Lavage[1,2], S. Mukherjee[3], O. Gottesman[3], H.L. Kirchner[1,2], F.E. Dewey[3], M.D. Ritchie[1].* 1) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 2) Phenotypic Analysis and Clinical Data Core, Geisinger Health System, Danville PA; 3) Regeneron Genetics Center, Tarrytown NY.

Genetic variation such as loss of function (LOF), can mimic the effect of drugs as well as increase risk or protection for specific diseases. There are ~800 unique genes in DrugBank (http://www.drugbank.ca/) that have been identified in pathways that most drugs target. To identify DrugBank genes associated with a comprehensive series of diseases we performed a gene burden based phenome-wide association analysis (PheWAS) using low frequency (minor allele frequency < 1%) variants. We used whole exome sequencing data from 38,568 unrelated European American adults (>18 years of age) from DiscovEHR, and 541 ICD-9 based diagnoses from the Geisinger Health System electronic health record. We contrasted binning rare variants across genes two ways: all rare variants within the genes and only LOF and non-synonymous variants via different filters. We collapsed low frequency variants by gene using a software tool Biobin, and for association used a Madsen Browning style weighted burden based approach with logistic regression. All models were adjusted for the covariates of age, sex and the first 4 principal components reflecting global ancestry. Among our many highly significant results, the most significant was between low frequency variants in the gene *CASR* associated with hypercalcemia (ICD-9 275.42, p=1.43x10^{-22}), passing a Bonferroni significance threshold of 1.18x1^{-7}. This gene is a calcium receptor, and the drug cinacalcet targeting this gene is a treatment for calcium homeostasis. With *CASR,* testing for all variants regardless of function did not show a significant association, showing the association is driven mainly from LOF variants. The gene *GUCY1A2* was significantly associated with orthostatic hypotension (p=2.41x10^{-9}). Drugs that target this gene are nitric oxide and isosorbide mononitrate, and are treatments for the respiratory and cardiovascular system. We also found a significant association between *TACR1* and chronic sinusitus (p=8.10x10^{-10}), however the diagnosis is unrelated to drug treatments targeting this gene. Our current work includes contrasting our associated diagnoses for these genes with why specific drugs are prescribed including direction of effect of the associations, and pathway based analyses. Also important is identification of potential pleiotropy showing contrasts in increased risk or protection for traits for these genes. This study represents a unique gene-based rare variant PheWAS with a series of novel associations.

511W

Using maximum allele frequencies across populations greatly increases power for Mendelian gene discovery. *T. Mori[1,2], S. Uchida[2], D.A. Nickerson[3], M.J. Bamshad[1,3,4], J.X. Chong[1], University of Washington Center for Mendelian Genomics.* 1) Department of Pediatrics, University of Washington, Seattle, WA, USA; 2) Department of Nephrology, Tokyo Medical and Dental University, Tokyo, Japan; 3) Department of Genome Sciences, University of Washington, Seattle, WA, USA; 4) Division of Genetic Medicine, Seattle Children's Hospital, Seattle, WA, USA.

Identification of a putative causal variant in exome/genome sequence data from an individual with a Mendelian condition (MC) typically proceeds by filtering for variants that follow the expected inheritance pattern and are rare (i.e. alternative allele frequency falls below a specified cutoff frequency in population controls). Data from large population control datasets, including the 1000 Genomes Projects (1KG), Exome Variant Server (EVS), and the Exome Aggregation Consortium (ExAC), are widely used, and each provides global allele frequencies (globalAAF) as well as allele frequencies within each constitutive subpopulation (i.e. Europeans, East Asians, Africans, etc.). Intuitively, causal variants for highly penetrant MCs should be rare across almost all human populations (excluding small founder populations) because the vast majority of pathogenic variants for MCs are pathogenic regardless of ancestry and should thus be rare in every population. Yet many published analyses [99% (80/81) of all Mendelian gene discoveries published in the American Journal of Human Genetics in the past year] continue to filter on globalAAF instead of the maximum population frequency across all subpopulations (maxAAF). To quantify the increased power obtained by using maxAAF instead of globalAAF, we used standard analytical parameters (e.g. filtering for variants that are non-synonymous, splice, or UTR) to analyze data from 2,504 unrelated individuals in 1KG under common Mendelian inheritance models, comparing the number of candidate genes identified using globalAAF versus maxAAF as the allele frequency filter. Under an autosomal dominant model, maxAAF decreased the median number of candidate genes per individual by nearly 40% (477 with globalAAF vs. 280 with maxAAF); under a homozygous recessive model, the median number of candidate genes was 2 vs. 1, respectively; and under a compound heterozygous model, the median number of candidate genes was 17 and 7. These differences were highly significant (Wilcoxon rank-sum test: $p < 2.2 \times 10^{-16 \text{ to } -12}$). Using maxAAF rarely eliminates variants classified as pathogenic/likely pathogenic by ClinVar and consistently results in a ~50-80% decrease in the number of candidate genes identified compared to using globalAAF. Adoption of maxAAF as the gold standard for frequency cutoff during variant filtration can substantially reduce the number of candidate genes for a given MC and should facilitate successful discovery of the underlying gene.

512T

Trajectory of new variants requiring pathogenicity assessment as potential secondary findings across 50,000 exomes in the DiscovEHR cohort. *U.L. Mirshahi, A.H. Wardeh, K. Manickam, B. Moore, T. Mirshahi, D.J. Carey, M.F. Murray, the Geisinger-Regeneron DiscovEHR Collaboration.* Weis Center for Research, Geisinger Clinic, Danville, PA.

Any project that seeks to deliver incidental or secondary genomic findings to participants in a large cohort faces pipeline bottlenecks related to the pathogenicity assessment for newly encountered variants in a gene of interest. The Geisinger GenomeFIRST return of results program intends to return secondary findings in 76 genes (G76) to a cohort of 50,000 participants who have undergone whole exome sequencing (WES) as part of the Geisinger-Regeneron DiscovEHR collaboration. In this study, the hypothesis is that the number of *new variants requiring pathogenicity assessment* (NVRPA) would decrease as the cohort increases. From our 50,000 WES, 5 groups of 10,000 samples were randomly selected. We examined all G76 non-synonymous coding and splicing variants characterized as NVRPA in each 10,000 exome increment. In a second examination, NVRPA for just one of the G76, *LDLR*, were identified. In the case of this gene, efforts to identify pathogenic/likely pathogenic (P/LP) variants had already taken place across the 50,000 (Abul-Nusn et al. abstract); therefore, the number of NVRPA called P/LP could also be ascertained.   In the G76, there were 6574, 3092, 2284, 1697, and 1380 NVRPA in the first, second, third, fourth, and fifth 10,000 exomes, respectively. For *LDLR* alone there were 152, 56, 49, 32, and 32 NVRPA in the first, second, third, fourth, and fifth 10,000 exomes, respectively. Finally for *LDLR*, there were 17, 6, 5, 5, and 2 newly encountered P/LP variants in the first, second, third, fourth, and fifth 10,000 exomes, respectively. In the first 10,000 samples, 44% of all G76 NVRPAs, 47% of all *LDLR* NVRPAs, and 49% of all P/LP *LDLR* NVRPAs were identified for assessment. Thus, most NRVPA will be encountered in the first few thousands of WES samples; the majority of NVRPA in the latter 10,000s are likely novel variants (no functional or family data). Thus, they will likely be classified as variant of unknown significance with a very small number of benign or putative loss of function variants.   In the predominantly European-American cohort, the NVRPAs are expected to become less of a bottleneck to return results to patients as we progress through the cohort. Our data suggests that the majority of unique P/LP variant calls are likely to be made early in the analysis of a large cohort. A more diverse cohort will likely see greater magnitudes of NVRPA; however, a similar pattern of decreasing NVRPA will likely emerge as the cohort grows.

Haplotype-based predictors for complex trait association. *R. Brown[1], B. Pasaniuc[1,2,3].* 1) Bioinformatics IDP, UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 3) Department of Human Genetics, UCLA, Los Angeles, CA.

A large portion of current genetic research looks for associations between phenotype and genotype. One of the most common methods for this is a standard linear regression of a phenotype on single nucleotide polymorphisms (SNPs). An assumption of this method is that underlying causal architectures disproportionally fall on the set of haplotypes defined by the presence of one of the SNP alleles. While this assumption may be valid for some loci if there is only a single causal architecture in a locus, recent work has shown that there are often multiple causal variants per locus and non-linear causal architectures. In such cases, no SNP necessarily tags the set of haplotypes that contains all the architectures positively affecting a trait. We develop a method that tags the greatest number of haplotype sets for a genetic region as opposed to the greatest number of SNPs in that region. We use the 1000 Genomes data and a list of DNase 1 hypersensitivity sites (DHSs) (Gusev, AJHG 2014) to determine all possible sets of common haplotypes (>5% frequency in Europeans) occurring in a DHS. We develop set predictors to tag the haplotype sets. Using the same number of set and SNP predictors, we show that set predictors tag (with an $r^2 > 0.8$) a greater proportion of the possible haplotype sets than do SNP predictors. Since the set predictors are tagging more of the possible haplotype combinations, it should increase power to detect loci that contain multiple causal variants or non-linear causal architectures.

514W

Interrogating gene-by-environment interactions using genetic risk scores. *N. Furlotte, V. Vacic, G. Benton, A. Auton, D. Hinds.* 23andMe Inc., Mountain View, CA.

The effect of genetic variation is dependent on the environment in which it is expressed. This interaction between genetic and environmental variation is of fundamental importance to our understanding of basic biology as well as the etiology and progression of disease. As such, the ability to quantify gene-by-environment interactions will play a key role in the application of personalized medicine. By understanding the effect of genetic risk factors in differing environmental contexts, clinicians will be better able to tailor therapeutic recommendations to specific patients. For example, the effectiveness of certain dietary and exercise recommendations may depend on underlying genetic propensity for obesity. Unfortunately, gene-by-environment interactions (GxE) remain notoriously difficult to identify, due in part to the low statistical power for discovery resulting from small effect sizes. However, recent work has demonstrated that it is possible to detect interactions by aggregating genetic effects, even when the power to detect individual GxEs is low. In this approach, GxE interactions are identified by constructing a genetic risk score (GRS) and testing for interaction between the score and an environmental condition. Here, we investigate interactions between a GRS computed using over 350 BMI-associated SNPs and different environmental conditions. Using a cohort of over 300,000 consented research participants from the 23andMe customer base, we show that there is a statistically significant interaction between the GRS for BMI (grsBMI) and exercise frequency (p = 1.32e-17) as well as fast food intake (p = 6.34e-18). To quantify the effect of the GRS on true BMI, we estimate the amount of increase in true BMI expected from a one unit increase in grsBMI and then compare estimates under different environmental conditions. The effect size among those who exercise is 0.97, increasing to 1.7 for those who do not exercise. Similarly, we find that the effect among those who frequently eat fast food is 1.87, while only 1.21 in those who consume infrequently. This discrepancy becomes more extreme depending on how you define "frequently." Additionally, we explore how environment affects heritability estimates. Taken together, our observations imply that the expected effects of diet and exercise are dependent on genetic predisposition.

515T

Trans-ethnic comparison of partitioned heritability reveals shared cell-type specific enrichment between East Asian and European genome-wide association studies. *M. Kanai[1], M. Akiyama[1], Y. Okada[1,2], M. Ikeda[3], N. Iwata[3], M. Kubo[4], Y. Kamatani[1].* 1) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 2) Department of Statistical Genetics, Osaka University Graduate School of Medicine, Osaka, Japan; 3) Department of Psychiatry, Fujita Health University School of Medicine, Aichi, Japan; 4) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan.

Genome-wide association studies (GWAS) have identified thousands of loci associated with human diseases and traits. There has long been a strong interest in the so-called "missing heritability", where genome-wide significant SNPs could only explain a small portion of heritability expected. Recent works in the LD score regression (LDSC) enable us to estimate the total variance explained by all or partial common SNPs, even when only summary statistics are available, which facilitates understanding the complex genetic backgrounds of human traits. With a sufficient sample size, the LDSC approach is theoretically applicable to any GWAS of any population. However, previous works were primarily based on the result of European GWAS, since currently fewer massive GWAS have been conducted for other populations, and there lacks both summary statistics and LD score references for them. Here, we report a trans-ethnic comparison of LDSC analysis (genetic heritability, genetic correlation and partitioned heritability) based on East Asian GWAS for 10 complex traits (including rheumatoid arthritis, body mass index, adult height, schizophrenia, bipolar disorder, and type 2 diabetes; mainly from the BioBank Japan project) and publically available European GWAS for the corresponding traits. We found that both overall and partitioned genetic heritability were largely consistent between populations where substantial heritability was observed. For example, we observed a similar proportion of estimated heritability (h_g^2 = 0.326 [s.e. 0.016] and 0.313 [0.014] for East Asians and Europeans, respectively) and significant correlations of categorical enrichment coefficient z-scores in 53 functional categories (r = 0.72, P = 1.22 × 10^{-9}), 10 cell-type-group specific categories (r = 0.96, P = 1.47 × 10^{-5}), and 220 cell-type specific categories (r = 0.92, P < 2.2 × 10^{-16}) between East Asian and European GWAS of adult height. Remarkably, cell-type specific enrichment showed a distinct pattern among related traits regardless of populations, which allowed us to cluster traits based on the earned profile of cell-type specificity. Our results suggested that the proportion of heritability was often shared between East Asians and Europeans, illuminating uniquely shared cell-type specificity of related traits across populations. In addition, we evaluated the trans-ethnic genetic correlation between East Asian and European GWAS, using the *popcorn* software.

516F

The effect of varying selection criteria at each stage of tiled regression on power and type I error. *J.A. Sabourin, H. Sung, A.J.M. Sorant, A.F. Wilson.* Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore MD, 21224, USA.

In staged modeling procedures such as tiled regression, which may use stepwise selection on subsets of genetic variants at hotspot-based tile, chromosome, and genome-wide stages, the choices for analysis parameters at each stage can affect the final outcome. The impact that these choices have on the SNPs selected at the final stage has not been fully explored. In this study, we investigated the effects of different critical value settings in tiled regression on both type I error and power with a simulated quantitative trait with a causal model based on the Trinity Student Study GWAS data comprised of 757533 SNP genotypes in 2232 unrelated individuals. The simulation model was based on additive effects of 5 independent causal SNPs on chromosome 4, each with a locus specific heritability of 0.01. The causal SNPs were selected such that there were no missing values in the data set and the minor allele frequency was approximately 0.05. Two-hundred replicates from this model were generated and analyzed with tiled regression, as implemented in TRAP v2.0, under two critical value settings: (1) a fixed critical value (10^{-5}) for each of the 3 stages and (2) a set of critical values beginning with a liberal value (10^{-3}) at the tile stage and becoming more conservative at each consecutive stage (10^{-4} at the chromosome stage and 10^{-5} at the genome stage) so that the critical value at the final stage matched that of setting 1. Observed type I error rates were estimated based on the 712,830 SNPs remaining after exclusion of SNPs on chromosome 4 to ensure an estimate based on SNPs that were independent of the causal SNPs. The observed type I error rate when using critical value setting 1 was 3.25x10^{-6} and when using critical value setting 2 was 5.72x10^{-6}, which, although still conservative, was closer to the nominal rate of 10^{-5}. Power was estimated as the proportion of the 5 causal SNPs selected at the final stage, averaged over replicates. Analysis using critical value setting 1 had observed power 0.386, slightly lower than that using setting 2, which was 0.395. In our simulation experiments, we found that the use of a liberal critical value at the first stage of tiled regression with successively more conservative values at later stages (setting 2) achieved a type I error rate closer to the nominal value along with increased power when compared to the setting using a fixed critical value at all stages (setting 1).

Contrasting regulatory architectures of complex traits. *A. Sarkar[1,2], Y. Park[1,2], M. Kellis[1,2].* 1) Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Several computational models (GREML, PCGC regression, and LD score regression) have been developed to address the missing heritability problem, revealing common variants explain much of the heritability of complex traits. These models have provided numerous insights about the genetic architecture of complex traits, but they make a critical, non-realistic assumption which calls into question their use in partitioning heritability across regulatory annotations. Specifically, these models assume every genetic variant has an infinitesimal effect on phenotype. This assumption makes model inference feasible, by replacing an ill-specified regression problem with a simpler optimization problem. However, the resulting class of models cannot distinguish whether the observed enrichment in regulatory annotations stems from a higher density of causal variants in regulatory annotations, or simply larger effect sizes of causal variants within regulatory annotations relative to causal variants outside regulatory annotations. Additionally, this class of models does not apply to higher-resolution regulatory annotations, where they become mis-specified, leading to incorrect inferences. Here, we present an efficient genome-scale Bayesian sparse regression model that overcomes these limitations by introducing three key ideas. (1) We use recent advances in variational methods to perform approximate Bayesian inference on the high dimensional imputed dosage matrix and directly fit the underlying regression problem. (2) We formulate a novel re-parameterization of the approximation so the inference algorithm scales in the number of individuals rather than the number of variants. (3) We use biologically-motivated priors to enforce sparsity and directly model the effect of regulatory annotations on the prior probability of each variant being causal and its causal effect size. We systematically apply this model to both simulated and real genomic datasets to demonstrate its scalability and its accuracy, using: (1) idealized simulations on synthetic genotypes and annotations; (2) realistic simulations on imputed genotypes and true annotations from the Roadmap Epigenomics consortium; and (3) true annotations and imputed genotypes from the Wellcome Trust Case Control Consortium. We show that we can accurately recover non-infinitesimal genetic architectures, lending new insights into the regulatory architectures of seven complex diseases.

Estimating the frequency dependence of SNP effect sizes in human complex traits. *A.P. Schoech[1], P. Loh[1,2], P.F. Palamara[1,2], L. O'Connor[1], H.K. Finucane[1,3], A.L. Price[1,2].* 1) Harvard T.H. Chan School of Public Health, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Massachusetts Institute of Technology, Cambridge, MA.

Understanding the role of rare variants is of crucial importance to elucidating the genetic basis of human complex traits and diseases. It is widely hypothesized that negative selection may cause rare variants to have larger per-allele effect sizes than common variants, but the extent of this trend is currently unknown. Here, we present a statistical method based on linear mixed models to estimate the frequency dependence of SNP effect sizes in sequenced samples. We estimate the parameter α in a model in which per-allele effect sizes have variance $[p(1-p)]^{\alpha}$, where p is allele frequency and negative values of α imply larger effect sizes for rare variants. We employ a profile likelihood approach, using restricted maximum likelihood to estimate the phenotypic variance explained by the genotype data for a given α. This computation is repeated for different α values over a biologically plausible range, choosing the value that maximizes the overall likelihood as the estimate of α. Our simulations show that this method produces unbiased estimates under a wide range of genetic architectures. We applied the method to 3,567 samples from the UK10K cohort with whole-genome sequencing data and measurements for 13 quantitative phenotypes: height, body mass index, waist to hip ratio, heart rate, diastolic blood pressure, FVC:FEV1 ratio, hemoglobin levels, homocysteine, fasting glucose, adiponectin, HDL, LDL and total cholesterol. We included SNPs down to a minor allele frequency of 0.03% in our analyses. We obtained an estimate of $\alpha = -0.76 \pm 0.28$ across phenotypes, which is significantly different from zero, confirming that rare variants have larger per-allele effect sizes than common variants in this data set and implicating significant negative selection on the SNPs affecting these traits. To our knowledge, this is the first study quantifying the frequency dependence of allelic effects in whole-genome sequencing data. Application of the method to larger data sets will enable trait-specific estimates of α, providing a quantitative comparison of the impact of negative selection on different traits and informing the design of genetic association studies.

519F

Identity-by-descent as a proxy rare variant association test in large-scale genome-wide association studies. *J.N. Torres[1], J.R. Homburger[1], G.L. Wojcik[1], G. Belbin[2], S. Prabhu[1], C.D. Bustamante[1], E.E. Kenny[2], C.R Gignoux[1].* 1) Center for Computational, Evolutionary Human Genomics, Stanford, Stanford, CA; 2) Charles Bronfman Institute for Personalized Medicine, New York, NY.

In the second decade of genome-wide association studies, researchers are increasingly turning to sequencing as a strategy to identify associated variants with rare minor allele frequencies (MAF<1%), motivated by the prediction that rare variants are often found to have larger effect sizes than common variants, and contribute to the heritability often missed by top hits identified in GWAS. While sequencing technologies are developing rapidly, genotyping arrays continue to provide a low-cost snapshot of genomic variation. These will not capture the entire frequency spectrum in the study as rare variants may not be in linkage disequilibrium with the array's tag SNPs. However, in this context, leveraging Identity-by-Descent in a GWAS framework (IBDGWAS) may provide an alternative to capturing patterns of trait-associated rare variants. Population genetic theory and recent empirical studies have shown that rare variants tend to have arisen more recently in human history and thus should be correlated with IBD tracts, and therefore detectable with genotyping arrays. The power to identify IBD segments for association testing scales quadratically so large sample sizes, as is becoming the standard with large-scale consortia and biobank studies, provide an emergent opportunity to uncover genomic variation. Therefore examining rare variant associations via IBDGWAS may provide a low-cost alternative to sequencing. To examine the relative power of IBDGWAS versus sequencing at capturing rare variant association, we employed both a coalescent-based framework for large-scale case-control simulation followed by examination in several biobank datasets. We compared IBDGWAS to exome and whole-genome sequencing assuming a fixed budget and evaluated the tradeoff between sequencing's resolution and the large boost in sample size possible with IBDGWAS. We first evaluate the effect of a population bottleneck on levels of IBD detectable in mega-scale datasets. We describe demographically realistic scenarios in which IBDGWAS outperforms sequencing strategies, in particular, whole genome sequencing given the relative expense. Based on these findings, we can integrate the findings from both IBDWAS and GWAS to learn about the relative contributions of rare and common variants to genomic architecture, as well as the portability of findings across populations with diverse demographic histories..

Testing family association with rare and common variants via wavelet transformation. *H. Wang, Y. Lin, D. Chen, S. Wu, C. Chang, C. Fann.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Many common diseases are known to cluster in pedigrees which have become a rich resource for detecting association between rare variants and complex traits. In recent years, many researchers have modified existing population-based methods for detecting family-based rare variant association. These tests including collapsing/burden test and variance-component tests focus on identifying a group of rare variants in a region associated with a disease, thereby effectively reducing the degrees of freedom as compared with individual rare variant test. In addition, both common and rare variants may be the causal variants in a region and therefore should be considered simultaneously. It is inevitable that the power may be loss if neutral variants are incorporated into test statistics. With the aims of improving the power of rare variants association in family design and reducing the noise caused by neutral variants, we extended the wavelet-based test to identify both common and rare causal variants within a region. The wavelet transformation which can suppress the noise data has been applied to rare variants association in case-control data but has not been used in family design. In our study, pedigree sequence datasets were simulated. We evaluated type I error rates and compared the power of family-based wavelet test (famwave) with two other family-based association tests, family-based weighted sum test (famWSS) and family-based SKAT (famSKAT). The results demonstrated that type I error rates under different scenarios were well-controlled and had a comparable or better power (0.4~0.98) than the other tests. In order to illustrate the feasibility and performance of the proposed methodology in realistic setting, the Genetic Analysis Workshop 17 datasets were utilized. The qualitative trait (affected/ unaffected) was used to test with 228 variants in 15 genes. The percentage of the number of significant results among the 200 replicates was used to evaluate the performance of these methods. For all 15 candidate genes, the results indicated that our proposed method detected the causal genes more frequently than the other tests, for example a large number variants in gene PIK3C2B (71 variants).

Improving imputation accuracy by inferring causal variants in genetic studies. *Y. Wu[1], F. Hormozdiari[1], J. Wha J Joo[1], E. Eskin[1,2].* 1) Computer Science, UCLA, Los Angeles, CA; 2) Department of Human Genetics, UCLA.

Genotype imputation has been widely utilized for two reasons in the analysis of Genome-Wide Association Studies (GWAS). One reason is to increase the power for association studies when the causal SNPs are not collected in the GWAS. The second reason is to aid in the interpretation of a GWAS result by predicting the association statistics at untyped variants. In this project, we show that the prediction of association statistics at untyped variants which do in fact have an influence on the trait is overly conservative. Current imputation methods assume that none of the variants in a region (locus consists of multiple variants) affect the trait which is often inconsistent with the observed data. In this paper, we propose a new method, CAUSAL-Imp, which can impute the association statistics at untyped variants taking into account that some of the variants in the region may affect the trait. Our method builds on recent methods that impute the marginal statistics for GWAS utilizing the fact that the marginal statistics follows a multivariate normal distribution. We utilize both simulated and real data sets to assess the performance of our method. We show that traditional imputation approaches underestimate the association statistics for variants involved in the trait while our approach provides less biased estimates of these association statistics.

Adjusting missing confounders in epigenome-wide association studies. *C. Wu[1], J. Pankow[2], E. Demerath[2], J. Bressler[3], M. Grove[3], M. Fornage[3], W. Guan[1].* 1) Division of Biostatistics, School of Public Health, University of Minnesota, Minneapolis, MN, USA; 2) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, MN, USA; 3) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA.

DNA methylation is a commonly studied epigenetic mechanism that may be involved in the development of common diseases. Unlike inherited changes in genetic sequence, variation in site-specific methylation varies by tissue, developmental stage, and may be impacted by aging and exposure to environmental factors. Failing to control for these non-genetic factors in epigenome-wide association studies (EWASs) may lead to false discoveries and loss of statistical power. These factors, if available, can be directly included in a regression model, or can be inferred through decomposition of the methylation matrix, e.g., using principal component analysis (PCA). Here we introduce a novel statistical method based on standard and supervised principal component analysis (SPCA) to correct for unobserved confounders in EWASs. Compared to standard PCA, SPCA will assist to capture confounders that only contribute to a small proportion of CpG sites among the genome-wide measures. Through simulation studies, we demonstrate that our proposed method can maintain acceptable false positive rate and improve statistical power of epigenetic association test. We also compare our results to existing methods, such as ReFACTor and FaST-LMM-EWASher, and apply our method to an EWAS of smoking in the atherosclerosis risk in communities (ARIC) study. We propose that our method will help to control for potential confounding and increase statistical power of epigenetic association studies.

523W

Detection of recessive selection identifies non-additive components of complex disease. *D.M. Jordan[1], D.J. Balick[2], I.A. Adzhubei[2], S.R. Sunyaev[2], R. Do[1].* 1) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mt. Sinai, New York, NY; 2) Division of Genetics, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Methods to identify genes and variants for complex diseases generally assume that effects of alleles are additive, meaning that a homozygous genotype confers twice the risk of a heterozygous genotype. Indeed, the majority of genome-wide association studies (GWAS) for complex diseases have assumed additive models of risk, but the few studies that have tested recessive models have discovered recessive associations that were not detectable using additive models[1]. Genes under recessive selection exhibit detectably different population dynamics[2]. Leveraging this property, we have developed a novel method to quantify the strength and recessivity of selection of all protein-coding genes across the human genome by comparing European population sequencing data from the Exome Aggregation Consortium (ExAC) (N=35,000) with simulated evolutionary histories for both additive and recessive alleles. This method could inform model choice by identifying genes and pathways likely to be under recessive selection. We find a variety of biologically meaningful categories enriched in the predicted recessive class, including glycoproteins (Benjamini P=6.3x10^{-13}), immunoglobulin domains (P=0.023), and inflammatory response (P=0.0052). The enrichment for inflammatory genes in particular suggests that many complex diseases with inflammatory and autoimmune components may be under recessive selection, such as Crohn's disease and rheumatoid arthritis (RA). In the case of Crohn's disease, we find that genes with large and well-validated effects are predicted to be under recessive selection, while genes implicated by GWAS studies have no enrichment for recessive selection. Similarly, RA loci discovered by GWAS show no enrichment for recessive selection, despite the fact that RA is known to involve inflammatory and immune pathways that are highly enriched for recessive selection according to our method. These examples highlight the potential usefulness of our catalog of recessive selection as a tool for variant and gene prioritization, and more broadly, for gaining biological insight into complex disease. 1. 524T

A new sparse Bayesian method for multi-trait genome wide association studies. *K. Sharp[1], V. Iotchkova[2], A. Dahl[3], J. Marchini[1,3].* 1) Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Welcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 3) Welcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Genetic association studies of complex traits have concentrated primarily on testing for association between a SNP and each trait separately. However, when measurements of multiple, correlated phenotypes are available, this approach ignores useful information. In such cases, statistical power can be increased by testing all traits simultaneously. Existing multi-trait approaches look for evidence of association by comparing the fit of just two models: a null model of no association at all and a saturated model incorporating non-zero effects of a SNP on all traits. However, we rarely expect such a dichotomy especially as the number of traits increases. We have developed a Bayesian model designed to detect association when correlations exist between high-dimensional phenotypes and between individuals due to relatedness. We impose a sparsity assumption through the use of a 'spike and slab' prior on the genetic effect sizes. This allows us to learn the subset of traits that are associated with each SNP or genetic region. In this way our method is able to perform model inference (association testing) and model selection simultaneously. To allow for relatedness and population structure, our method generalizes single-trait, linear mixed model analysis to high-dimensional traits. We use MCMC to fit the model at SNPs showing some marginal evidence of an effect. On simulated datasets of unrelated individuals, when the true signal is sparse, our approach has significantly more power to detect association than simpler approaches based on fitting a saturated model (SM) or single phenotype tests (minP). For 10 simulated phenotypes, of which only 1 had a true association, we observed a mean increase in power to detect association of 25% and 32% over SM and minP respectively (fpr=0.01). We applied our method to 15 glycomics phenotypes for individuals from 3 isolated populations. Two previous meta-analyses discovered associations at 19p13.3, 14q23.3 and 12q24.31. The second, larger, study also identified a QTL at 2q21. Our method is able to uncover strong evidence of association at these SNPs (log10 BF > 9.5) and produces a stronger signal at the 2q21 locus in the Korcula and Vis cohorts than p-value based approaches. We also find strong evidence of association with additional phenotypes at each locus. For example, the larger meta-analysis reported associations with 4 phenotypes at 19p13.3, and with only 1 at 2q21. We find associations with 7 and 3 phenotypes respectively.

525F

The impact of genotype imputation on the statistical power of rare variant association studies. *D.M.H. Tong, R.D. Hernandez.* University of California San Francisco, San Francisco, CA.

Genome-wide association studies have discovered a large number of associations for many complex human diseases. Despite these successes, much of the heritability of these traits remains unexplained. Low frequency and rare variants are a common explanation, and genotype imputation has been widely used to introduce low frequency variants into GWAS to boost power. In this study, we evaluated the power of gene-based rare variant association methods on simulated whole genome sequences against simulated imputed sequences. We simulated DNA sequences for 20,000 individuals under a demographic model representing three different ancestries (African, European, and Asian) with evolutionarily conserved and neutral sequence variation. Phenotypes for each individual were simulated under a range of models encompassing a diverse set of genetic architectures. Each individual genome was then downsampled to match common genotyping arrays, and imputed using minimac and IMPUTE2 with a subset of held-out individuals as a reference panel. The statistical power of a diverse set of rare variant association methods was evaluated and compared on both the entire set of simulated sequences as well as the imputed sequences.

526W

A unified approach to estimating population structure and relatedness. *B.S. Weir[1], J. Goudet[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Ecology and Evolution, UNIL-Sorge, Switzerland.

Evolutionary studies, association mapping and forensic identification rely on estimates of population structure or relatedness. Estimates of quantities depending on allelic identity by descent cannot be estimated in an absolute sense, but only relative to a reference set of alleles. The usual Fst reference set is alleles among independent populations. The EIGENSTRAT kinship estimates reference set is for other unrelated pairs of individuals in a sample. KING-robust uses non-ibd alleles within individuals as a reference. However, migration leads to dependent populations, all pairs of individuals in a study may have low kinship levels and consequent inbreeding. We have therefore re-cast population structure, relatedness and inbreeding estimation to make explicit what is being estimated by standard estimates, and to provide simple alternatives. We use allelic matching, or ibs. If a series of populations i have reference allele sample frequencies P_i then within-population matching proportions are $P_i^2+(1-P_i)^2$, with average M(W). For populations i,j the matching proportions $P_iP_j+(1-P_i)(1-P_j)$ have average M(B). The corresponding ibd parameters are theta(i), theta(ij) with averages theta(W), theta(B). We avoid confounding by the number of populations by using M(B) instead of the usual total heterozygosity. Our population-specific estimates [M(i)-M(B)])/[1-M(B)] are unbiased for [theta(i)-theta(B)]/[1-theta(B)]. In effect, standard methods set theta(B)=0. The new estimates are good indicators of natural selection, they are sensitive to population divergence times and migration rates for rare variants, and they give preliminary indicators of association when the populations are cases and controls. The usual Fst quantity is [theta(W)-theta(B)]/[1-theta(B)], and for pairs of populations drifting apart this is proportional to the time since divergence from an ancestral population. For population sample sizes of 1, the matching proportions are $M(i)= (1-X_i)^2$ within individual i, or $M(ii)=[1+(1-X_i)^2]/2$ for an individual with itself, and $M(ij)=[1+(1-X_i)(1-X_j)]/2$ for individuals i,j where X_i is the reference allele dosage for i. Now [M(ij)-M(B)]/[1-M(B)] provides estimates of [theta(ij)-theta(B)]/[1-theta(B) where theta(ij) is the coancestry for i,j. When i=j, $theta(ii)=(1+F_i)/2$ where F_i is the inbreeding coefficient of individual i. The estimates of theta(ij) for distinct i,j sum to zero by construction, as do large-sample expected values of EIGENSTRAT estimates.

527T

Prediction accuracy of combined genetic and non-genetic risk scores. *F. Dudbridge.* Non-communicable disease epidemiology, London Sch of Hygiene and Tropical Medicine, London, United Kingdom.

The substantial heritability of most complex diseases suggests that genotypic data could be a useful predictor of individual disease risk. Such risk prediction could identify individuals who would benefit from preventive medication, such as statins, and could improve the efficiency of screening programs for early detection of diseases such as breast cancer. To date the performance of genetic risk scores has fallen short of the potential implied by heritability, but this shortfall can be explained by inadequate sample sizes used to estimate effect sizes in highly polygenic models. However, as sample sizes approach hundreds of thousands, more accurate genetic risk prediction is becoming feasible. When there are existing risk predictors based on environment or lifestyle, the main questions are to what extent can these predictors be improved by adding genetic information, and what is the ultimate potential of combined genetic and non-genetic risk scores? A key issue is the correlation between genetic and non-genetic risk, which may occur when the non-genetic risk factors mediate the genetic risk, or when one of the risk factors is family history. Here I extend previous work on the predictive accuracy of polygenic risk scores to allow for a non-genetic score that may be correlated with the polygenic score. I derive measures of predictive accuracy including liability R^2, area under the ROC curve and net reclassification improvement, as functions of the sample size used to discover the polygenic score, chip heritabilities of the disease of interest and of the non-genetic score, and genetic correlation between disease and non-genetic score. I consider simple addition of the two scores and a weighted sum that adjusts for their correlation. Using current examples from cardiovascular disease and breast cancer, I show that improvements in AUC are generally small but reasonably large NRI could be obtained with current sample sizes. Correlation between genetic and non-genetic scores turns out to have only minor effects on numerical results. Since existing risk predictors tend to explain less variation than the heritability, the long term prospect might be that polygenic scores become the default predictor and the burden is on epidemiologists to find sufficiently informative additional risk factors.

Gene-based segregation method for identifying rare variants in family-based sequencing studies. *D. Qiao[1], C. Lange[3], N.M. Laird[3], S. Won[4], B. Hobbs[1], S.M. Lutz[5], J.D. Crapo[6], T.H. Beaty[7], E.K. Silverman[1,2], M.H. Cho[1,2].* 1) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 2) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 4) Department of Public Health Science, Seoul National University, Seoul, Republic of Korea; 5) Department of Biostatistics, University of Colorado, Aurora, CO, USA; 6) Department of Medicine, National Jewish Health, Denver, CO, USA; 7) John Hopkins Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA.

Background: Family-based whole-exome sequencing data have been used to identify rare coding variants of large effect and complete or near-complete penetrance associated with Mendelian diseases or complex diseases with Mendelian subtypes. A filtering approach based on variant novelty, functionality, and segregation with phenotype within families has led to successful discoveries for some diseases; however formal statistical approaches are limited. **Methods**: We propose a GEne-based SEgregation Test (GESE), constructed using the marginal probabilities of segregating events under the null hypothesis of Mendelian transmission. This test takes into account different degrees of relatedness in the families and genetic background variation in each gene. In addition, a weighted version of this test allows incorporating additional subject phenotypes and functional annotations to improve the power for identifying the causal genes. **Results:** We showed via simulations that the GESE and weighted GESE tests maintain appropriate type I error rate, and have greater power than several commonly used association methods. We applied the methods to whole-exome sequencing data of 347 subjects from 49 extended pedigrees with severe, early-onset chronic obstructive pulmonary disease (COPD) in the Boston Early-Onset COPD Study (BEOCOPD) and proposed several candidate genes for future validation. **Conclusions**: Our proposed methods show great promise in identifying rare coding variants of large effect and high penetrance for family-based sequencing data. The proposed tests are implemented in an R package that is publicly available. .

Metrics to assess imputation quality in the presence of complex relatedness. *C. McHugh[1], B.K. Cornes[1], B.J. Chen[1], M.C. Zody[1], D.E. Housman[2], N.S. Wexler[3], R.B. Darnell[1].* 1) New York Genome Center, New York, NY; 2) Massachusetts Institute of Technology, Department of Biology, Cambridge, MA; 3) Columbia University Medical Center, New York, NY.

With the decreasing cost of genotyping technology, researchers can afford to generate SNP chip array genetic data for a large number of samples, resulting in a set of relatively common variants in all study individuals. On the other hand, obtaining rare variant calls for all samples using whole genome sequencing (WGS) is more expensive. Oftentimes a cost-effective approach is used where only a small number of samples are submitted for WGS, then imputation is performed in all samples using the directly sequenced samples as references. Currently, some imputation methods specifically take into account pedigree structure while others are pedigree-agnostic. In family-based studies, we may sequence only a select number of relatives, but want to choose them intelligently in order to provide the most information for imputation quality and accuracy. A few tools are available that offer algorithms to select samples for WGS but they have a large computational burden, especially for complex pedigrees. Furthermore, they do not offer comprehensive assessment of imputation quality in the context of a pedigree. Here, we develop metrics to assess imputation quality and accuracy in related individuals, by sample and by variant. We perform imputation using various software packages, including IMPUTE2 and MaCH, in a large, complex pedigree where we have SNP array data on all subjects but have only directly sequenced a subset of the study samples. From sample-based metrics, we can determine expected imputation accuracy, taking into account the position of the individual within the pedigree. One sample-based metric calculates the concordance between imputed and sequenced genotype calls. Other metrics are devised to analyze characteristics of discordant sites. We assess the sample-based metrics for all individuals stratified by pedigree characteristics such as how many relatives they have. Quality is also evaluated by variant, taking into account various characteristics such as minor allele frequency and call rate. With this comprehensive assessment of imputation output, we gain insight into why some samples and variants perform better than others in the presence of complex relatedness. In the future, such metrics may be used to select the most informative samples for WGS, an important design decision for many family-based studies.

530T

Linkage analysis and regional heritability vs GWAS in family-based cohorts. *R. Nagy[1], P. Navarro[1], C. Hayward[1], J.F. Wilson[1,2], C.S. Haley[1,3], V. Vitart[1].* 1) Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; 2) Centre for Population Health Sciences, University of Edinburgh, Edinburgh, United Kingdom; 3) Roslin Institute and Royal (Dick) School of Veterinary Studies, Edinburgh, United Kingdom.

Alternatives to traditional GWAS are needed to tackle complex associations of inherited haplotypes and allelic heterogeneity. Here, we tested how using family-based data and haplotype-based methods can provide additional insights into genetic analysis. Analyses were performed in four population isolate cohorts of Croatian or Scottish heritage (CROATIA-Vis, CROATIA-Korcula, ORCADES and Viking Health Study Shetland) and Generation Scotland: The Scottish Family Health Study (GS:SFHS), a family-based biobank from the Scottish general population. These cohorts all have extensive pedigree information, making them ideal for linkage analysis. Some of these cohorts are also population isolates, which means individuals share longer haplotypes derived from common ancestors. We performed variance component-based linkage analyses, regional heritability and single SNP GWAS in these cohorts, for measured quantitative traits of public health importance. Using linkage analysis and regional heritability, we identified regions that were missed by GWAS (in our own analyses and in published large consortium GWAS meta-analysis). Some regions harbour genes whose expression patterns and functions make them good candidates for follow-up. We will present two such examples resulting from scans of alanine transaminase, a liver enzyme associated with metabolic disease and intra-ocular eye pressure, a trait associated with glaucoma. The studied cohorts range in size from 1000 to 20000 individuals with average family sizes ranging from 3 to 43 individuals. Due to their family structures, both the 20000-individual Generation Scotland cohort (average of 6 people per family) and the 2000-individual ORCADES cohort (average of 43 people per family) have similar power to detect linkage, showing that simply increasing sample size is not always the best solution to increasing the power of these analyses.

531F

TreeLMM: Modelling heterogeneity of genetic effects. *R. Moore[1,2], F. Casale[2], I. Barroso[1], O. Stegle[2].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) European Bioinformatics Institute, Hinxton, Cambridge, United Kingdom.

Genetic effects can vary between individuals. For example, the effect of a genetic variant may depend on environmental exposure such as smoking status, life style covariates, etc. However, widely used approaches to analyse genotype-phenotype associations commonly assume that genetic effects are identical across all samples within a cohort. One approach to address these differences in genetic effects is to divide the samples into distinct groups and then either perform analyses for individual groups followed by meta analysis or conduct multi-trait modelling, for example using linear mixed models. Such approaches can result in a prohibitive numbers of groups, with small sample sizes, that are not fully independent of one another. Hence, both independent analyses and existing multi-trait models do not fully leverage the structure in the data. Here, we propose TreeLMM, an approach that explicitly accounts for heterogeneity in effect sizes and group structure. This is achieved by defining a prior on effect sizes that encodes the similarity between the different groups of individuals; these groups can contain just one individual. The method uses score tests ensuring that it is efficient and in principle enables the analysis of thousands of samples and arbitrary numbers of groups. To illustrate our approach, we have applied the method to perform eQTL mapping in 44 tissues made available through the GTEx project. We have leveraged expression profiles to estimate similarities and mapped *cis*-eQTLs across the cohort of 7,051 samples. Compared to independent modelling and methods that ignore heterogeneity in effect size, we identify a 2-fold and 4-fold increase respectively in the number of independent variants that are associated with gene expression changes. Additionally, our model allows for estimating posterior probabilities of the effect of genetic variants in individual tissues. This approach gives a powerful handle on dissecting tissue-specific effects as well as secondary association signals.

532W

Missing genetic interactions result in prediction bias at the extremes of risk for time-to-event models. *D. Soave[1,2], L.J. Strug[2,1].* 1) University of Toronto, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Toronto, Ontario, Canada.

Background: Risk prediction models can translate genetic association findings to inform clinical decision-making. Most models are evaluated on their ability to discriminate, and the calibration of risk-prediction models is largely overlooked in applications. Models that demonstrate good discrimination in training datasets, if not properly calibrated to produce unbiased estimates of risk, will generally perform poorly in new patient populations. Poorly calibrated models arise due to missing covariates, such as genetic interactions that in many instances are unknown or not measured. Methods: We demonstrate that models omitting interaction effects can lead to increased bias in predicted risk for patients at the tails of the risk distribution; i.e those patients who are most likely to be affected by clinical decision making. We propose a new calibration test for Cox risk-prediction models for time-to-event data that leverages additional power from bias in risk estimates at the extremes of the risk distribution. Our test aggregates martingale residuals for subjects from extreme high and low risk groups with a test statistic maximum chosen by varying which risk groups are included in the extremes. We show how to estimate the empirical significance of our test statistic by simulating from a Gaussian distribution using the covariance matrix for the grouped sums of martingale residuals. Results: A simulation study shows our new test maintains control of type 1 error and demonstrates improved power over conventional goodness-of-fit tests when risk prediction is poorest at the tails of the risk distribution. We apply our method in the development of a prediction model for onset of cystic fibrosis-related diabetes. Conclusions: Our study highlights the importance of assessing both calibration and discrimination in the development of predictive time-to-event models, and we show our new test to be a useful, complimentary tool in the assessment of risk model calibration.

533T

An efficient gene-gene interaction test for rare variants in case-control studies. *R.H. Chung, C.Y. Kang.* National Health Research Institutes, Zhunan, Taiwan.

Gene-gene interaction can play an important role in complex disease etiology. With the advancement of next-generation sequencing, many rare variants have been discovered. Current gene-gene interaction tests for disease studies are mainly developed for common variants. A few gene-gene interaction tests accounting for rare variants are available. However, they tend to be computationally intensive and may not be applicable to genome-wide gene-gene interaction analysis. Therefore, an efficient gene-gene interaction test for rare variants in disease studies is desirable. We developed a powerful and efficient gene-gene interaction test based on the goodness-of-fit (GOF) test statistic (iGOF). For a pair of SNPs, two 3 by 3 genotype tables are created with the observed genotype counts in cases and controls, respectively. Based on the 3 by 3 tables, the GOF statistic is calculated as the sum of differences in counts between the observed and expected genotype counts, each squared and divided by the expectation, under the null hypothesis of no interaction. The observed and expected counts from cases and controls both contribute to the statistic. For a pair of genes, the algorithm includes several steps: (1) assign SNPs with minor allele frequencies less than 5% to the genes; (2) exclude SNP pairs with minor allele counts in cases less than those in controls; (3) calculate the GOF statistics for the remaining pairs of SNPs between the two genes; (4) calculate the iGOF statistic, which is the sum of the GOF statistics; (5) permute the case and control status and calculate the p-value. We used simulations to demonstrate that the iGOF test has correct type I error rates under various scenarios. We also used simulations to compare the power of iGOF with other interaction tests considering rare variants, including SPAr, KBAC, and SKAT. The results suggest that iGOF has more power than other tests under most of the scenarios. To improve the performance of the iGOF test, the iGOF statistic is approximated by a chi-square distribution; permutations will only be performed if the p-value from the chi-square distribution is less than a pre-specified threshold. Moreover, permutations are performed based on the genotype tables stored in memory, which significantly reduces the run time. In conclusion, we developed a powerful and efficient gene-gene interaction test for rare variants in case-control studies using sequencing data.

534F

A novel and efficient study design to test parent-of-origin effects in family trios. *R. Feng, X. Yu.* Department of Biostatistics & Epidemiology, University of Pennsylvania, Philadelphia, PA.

Increasing evidence has shown that certain genes affect various prenatal, neonatal, and pediatric diseases differently depending on their parental origins. Parent-of-origins have been accommodated in genetic models to improve the power of detecting disease-associated genes and partially recover missing heritability. In many genetic studies, children's DNA samples were collected for initial testing and their parents contributed their own DNA samples for further investigations. Nowadays, next-generation sequencing (NGS) is often done on children's DNA samples to search for common and novel variants responsible for diseases. However, the cost of NGS of their parents is generally not affordable to all investigators, making the assessment of parent-of-origin effects impossible. Motivated by the reality, we proposed a new study design collecting children's NGS data, in combination with the parental genotypes obtained from the traditional genotyping array, at a fractional cost of sequencing all family members. We developed a powerful and efficient likelihood-based method, which incorporates both sequence alignments and linkage disequilibrium into inferring the parental origins of children's alleles and estimating their effect on the disease phenotype. We evaluated the performance of our method and compare with existing genotype-based methods using simulations. With a common read length of 100 base pairs, our method showed improved power over a haplotype-based method using SNP data only. When either read depth or pair-end length increased, our method achieved optimal power closer to an ideal test that assumed known parental origins of children's alleles. With its flexibility to accommodate missing genotypes, our method is also helpful to recover the power lost due to missing single parent's DNA.

Heterozygosity rate is not a good quality check metric in association studies of admixed populations. *A. Gaye[1], S. Davis[1], G. Gibbons[2].* 1) NHGRI, NIH, Bethesda, MD., USA; 2) NHLBI, NIH, Bethesda, MD., USA.

BackgroundHeterozygosity rate and genotype failure rate are routinely used to identify samples with low DNA quality at the data quality control stage of genetic association studies. Excessive heterozygosity rate may indicate sample contamination whilst a reduced heterozygosity rate could indicate inbreeding. Samples with heterozygosity > 2-3 standard deviations from the mean heterozygosity are routinely excluded from genetic case-control studies. We show that for admixed populations this leads to the exclusion of good quality samples because outlying heterozygosity might just be due to particular ancestry composition.MethodsWe conducted admixture and principal component analyses of two African American datasets together with data from the 1000 Genome Project. We first calculated the observed heterozygosity rate per individual and identified heterozygosity outliers. We the used the algorithm ADMIXTURE, a model-based approach, to estimate the fraction of global ancestry from each of the populations (admixed, African and European populations). We subsequently plotted the PCA results and identified heterozygosity outliers whose ancestry composition causes them to cluster away from the admixed group.ResultsIn this work we confirmed that heterozygosity rate is valid a QC metric to identify sample that should be excluded from a genetic association study. However, we have also showed that heterozygosity rate can be misleading if used in studies of admixed groups because samples that have a genetic diversity relatively different from that of the majority of the study participants are flagged as outliers to exclude. Therefore we will recommend carefully checking the ancestry composition of samples away from the mean heterozygosity at the QC stage to ensure valid samples are not incorrectly discarded particularly in settings where sample size is limited and where each exclusion has a greater impact on power than in large studies.

Single-marker tests using a new joint modeling approach of multiple traits outperform current single- and multi-marker tests in rare variant association studies. *S. Konigorski[1,2], Y.E. Yilmaz[2,3,4], T. Pischon[1,5,6].* 1) Department of Molecular Epidemiology, Max Delbrück Center for Molecular Medicine in the Helmholtz Association, Berlin, Germany; 2) Department of Mathematics and Statistics, Memorial University of Newfoundland, St. John's, NL, Canada; 3) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada; 4) Discipline of Medicine, Faculty of Medicine, Memorial University of Newfoundland, St. John's, NL, Canada; 5) Charité Universitätsmedizin Berlin, Germany; 6) DZHK (German Center for Cardiovascular Research) partner site Berlin, Germany.

Investigating the role of rare variants in complex phenotypes has received increasing interest in recent years. Yet, the low statistical power of rare variant association tests remains one of the main challenges and it is an open question which statistical methods are the most powerful. Much focus has been on multi-marker tests, which combine the rare variants' information in a given region and test the association of the region with the phenotype. There is a common belief that they are more powerful than single-marker tests, which test the association of each marker separately. However, different hypotheses are tested in the two approaches, which has to be considered for any comparison and conclusion as to which method has highest power, but is lacking from the literature. In this study, based on the underlying hypotheses considered for each type of test, we describe a framework to compare their empirical type I error and power and conduct extensive simulation studies. In addition, we propose a new single-marker test obtained through a copula-based joint analysis of multiple traits of a phenotype (C-JAMP) to increase the power of standard single-marker tests. The results demonstrate that the power to identify causal loci depends largely upon whether the research interest is limited to conclusions on the gene/region level or seeks to reveal causal variants, and that previous comparisons have been misleading. We show that in a number of realistic situations, standard single-marker tests lead to more powerful association tests than multi-marker tests when the same genetic locus is investigated. Furthermore, C-JAMP allows increasing the power for identifying functional loci significantly, and is able to identify 2 or 3 times more causal loci compared to both standard single-marker tests and popular multi-marker tests. It uses the information contained in the association between different traits and allows building more biologically meaningful modeling approaches. Hence, we suggest modeling multiple dependent traits and performing single-marker tests instead of aggregating rare variants in a region and performing multi-marker tests.

Increasing the probability that a finding is genuine for next-generation sequencing studies. *W. Lin, J. Li.* Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan.

With the advancement of next-generation sequencing technology, searching for rare causal variants (minor allele frequency < 1%) gradually becomes possible. However, the statistical power for detecting individual rare causal variants is very low due to the extreme sparsity. Most analysis approaches strengthen the association signals by aggregating the information of multiple rare variants in a gene/region. The BURDEN test and the sequence kernel association test (SKAT) are two commonly used methods for rare-variant association analyses. If we find an association for a gene/region with a phenotype, the next important step is to pinpoint individual rare causal variants from among a large number of variants within the region. To this end, statistical approaches such as the BE (backward elimination) procedure and the ADA method ('adaptive combination of *P*-values method'), have been proposed. It has been shown that the signal-to-noise ratio of variants identified by ADA is larger than that of variants identified by BE. In this study, we develop an ADAQ approach ('adaptive combination of *Q*-values method') to further increase the probability that a finding is genuine. With synonymous / non-synonymous annotations for variants, we first allocate all variants into a non-synonymous group and a synonymous group, and transform two groups of per-site *P*-values into Benjamini-Hochberg *Q*-values, respectively. We then remove the variants with *Q*-values larger than the optimal *Q*-value truncation threshold, which are more likely to be neutral. The optimal *Q*-value truncation threshold is searched through our ADAQ algorithm. Comprehensive simulations have shown that ADAQ produces an even larger signal-to-noise ratio than ADA. Moreover, we applied ADAQ to the Genetic Analysis Workshop 17 (GAW 17) data sets. It controls the number of false positives more effectively and generates a larger signal-to-noise ratio than ADA. Therefore, we recommend using ADAQ to pinpoint individual rare causal variants, when synonymous / non-synonymous annotations for variants are available.

Polygenic scores using summary statistics via penalized regression. *T.S.H. Mak[1], R.M. Porsch[2], S.W. Choi[2], X. Zhou[2], P.C. Sham[1,2,3].* 1) Centre for Genomic Sciences, University of Hong Kong, Hong Kong; 2) Department of Psychiatry, University of Hong Kong, Hong Kong; 3) State Key Laboratory of Brain and Cognitive Sciences, University of Hong Kong.

Polygenic scores (PGS) summarize the genetic contribution of a person's genotype to a disease or phenotype. They are useful in a wide variety of analyses of genetic data. Many possible ways of calculating polygenic scores have been proposed, and recently there is much interest in methods that incorporate information available in published summary statistics. As there is no inherent information on linkage disequilibrium (LD) in summary statistics, a pertinent question is whether we can make use of LD information available elsewhere to supplement such analyses. To answer this question we propose a method for constructing PGS using summary statistics and a reference panel in a penalized regression framework, which we call lassosum. We also propose a general method for choosing the value of the tuning parameter in the absence of validation data. We then assessed the performance of lassosum, with a particular emphasis on whether the use of a ``wrong'' reference panel can negatively impact the predictive power of the PGS, and whether it is beneficial to combine lassosum with the method of clumping when faced with summary statistics of a large number of SNPs. Results from our study suggest that lassosum is faster and more robust than other similar methods in almost all scenarios. They also suggest that accounting for LD with a reference panel is beneficial only when the signals from the data are strong. Using a ``wrong'' reference panel can impair the performance of the PGS when signals are strong and correlated with one another. In the presence of summary statistics from a large number of SNPs, clumping may both enhance or decrease the performance of standard PGS, although its effects on lassosum is attenuated. lassosum combined with pre-filtering by clumping appears to be a robust and reliable option for calculating predictive PGS.

539T

Properties of global and local ancestry adjustments in genetic association tests in admixed populations. *E. Martin[1], I. Tunc[2], Z. Liu[1], A. Beecham[1], G. Beecham[1].* 1) Dr. John T. Macdonald Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Bioinformatics and Systems Biology, National Heart Lung and Blood Institute, National Institutes of Health, Bethesda MD.

Population substructure can lead to confounding in genetic association tests and failure to adjust properly can result in spurious findings. Genetic ancestry can be measured on a global level, e.g., with principal components, or on a local level for regions across the genome. Recent reports have considered whether it is preferable to adjust for local or global ancestry, but the conclusions depend highly on the model for population structure and trait/disease model. Here, we formally address the question of confounding by ancestry, express regression parameters in terms of population genetics parameters to clarify hypotheses from adjusted and unadjusted models, and consider questions of relative power. We examine theoretical expectations to show population substructure scenarios under which we might expect confounding, and to show the consequence of ancestry adjustment to genetic association tests. Theoretical calculations were verified and generalized using simulations. We show that in a single admixed population, testing the trait locus itself does not lead to confounding by ancestry so it is not necessary to adjust, and in fact adjusting tends to decrease power. However, when testing a marker locus, both global and local ancestry can be confounders. We show that the genetic parameter of adjusted and unadjusted models provides different tests for linkage disequilibrium (LD): the unadjusted model tests for LD in the admixed population, while the local-ancestry adjusted model tests for LD in the ancestral populations. As such, it is recommended that global ancestry adjustment be used for initial screening and that local ancestry for fine-mapping. Similar conclusions hold in stratified admixed populations. We further show how parameters relate to the fixation index F_{ST} (a measure of population diversity), which allows us to discuss results in the context of existing admixed populations.

540F

BinomiRare: An efficient and robust test of the association of a rare-variant with a disease, for pooled and meta-analyses. *T. Sofer.* Biostatistics, University of Washington, Seattle, WA.

Most regression-based tests of the association between a low-count variant and a binary outcome do not protect type 1 error, especially when tests are rejected based on a very low significance threshold. Exception is the Firth test that corrects for biases in the asymptotic properties of the logistic regression model. However, even the Firth test may not control type 1 error well when combining multiple case-control studies via meta-analysis, and it may suffer a substantial loss of power. The problem is exacerbated when the case-control proportions differ between studies. We propose a novel test, BinomiRare, which only requires modeling of the disease risk, independently of the variant, and avoids the calibration problem of other regression-based tests. Disease probabilities are adjusted to confounders using regression models. We quantify the strength of association between a variant and the disease based on the departure of the number of diseased individuals carrying the variants from the expected distribution of disease probability under the null hypothesis of no association between the disease and the variant. We use the Poisson-Binomial distribution to obtain p-values. To meta-analyze the test across multiple cohorts, each cohort provide the disease probabilities of all carriers of the variant of interest and the number of diseased individuals among the carriers. BinomiRare is computationally quick, and faster than the Firth test. It controls type 1 error in both pooled and meta-analysis, even when the case-control proportions differ between the studies. It is more robust than regression-based tests due to fewer assumptions, and thus less prone to false positives. We demonstrate the test in studying the association of rare variants with asthma in the Hispanics Community Health Study/Study of Latinos (HCHS/SOL). The proportion of asthma cases varies substantially between the HCHS/SOL's ethnic groups, from 4% in Mexicans, to 26% in Puerto-Rican. The BinomiRare test results are similar to the results of the Firth test on the pooled cohort, both when the entire pooled sample is analyzed together, and when the dataset is stratified by ethnic group and than meta-analyzed (correlation 0.93 between Firth and BinomiRare p-values). In comparison, meta-analyzing Firth test results across ethnic group results in substantial differences (correlation 0.30 between Firth on stratified and on pooled data), and evidence of inflation (genomic control lambda = 1.32).

Smooth-threshold multivariate genetic prediction with unbiased model selection. *M. Ueki[1], G. Tamiya[2]. 1) Biostatistics Center, Kurume University, Kurume, Fukuoka, Japan; 2) Tohoku Medical Megabank Organization, Tohoku University, Aoba-Ku, Sendai, Miyagi, Japan.*

We develop a new genetic prediction method, smooth-threshold multivariate genetic prediction, using single nucleotide polymorphisms (SNPs) data in genome-wide association studies (GWASs). Our method consists of two stages. At the first stage, unlike the usual discontinuous SNP screening as used in the gene score method, our method continuously screens SNPs based on the output from standard univariate analysis for marginal association of each SNP. At the second stage, the predictive model is built by a generalized ridge regression simultaneously using the screened SNPs with SNP weight determined by the strength of marginal association. Continuous SNP screening by the smooth thresholding not only makes prediction stable but also leads to a closed form expression of generalized degrees of freedom (GDF). The GDF leads to the Stein's unbiased risk estimation (SURE), which enables data-dependent choice of optimal SNP screening cutoff without using cross-validation. Our method is very rapid because computationally expensive genome-wide scan is required only once in contrast to the penalized regression methods including lasso and elastic net. Simulation studies that mimic real GWAS data with quantitative and binary traits demonstrate that the proposed method outperforms the gene score method and genomic best linear unbiased prediction (GBLUP), and also shows comparable or sometimes improved performance with the lasso and elastic net being known to have good predictive ability but with heavy computational cost. Application to whole-genome sequencing (WGS) data from the Alzheimer's Disease Neuroimaging Initiative (ADNI) exhibits that the proposed method shows higher predictive power than the gene score and GBLUP methods.

As genetic association studies increase in size to 100,000s of individuals, subtle biases may influence conclusions. One possible bias is "index event bias" (IEB), also called "collider bias", caused by the stratification by, or enrichment for, disease status when testing associations between gene variants and a disease-associated trait. We first provide a statistical framework to analytically quantify and account for IEB in a study, where only summary statistics are available. We then use a combination of real and simulated data to identify and quantify real examples of IEB, including a single large study (120,000 individuals from the UK Biobank) and a meta-analysis of independent studies. We observed evidence of biased associations for some disease alleles and genetic risk scores, even in population-based studies. For example, a genetic risk score consisting of type 2 diabetes variants was associated with lower BMI in 113,203 type 2 diabetes controls from the population based UK Biobank study (-0.010 SDs BMI per allele, P=5E-4), entirely driven by IEB. Three of 11 individual type 2 diabetes risk alleles, and 10 of 25 hypertension alleles were associated with lower BMI at p<0.05 in UK Biobank when analyzing disease free individuals only, of which all but six hypertension alleles remained associated at p<0.05 after correction for IEB. Our formula (implemented in R) suggested that the associations between *CCND2* and *TCF7L2* diabetes risk alleles and lower BMI could (at least partially) be explained by IEB. Variants remaining associated after correction may be pleiotropic and include those in *CYP17A1* (allele associated with hypertension risk and lower BMI). The formula suggested IEB could also mask a true pleiotropic association: the type 2 diabetes risk allele at *MTNR1B* was associated in the UK Biobank with higher BMI and this result strengthened on correction for IEB. The extent of IEB depends on several factors including the association strength between the trait being analysed and the disease, disease prevalence, sample size, and the effect size and minor allele frequency of the disease associated variant. In conclusion, IEB may result in false positive or negative associations in very large studies stratified or strongly enriched for/against disease cases. Studies examining the joint effect of multiple variants (for example in Mendelian randomization studies) will be more prone to index event biases than those of single variants.

Statistical approaches to replicability crisis in genetic epidemiology. *D. Zaykin[1], O. Vsevolozhskaya[2].* 1) Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC; 2) Dept. Biostatistics, U Kentucky.

Lack of replicability in science has been a recent concern. While the causes are diverse, genetic epidemiology studies in particular are susceptible to biases and errors introduced by the very nature of the statistical approach. Despite the best intentions, important factors may be unknown, mis-measured, or modeled incorrectly. Still, there is also a question of whether most commonly used approaches to analysis, such as significance testing are inherently flawed. P-values go hand in hand with testing the unrealistic "point null" hypothesis of complete lack of effect, and there are calls that their usage should be abandoned. P-values are often misinterpreted as measures about the hypothesis credibility while another line of criticism is itself statistical and in the context of replicability refers to great variability of P-values in future replication experiments, given a specific small P-value in a discovery study. Despite their flaws P-values are ubiquitous and are here to stay. Fortunately, when augmented with minimal additional information, P-values that result from common statistical tests employed in genetic epidemiology can yield full posterior distributions for the usual measures of effect sizes, such as odds ratios and relative risks. The proposed method alleviates many shortcomings of P-value and their usage, not the least of which is testing an implausible hypothesis of complete absence of effect.

544W

Imputation of low frequency and rare coding variants in founder population improved by usage of whole exome sequence based reference panel. *I. Surakka[1,2], A.P. Sarin[1,2], K. Karczewski[3,4], R. Durbin[5], D. MacArthur[3,4], V. Salomaa[2], A. Palotie[1,4,6,7,8], S. Ripatti[1,5,9], SISu project group.* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, USA; 4) Program in Medical and Population Genetics, Broad Institute of Massachusetts Institute of Technology (MIT) and Harvard, Cambridge, USA; 5) Wellcome Trust Sanger Institute, Hinxton, UK; 6) The Stanley Center for Psychiatric Research, The Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 7) Psychiatric & Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts, USA; 8) Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts, USA; 9) Department of Public Health, University of Helsinki, Helsinki, Finland.

Population specific reference panel improves imputation accuracy especially for rare and low frequency variants, particularly in population isolates, such as Finns. However, the gain in imputation precision has not been quantified for sequence-based reference panels. We compared the imputation quality between a Finnish population based sequence reference panel and global reference panels from 1000 Genomes project (1000G) and the Haplotype Reference Consortium (HRC). In addition, we evaluated the utility of extending the Finnish low-coverage whole genome sequencing (WGS) panel (N = 1,941) with a jointly called whole exome sequencing (WES) based reference panel (N = 4,932) when imputing coding variation into our test dataset of 10,489 Finns with Illumina CoreExome genotypes. We masked all variation with minor allele frequency (MAF) < 1%. Using the Finnish WGS reference panel we saw a ~100% increase in the sensitivity (the number of high confidence imputed exonic variants) in 0.1-0.5% allele frequency range compared to the 1000G panel. The HRC reference panel provided 7% more variants compared to the Finnish WGS panel but with the cost of introducing 0.8% false positive variant calls compared to 0.1% with the Finnish WGS reference panel. The highest sensitivity we observed for the combined panel of 1000G and WGS. However, the use of the combined reference panel introduced high number of false positive variants with high imputation quality measures; over 3% of the monomorphic variants observed in the test dataset imputed as polymorphic with info > 0.7. By combining the WES panel with the population specific WGS reference panel, we observed over 20% more high confidence imputed coding variants in the 0.1-0.5% allele frequency range compared to the Finnish WGS only panel. When looking at the imputation results of the polymorphic masked variants we observed that especially in the lowest allele frequency range (MAF < 0.1%) the population specific panels induced less false negative calls and the percentage of well-imputed variation was larger than when using the admixed reference panels. Our results highlight a problem of introducing falsely polymorphic low frequency and rare variants when using dual panels with different ancestries. In addition, our study shows that a population specific WES based reference panel boosts considerably the imputation of rare and low frequency coding variants.

545T

Correcting subtle stratification in summary association statistics. *G. Bhatia[1,2], N. Furlotte[3], X. Liu[1], H.K. Finucane[1,4], A. Gusev[1,2], A.L. Price[1,2].* 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 3) 23andMe, Inc. Mountain View, CA; 4) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA.

   Population stratification is a well-documented confounder in GWAS. While inclusion of PC covariates computed from common SNPs (SNP-PCs) often provides an effective solution to stratification, it is not applicable post-hoc to meta-analyses without access to individual-level data. In addition, this strategy will not correct for subtle stratification that is not captured by SNP-PCs. In analyses of summary statistics from 39 GWAS (mean sample size n=89k), including 21 GWAS from 23andMe that used SNP-PC covariates, we observed a significantly inflated LD score regression (LDSC) intercept for several traits—suggesting that subtle, uncorrected stratification can be a major concern, even when SNP-PC covariates are included. Here we propose a new method, PC loading regression, to correct for stratification in summary statistics by leveraging SNP loadings for PCs computed in a large reference panel. In addition to SNP-PCs, the method can be applied to haploSNP-PCs, i.e. PCs computed from a larger number of rare haploSNPs (haplotype variants constructed using a 4-gamete test) that better capture subtle structure. Using simulations based on real genotypes from 54k GERA individuals of diverse European ancestry, we show that application of PC loading regression to summary statistics computed without PC correction can effectively correct for stratification along top PCs. Correcting for the top 4 SNP-PCs in GERA data, we did not observe a significant reduction in LDSC intercept for 23andMe summary statistics, which already included SNP-PC covariates. However, when correcting for additional haploSNP-PCs in 23andme GWAS, inflation in the LDSC intercept was eliminated for eye color, hair color, and skin color and substantially reduced for height (1.34 to 1.16; n=430k individuals). After correcting for SNP-PCs and haploSNP-PCs in GIANT height summary statistics (Wood et al. 2014 Nat Genet), the LDSC intercept was reduced from 1.27 to 0.97 (n=250k individuals) consistent with no confounding after correction. Many association signals were eliminated by this correction including all 11 genome-wide significant SNPs at the LCT locus, which is highly differentiated among European populations and widely known to produce spurious signals (Campbell et al. 2005 Nat Genet). Overall, our results suggest that subtle stratification is a concern in GWAS of large sample size and that PC loading regression can correct for this stratification.

546F

Improving transcriptome-wide association studies with gene-network aided prediction of gene expression. *D. Chang, A. Wuster, T. Behrens, R. Graham, T. Bhangale.* Genentech, South San Francisco, CA.

   Several new methods have been developed to impute gene expression data into GWAS cohorts where expression data is not routinely collected. These methods use reference data, where genotype and expression data are collected in the same individuals, to train models that predict expression from genotype data. After applying the learned models to GWAS samples, imputed expression can be associated with disease risk. These methods both lower the multiple testing burden, and test a more direct hypothesis –is genic transcription associated with disease risk? However, expression cannot be reliably predicted from SNPs for many genes (genes with low heritability), limiting the utility of these methods. Gene expression is often influenced by (or correlated with) several other genes. We thus developed a new method that uses SNPs predictive of expression for a given gene's interacting partners to improve overall prediction accuracy. We applied the method to an RNA-sequencing dataset of monocyte derived dendritic cells (Lee *et al.* Science 2014) stimulated with influenza virus (N=183, training data) and interferon-beta (N=165, test data). Genotypes were obtained from Illumina one million SNP array, imputed using 1000 Genomes haplotypes. We first applied regularized regression (Gamazon *et al.* Nature Genetics 2015), to obtain predictive models for each gene based on *cis* SNPs. Next we applied graphical lasso (*huge* R package) to estimate the gene network from the gene expression data. Due to the computational burden of this estimation, we first separated genes into clusters based on correlated expression (*WGCNA* R package) and estimated networks separately for each cluster. Finally, the expression level of a gene was predicted based on *cis* SNPs of the gene and its interacting partners, and the estimated correlation between genes in the network. Of the 7,118 robustly expressed genes (RPKM>5), 6,379 genes were assigned to a cluster. Overall, for genes with *cis*-predictive SNPs, we found the average correlation between observed and predicted expression from *cis* SNPs alone to be 0.256, while for our method it was 0.349. For 4,396 genes, expression could not be predicted using *cis* SNPs as the regularized regression failed to include any SNP in the model. However, their expression could be predicted using our method (mean correlation=0.339). In conclusion, incorporating gene networks can improve prediction accuracy and power when imputing gene expression into GWAS datasets.

Guidance for the utility of linear models in meta-analysis of genetic association studies of binary phenotypes. *J.P. Cook[1], A. Mahajan[2], A.P. Morris[1].* 1) Department of Biostatistics, Farr Institute, Liverpool, Liverpool, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Linear mixed models (LMMs) are becoming increasingly popular for the analysis of genome-wide association studies (GWAS) because they account for relatedness and population structure via a kinship matrix. However, these models assume that the outcome of interest is quantitative, and their properties for binary traits have not been widely investigated, particularly in the context of meta-analysis. In this study, we performed simulations to compare the performance of linear and logistic regression models under alternative weighting schemes in a fixed-effects meta-analysis framework, considering designs that incorporate variable case-control imbalance, confounding factors and population stratification. Fixed-effects meta-analysis was undertaken with inverse-variance weighting of effect sizes (implemented in GWAMA) and effective sample size weighting of directed Z-scores (implemented in METAL). We simulated three scenarios for case-control imbalance: (i) no imbalance (1:1 ratio across all studies); (ii) moderate imbalance (variable ratio of 3:1 to 1:3 across studies); and (iii) extreme imbalance (variable ratio of 19:1 to 1:19 across studies). Within each set of simulations, comparisons were performed at effect allele frequencies of 0.5, 0.2, 0.1, 0.05 and 0.01. Our results show that linear models can be used for the analysis of binary traits, without loss of power compared to logistic models, irrespective of the extent of case-control imbalance, provided that one of the following meta-analysis schemes is used: (i) effective sample size weighting of *Z*-scores; or (ii) inverse-variance weighting of allelic effect sizes after conversion onto the log-odds scale. However, in the presence of extreme case-control imbalance, there is a substantial loss in power through application of inverse-variance weighting of allelic effect sizes from the linear model, without conversion onto the log-odds scale. Our conclusions are valid in the presence of binary confounder with moderate effect size (odds-ratio <5) and extreme population structure through application of LMMs. Our study has important implications for the design and analysis of GWAS, and the utility of linear modelling approaches in large-scale meta-analysis of complex binary traits.

548T

A fast and accurate algorithm to test for binary phenotypes and its application to PheWAS. *R. Dey, E. Schmidt, G. Abecasis, S. Lee.* Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI.

We propose a fast and well-calibrated single variant test for binary phenotypes with an application to Phenome-wide Association Studies (PheWAS). The availability of electronic medical record (EMR)-based phenotypes allows for genome-wide association analyses in thousands of traits, and has great potential to identify novel genetic variants associated with clinical phenotypes. We can interpret the 'PheWAS' result for a single genetic variant by observing its association across a landscape of phenotypes. Since PheWAS can test 1000s of phenotypes, and many of the binary phenotypes are relatively unbalanced (case:control=1:5) or often extremely unbalanced (case:control=1:600), existing methods cannot efficiently analyze them. For example, score test, which is computationally efficient, can have highly inflated type I error rates. Firth's penalized likelihood ratio test is more robust for controlling the type I error, but it is not scalable to handle large PheWAS datasets. Here we propose a computationally fast score test based method that estimates the distribution of the test statistic using the saddlepoint approximation. Our method is much faster than Firth's test (~10-100 times). It can also adjust for covariates and control type I error rates even when the case-control ratio is extremely unbalanced. Further, we extend our method to allow meta-analysis by identifying a minimal set of statistics that can be shared across different studies. We demonstrate superior performance of our method through extensive simulation studies and apply it to a real data example from the Michigan Genomics Initiative.

Genome-wide association of 2,500 structural and functional brain imaging phenotypes in the UK Biobank study. *L.T. Elliott[1], F. Alfaro-Almagro[2], M. Jenkinson[2], K.L. Miller[2], S.M. Smith[2], J. Marchini[1,3].* 1) Department of Statistics, University of Oxford, 24-29 St. Giles', Oxford, OX1 3LB; 2) Oxford University Centre for Functional MRI of the Brain (FMRIB), Oxford, OX3 9DU; 3) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN.

Brain function, connectivity and structure are known to be heritable and are important for the study of many human disease traits, but the localization within the genome of the genetic variants driving this heritability has remained elusive due to the sample size and quality of data required for this task. The UK Biobank has collected genetic data on around 500,000 UK individuals, and (to date) brain imaging data on 10,000 individuals, later to rise to 100,000. We will present the results of a genome wide association study on the intersection of the genetic and imaging datasets, which consists of 2500 brain imaging derived phenotypes and up to 10,000 individuals genotyped at around 10 million polymorphic SNPs. The phenotypes include connection strengths between brain areas assessed during a resting state analysis, volumes of brain structures and tissues, and microstructural white matter properties. Along with univariate tests for association, we will report results from multi-phenotype approaches that work on the phenotype-by-SNP summary statistic matrix, thereby uncovering latent phenotypes with strong associations.

Is selective inference more powerful in meta-, gene-based and pathway analyses? *E.T. Goossens[1], L. Sun[2,3].* 1) Department of Statistics, Purdue University, West Lafayette, IN; 2) Department of Statistics, University of Toronto, Toronto, ON; 3) Dalla Lana School of Public Health, University of Toronto, Toronto, ON.

Statistical analyses of high dimensional data, including genetic association studies, are often interested in combining evidence across multiple sources. The most common setting is meta-analysis, in which p-values (or other types of summary statistics) are combined across all studies to test the global null hypothesis that there is no association. This agnostic (either fixed-effect or random-effect) approach, however, may not be powerful when a proportion of the studies have truly null effects. Selective inference (appropriately testing parameters after some selection algorithm) has the potential to address this issue, but requires explicitly accounting for inherent selection bias. We propose a novel ordered-subset approach that simultaneously performs signal selection and adjusts for selection bias. We derive the approximate distribution for the test statistic under the null, and show the proposed method is accurate in finite samples. The performance of this method depends on a combination of factors: k, the total number of variables to be combined; k1 (k0), the number of true (null) variables; and the corresponding signal strength. Compared with traditional meta-analysis, our method improves power in the presence of heterogeneity when k0/k1 is large and each signal is relatively weak. In the absence of a mixture of null and non-null signals, we show the loss of power is limited via a simulation study. We also employ our method in the regression setting, illustrating its suitability for joint analysis of multiple SNPs in gene-based association studies and multiple genes in pathway analyses.

551T

An independent component analysis framework for modeling confounding factors in expression quantitative trait loci analysis. *J. Ju[1,2,3], S. Shenoy[3], J. Mezey[2,3,4].* 1) Physiology, Biophysics and Systems Biology Graduate Program, Weill Cornell Graduate School of Medical Sciences, New York, NY; 2) Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY; 3) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY; 4) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Expression Quantitative Trait Loci (eQTL) studies provide valuable insights into genetic mechanisms by identifying associations between genetic variations and gene expression. These types of analyses are complicated by non-genetic factors that influence expression levels, such as sample-specific environmental effects or technical effects related to differences between laboratories and procedures, which often remain unaccounted for and can potentially cause spurious correlations and reduce power to detect true associations. The importance of correcting for confounding factors is increasing with the recent rise of consortium scale studies in which samples from various populations are processed across multiple laboratories and have more potential sources of variation. Here we introduce CONFETI: CONfounding Factor Estimation Through Independent component analysis, a method to correct for non-genetic confounding variance in eQTL analysis. CONFETI uses Independent Component Analysis (ICA) to estimate generative sources from the observed data under the assumption that the data is a linear combination of statistically independent components. These components can be individually inspected for exploratory data analysis and can be further characterized as genetic or non-genetic components. The similarity between samples is calculated using a lower dimensional representation of the observed data constructed with non-genetic independent components, which is subsequently incorporated in a linear mixed model framework for eQTL analysis. To evaluate the performance of CONFETI, we compared it with published methods in synthetic eQTL data and multiple human datasets. In simulations we introduced a mix of sparse and Gaussian confounding factors and found that CONFETI most accurately corrected the effects of sparse confounding factors, while being able to separate genetic components from non-genetic components. We analyzed multiple tissues from the Genotype-Tissue Expression (GTEx) consortium, and evaluated the performance of different methods by measuring eQTL replication. We found the highest number of replicating eQTLs in similar tissues and across different tissues using CONFETI.

552F

A powerful framework for combining heterogeneous data in genetic association studies. *C. Lee[1], E. Eskin[2,3], B. Han[1].* 1) Department of Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center, 88, Olympic-ro 43-gil, Songpa-gu, Seoul 138-736, Korea; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, California 90095, USA; 3) Department of Computer Science, University of California, Los Angeles, Los Angeles, California 90095, USA.

Meta-analysis has become essential for combining genome-wide association studies (GWASs). Recent study designs of meta-analysis of GWASs now combine different layers of information, such as different phenotypes (multiple autoimmune diseases, psychiatric diseases, or expression levels from different tissues), different ethnicities, and different environmental interventions. In these study designs, it is important to account for heterogeneity, which refers to the effect size differences between datasets. Previously developed meta-analysis methods including RE2 (Han and Eskin, AJHG 2011) and ASSET (Bhattacharjee et al., AJHG 2012) can account for heterogeneity, but it is unclear if they achieve optimal power. Here, we propose a powerful method called RE3, which accounts for heterogeneity to obtain high power in meta-analysis of GWASs. The core idea of RE3 is to utilize the observation that the magnitude of heterogeneity likely lies within an expected range in meta-analysis of GWASs. By focusing on the expected range of heterogeneity in the newly designed statistic, RE3 can dramatically improve power compared to our previous approach, RE2. We simulated different patterns of heterogeneity, and RE3 outperformed RE2 and ASSET in all simulated scenarios. Then we performed a full literature search for publications that cited RE2 method, and obtained meta-analysis input data from them, which can represent the real patterns of heterogeneity. When we applied the methods to this real data gathered without bias, RE3 consistently produced more significant p-values compared with competing methods for all associated variants that we tested (5.4 times smaller p-values on average). These results underscore that RE3 can potentially be a useful tool for future study designs that aggregates different layers of information. Unlike other competing methods, RE3 is highly efficient even for combining a large number of datasets; it only takes a day for meta-analyzing a hundred GWASs. RE3 is freely available at http://software.buhmhan.com/RE3.

Modeling ancestry-dependent phenotypic variance reduces bias and increases power in genetic association studies. *S. Musharoff[1], D. Park[1], S. Huntsman[1], C. Eng[1], E. Burchard[1,2], N. Zaitlen[1].* 1) Lung Biology, University of California, San Francisco, San Francisco, CA; 2) Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA.

Many complex human phenotypes vary dramatically in their distributions between populations. Genetic association studies typically use estimates of ancestry, such as principal components (PCs), as fixed-effect covariates to prevent confounding caused by a dependence of phenotypic mean on ancestry. However, the current gold standard approach approach of including PC covariates in linear regression models (LR+PC) assumes that different populations have the same phenotypic variance, which may not hold for recently admixed populations. In this work we consider the possibility that populations with differences in phenotypic mean also have differences in phenotypic variance. First, we show this is the typical case under an additive genetic architecture. Then, we develop ADGLM, a likelihood-based method based on a double generalized linear model, to account for relationships between ancestry and phenotypic variance in genetic association studies. In simulations, our test ADGLM has better power than several linear regression tests that assume equal variance across groups. We observe power increases of 12 - 66% and obtain unbiased parameter estimates for data simulated with realistic effect sizes and minor allele frequency differences of 0.45. Furthermore, we show that the standard approach LR+PC can lead to inflation or deflation of p-values for tests of genetic association when population phenotypic variances differ. For example, simulated populations with minor allele frequencies of 0.05 and 0.5 produce test statistics with an inflation factor (lambdaGC value) of 1.56, which ADGLM fixes. When applied to the Study of African Americans, Asthma, Genes and Environments (SAGE), ADGLM find significant associations of baseline lung function (FEV1) with global ancestry proportion when either sex or BMI is a sole covariate. By contrast, LR+PC requires additional covariates (age, sex, height, and weight) for significant associations. When applied to GALA II Puerto Ricans, ADGLM finds ancestry significantly associated with mean methylation at 8 of ~320K genome-wide probes while LR+PC finds 1 significant association. ADGLM also finds 44 probes significantly associated with methylation variance, which may be due to ancestry-associated environmental effects. Overall, ADGLM finds more significant associations than linear regression with PCs possibly because ancestry affects phenotypic variances as well as phenotypic means, and is promising for other association studies.

554T

Statistical correction of the winner's curse explains replication variability in quantitative trait genome-wide association studies. *C. Palmer[1], I. Pe'er[1,2].* 1) Department of Systems Biology, Columbia University Medical Center, New York, NY, USA; 2) Department of Computer Science, Columbia University, New York, NY, USA.

Genome-wide association studies (GWAS) have identified hundreds of candidate SNPs putatively responsible for variation in human quantitative traits. However, effect sizes are often small and replication can appear inconsistent, leading to pervasive questions about the utility of the field as a whole. We seek to validate the performance of GWAS discovery of SNPs by systematically evaluating replication efficiency across the field of human quantitative trait genetics. We extract all 332 studies of quantitative, normally-distributed traits from the NHGRI GWAS database that attempted replication of results, and apply filters to find studies providing enough published data to perform power calculations. We find that 229 of these studies fail to provide full information of sample sizes, allele frequencies, or effect sizes for replicated and non-replicated SNPs. We find that, in 87 studies attempting replication of 1269 loci in samples with similar continental ancestry to the discovery population, discovery and replication additive effect estimates are statistically indistinguishable once adjusted for the winner's curse. Replication of 385 loci in 13 studies across populations of different continental ancestry shows a detectable attenuation of replication effect estimate for replication p-values below 1e-7, attributable to linkage disequilibrium variation across distinct ancestries. We see no systematic evidence for distinct behaviors of a given allele across different samples beyond those attributable to LD interactions with tagged true variants. Outlier detection using predicted replication rate estimates can successfully detect studies with clear study design failures unrelated to GWAS itself. Given the evident reliability of replication in human quantitative trait biology, we provide a tool that can diagnose systemic failures of study design by detecting significant deviations from expected replication when considering any variable replication p-value threshold.

Cost-effective strategies for rare-variant genome-wide association studies in the age of large reference panels. *C. Quick, C. Fuchsberger, M. Boehnke. Department of Biostatistics, University of Michigan, Ann Arbor, MI.*

Rare variants (RVs) are hypothesized to be a major source of missing heritability for complex diseases, establishing a need for efficient RV genome-wide association study (GWAS) designs. While array genotyping and imputation using a publicly available reference panel is cost-effective for detecting association at common variants, this strategy is less effective for RV GWAS. In particular, imputed genotyping array data only include RVs that are present in the reference panel or assayed by the array, and imputation accuracy for RVs is typically lower than for common variants. Here, we consider a hybrid GWAS strategy in which a subset of study participants is whole-genome sequenced and the remainder are array genotyped and imputed with a reference panel comprised of the sequenced study participants and an external reference panel (for example from the 1000 Genomes Project (1000G) or the Haplotype Reference Consortium (HRC)). We use analytic and simulation approaches to compute GWAS power as a function of the numbers of sequenced and array-genotyped study participants given a specified external panel and complex disease model. We applied our approach to find optimal numbers of study participants to sequence and array-genotype for a range of complex disease models and external panel sizes given current sequencing and array-genotyping costs. Our results show optimal hybrid strategies can substantially increase GWAS power relative to sequence-only and array-only strategies under a budget constraint when risk RVs of large effect contribute substantially to disease heritability. Gains in GWAS power over an array-only strategy decrease as external panel size increases; we discuss implications of small versus increasingly large publicly available reference panels (e.g., 1000G with ~1K samples versus HRC with ~33K samples) for cost-effective RV GWAS strategies. Finally, we introduce a web-based power calculator with flexible disease model and reference panel specification to facilitate identifying cost-effective strategies and estimating sample size for RV GWAS.

Combining patient electronic health information with genetic data to gain novel biomedical insights. *E. Schmidt[1], L. Fritsche[2], S. Lee[1], P. VandeHaar[1], C. Scheller[1], C. Brummett[3], S. Kheterpal[3], G. Abecasis[1]. 1) Department of Biostatistics and Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, MI; 2) K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health, NTNU, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, MI.*

The Michigan Genomics Initiative (MGI) is a collaborative research effort among physicians and researchers at the University of Michigan (UM) with the goal of combining patient electronic medical records (EMR) with genetic data to gain novel biomedical insights. Patients undergoing surgery at the UM Health System are invited to participate. The surgical procedural period provides a unique opportunity to collect patient biospecimens and enriched health information. Together, these data offer a powerful resource for innovative data analysis and discovery. Here we interrogate 7.7M common variants and 1,448 ICD-9 code-defined disease states to establish relationships between the genome and a diverse set of EMR-based outcomes, providing a comprehensive resource for the biomedical and genetic research communities. Blood samples from consenting surgical patients are collected and genotyped at 270K common markers on the Illumina HumanCoreExome array, which contains exome and custom GWAS content. Genotypes are imputed using the Haplotype Reference Consortium reference panel, providing dense mapping at over 7.7M common genetic markers. Phenotypes inferred from ICD-9 (International Classification of Disease, 9th edition) billing codes assigned to patients during their hospital or clinic visits are translated into broader 'PheWAS' (phenome-wide association study) code groups of shared disease etiology. The MGI cohort is enriched for cases with neoplasms including skin cancer (n=2,359) and breast cancer (n=1,160), reflecting the specialties of the UM hospital. In total, we perform genome-wide analyses in 18,267 unrelated European individuals for 1,448 PheWAS codes with at least 20 cases, across common variants with minor allele frequency > 0.01. We replicate several well-known genetic associations at genome-wide significance including Factor 5 and thrombosis (P=4x10^{-39}), *TCF7L2* and type 2 diabetes (P=2x10^{-11}), *PITX2* and atrial fibrillation (P=3x10^{-9}), and *FGFR2* and breast cancer (P=4x10^{-8}). In addition, we examine the shared genetic effects among different related and apparently unrelated traits, providing insight into relationships between traits not previously studied. Finally, we expose potential limitations of using electronic billing data for research such as the misclassification of type 1 and type 2 diabetes. Associations for a total of 1,448 traits can be explored in dynamic GWAS-to-PheWAS landscapes via our interactive browser at http://pheweb.sph.umich.edu.

Assessment and control of batch effects in genotyping Million Veteran Program (MVP) subjects. *N. Sun[1,2], M. Li[3,4], Y. Shi[3], H.S. Hunter-Zinck[3], J. Huang[3], C. Pan[5,6], J. Gelernter[1,7], T.L. Assimes[5,6], P.S. Tsao[5,6], C.J. O'Donnell[3,8], E.R. Hauser[9,10], S. Pyarajan[3,8], H. Zhao[1,2] for MVP Genomic Working Group.* 1) VA Connecticut Healthcare System, West Haven, CT; 2) Yale School of Public Health, New Haven, Connecticut; 3) VA Boston Healthcare System, Boston, MA; 4) University of Utah, Salt Lake City, UT; Johns Hopkins University, Baltimore, MD; 5) VA Palo Alto Health Care System, Palo Alto, CA; 6) Stanford University School of Medicine, Stanford, CA; 7) Yale School of Medicine, New Haven, CT; 8) Harvard Medical School, Boston, MA; 9) Durham VA Medical Center, Durham, NC; 10) Duke University, Durham, NC.

The Million Veteran Program (MVP) is an observational cohort study and mega-biobank in the Department of Veterans Affairs (VA) health care system. Like the Kaiser Permanente Research Program on Genes, Environment, and Health (RPGEH) and UK biobank, MVP integrates electronic health records with genomic laboratory testing data for all individuals. The first set of the biological samples of MVP subjects were collected over a 3-year period from over 50 different recruitment sites at the VA and processed at a central biorepository using standard sample quality metrics for DNA quality to allow genotyping. Duplicated samples were included to assess genotyping quality. A custom Affymetrix Axiom MVP_1.0 array with 723,305 probe sets was genotyped for 200,846 samples by two independent laboratories. In order to produce high quality genotyping data, we analyzed evidence for batch effects, which are well known to have a significant impact on genotype calling results. The large MVP dataset provides the opportunity to identify the most important experimental variables needed to adjust for technical and experimental variation when genotyping is performed over time and in different laboratories. We performed ANOVA analysis on a total of 17 experimental conditions to identify time and plate lot as the main factors affecting genotype calling variation. Various batching strategies were compared using the genotyping calls obtained from applying Affymetrix Power Tools (APT) and SNPolisher. The size of each batch was controlled at 4000 to 5000 samples to optimize the calling quality and the computational time of APT. The final 45 batches were identified to maximize the number of recommended probe sets in common across multiple batches, increase the concordance for duplicates within lab (>97%) and between labs (>96%), and reduce the discordance fractions per paired genotypes with at least one minor allele over duplicates. In this presentation, we will describe our strategies to minimize batch effect for the mega-cohort of MVP samples.

558F

Novel nonparametric test for multiple traits of sequencing data. *X. Wang[1], H. Huang[2].* 1) University of North Texas, Denton, TX; 2) University of Wisconsin-Milwaukee, Milwaukee, WI.

Pleiotropy, the effect of one variant on multiple traits, is a widespread phenomenon in complex diseases. Joint analysis of multiple traits can not only increase statistical power to detect disease susceptible genetic variants but also improve our understanding of the etiology of complex diseases. Although the cost of next generation sequencing (NGS) has been reduced, it is expensive to detect rare variants, and typically requires large samples. Moreover, most of the existing methods are parametric. These methods often assume parametric models and particular probability distributions. However, for NGS data, those assumptions may not be correct and it is typically difficult or impossible to ascertain whether or not certain parametric assumptions are justifiable. Therefore, parametric statistical methods can be very misleading. We developed novel nonparametric statistical methods to efficiently detect rare variants for multiple traits, which can not only be applied in large samples, but also work well for small samples. To perform the proposed nonparametric method, we first classified subjects into two categories; whether they carry rare variants or not in a gene. We then employed a nonparametric test to find out whether the two different categories differ significantly with regard to their risk. In this study, we propose three different nonparametric tests: Dempster-ANOVA type, Lawley-Hotelling type, and Bartlett-Nanda-Pillai type. To evaluate the performance of the nonparametric tests, we conducted extensive simulation studies with different underlying population distributions, namely, multivariate normal traits, t-distributed traits, and Cauchy type of traits. We accessed the type I error rates and compared the power of proposed tests with the existing test MSKAT. The type I error rates of all three tests are under control with different underlying population distributions, while MSKAT has inflated type I error rates for t-distributed traits and Cauchy type of traits. When sample size is less than 800, the nonparametric methods are more powerful than MSKAT in most scenarios for multivariate normal traits and t-distributed traits. The proposed tests are more powerful than MSKAT for Cauchy type of traits when the sample size is 1000 though MSKAT has inflated type I error rate. Therefore, our new methods are valid and powerful tests to detect rare variants for multiple traits in next generation sequencing data.

559W

Imputation quality scores are poorer predictors of true quality for rare than for common variants. *P. Yajnik[1], C. Fuchsberger[2], M. Boehnke[1].* 1) Biostatistics - School of Public Health, University of Michigan, Ann Arbor, MI; 2) Center for Biomedicine, EURAC, Bolzano, Italy.

The advent of high-throughput DNA sequencing has made it possible to assay nearly the complete spectrum of genetic variation. However, genome sequencing remains expensive for large epidemiologic studies. Genotyping on dense arrays followed by imputation is a cost-effective alternative to sequencing. Since genotype imputation is imperfect, imputation algorithms also output a variant level quality score that is typically used to filter out variants believed to have been imputed poorly. As with genotypes, the true quality of imputation is unknown and the quality scores are predictions of the true quality. The quality scores are known to work well as classifiers of true imputation quality for common variants (MAF ≥ 5%). We study their classification properties for low-frequency ($0.5\% \le$ MAF $< 5\%$) and rare variants (MAF $< 0.5\%$). We imputed variants on chromosome 20 in 8800 participants recruited from Finland (METSIM study) using Minimac3 with the 1000 Genomes Phase 3 reference panel and Illumina OmniExpress array as the backbone. Participants were also genotyped with the Illumina Exome array. Exome array genotypes were assumed to be true. 1206 imputed variants were also present on the Exome array of which 54.1%, 24%, and 21.9% were rare, low-frequency, and common, respectively. True imputation quality (defined as the squared correlation between imputed dosages and true genotypes) decreased with decreasing MAF. The classification accuracy of the Minimac3 quality score (MachRSQ) also decreased with decreasing MAF. The conventional cutoff of 0.3 used for common variants resulted in a positive predictive value (probability that the true r-squared exceeded 0.5 given that MachRSQ > 0.3) of 100%, 93.4%, and 71.4% for common, low-frequency and rare variants, respectively. We also observed that posterior genotype probabilities were miscalibrated for rare variants; the observed proportion of heterozygotes and alternate homozygotes was smaller than the respective imputed posterior probabilities. Finally, the mean squared error between true quality and MachRSQ was larger for rarer variants. The poorer performance of quality scores for rarer variants is partly due to the larger proportion of poorly imputed variants. However, the larger variance of prediction and bias due to miscalibrated posterior probabilities also decreased classification efficiency. We use our results to recommend best practices for evaluating and interpreting imputation quality metrics.

560T

Integrated enrichment analysis of genetic variants and biological pathways using GWAS summary statistics. *X. Zhu[1], M. Stephens[1,2].* 1) Department of Statistics, The University of Chicago, Chicago, IL; 2) Department of Human Genetics, The University of Chicago, Chicago, IL.

Statistical analyses that integrate genome-wide association studies (GWAS) with external genomic information, such as biological pathways, can increase power and yields new biological insights. We develop a regression-based approach to these analyses using GWAS summary statistics. Specifically, we perform Bayesian multiple regression analysis by combining a likelihood based on summary data (Zhu and Stephens, 2016) with a prior that incorporates pathway information (Carbonetto and Stephens, 2013). This combination not only allows the discovery of enriched pathway, estimation of enrichment level and prioritization of associated variants simultaneously, but also removes the need for individual-level data. Within the regression framework, our method automatically accounts for linkage disequilibrium, whereas other methods address this issue with extra complexity. We design a parallel variational algorithm for large-scale inference. Indeed, using moderate computational resources, a single analyst can finish the integrated analysis of 1.1 million SNPs and 3915 pathways within 1.5 day. We apply our method to the summary data of 21 complex human traits. Our analyses confirm many published links between pathways and phenotypes, including hedgehog signaling and adult height (BF=2.4E36), ERK MAPK signaling and body fat distribution (BF=3.2E67), IL23-mediated signaling and inflammatory bowel disease (BF=1.0E29), T helper cell surface molecules and rheumatoid arthritis (BF=3.3E8), adipocytokine signaling and type 2 diabetes (BF=2.7E55). Our analyses also implicate several links that were not highlighted in earlier GWAS, such as endochondral ossification (EO) and height (BF=3.0E63), S-Adenosyl-L-methionine biosynthesis and Alzheimer's disease (BF=3.3E88), synthesis of phosphatidylserine and heart rate (BF=1.6E244), thyroid hormone metabolism and myocardial infarction (BF=3.8E191). Moreover, our method uncovers biologically relevant genes in the enriched pathways that were not identified in previous analyses of the same data. For example, prioritization of EO genes shows that a putatively novel locus contains at least 1 height-associated SNP with posterior probability 1.00; in contrast, this probability is only 0.41 without considering the pathway. This locus is not near any of the previous 697 GWAS hits (distance>3.9Mb), and covers the gene *PTH1R*, which is involved in bone formation (Datta et al, 2010) and osteocyte survival (Maycas et al, 2015).

561F

A comparison study of multivariate fixed models and Gene Association with Multiple Traits (GAMuT) for next-generation sequencing. *R. Fan[1], C. Chiu[1], J.L. Mills[1], J.S. Jung[2], Y.F. Wang[3], A.F. Wilson[4], B.E. Bailey- Wislon[4], D.E. Weeks[5], C.I. Amos[6], M. Boehnke[7], M.M. Xiong[8].* 1) BBB, DIPHR, NIH, NICHD, Rockville, MD; 2) National Institute on Alcohol Abuse and Alcoholism; 3) Center for Drug Evaluation and Research, FDA; 4) National Human Genome Research Institute, NIH; 5) University of Pittsburgh; 6) Dartmouth Medical College; 7) The University of Michigan, Ann Arbor; 8) University of Texas – Houston.

In this project, extensive simulations are performed to compare two statistical methods to analyze multiple correlated quantitative phenotypes: (1) approximate F-distributed tests of multivariate functional linear models (MFLM) and additive models of multivariate analysis of variance (MANOVA), and (2) Gene Association with Multiple Traits (GAMuT) for association testing of high-dimensional genotype data. It is shown that approximate F-distributed tests of MFLM and MANOVA have higher power and are more appropriate for major gene association analysis (i.e., scenarios in which some genetic variants have relatively large effects on the phenotypes); GAMuT has higher power and is more appropriate for analyzing polygenic effects (i.e., effects from a large number of genetic variants each of which contributes a small amount to the phenotypes). MFLM and MANOVA are very flexible and can be used to perform association analysis for: (i) rare variants, (ii) common variants, and (iii) a combination of rare and common variants. Although GAMuT was designed to analyze rare variants, it can be applied to analyze a combination of rare and common variants and it performs well when (1) the number of genetic variants is large and (2) each variant contributes a small amount to the phenotypes (i.e., polygenes). MFLM and MANOVA are fixed effect models which perform well for major gene association analysis. GAMuT can be viewed as an extension of sequence kernel association tests (SKAT) of mixed models. Both GAMuT and SKAT are more appropriate for analyzing polygenic effects and they perform well not only in the rare variant case, but also in the case of a combination of rare and common variants. Data analyses of European cohorts and the Trinity Students Study are presented to compare the performance of the two methods.

562W

Bayesian evaluation of variant involvement in Mendelian disease. *D. Greene[1,2,3], E. Turro[1,2,3], S. Richardson[3].* 1) Department of Haematology, University of Cambridge, Cambridge Biomedical Campus, Cambridge, UK, CB2 0XY; 2) NHS Blood and Transplant, Cambridge Biomedical Campus, Cambridge, UK, CB2 0PT; 3) Medical Research Council Biostatistics Unit, Cambridge Biomedical Campus, Cambridge, UK, CB2 0SR.

Rare diseases are often caused by high-penetrance rare variants. Because of genetic heterogeneity and low numbers of cases, statistical procedures testing each variant for marginal association with phenotype are often underpowered. Procedures which aggregate rare variants across regions also sacrifice power because they are likely to include non-pathogenic rare variants in the aggregation. Therefore, models are required which account for a mixture of pathogenic and non-pathogenic rare variants explicitly. Ideally, the composition of this mixture would be informed by additional information such as sequence conservation across species and population allele frequency. It is also important to model the modes of inheritance typical in Mendelian disease, including autosomal dominant, autosomal recessive, and X-linked recessive inheritance. We present a new method, `Bayesian Evaluation of Variant Involvement in Mendelian Disease' (BeviMed), which assesses the evidence of association between a case-control label and presence of one or more genetic configurations of alleles at rare variant sites. The configurations depend on a latent partitioning of variants into pathogenic and non-pathogenic groups and can be informed by external information. Different modes of inheritance are modelled by conditioning on the number of pathogenic alleles carried by each individual (and gender, in the case of X-linked inheritance). Thus compound heterozygosity and homozygosity can be treated equivalently. Inference is performed by obtaining posterior probabilities of the different models of association and a baseline model of no association. Our approach performs as well or better than existing methods in terms of sensitivity and specificity at the region level (which could correspond to a gene) and at the individual variant level. BeviMed can analyse 10,000 samples genotyped at 100 rare variant sites with minor allele frequencies averaging 2.5% in under a second, enabling fast genome-wide rare variant evaluation. We show the results of analysing a dataset of 5,000 whole-genome sequenced samples from patients with diverse rare diseases.

563T

On the difference between genealogical and genetic ancestors. *M. Jeanpierre[1,2].* 1) Université Paris Descartes, Paris, France; 2) Genetics Dept, Assistance Publique-Hôpitaux de Paris, Paris, France.

   The correct interpretation of genetic variation requires an accurate estimation of the penetrance of disease-causing variants. Such estimates are dependent on the context in which they are obtained and are sensitive to sampling biases due to the clustering of cases in highly affected families. Low-penetrance variants may be analyzed as negatively selected traits, through ancestral graphs representing the common ancestry of variant carriers. The expected number of ancestors for a given individual doubles with each generation, until the simple dichotomous division is interrupted by the occurrence of a common ancestor. However, this simple pattern does not reflect the highly variable size of the chromosome segments actually inherited. The distribution of the mosaic of inherited segments can be visualized with a simple analytical model. The highly asymmetric distribution of the lengths of genetic contributions implies that some ancestors may not actually have contributed anything to the genetic make-up of contemporary chromosomes. The difference between the mean numbers of genetic ancestors (defined as those actually contributing to distant offspring) and genealogical ancestors (some of whom may have made no contribution to the genome of the descendants considered) becomes more marked the further back in time we look, because the number of genetic ancestors increases linearly with the number of generations, whereas the number of genealogical ancestors increases exponentially. New variants are annotated with existing pathogenicity prediction tools. The reuse of recently identified variants as a training set thus presents a real risk of circularity. Assessments of pathogenicity from the network of ancestral links may provide an independent source of experimental evidence, particularly for the weakest variants, because some of these ambiguous variants may reach moderate frequencies. However, it remains challenging to understand the birth and death of mutations subject to weak selection, because human populations are not in equilibrium. Here is shown that algebraic expressions exploiting subtree structures provide an analytical representation of pathogenicity that is useful in practice, because stochastic methods are not suitable for the analysis of large datasets. Contemporary chromosomes are mosaics of ancestral genomes, with highly asymmetric distributions of information that become increasingly apparent the further back into the past we delve. .

Chan School of Public Health, Boston, MA.

   Haplotype phasing is a central problem in human genetics. Over the past decade, phasing has most commonly been performed via statistical methods applied within a genotyped cohort. In general, the accuracy of statistical phasing methods increases steadily with sample size; as such, we and others have recently developed methods that achieve very high statistical phasing accuracy in very large cohorts ($N>$100,000). However, for smaller cohorts, accuracy of cohort-based statistical phasing is fundamentally limited by the quantity of data available. Here, we explore an alternative paradigm, reference-based phasing, which can achieve high accuracy even in smaller cohorts by leveraging information from an external reference panel. We present a new reference-based phasing algorithm, Eagle2, which we have incorporated into the Sanger Imputation Service and the Michigan Imputation Server to perform free reference-phasing using the 32,470-sample Haplotype Reference Consortium (HRC) panel. This approach achieves >2x improved phasing accuracy over publicly available alternatives when used to phase small European-ancestry cohorts, with smaller improvements for larger cohort sizes. The Eagle2 algorithm represents a substantial computational advance over existing reference-based phasing algorithms: Eagle2 achieves a 20x speedup over SHAPEIT2—i.e., genome-wide phasing in 1.5 minutes per sample—with a 10% improvement in accuracy across a range of ancestries. (SHAPEIT2 is not available for reference-based phasing on public HRC servers due to licensing restrictions.) Eagle2 achieves this performance via two key ideas that distinguish it from previous phasing algorithms: a new data structure based on the positional Burrows-Wheeler transform and a rapid search algorithm that explores only the most relevant phase paths through a hidden Markov model (HMM). We have released Eagle2 as open-source software. We note that Eagle2 targets a complementary user group compared to very recent work on phasing very large cohorts. In particular, our Eagle1 method (Loh et al. 2016 Nat Genet) is targeted at phasing very large ($N>$100,000) cohorts and achieves much lower accuracy than both Eagle2 and previous methods when used to phase smaller cohorts. Likewise, the SHAPEIT3 method (O'Connell et al. in press Nat Genet), which is unreleased at the time of this writing, is targeted at phasing "biobank scale datasets.".

Estimating regional heritability in the presence of linkage disequilibrium.
L. Gai[1], S. Mangul[1], E. Kang[1], S. Eyheramendy[2], E. Eskin[1,3]. 1) Department
of Computer Science, UCLA, Los Angeles, CA; 2) Department of Statistics,
Pontificia Universidad Catolica de Chile; 3) Department of Human Genetics,
UCLA, Los Angeles, CA.

The study of expression quantitative trait loci (eQTL) has emerged as a
promising area of research for understanding the mechanisms behind many
complex diseases and traits. Recently, there has been increased interest in the
genetic architecture of gene expression, which can be studied by estimating
the contribution of genomic regions to heritability. However, methods for par-
titioning heritability typically assume variants in each region are not in linkage
disequilibrium (LD) with variants in other regions. This assumption is violated
if proximal variants are partitioned into different regions, as is often the case
when partitioning by functional annotation or variant frequency. This can lead
to inaccurate estimates of a region's contribution to heritability. We present an
alternative partitioning scheme, Local Heritability using Linear Mixed Models
(locLMM) which accounts for the inherent ambiguity arising from the presence
of LD. We demonstrate that locLMM provides accurate estimates of the lower
bound of regional heritability and its application to eQTL data.

**Using shared IBD haplotypes in unrelated samples to obtain near unbi-
ased estimates of the full narrow-sense heritability.** *M. Keller[1], L. Evans[1],
R. Tahmasbi[1], T. de Candia[1], D. Bjelland[1], J. Yang[2], M. Goddard[3], P. Visscher[2].*
1) Inst Behavioral Genet, Univ Colorado, Boulder, Boulder, CO; 2) Queensland
Brain Institute, University of Queensland, Brisbane, 4072, Queensland, Austra-
lia; 3) Faculty of Veterinary and Agricultural Science, University of Melbourne,
Parkville, Victoria, Australia.

Despite 50 years of estimates of narrow-sense heritability (h^2) from twin
and family studies, and more recently from unrelated individuals using
genome-wide SNP data, the true levels of h^2 remain elusive. Twin and family
studies over-estimate h^2 to the degree that non-additive genetic and common
environmental factors inflate phenotypic similarity between close relatives,
while models based on SNP similarity only capture the effects of (typically
common) causal variants tagged by SNPs on arrays. The use of IBD sharing
has been proposed as a method to derive estimates of h^2 due to both common
and rare causal variants; if this method is done on a sample of unrelated
individuals, the estimates are not biased by factors shared by close relatives.
Here, we use real whole genome sequences to thoroughly investigate the
behavior of h^2 estimates based on IBD sharing. We simulated phenotypes
of different allelic spectra (from common to very rare) and different levels of
population stratification from ~21K whole genome sequences from the Haplo-
type Reference Consortium. We simulated SNP array data by extracting from
this data ~500K common SNPs found on the UK Biobank Axiom Array. We
calculated genomic relationship matrices (GRMs) from IBD shared segments
estimated from computationally phased Axiom SNPs, and estimated h^2 using
random effects models. GRMs based on longer IBD segments provide
increasingly unbiased h^2 estimates. Once IBD segments are ~4 centimorgans
(cM) in length, this method accurately estimates all of the h^2 except that due
to the rarest causal variants (those observed < 3 times in the sample). GRMs
based on IBD segments > 4 cM become increasingly less reliable and, in strat-
ified samples, lead to over-estimates of h^2. We conclude that estimates based
on IBD segments ~4 cM in homogeneous samples provide unbiased estimates
of the h^2 due to all but extremely rare causal variants, and the method provides
sufficiently reliable h^2 estimates to be used in large sample SNP array data
in outbred populations (predicted standard errors of ~.03 in 120K unrelated
individuals), such as that currently being collected by the UK Biobank. We
believe that this is the most thorough investigation to date of the behavior of h^2
estimates from IBD sharing, and our results provide a clear roadmap for how
near full h^2 can be estimated in unrelated samples in a way that is not biased
by non-additive genetic and environmental factors shared by close relatives.

567F

Calculating the statistical significance of rare variants causal for Mendelian and complex disorders. *A.R. Rao, S.F. Nelson.* David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA.

To calculate the significance of finding a rare protein-altering variant in a given gene, one must know the frequency of seeing a variant in the general population that is at least as damaging as the variant in question. Based on data from 2504 individuals in the 1000 Genomes Project dataset, we calculated the number of individuals who have a rare variant in a given gene for numerous filtering threshold scenarios, which may be used for calculating the significance of an observed rare variant being causal for disease. Examining the dataset, we find that fewer individuals tend to carry rare, heterozygous loss-of-function (LOF) variants in genes that are known to be causal for Mendelian disorders, and fewer yet carry variants in genes essential for the survival of human cell lines. Additionally, we provide data on the number of individuals with rare variants in genic regions mapping to protein domains, which is useful information to have when vetting putative variants found in certain regions of a gene. We also apply our methods to previous findings in 19 next-generation sequencing studies and demonstrate that incorporating mutational burden data would have provided statistical evidence in support of the causal gene in all studies, with the benefit of being easy to compute from our dataset, as opposed to running simulations of populations and estimated mutation rates. If we use the frequency counts to rank genes based on intolerance for variation, the ranking correlates well with Z scores derived from the ExAC dataset ($\rho = 0.485$), with the benefit of being directly interpretable and useful for developing a quantitative, statistics-based approach for presenting clinical findings. We describe methods to use the mutational burden data for calculating the significance of observing rare variants in a given proportion of sequenced individuals, and we make the datasets, collectively named Significance of Rare VAriants (SORVA), freely available for download or querying at https://sorva.genome.ucla.edu.

Maternal-fetal genotype interaction testing: Human birth weight and reproductive immunity. *M.M. Clark[1], O. Chazara[2,3], E.M. Sobel[4], H.K. Gjessing[5], P. Magnus[5], A. Moffett[2,3], J.S. Sinsheimer[1,4,6].* 1) Department of Biostatistics, Fielding School of Public Health, University of California, Los Angeles, CA, USA; 2) Department of Pathology, University of Cambridge, Cambridge, United Kingdom; 3) Center for Trophoblast Research, University of Cambridge, Cambridge, United Kingdom; 4) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA; 5) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway; 6) Department of Biomathematics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA.

The interplay between mother and offspring gene products is often neglected in epidemiological studies of human complex traits. One likely example of a maternal-fetal genotype (MFG) interaction is due to the direct contact of semiallogenic cells at the site of placentation. During pregnancy, invasive trophoblast cells emerge from the placenta into the uterine wall and assist in remodeling the uterine vasculature to provide an adequate blood supply to the fetus. Killer cell immunoglobulin-like receptors (KIRs) on the surface of uterine NK cells produced by the maternal immune system bind to HLA-C molecules expressed by the invasive trophoblasts from the fetus. Previous work (Hiby *et al.*, 2014) found evidence of an association between variation in normal birth weight and an interaction of maternal *KIR* and maternal and offspring *HLA-C*, but models involving the joint but independent effects of *KIR* and *HLA-C* could not be compared. Although a number of statistical approaches exist to test for the association of maternal-fetal genotype (MFG) interactions and disease, very few approaches exist to test for their association with quantitative traits. These approaches have been limited to case-parent trios, cannot easily account for covariates, and parameter interpretations can be unclear. To address these limitations and motivated by the hypothesis that both *KIR* and *HLA-C* jointly affect birth weight, we developed the multi-locus Quantitative-MFG (QMFG) test, using an underlying linear mixed effect model (LMM). We demonstrate the QMFG test's statistical properties with simulation studies. We also show that standard methods that focus only on the offspring genotype will miss these effects. We then reexamine the association of maternal *KIR*, maternal *HLA-C*, offspring *HLA-C*, and birth weight using data from a cohort of mothers and babies from a United Kingdom cohort study and from the Norwegian Mother and Child Cohort (MoBa) study. We find evidence for a *KIR-HLA-C* interaction along with main effects of maternal *KIR* and maternal and offspring *HLA-C*, indicating that these two loci may provide independent effects in addition to their interaction or they may be involved in a more complex pathway than a simple multiplicative interaction. More generally, our results show the value of using a LMM with maternal and offspring genotypes as predictors when these data are available.

569T

How to combine sequence data: Recommended meta-analysis strategies of sequencing data for association testing of rare variants. *Z. Chen, C. Fuchsberger, M. Boehnke.* Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Recent technological advances in high-throughput DNA sequencing have dramatically increased the abundance of whole-genome sequence data. These data offer new opportunities to discover disease variants but are also less standardized and depend heavily on the sequencing and variant calling protocols employed. The lack of uniformity is accentuated in the context of studying rare and low-frequency variants where an aggregated dataset is commonly used to increase the power of association tests. For array-based association studies, joint and meta-analysis strategies are well-developed but it is not yet known how best to combine sequencing studies of varying protocols. Here, we seek to quantify the differences in terms of variant identified and variant quality between joint and by-study genotype calls that used different standard protocols and compare the relative power of joint and meta-analysis of single variant tests considering these technical differences. We ran low-coverage (~5X) whole-genome sequencing data from 2772 individuals in the GoT2D study through the GotCloud and GaTK variant calling pipelines using default settings jointly and then separately in 5 sub-cohorts determined by geographic location. We compared the variants discovered between the two pipelines and then assessed the quality of their genotype calls by calculating their non-reference concordances with a set of highly confident ("gold standard") genotypes from deep exome sequence and Illumina HumanOmni2.5 array data. We then conducted single-variant association tests of type 2 diabetes (T2D) status for each of the joint and by-study call sets and combined the by-study results using fixed-effects meta-analysis. 85% of SNPs discovered in each joint and by-study call set were found by both GotCloud and GaTK pipelines while the rest were found by one pipeline but not the other. SNPs discovered by both pipelines have >99% non-reference concordance with our gold standard genotypes while SNPs found by GotCloud alone or GaTK alone have on average 97% and 71% non-reference concordances, respectively. Meta-analysis of by-study single variant association results show reduced power compared with joint analysis when covariates (sex, principal components, etc.) are included in the regression model (genetic variants versus T2D status). We propose strategies for combining sequencing studies that will offer improved power for analysis of rare and low-frequency variants.

570F

A polygenic risk modeling technique based on penalized estimation approach to incorporate linkage disequilibrium and functional information of SNPs using genome-wide association study summary-level data. *T. Chen[1], J. Shi[2], N. Chatterjee[3].* 1) Département de mathématiques et de statistique, Université Laval, Québec (Québec), Canada; 2) Biostatistics Branch, NCI/DCEG, Bethesda, MD, USA; 3) Depts Biostatistics and Medicine at the Johns Hopkins University Bloomberg School of Public Health and Johns Hopkins School of Medicine, Baltimore, MD, USA.

Polygenic risk score (PRS) has been a popular tool for genetic risk prediction of complex diseases. It can be constructed based on the summary statistics from genome-wide association studies (GWAS). Several methods have been proposed to improve the performances of PRS. The standard version is based on a set of independent SNPs with p-values less than a predefined significance level. Moreover, winner's-curse adjustments and external functional/annotation on a set of independent SNPs have been proposed to improve the performances of PRS. Another type of modification is to incorporate LD information based on Bayesian modelling technique, but without the usage of the functional knowledge. We propose a new method to incorporate both LD and functional annotation based on a penalized estimation approach. We applied our methods to GWAS summary-level data of 6 traits including height, BMI and complex diseases. Overall, the incorporation of LD enhances the prediction efficiency as 10-75% augmentation in prediction R squares compared to the standard PRS. For instance, the improvements of BMI and type 2 diabetes are from 4.3% to 6.6% and 2.1% to 3.6% respectively. The additional information of functional annotation of SNPs has only benefited certain traits such as type 2 diabetes to 4.2%. Extensive simulation studies have been conducted to illustrate the performances of the proposed method. In addition, we provide the prediction R squares obtained from other competing methods in both real data and simulation studies and the results demonstrate that our proposed methods have significant advantages.

571W

Bayesian meta-analysis for cross-phenotype genetic association study.
A. Majumdar[1], S. Bhattacharya[2], J. Witte[1]. 1) University of California, San Francisco, San Francisco, CA, USA; 2) Indian Statistical Institute, Kolkata, India.

Simultaneous analysis of genetic association across multiple traits may reveal shared genetic susceptibility among traits (pleiotropy). While assessing pleiotropy, alongside measuring the evidence of overall pleiotropic association, it is crucial to identify the traits associated with a risk locus since only a subset of the traits may have the true genetic effects. We propose a Bayesian cross-phenotype meta-analysis using a spike and slab type of prior that provides a Bayes factor measuring the global pleiotropic association and an optimal subset of traits associated with the risk locus. In the spike and slab type of prior, the spike corresponding to the null genetic effects can either be a positive mass at zero (Dirac spike), or a normal distribution with zero mean and a variance smaller than that of the normal distribution (with zero mean) representing the slab corresponding to the non-null genetic effects (continuous spike). Gibbs samplers are designed for these two types of priors in the case of both uncorrelated and correlated summary statistics corresponding to multiple traits. We demonstrate by simulations for multiple normally distributed traits that a continuous spike is an overall better alternative than Dirac spike for drawing inference. This meta analysis approach allows heterogeneity in both the direction and magnitude of the genetic effects across traits. Unlike a frequentist method, it also estimates the posterior probability of a trait being associated with a risk locus. It is applicable to both cohort data and separate studies of multiple traits having overlapping or non-overlapping subjects. For strongly correlated summary statistics, the Gibbs sampler can suffer from poor mixing due to multi-modality of the posterior distribution of the model parameters. To address this issue, we propose an empirical Bayes version of the meta analysis by leveraging the information obtained by a false discovery rate (FDR) controlling procedure using the same data. Simulations show that in common scenarios, our method produces better accuracy in the selection of traits than a subset-based meta analysis ASSET (Bhattacharjee et al., 2012) with respect to both specificity (correctly discarding null genetic effects) and sensitivity (correctly including non-null genetic effects). Finally we analyze 22 traits in the large Kaiser cohort using our proposed approach.

572T

Region-based association tests for sequencing data on survival traits. *Y. Chiu[1], L. Chien[2], D. Bowden[3].* 1) National Health Research Institutes, Zhunan, Miaoli 35053, Taiwan, ROC; 2) Institute of Statistical Science, Academia Sinica, Taipei 11529, Taiwan, ROC; 3) Center for Diabetes Research, Center for Genomics and Personalized Medicine Research, Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, North Carolina 27157, USA.

Identification of functional variants has been one of the important steps to understand the genetic basis of complex diseases. Family-based designs enriched with affected subjects and disease associated variants can increase statistical power for identifying functional rare variants. However, few rare variant analysis approaches are available for time-to-event traits in family designs. We developed novel pedigree-based burden and kernel association tests for time-to-event outcomes with right censoring for pedigree data, referred to FamRAS (Family-based Rare variant Association tests for Survival traits). Cox proportional hazard models were employed to relate a time-to-event trait with rare variants (MAF < 0.05) with flexibility to encompass all ranges and collapsing of multiple variants. In addition, the robustness of violating proportional hazard assumptions was investigated for the proposed and four current existing tests including the conventional population-based Cox proportional model and the burden, kernel and sum of squares statistic (SSQ) tests for family data. The proposed tests can be applied to large-scale whole-genome sequencing data. They are appropriate for the practical use under a wide range of misspecified Cox models, as well as for population-based, pedigree-based or hybrid designs. In our extensive simulation study and data example, we showed that the proposed kernel test is the most powerful and robust choice among the proposed burden test and the existing four rare variant survival association tests. When applied to the Diabetes Heart Study, the proposed tests identified exome variants of the *JAK1* gene on chromosome 1 to be associated with age at onset of type 2 diabetes ($P < 4.82 \times 10^{-5}$, the Bonferroni significance threshold for testing multiple genes on chromosome 1).

573F

A novel approach to genetic association testing: The Conditional on Opposite Alleles Test (COAT). *B. Maher.* Johns Hopkins School of Public Health, Baltimore, MD.

The topic of allelic versus genotypic models for genetic association testing using the usual statistical models has been explored by a number of investigators over the past few decades. Generally, the results of these investigations have lead to widespread use of genotypic dosage tests in spite of some advantages of allelic tests. Presented here is a set of tests that is a middle ground between genotypic and allelic tests, referred to as the Conditional on Opposite Alleles Tests (COAT). The basis for COAT is to model alleles at a SNP as paired data, not as fully indistinguishable (as in genotype tests) or as fully independent (as in allelic tests). This is accomplished using mixed models, allowing for random intercepts, to account for the effect of the opposite allele in the pair, or slopes, to allow for non-additive effects or by adjusting for the effect of the opposite allele in a linear model. COAT is compared via simulation to common existing allelic and genotypic tests and to other novel approaches. Under the models tested, COAT using a random intercept maintains or exceeds the power of the usual approaches under additivity and exhibits increases in power to detect association when dominance is present. Overall, COAT is an important alternative to existing tests, is valid for discrete and continuous traits, and is easily extended to family-based data. .

574W

Effects of imputation on combined admixture and association mapping.
D. Yorgov[1], S.A. Santorico[1,2,3]. 1) Mathematical and Statistical Sciences, University of Colorado, Denver, USA; 2) Human Medical Genetics and Genomics Program, University of Colorado School of Medicine, Aurora, Colorado, USA; 3) Department of Biostatistics and Informatics, Colorado School of Public Health, University of Colorado, Aurora, Colorado, USA.

For populations like African Americans and Latinos, the long-range correlations introduced by the admixture process allow for gene mapping methods that combine genotype with ancestral origin information (local ancestry). In several studies, combining admixture and association information resulted in findings that were not detectable with standard association testing, suggesting that for a genome-wide association study (GWAS) power can be gained from combining two different sources of genetic information. Using extensive simulations based on real Latino genomes, we investigate the possible gains in power from different ways of incorporating local ancestry into single variant association testing at GWAS chip resolution. We compare such approaches to imputation followed by a standard association test. We simulate polygenic traits with a single causal common variant per locus, and a causal allele with the same effect regardless of its ancestral origin. Markers with sufficient degree of allele frequency differentiation in the ancestral populations that do benefit from the admixture information were (1) those with differential linkage disequilibrium patterns in the ancestral populations (for combined tests) and (2) those with causal allele originating largely from one of the ancestral populations (for admixture mapping). For this simulation scenario our results suggest that, at GWAS chip resolution, there is limited benefit from incorporating local ancestry in admixture mapping or in combined admixture and association testing since higher power can be achieved by the imputation approach. Specifically, imputation of the causal marker followed by association testing was the best approach with respect to power both on average across all regions containing causal markers and individually at each region. Imputation and association yielded increases of the average power compared to the best powered admixture and combined tests by factors of 5.3 and 2.13, respectively. We further show that the standard linear mixed model approach, without local ancestry adjustment through a fixed effect, controls well for Type I error in both the association test and in the combined admixture and association tests. Additional simulation scenarios that allow for allelic heterogeneity are being considered to assess the utility of a combined approach as a complementary scan when high resolution genotypes are available via sequencing or imputation.

575T

A statistical method for phenotype-genotype association that is robust to sequencing misclassification. *L. Zhou[1], D. Londono[1], A. Musolf[2], T.C. Matise[1], D. Gordon[1].* 1) Department of Genetics, Rutgers, the State University of New Jersey, Piscataway, NJ; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Regions of the human genome where genotype frequencies significantly differ among cases and control groups may be regions that harbor disease loci. The purpose of this study is to develop a statistical test of association between multi-locus genotype (MLG) frequencies and a disease phenotype in a case/control study utilizing Next Generation Sequencing (NGS) data. This statistic is a likelihood ratio test whose asymptotic null distribution is central chi-square (degrees of freedom dependent upon the number of MLGs). We designed the statistic to be robust to differential sequencing misclassification (sequencing errors) in NGS variant calls. The parameters utilized in the test are (for each individual): (i) the observed alternative read counts at the set of SNPs; (ii) corresponding sequencing coverage at the SNPs; and (iii) phenotypes. Maximum likelihood estimates of MLG frequencies, sequencing errors and log-likelihoods are determined by an expectation-maximization (EM) algorithm. We apply permutation and bootstrapping to assess the type I error and power. We also use the factorial design to determine the performance of this statistic under specific genetic-model parameter situations. We find that this method maintains the correct type I error rate in simulation data and the 1000 Genome data for permutation with significant levels of 1%, 5%, and 10%.

576F

Quality control analysis of the 1000 Genomes Project Omni2.5 genotypes. *N.M. Roslin[1], W. Li[1], A.D. Paterson[1,2,3], L.J. Strug[1,2,4].* 1) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 2) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 3) Epidemiology and Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 4) Biostatistics and Statistics, University of Toronto, Toronto, ON, Canada.

The 1000 Genomes Project genotyped 2318 individuals (48.1% male) from 19 populations in 5 continental groups on the Illumina Omni2.5 platform. The data are publicly available, and will prove a valuable resource to obtain ethnic-specific allele frequencies, as well as exploring population histories through principal components analysis (PCA), estimation of inbreeding coefficients, and admixture analysis. As in any study, the data should be cleaned prior to analysis, to remove individuals or markers of questionable quality. Furthermore, a thorough understanding of the relationships between individuals must be established. Here we report our findings after comprehensive examination of the data for quality control. The basic quality of the genotypes was assessed using standard procedures. KING version 1.4 was used to confirm the relationships in the provided pedigrees, and also to detect undeclared relationships. PCA was used to examine the similarities and differences between individuals among and between population groups. In general, the data was found to be of high quality. No samples were removed due to low call rate (<97%), or excess heterozygosity. Sex chromosome genotypes showed one individual with a discrepancy between reported and inferred sex, and were unable to determine sex in an additional 20 individuals; the sex for these was changed to unknown. Relationship checking found discrepancies between first-degree relationships in the provided pedigrees and the genotypes in 9 families, including one instance where a reported parent/child pair was unrelated, two instances where full sibs were unrelated, and one set of three individuals who formed a newly defined trio. A set of 1756 individuals who were inferred to be no closer than 4th degree relatives was extracted and used in PCA. These individuals clustered in a pattern that is consistent with other published reports of global populations. We identified 4 individuals whose genotypes clustered more closely with a different geographic region than the one in the provided data. Although the genotype data is of high quality, errors exist in the publicly available dataset that require attention prior to using the genotypes. A list of SNPs with good quality metrics, as well as a revised pedigree file and a list of unrelated individuals is available at http://tcag.ca/.

577W

Quantifying the reproducibility/repeatability of a multivariate assay. *R. Makowsky, B.J. LaFleur.* Biostatistics, HTG Molecular, Tucson, AZ.

Establishing diagnostic Reproducibility / Repeatability (RR) of highly multivariate assays is a challenging statistical problem. One common approach is to do multiple pairwise comparisons and assess the correlation coefficients across various conditions (e.g., instruments, lots, etc.). This approach is statistically unsatisfactory in that pairwise correlation is a measure of linear association, and not a measure of reproducibility. Interclass correlation coefficients derived from variance components are a suitable alternative, but it is not obvious how to utilize them in a highly multivariate setting. We propose a general strategy for how to conduct, visualize, and evaluate such an analysis with high-dimensional outcomes. We exemplify our approach using the HTG EdgeSeq miRNA Whole Transcriptome Assay (WTA). This assay measures the expression of 2,084 human miRNA transcripts using next generation sequencing. For this study, we were interested in quantifying the RR of the assay when run on different days and processors using eight replicates of three different Sample types per combination of Day and Processor. We show that the ICC values for Day and Processor were consistently low across probes (each < 1% on average), with Sample Type accounting for the majority of the observed variance. Additionally, we demonstrate how this approach is invariant to standard transformation (CPM) and normalization (Median, as proposed by Ander and Huber, 2010, and implemented in Bioconductor packages DESeq / DESeq2) approaches. In summary, we found that this analytic approach provides a useful quantification of RR, is easy to visualize and summarize for high dimensional data, and correctly accounts for the intended use population's variability.

578T

A unifying statistical test for privacy in the era of large-scale genomic and medical data sharing. *S. Prabhu, C. Bustamante.* Department of Genetics and Biomedical Data Science, Stanford University, Stanford, CA.

Widespread sharing of genomic and clinical datasets between researchers is necessary to unleash the personalized medicine revolution. This rationale has motivated large-scale international projects like the NIH's PMI-CP and Genomics England's 100K genomes, among others. However, proposals to disseminate sensitive biological data have raised pressing questions about privacy – particularly the risk of study partyicipant re-identification. The concerns are valid, and they need to be addressed immediately. Current guidelines for mitigating risk largely amount to a two-pronged approach: (a) permit broad access to study-wide summary statistics, while (b) control and limit access to individual-level data. From a statistical privacy standpoint, these are known to be inadequate. Multiple studies have already established that at least some quantitative summaries (allele frequency in a dataset, allele carrier status in a dataset) are vulnerable to attack, while the safety of other summaries (effect sizes, p-values) remains tentative. Changes to federal policy in response to these attacks have been ad-hoc and reactionary (e.g. stop sharing allele frequencies), rather than quantitative, principled and measured. This confusion stems from multiple definitions of privacy, utility, and attack techniques. In light of these anecdotal demonstrations, there is an urgent need for an overarching statistical framework in which various publication schemes might be assessed, risk to participant privacy (from both existing and future attacks) might be measured, and appropriate policies might be devised. Here, we present such a unifying framework. Specifically, we unify statistical attacks based on Hypothesis Tests and Bayesian formulations (popular in the genomics and statistics communities), with the widely adopted Differential Privacy definition (popular in the computer science community). We present the Model Indistinguishability Criterion (MIC), a new information theoretic metric that conveys a natural and intuitive meaning of risk to a study participant. The MIC is almost assumption free, and offers a practical means for data stewards to test whether their publications are secure. We characterize the connection between MIC and well-established model selection criteria like AIC (Akaike) and BIC (Bayes). To the best of our knowledge, this is the first body of work to comprehensively integrate the major frameworks of statistical privacy analysis used across multiple disciplines.

579F

Characterizing the health phenome in communities of distantly related individuals in a multi-ethnic biobank in New York City. *G.M. Belbin[1,2], B.S. Glicksberg[1,3], N.D. Beckmann[1,3], G. Nadkarni[1,2], D. Park[4], M.C. Yee[5], S. Ellis[1,2], A. Auton[6], J. Cho[1,2,3], R.J.F. Loos[1,2], N. Abul-husn[1,2], N. Zaitlen[7], E.E. Kenny[1,2,3].* 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mt Sinai, New York, NY; 3) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mt Sinai, New York, NY; 4) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA; 5) Carnegie Institution for Science, Dept. of Plant Biology, Stanford, CA; 6) Department of Genetics, Albert Einstein College of Medicine, 1301 Morris Park Avenue, Bronx, New York, NY; 7) Department of Medicine, University of California, San Francisco, CA.

Shifting patterns of demography may profoundly shape population health landscapes. Yet in US healthcare systems demography is often crudely captured, and some populations are often misclassified *e.g.* Hispanic/Latinos. Here we propose using genomic data in a healthcare system in New York City (NYC) to detect fine-scale population structure and evaluate whether it is informative for the population health phenome. We utilized the Mount Sinai Bio*Me* Biobank, a multi-ethnic biobank, where 21665 participants with genotype data are linked to Electronic Health Records (EHR). To detect finescale population structure we created a network of distant relatedness between pairs of individuals in Bio*Me via* haplotypes shared identical-by-descent (>3cM). Using a machine learning method for community detection we find that 83% of participants fall into one of 36 distinct communities. Using ethnicity and place of birth data provided by participants, we find that these communities reflect recent, shared ancestry at country and regional levels. We showed >90% sensitivity and specificity to detect several groups including self-reported Jewish (N=808), participants born in Puerto Rico (PR; N=2702), Dominican Republic (DR; N=1695) and Japan or Korea (N=138). Other communities showed high specificity (>95%) but lower sensitivity (<60%) *i.e.* participants born in Mexico (N=188) or Colombia (N=138). We find multiple communities enriched for people born in Ecuador and India, perhaps reflecting substructure in those populations. We also predict finescale demographic ancestry for 9,600 participants born in NYC *via* their community membership. Next we show that some communities are significantly enriched for EHR derived billing codes. Top signals recapitulate known differential prevalences of traits. *e.g* sickle cell trait (p<5e-17) in African-Americans (AA); and diseases, *e.g* chronic kidney disease (p<2e-23) in AA, asthma (p<4e-193) in PR, type 2 diabetes (p<0.03) in Mexican, and Hepatitis B (p<1e-24) in East Asian communities. Other signals indicate previously unreported community-specific disease risks that may be due to shared genetic or environmental factors *e.g.* enrichment of peripheral vascular disease in the DR community (p<1e-46). Integrating genomic data into healthcare systems can improve our understanding of population health phenomes, lead to previously unrecognized health conditions enriched within communities and will be an important step forward for precision medicine.

Kinship estimation based on extremely low-coverage sequencing data. *J. Dou[1], S. Chothani[1], X. Sim[2], J. Hughes[3], D. Reilly[3], E. Tai[2], J. Liu[1], C. Wang[1].* 1) Genome Institute of Singapore, Singapore; 2) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 3) Merck Research Laboratories, Kenilworth, New Jersey, United States.

Estimation of kinship is important to genetic association studies, both for control of cryptic relatedness to avoid spurious associations and for estimation of trait heritability. However, estimation of kinship is challenging for target sequencing studies, where sequencing efforts focus on small regions of the genome. Existing methods often assume accurate genotypes at a large number of markers across the genome. We show that these methods, without accounting for the genotype uncertainty in shallow sequencing data, can yield a strong downward bias in kinship estimation. We develop a novel method that explicitly models the uncertainty and thus reduces the bias. Our method includes kinship estimators for homogeneous samples and for samples with population structure and admixture. We tested the method on a target sequencing dataset of Singapore Chinese and Malays, which includes many admixed individuals. We show that our method, with imputation to the 1000 Genomes data, can accurately estimate kinship coefficients using the off-target sequencing data at ~0.1x depth. Our method enables control of cryptic relatedness in target sequencing studies without additional genotyping data. We have implemented the method in a fast and memory efficient C++ program called SEEKIN. .

DNAForest: Rapid genome-wide reconstruction of coalescent trees from thousands of phased genomes. *H.M. Kang[1], F. Zhang[2].* 1) Biostatistics Dept, Univ Michigan, Ann Arbor, Ann Arbor, MI; 2) Department of Computational Medicine & Bioinformatics, Univ Michigan, Ann Arbor, Ann Arbor, MI.

Recent advances of sequencing technologies and statistical phasing methods now allow us to accurately phase diploid genomes. Even with accurate haplotype map, inferring coalescent tree of diploid genome is still one of the most challenging problems in human genetics due to stochastic mutation and recombination procedures make the time complexity of the algorithm to increase exponentially to the sample sizes. If coalescent tree of individual haplotypes could be accurately reconstructed for every individual genomic position, it will allow us to expand our ability to precisely understand the history of individual genomes and individual genetic variants. We propose a novel algorithm DNAForest, that allows us to rapidly approximate coalescent tree at every variant position in a scalable way. DNAForest leverages the data structure implemented for the Positional Burrows-Wheeler Transform (PBWT) algorithm. PBWT enables extremely compact encoding of haplotypes by compressing prefix- or suffix-sorted haplotypes. In DNAForest, we use both prefix- and suffix- ordered haplotypes together to rapidly approximate the coalescent tree using 2-dimensional hierarchical clustering. The pairwise distance between haplotypes are calculated from matching haplotype lengths, and the the time complexity of hierarchical clustering can be reduced from $O(n^2)$ to $O(n \log n)$ the sorted nature of PBWT. Because PBWT provides compact storage of haplotypes, the actual computational gain is even larger due to reduce storage and memory bottleneck. Adjacent coalescent trees can be reconciled together to refine the colescent tree or to generate ancestral recombination graph (ARG). We constructed coalescent tree of ~5,000 phased haplotypes from the 1000 Genomes project. As expected, a subset of African population most belongs to an outgroup clades while the other almost always clustered together with Admixed Africans. We also observed many clades consisting of hundreds of haplotypes mixed between European, Asian, and African ancestry, suggesting shared ancestry within the specific region of genome. As expected, we observed that time to most recent common ancestor (MRCA) are extremely small for most pairs of individual within the same clade, but they are orders of magnitude distant between individuals from different clades. We also observe that DNAForest improves statistical phasing beyond existing reference panel. DNAForest also allows us to estimate the age of each variant precisely.

RVMMAT: Rare-Variant Mixed Model Association Tests for binary traits in structured and related samples. *H. Chen, X. Lin.* Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA.

We develop the computationally efficient Rare-Variant Mixed Model Association Tests (RVMMAT) for binary traits in structured and related samples. With the advance in next-generation sequencing technology, statistical methods for testing genetic association with rare variants have been proposed and widely applied to unrelated samples. These methods are also known as gene-based or SNP-set tests, since rare variants are often grouped by genes or genomic regions in the analysis. The burden test and sequence kernel association test (SKAT) are two widely applied rare variant tests. Here we propose and implement the burden test, SKAT and a novel combined test in RVMMAT. All tests share the same null generalized linear mixed model, which only needs to be fitted once in a whole-genome analysis. We show in simulation studies that the proposed tests control correct type I error rates in the presence of population stratification and cryptic relatedness, in both single-cohort studies and meta-analysis. We compare the power of these tests in various scenarios and illustrate how they can be used to test a broad class of different scientific hypotheses in large-scale sequencing studies. We also apply RVMMAT to a real data whole-exome analysis.

Exploring ancestry of your sample using genotypes or sequence read data: The LASER server. *D. Taliun[1], S.P. Chothani[2], S. Schönherr[3], L. Forer[3], M. Boehnke[1], G. Abecasis[1], C. Wang[2].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Computational and Systems Biology, Genome Institute of Singapore, Singapore; 3) Division of Genetic Epidemiology, Department of Medical Genetics, Molecular and Clinical Pharmacology, Innsbruck Medical University, Innsbruck, Austria.

Recent genetic association studies focus on detecting association with rare variants, an analysis that typically requires large samples to achieve reasonable statistical power. Augmenting case samples with controls from other studies is an efficient, cost effective way to improve statistical power. However, external controls that have different ancestries from cases can lead to false positive association results. Ancestry matching between cases and external controls can be challenging due to possible differences in available array genotyping or sequencing data and data sharing restrictions. We introduce the LASER server that allows ancestry comparison for samples from multiple studies without pooling raw data together and even when samples are genotyped with different arrays, sequenced at only a few genes or the exome, or genome sequenced at different depths. The server is based on our LASER method (Wang et al., 2014, 2015) that uses a set of reference samples with known ancestry to compute a reference principal component space. LASER places all study samples in the same reference principal component space enabling direct comparison of ancestries. LASER allows studies to share only principal components coordinates for ancestry matching as long as the same ancestry reference panel was used. Our most recent implementation of the LASER server allows the user to choose between three ancestry reference panels: 1) the Human Genome Diversity Panel covering 53 worldwide populations; 2) the POPRES panel covering 37 European populations; and 3) an Asian panel covering 43 Asian populations. Users can upload genotype data or sequence reads in a web browser, or by giving restricted access to their SFTP server. Ancestry estimation results can be quickly and easy explored using integrated 2D and 3D interactive web visualizations, where users can instantaneously get information about selected individuals and the ancestry composition of their K nearest-ancestry neighbors. The LASER server can be accessed at http://laser.sph.umich.edu.

Matching controls for independently ascertained case cohorts in population based association analyses. *C. Van Hout, C. O'Dushlaine, B. Ye, F. Dewey, A. Baras, A. Shuldiner, I. Borecki.* Regeneron Genetics Center, Tarrytown, NY.

Canonical design for case-control genetic association studies includes recruitment of cases and controls from the same population. In practice, patient care providers and specialty clinics often focus on specific diseases, collecting rich data on affected individuals, cases, but often not from controls. To enable genetic discovery using cases from independently ascertained cohorts, it is essential to identify suitable controls from other studies or public resources. Controlling for confounding due to population stratification to limit type 1 error in matching controls to cases is crucial. While increasing the ratio of controls to cases offers increased power to detect truly associated variants, sub-optimal matching may introduce population stratification. Furthermore, practices to control inflation may differ between common and rare variants, and may depend on case:control ratios. We compared several approaches to matching controls to cases: random matching, IBS matching, and principal components (PCs) based matching. We evaluated the performance of these approaches under the null hypothesis of no true association using using exome sequence data from DiscovEHR cohort from Geisinger Health System (GHS) in Northern Pennsylvania, and Dallas Heart Study (DHS) cohorts. We selected 500 individuals at random from 1,329 putatively unrelated participants of European ancestry from DHS as cases, and matched controls from 38,333 GHS participants of European ancestry. We compared matching approaches at case:control ratios ranging from 1:1 to 1:10, and measured control of inflation using regression based λGC within various Minor Allele Count (MAC) bins. To evaluate sampling variation, we evaluated 100 replicates for each configuration. Control of inflation was similar using IBS and PC based matching, offering substantial improvement over random matching. In general, we observed increased inflation for higher ratios of controls:cases. However, there was no superior matching method across all MAC bins. Importantly, by comparing case:control matching within GHS, i.e., no true population stratification, we observed systematic decrease in λGC in rarer MAC bins, likely driven by data sparseness. Accounting for these features and confounders in evaluations of matching approaches will be important as high throughput sequencing in independently ascertained case cohorts becomes increasingly available.

Estimating population-specific FST. *Q. Zhang[1,2], B. Weir[2].* 1) Medicine, University of Washington, Seattle, WA; 2) Biostatistics, University of Washington, Seattle, WA.

   Population-specific FST is a parameter relevant to forensics, the detection of natural selection, and the adjustment of population structure in genome-wide association studies. A frequentist method of moments estimator (MME) is commonly used to estimate this parameter, and we prove that it is unbiased assuming an island model. By incorporating a likelihood and priors to generate a posterior distribution, a Bayesian estimator may be preferable. However, existing Bayesian approaches for estimating this parameter generally do not account for dependence between populations, which arises when there is migration between populations. We investigate a new Bayesian estimator of population-specific FST that accounts for dependence between populations. With the software GENOME, we simulated genetic data according to an island model with random mating between two populations, mutation, and migration. For each combination of population genetic parameter values, we simulated 500 data sets and calculated the MME, an existing Bayesian estimator, and our proposed Bayesian estimator on each data set. To obtain Bayesian posterior mean estimates, we implemented and extensively checked a Gibbs sampler with accept-reject algorithm to draw from full conditional distributions, and a Metropolis within Gibbs algorithm. We tested for convergence of MCMC chains using the Geweke test. We compared the three estimators in terms of RMSE for a variety of population genetic parameter combinations.

The problem of heritable PCs in multivariate data with related subjects. *M. Abney.* Dept Human Gen, Univ Chicago, Chicago, IL.

   Powerful analysis of multivariate data (e.g. gene expression) is hampered by the presence of hidden confounders and other unknown variates. Approaches for discovering these confounders, such as principal components analysis (PCA) assume samples are independent. This assumption, however, is violated when the sample is from a population with elevated kinship, e.g. isolated and/or founder populations, or one where there is familial relatedness. Applying PCA, or PCA-based methods, in these samples results in the estimated unknown variates to be a mixture of true hidden variates and genetic effects. Here, we discuss the causes and consequences of identifying hidden variates that unintentionally include a genetic component. In particular, we demonstrate this effect by applying PCA to an expression data set from an isolated population and find the first 200 PCs to have substantial heritability. We also show that using these PCs as covariates can substantially reduce the estimate of heritability of the expression traits. That is, genetic signal is being removed from expression. Using simulations we study how the heritable PC covariates affects estimates of eQTL effect size, type 1 error and power. We also propose approaches to solve these problems.

587T

Comparing total and allelic expression for mapping polymorphisms associated with modulation of expression in *cis*. *M.F. Santibanez Koref.* Insitute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, Newcastle upon Tyne, United Kingdom.

Modulation of transcription, in particular through changes in DNA sequence acting in *cis*, plays an important role in modifying disease susceptibility. The effects of genetic variation on expression can be assessed by comparing the total levels of a transcript, without differentiating the contributions of each allele, in individuals with different genotypes at the polymorphism of interest, and treating expression levels as a quantitative trait. Proximity to the target gene is seen as evidence for a *cis* effect. Expression is also affected by influences acting through diffusible factors in *trans*. These include environmental, genetic and technical factors and affect transcripts from both alleles. Alternative approaches for mapping *cis* acting loci on autosomes use the relative contribution of each the two alleles within an individual to total expression of the transcript of interest. This can be quantified as allelic expression ratio. Instead of comparing expression values across individuals, such approaches compares ratios across individuals. Here we use published and simulated data to compare the ability of different approaches to detect genetic variation acting in *cis*. We show that factors such as the extent of transacting variation can increase the relative advantage of using methods that rely on relative allelic expression levels. However, these procedures rely on the heterozygosity transcribed markers to differentiate between the contributions of each allele and could therefore exclude information from a substantial proportion of the material available. This shortcoming can be addressed by integrating both total and allelic data. Such methods can also be used to map *cis* and *trans* influences separately obviating the needs to use arbitrary distance criteria, and they can also help to overcome issues such as biases in the ability to detect transcripts from different alleles.

588F

Polygenic profiles for predicting risk of early menopause. *T. Laisk-Podar[1,2], A. Salumets[1,2], R. Mägi[3].* 1) Women's Clinic, University of Tartu, Tartu, Estonia; 2) Competence Centre on Health Technologies, Tartu, Estonia; 3) Estonian Genome Center, University of Tartu, Estonia.

Introduction. Reproductive aging impacts female fertility and health, and involves a considerable genetic component as evidenced by recent genome-wide association studies (GWAS). Currently, no genetic markers are used for predicting menopausal age. The aim of this study was to evaluate the applicability of polygenic risk scores (PRS) to predict the risk for early menopause (before age 45). **Material and methods.** PRS were generated using the publicly available ReproGen consortium menopausal age GWAS meta-analysis summary statistics including data for 2.4 million markers and involving approximately 70,000 women. Correlation between PRS and menopausal age was tested among 3,072 women (age at least 45) in the Estonian Biobank. Receiver operating characteristic (ROC) curves were generated to evaluate the predictive value of PRS for discriminating women with early menopause. **Results.** Polygenic risk profiles generated using different marker cut-offs were significantly correlated with age at natural menopause (p=1.7 x 10^{-24}). The same profiles enabled to predict early menopause with an AUC (area under curve) of 0.65, outperforming the predictive value of smoking status (AUC=0.54), which is one of the most important lifestyle factors affecting menopausal age. When the extremes of the PRS were compared, a 10-fold difference in risk for early menopause was observed. **Conclusion.** Polygenic risk profiles could be considered for detecting women at risk of early menopause and have the potential to become an additional tool to increase the accuracy of ovarian reserve assessment, leading to more personalized counselling regarding family planning and patient management.

Multi-ethnic polygenic risk scores improve risk prediction in diverse populations. *C. Marquez-Luna[1], P. Loh[2,3], A. Price[1,2,3], The SIGMA Type 2 Diabetes Consortium.* 1) Biostatistics Department, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Methods for genetic risk prediction have been widely investigated in recent years. However, most available training data involves European samples, and it is currently unclear how to accurately predict disease risk in other populations. Previous studies have used either training data from European samples in large sample size or training data from the target population in small sample size, but not both. Here, we introduce a multi-ethnic polygenic risk score approach, MultiPRS, that combines training data from European samples and training data from the target population. We applied MultiPRS to predict type 2 diabetes in a Latino cohort using both publicly available European summary statistics in large sample size (effective N=40,100) and Latino training data in small sample size (effective N=8,181), and observed a >70% relative improvement in prediction accuracy compared to methods that use only one source of training data, consistent with large relative improvements observed in simulations. Notably, the polygenic risk score derived from European summary statistics was strongly negatively correlated with proportion of European ancestry in the Latino cohort ($R = -0.70$); this systematically lower load of T2D risk alleles in Latino individuals with more European ancestry could be explained by polygenic selection in ancestral European and/or Native American populations. We also applied MultiPRS to predict height in a UK Biobank cohort with samples of UK European (N=113,851), South Asian (N=1,730) and African (N=1,767) ancestry. Despite the much larger European sample size, MultiPRS again significantly improved prediction accuracy in each non-European data set, with 27% to 35% relative improvements compared to single ancestry methods. In addition, the polygenic risk score derived from European summary statistics was positively correlated with proportion of European-related ancestry in South Asian (R=0.14) samples; again, the systematically higher load of alleles associated with increased height in individuals with more European ancestry could be explained by polygenic selection. Our work reduces the gap in risk prediction accuracy between European and non-European target populations.

590T

Modeling allele-specific expression by single-cell RNA-sequencing. *Y. Jiang[1], N. Zhang[1], M. Li[2].* 1) Department of Statistics, University of Pennsylvania, Philadelphia, PA; 2) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA.

The two alleles of a gene can be expressed at different levels, with monoallelic expression, in which one allele is completely silent, being the extreme case. Allele-specific expression (ASE) has been associated with disease, and to understand the mechanisms of such association, it is important to study ASE at the cellular level. ASE is traditionally studied by bulk RNA-seq, in which genes showing imbalanced expression between alleles are declared to have ASE. Although useful, bulk RNA-seq measures the average expression across many cells and is prone to confounding caused by the mixing of disparate cell types. Single-cell RNA sequencing (scRNA-seq) now offers the opportunity to study ASE at single-cell resolution; however, current scRNA-seq protocols introduce technical biases that, if not properly removed, can mislead analyses. Additionally, ASE modeling at the single-cell level needs to account for the stochasticity of gene expression as exhibited by the pervasive phenomenon of transcriptional bursting. Here we propose a framework to study ASE at the single-cell level. First, by an empirical Bayes method we classify genes into *silent*, *monoallelically expressed*, *bursty*, and *constitutively expressed*, and quantify the genomic distribution across categories. Second, we adopt a Poisson-Beta hierarchical model to estimate allele-specific transcription kinetics while accounting for dropout, amplification and sequencing bias. Third, we devise statistical procedures to test for independent firing and differential kinetics between the two alleles. We apply our method to a scRNA-seq dataset profiling mouse cells during preimplantation development. Our results indicate that: 1) single-cell ASE patterns change through embryonic stem cell differentiation, 2) the two alleles from 90% of the bursty genes fire independently and share the same transcription kinetic parameters, 3) there are six times more genes whose differential ASE are modulated by differential burst frequency than by differential burst size, 4) genes with non-independent and repulsed allelic firing are enriched for cell surface and transmembrane proteins, which are associated with cell diversity and identity. In addition to known positive controls such as X-chromosome and imprinted genes, we are currently seeking experimental validation by RNA-FISH. Collectively, our method offers a genome-wide approach to systematically study gene regulation in an allele-specific manner with single-cell resolution.

591F

Joint allele-specific analysis and molecular QTL mapping with large samples. *Y. Lee, X. Wen.* Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

Quantitative trait loci (QTL) of molecular phenotypes (e.g., gene expressions) can be identified by genetic association testing of inter-individual variations (e.g., allele-specific expression) and intra-individual variations (e.g., traditional QTL analysis). To improve the power of QTL discovery, recently several approaches have been proposed to perform joint analysis of aseQTL and expression QTL (eQTL). In eQTL mapping, majority of these approaches directly model the read counts of RNA-seq data and assume genetic effects of a causal variant measured by aseQTL and eQTL are identical. While statistical tests from combined likelihoods have shown the improvement of QTL discovery, we found that count model assumptions on eQTL analysis are inferior to the approach that performs explicit latent factor control and maps QTLs using normalized data. However, there is no principled way to perform joint analysis with aseQTL using the standard QTL mapping approach. We propose a computational approach to perform joint analysis of aseQTL and eQTL without combined likelihoods, which allows to apply standard procedures for eQTL analysis and simultaneously improve the power of QTL discovery by utilizing aseQTL information. In our approach, we analyze aseQTL and eQTL separately by applying standard procedures for eQTL analysis with normalized expression and likelihood tests for aseQTL analysis with read counts. In particular, we do not assume that genetic effect sizes measured by aseQTL and eQTL are at the same scale. However, the causal QTL should exhibit directional consistency in effects despite of effect size heterogeneity. To this end, we propose a Bayesian approach with a novel prior. This approach can be applied to analyze other molecular QTL data such as ATAC-seq. We evaluate our method by applying it to both simulated and real data. Simulation study shows joint analysis has better power on detecting genuine QTL compared to separate aseQTL and eQTL analyses in various effect sizes and minor allele frequencies. In real data analysis, we also find that joint analysis can potentially narrow the confidence set of causal variants.

KCNQ1 **p.L353L affects splicing and modifies the phenotype in a founder population with long QT syndrome type 1.** *L. Arbour[1,2], J. Kapplinger[3,4], A. Erickson[2], S. Asuri[2], S. McIntosh[2], D. Tester[5], C. Kerr[6], J. Morrison[7], A. Tang[8], S. Sanatani[9], M. Ackerman[3,4,5,10].* 1) Department of Medical Genetics, University of British Columbia, Victoria, BC, Canada; 2) Division of Medical Sciences, University of Victoria, Victoria, BC, Canada; 3) Mayo Medical School, Mayo Clinic, Rochester, MN, USA; 4) Department of Molecular Pharmacology & Experimental Therapeutics, Windland Smith Rice Sudden Death Genomics Laboratory, Mayo Clinic, Rochester, MN, USA; 5) Department of Cardiovascular Diseases, Division of Heart Rhythm Services, Mayo Clinic, Rochester, MN, USA; 6) Division of Cardiology, University of British Columbia, Vancouver, BC, Canada; 7) Gitxsan Health Society, Hazelton, BC, Canada; 8) Department of Medicine, University of Western Ontario, London, Ontario, Canada; 9) Department of Pediatrics, Division of Cardiology, University of British Columbia, BC Children's Hospital, Vancouver, British Columbia, Canada; 10) Department of Pediatrics, Division of Pediatric Cardiology, Mayo Clinic, Rochester, Minnesota, USA.

Background: Variable expressivity and incomplete penetrance between individuals with identical long QT syndrome (LQTS)-causative mutations largely remains unexplained. Founder populations provide a unique opportunity to explore the effects of multiple genetic factors. **Objective:** We examined the role of a novel (ExAC MAF 0.000) synonymous *KCNQ1* p.L353L variant on the splicing of exon 8 and on heart rate corrected QT interval (QTc) in a population known to have a pathogenic, LQT1-causative mutation, p.V205M, in *KCNQ1* encoded Kv7.1. **Methods:** Four hundred and twenty adults were genotyped for p.V205M, L353L, and a previously described QTc modifier (*KCNH2*-K897T). Adjusted linear regression determined effect of each variant on the QTc, alone and in combination. In addition, peripheral blood RNA was extracted from 3 controls and 3 L353L-positive individuals. The mutant transcript levels were assessed via quantitative PCR and normalized to overall *KCNQ1* transcript levels to assess the effect on splicing. **Results:** The L353L alone conferred a 9.7 ms increase in QTc for females (p=0.04) and 13.2 ms for males (p=0.06) above baseline. The mechanism of L353L's effect was attributed to a ~3-fold increase in exon 8 exclusion resulting in ~25% mutant transcripts of the total *KCNQ1* transcript levels. Of interest, a significant interaction effect on the QTc was observed when male participants were compound heterozygotes for the L353L and theV205M. In men, the V205M mutation alone increased the QTc by 28.2 ms (p<0.001) above baseline, but the L353L*V205M variant combination increased the QTc by another 32.3 ms (p=.03) above that dictated by each variant alone, with a predicted over-all QTc of about 500ms. This combination effect was not seen in women who were compound heterozygotes for the same variants. **Conclusion:** Our results provide first evidence that synonymous variants outside the canonical splice sites in *KCNQ1* can alter splicing and clinically impact repolarization reserve. Through this mechanism, we identified that L353L can precipitate QT prolongation by itself, and produce a clinically relevant interactive effect in conjunction with other LQTS-causative and modifier variants. Our study suggests the modifying effect may be sex specific, a phenomenon observed in other LQTS founder populations.

593T

Molecular genetic alterations contributing to CCM pathogenesis: Do multiple lesions arise from a shared second-hit somatic mutation? *C. Gallione[1], A. Peiper[1], H. Zeineddine[2], O. Fedrigo[3], I. Awad[2], D. Marchuk[1].* 1) Department of Molecular Genetics & Microbiology, Duke University Medical Center, Durham, NC; 2) Department of Neurosurgery, University of Chicago Medical Center, Chicago, IL; 3) Duke Center for Genomic and Computational Biology, Duke University Medical Center, Durham, NC.

Cerebral cavernous malformations (CCMs, [MIM 116860]) are vascular lesions of the central nervous system consisting of clusters of dilated blood vessels which are associated with vascular leak and hemorrhage. These lesions frequently occur sporadically but are also seen as an autosomal dominant trait, the latter involving multiple, distinct lesions in the brain. Mutations in any one of three identified genes, *CCM1/KRIT1, CCM2,* and *CCM3/PDCD10,* cause the inherited form. Our lab has previously found bi-allelic germline/somatic mutations in the endothelial cells lining the vascular caverns of the mature CCM lesion, suggesting a Knudsonian two-hit mutation model for CCM pathogenesis. The question remains as to whether the multiple CCM lesions seen in inherited cases, which can range in number from a few to over one hundred, are seeded by independent somatic mutational events or a single somatic mutation in a precursor cell during development. Due to the paucity of available surgical material and the nearly complete lack of cases where multiple lesions are resected from an individual CCM patient, we are using our mouse models of CCM to investigate this question. Our mouse models recapitulate the human disease in that the mice, heterozygous for either *Ccm1, -2,* or *-3,* exhibit multiple brain lesions with histology, molecular signatures and ultrastructure identical to human lesions. Using DNA extracted from the mouse CCM lesions, we employ targeted deep resequencing of the three CCM genes to identify second-hit somatic mutations. We report here preliminary evidence from our pilot study of a common somatic mutation seeding multiple lesions, specifically, in our *Ccm3* model, a c.316A>T, p.106Lys>Ter variant in two lesions from the same animal. We are currently examining additional lesions using this same approach.

594F

Changes in heterochromatin structure are associated with a new form of cardiomyopathy with extensive fibrosis and juvenile cataract in the Hutterite population. *N. Abdelfatah[1], C. Seifer[5], C. Huculak[2], I. Buffo[3], H. Duff[1], P. Frosk[3,4], B. Gerull[1,2].* 1) Department of Cardiac Sciences and Libin Cardiovascular Institute, University of Calgary; 2) Department of Medical Genetics, Alberta Health Services, University of Calgary; 3) Department of Pediatrics and Child Health, Rady Faculty of Heath Sciences, University of Manitoba; 4) Department of Biochemistry and Medical Genetics, Rady Faculty of Heath Sciences, University of Manitoba; 5) Section of Cardiology, Rady Faculty of Heath Sciences, University of Manitoba.

   Introduction: Dilated cardiomyopathy (DCM) is an inherited cardiac condition characterized by ventricular dilatation and reduced systolic function. Patients including young children suffer from heart failure or sudden death. Nuclear envelope proteins have been shown to play an important role in the pathogenesis of DCM. Here, we present a remarkable cardiac phenotype associated with a novel homozygous *LEMD2* mutation c.38C>T in patients of the Hutterite population with juvenile cataract. *LEMD2* encodes an inner nuclear protein which has an important role in stabilization of the nuclear membrane. **Purpose:** To characterize the cardiac phenotype in homozygous mutation carriers and evaluate structural and functional effects of the mutation in heart tissue and *in vitro* cell culture. **Methods and Results:** Homozygous mutation carriers with a history of bilateral juvenile cataract at different age groups underwent detailed cardiac investigations. 8 out of 15 carriers between age 12 and 43 years showed signs of a cardiomyopathy phenotype with normal or mildly reduced cardiac function, segmental wall motion abnormalities and delayed enhancement of the left ventricle. One subject died suddenly at the age of 43, another one survived a sudden cardiac arrest at the age of 33. Heart tissue of the deceased individual has been examined by electron microscopy and revealed extensive changes of myocyte nuclei which demonstrate severe morphologic changes, including extensive elongation and bizarre shapes with clumping of peripheral heterochromatin. Histology showed myocyte disarray and extensive interstitial fibrosis. However, immunohistochemistry demonstrated regular nuclear membrane localization of LEMD2 in affected cardiac tissue. In addition, recombinant expression of LEMD2 protein in C2C12 cells showed no difference between the mutant and wild-type form as well as proper co-localization with lamin A/C indicating that localization and expression level of LEMD2 are not impaired by the mutation. **Conclusion:** Mutations in *LEMD2* lead to adult onset cardiomyopathy with risk for sudden death. Affected cardiac tissue shows remarkable changes in nuclei with abnormal heterochromatin, whereas the expression and localization of the mutant protein did not differ. Further investigations will focus on the interaction of LEMD2 with BAF, an important factor which is involved in heterochromatin formation. .

Identification of *FLNC* variants in arrhythmogenic right ventricular cardiomyopathy. *R.L. Begay[1], T.J. Rowland[1], D.B. Slavov[1], S.L. Graw[1], G. Sinagra[2], K.L. Jones[3], K. Gowan[3], L. Mestroni[1], M.R.G. Taylor[1].* 1) Department of Medicine, University of Colorado - CU Cardiovascular Institute, Aurora, CO; 2) Cardiovascular Department, Ospedali Riuniti and University of Trieste, Trieste, Italy; 3) Department of Biochemistry and Molecular Genetics, University of Colorado Denver, Aurora, CO.

   Background – Arrhythmogenic right ventricular cardiomyopathy (ARVC) presents as a fibro-fatty replacement of the right ventricular myocardium leading to arrhythmias and heart failure. ARVC is familial in 30-50% of cases and is transmitted by autosomal dominance with incomplete and age-related penetrance. ARVC is mainly associated with variants in desmosomal genes, however, efforts continue to identify additional ARVC genes. *FLNC* encodes for filamin-C, an actin-binding protein localized at the Z-disc of striated muscle. Variants in *FLNC* cause skeletal myopathies and hypertrophic cardiomyopathy, restrictive cardiomyopathy, and dilated cardiomyopathy in the absence of skeletal muscle pathology. Here we present data that *FLNC* may be a novel disease-causing gene producing an ARVC phenotype in two families. *Methods and Results* – Our group sequenced families with ARVC utilizing Illumina TruSight One Sequencing Panel, which queries 4,813 genes associated with clinical phenotypes. Two FLNC variants (one truncation and one missense) were identified in ARVC probands (probands were screened for variants in 54 other cardiomyopathy-related genes and no pathogenic variants were detected). Both variants were confirmed by Sanger sequencing with a c.G6565T truncation variant present in family TSRVD029 and a c.G6988A missense variant in family TSRVD021. In addition, both variants are absent from the 1000 Genomes Project and ClinVar, and the truncation variant is additionally absent from the Exome Aggregation Consortium (ExAC) Browser database, while the missense variant is present at a frequency of 0.0007887 in the latter database. Both variants had a GERP score >4.2. Our next step is to expand the family pedigrees to enroll other affected family members for segregation analysis. *Conclusion* – *FLNC* variants have been inadequately understood with respect to cardiac muscle diseases. This study provides additional findings that *FLNC* truncation and even missense variants may lead to ARVC.

596T

A novel variant in the *ANK2* membrane-binding domain is associated with ankyrin-B syndrome and structural heart disease in a First Nations community of Northern British Columbia. *L. Chen[1,2], N. Murphy[3], S. McIntosh[4], S. Asuri[4], C. Kerr[5], S. Sanatani[6], E. Sherwin[6], P. Mohler[3], L. Swayne[1,2], L. Arbour[2,4].* 1) Division of Medical Sciences, University of Victoria, Victoria, BC, Canada; 2) Island Medical Program, University of British Columbia, Victoria, BC, Canada; 3) Dorothy M. Davis Heart and Lung Research Institute, Division of Cardiovascular Medicine, Department of Internal Medicine, and Department of Physiology and Cell Biology, The Ohio State University Wexner Medical Center, Columbus, OH, USA; 4) Department of Medical Genetics, University of British Columbia, Victoria, BC, Canada; 5) Division of Cardiology, University of British Columbia, Vancouver, BC, Canada; 6) Department of Pediatrics, Division of Cardiology, University of British Columbia, BC Children's Hospital, Vancouver, BC, Canada.

   Background: Long QT syndrome (LQTS) confers susceptibility to ventricular tachyarrhythmia, predisposing to syncope, seizures, and sudden death. LQTS type 4, also called 'ankyrin-B syndrome' due to the prevalence of other cardiac phenotypes, is caused by loss-of-function variants in *ANK2* (encodes ankyrin-B). Ankyrin-B syndrome-causing variants have been identified in the spectrin-binding and C-terminal regulatory domains of ankyrin-B. Here, we report the clinical, molecular, and cellular phenotypes associated with the first disease-causing variant identified in the membrane-binding domain (*ANK2* c.1937C>T p.Ser646Phe).   **Methods:** Two families, not known to be related, but from the same community were identified with LQTS. Sequencing of the 12 most common genes causing LQTS was carried out in the index case of each family. Genotyping and clinical information was collected on family members. A combination of in silico, biochemical, and primary cardiomyocyte cellular techniques were used to assess the functional significance.   **Results**: The *ANK2* p.S646F variant was detected in each index case. We identified 16 additional p.S646F carriers. Average QTc was 476.2 ms (± 33 ms) with a range of 430-560 ms in carriers. Two carriers presented with structural heart disease, one (age 36) with cardiomyopathy resulting in sudden death, another with congenital heart disease (TAPVR). This variant allele was not reported in the ExAC, NHLBI and 1000 Genomes (global MAF of 0.000). Ankyrin-B p.S646F resides on the αB of the 19th *ANK* repeat on the outer surface of the *ANK* repeat solenoid. Recombinant purified membrane-binding domain containing the p.S646F mutation displayed normal folding properties. Ankyrin-B p.S646F displayed reduced stability in myoblasts and expression in primary ankyrin-B+/- cardiomyocytes revealed aberrant targeting of the ankyrin-B p.Ser646Phe polypeptide and inability to rescue abnormal targeting of Na/Ca exchanger.   **Conclusion:** We identify the first disease-causing *ANK2* variant localized to the membrane-binding domain resulting in reduced expression and abnormal localization. Further study is warranted on the potential association of this variant with structural heart disease given the role of *ANK2* in targeting and stabilization of key structural and signaling molecules in cardiac cells.

597F

Differences in vascular disease presentation of patients with null and missense *SMAD3* mutations. *E.M. Hostetler[1], E.S. Regalado[1], P. Arnaud[2], N. Hanna[2], M. Aubart[2], M. Langeois[2], S.E. Wallace[1], D. Guo[1], G. Jondeau[2], C. Boileau[2], D.M. Milewicz[1].* 1) Department of Internal Medicine, The University of Texas Health Science Center at Houston, Houston, TX; 2) Département de Génétique, Hôpital Bichat, Paris, France.

   SMAD3 mutations cause heritable thoracic aortic aneurysms and dissections, along with aneurysms of other arterial beds. Both null (nonsense and frameshift mutations) and missense mutations that disrupt the MH2 domain of the SMAD3 protein have been identified to cause disease. We sought to determine whether there are differences in clinical presentations and underlying disease mechanisms between null and missense *SMAD3* mutations. We analyzed a cohort of 156 individuals from 42 families with 35 different mutations, categorized as null (n=85) and missense (n=71). This cohort had a mean age of 39 years (SD 9.0) at enrollment and was 88% Caucasians and 56% males. Thirty-five percent (n=54) had an aortic event, defined as aortic dissection (n=38) or aneurysm requiring repair (n=16). There was no significant difference in frequency of aortic events in the missense and null mutation groups; however, the mean age of aortic event was significantly younger in individuals with missense mutations (mean 42 years, 95% CI 37.7, 45.5) than those with null mutations (mean 48 years, 95% CI 44.8, 51.7). Overall cumulative freedom from aortic event for *SMAD3* mutations was 21% (95% CI 6.2, 41.8) at the age of 76 years, but the survivor functions differed significantly between missense and null mutations (log rank test p value =0.03). Hazard rate of aortic event was 1.8 (95% CI 1.2, 2.7) times higher in patients with missense mutations as compared to null mutations after adjusting for intra-familial correlation, sex and site of recruitment. Interestingly, more individuals with null mutations presented with distal aortic disease compared to those with missense mutations, i.e. descending thoracic dissections (15% vs 5%) and abdominal aortic aneurysms (10% vs 0%). Also, more individuals with missense mutations than null presented with intracranial aneurysms (12% vs 3%) and other arterial aneurysms (9% vs 6%). These findings show that individuals with missense *SMAD3* mutations have earlier onset and higher risk of vascular events compared to null mutations. Assessment of additional individuals through the multi-site Montalcino Aortic Consortium will help elucidate these differences.

Multiple rare variants in dilated cardiomyopathy are more frequent than expected. *A. Morales[1], D.D. Kinnamon[1], A. Whiting[1], M. Bamshad[2], D. Nickerson[2], R.E. Hershberger[1].* 1) Ohio State Univ. Human Genetics, Columbus, OH; 2) University of Washington Center for Mendelian Genomics.

   INTRODUCTION: Dilated cardiomyopathy (DCM) is primarily an autosomal dominant condition in which plausible genetic cause can be found in approximately 40% of cases. Previous reports in hypertrophic cardiomyopathy (HCM) have shown that multiple rare variants are uncommon, occurring in 3-5% of individuals. METHODS: To examine the frequency of multiple rare variants in DCM, we analyzed exome sequence, conducted at the University of Washington Center for Mendelian Genomics, of 405 individuals affected with DCM from 279 pedigrees, 103 who reported a negative family history of DCM and 176 with familial DCM (FDC). Using DCM variant adjudication rules developed by our group, variants from 40 previously reported DCM genes were analyzed and adjudicated as pathogenic (P), likely pathogenic (LP), or variant of uncertain significance (VUS). Multiple variants were analyzed if segregation occurred among all available affected DNAs in a family. RESULTS: We identified 62 (22%) pedigrees with more than one rare variant, for a total of 147 unique variants in 33 genes (9 P, 34 LP, 104 VUS). Among these probands, 34 were male; 28 were female. Fifty two were White (3 Hispanic), 9 were Black, 1 was Asian, and 1 reported more than one race. The median age of diagnosis was 42 years. Of these, 25 (41%) were diagnosed at <40 years and 4 (6%) were diagnosed before age 18. The median left ventricular (LV) size was 64 mm and the median ejection fraction was 27%. The multiple variant pedigrees involved 4 (n=2), 3 (n=15), 2 (n=42), or 1 (n=3) genes and had 4 (n=4), 3 (n=15), or 2 (n=43) variants. Variant combinations involving confirmed relevant DCM genes (*LMNA*, n=5; *MYH7*, n=5; *TNNT2*, n=3) were identified. Truncating variants (tv) in *TTN* were most frequently found (21/147=14%), mainly along with variants in *MYBPC3* (n=4), *BAG3* (n=3), *ACTN2* (n=3), *NEBL* (n=3), *MURC* (n=3), and *MYPN* (n=2). Thirty four multiple variant pedigrees had FDC confirmed by medical records. Of those, 13 had relatives available for segregation analysis. Of the 13 pedigrees with multiple variants and available family members' DNA, 5 (38%) had more than one multiple variant classified as P or LP. In these families, P and LP variants in *BAG3* and *TTN*tv were most frequent (4 times each), followed by *RBM20, ANKRD1*, and *MYH6*. CONCLUSION: Multiple variants classified as LP or P are present in 38% of evaluable pedigrees. Our findings suggest that a significant proportion of DCM cases carry relevant variants in multiple genes.

599T

Genetic aortopathy due to gene mutations related and not-related to TGF-β signal pathway in Japan. *H. Morisaki[1,2,3], T. Watanabe[3], A. Yoshida[3], H. Sasaki[3], K. Minatoya[3], T. Morisaki[2,3].* 1) Dept Medical Genetics, Sakakibara Heart Institiute, Fuchu, Tokyo, Japan; 2) Tokyo University of Technology School of Health Sciences, Ota, Tokyo, Japan; 3) National Cerebral and Cardiovascular Center, Suita, Osaka, Japan.

   Recent progress of molecular study revealed similar to Marfan syndrome (MFS) but distinct disorders caused by gene mutations in TGF-β signal pathway and contractile molecule. During more than 10 years, we performed mutation analysis in more than 1000 probands with young-onset or hereditary aortopathy in National Cerebral and Cardiovascular Center. Among these patients, we found pathogenic *FBN1* mutations in 496 patients. In addition, we found 119 patients in 91 families to have pathogenic gene mutations in *TGFBR1* (45 patients), *TGFBR2* (45 patients), *SMAD3* (18 patients), *TGFB2* (3 patients) or *TGFB3* (8 patients). Also, we found 91 patients in 61 families to have pathogenic gene mutations in *ACTA2* (38 patients), *COL3A1* (52 patients) and *MYH11* (1 patient). Ten probands with pathogenic *COL3A1* mutations were surgically treated with little complication even with noticeable tissue fragility and bruising tendency. Patients with *TGFBR1* or *TGFBR2* mutation frequently showed enlargement of Valsalva sinus, sometimes even in young childhood. Skeletal features including scoliosis and/or funnel chest and the history of pneumothorax were also frequently seen in these patients. Bifid uvula, hypertelorism, or arterial tortuosity, characteristic for Loeys-Dietz syndrome, was also observed in some MFS patients but less common. Some patients with young-onset or hereditary aortopathy showed cerebral arterial aneurysm and/or abnormality as reported before. These results indicate that patients with young or familial aortopathy patients need to be diagnosed properly not only by the clinical features but by the genetic study since it may not be easy to distinguish those patients from those with MFS.

600F

A platform for large-scale functional annotation of cardiomyopathy gene variants. *L. Qiao[1], W. Lv[2], K. Musunuru[2].* 1) Department of Stem Cell & Regenerative Biology, Harvard University, Cambridge, MA; 2) Department of Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

   TNNT2 [MIM 191045], which encodes the sarcomere protein troponin T, has been linked to familial hypertrophic cardiomyopathy (HCM [MIM 115195]) and dilated cardiomyopathy (DCM [MIM 601494]), as well as other myocardial disorders such as restrictive cardiomyopathy [MIM 612422] and left ventricular noncompaction [MIM 601494]. The introduction of next-generation DNA sequencing into the clinic is dramatically increasing the discovery of variants of unknown significance in *TNNT2* and other genes linked to cardiomyopathies. Roughly 120 *TNNT2* variants have been catalogued in ClinVar; while some are reported as pathogenic for cardiomyopathies, many have conflicting evidence or are of unknown significance. We are developing a platform for large-scale functional annotation of these 120 variants, using a novel genome-editing approach that combines clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9) and dual integrase cassette exchange (DICE) to rapidly introduce single copies of the *TNNT2* variants into a wild-type induced pluripotent stem cell (iPSC) line with a pooled approach requiring only a single targeting procedure. The allelic series of isogenic cell lines can then be differentiated into cardiomyocytes, followed by gene expression profiling and phenotyping to ascertain whether each mutation is pathogenic and, if so, to which type of cardiomyopathy it predisposes. In a proof-of-principle application of the platform, we generated 14 unique mutant cell lines and found that differentiated cardiomyocytes with a variant previously linked to DCM (p.R173W) displayed a substantial increase in *PDE2A* gene expression compared to control cardiomyocytes, consistent with previously published observations. We envision that the platform could ultimately be used in a clinical context to rapidly annotate novel patient-specific variants in cardiomyopathy genes.

601W

Phenotype variability in twins and sibling pairs with genetic predisposition to thoracic aortic aneurysms and dissections. *E. Regalado, E. Hostetler, S. Wallace, L. Mellor-Crummey, D. Guo, D. Milewicz.* Internal Medicine, University of Texas Health Science Center at Houston, Houston, TX.

   Heritable thoracic aortic aneurysms and dissections are commonly passed down in families as a dominant disorder with reduced penetrance and widely variable age of onset, even within the same family. An unanswered question is whether this variability is due to genetic or modifiable environmental factors. We aimed to quantify the variability of age of onset (AO) of aortic event (aortic dissection or aneurysm repair) in monozygotic (MZ), dizygotic (DZ) twins and sibling pairs, and examine the concordance of aortic event and AO. We identified twins and sibling pairs from a large cohort of patients with familial thoracic aortic disease. Zygosity was confirmed by analysis of 15 microsatellite markers, when DNA was available, or by self-report. All possible sibling pair combinations whose mutation status or aortic disease could be ascertained were included. There were 15 pairs of MZ twins, including twins with known mutations of *ACTA2*, *FBN1*, *LOX*, *SMAD3* and *TGFBR2*, only two pairs of DZ twins, and 276 full sibling pairs from 60 families with mutations of *ACTA2* (135), *TGFBR1* (32), *TGFBR2* (71), and *SMAD3* (38). Concordance for aortic event was 80% for MZ twins and 56% for *ACTA2*, 47% for *TGFBR1*, 55% for *TGFBR2* and 58% for *SMAD3* sibling pairs. AO was not statistically different between MZ twins (paired t test p=0.08; 6.6 years, 95% CI -3.5, 16.7), but correlation of AO was low (0.4983) and was influenced by a twin pair in which one twin dissected and the second twin was medically managed for 20 years without an event. In comparison, mean difference in AO between sibling pairs was statistically significant (p <0.01): 12 years (95% CI 9.4, 14.2) for *ACTA2*, 7.2 (95% CI 3.3, 11) for *TGFBR1*, 10.9 (95% CI 6.2, 15.5) for *TGFBR2*, and 5.1 (95% CI 2.6, 7.5) for *SMAD3*, and intra-pair correlations were 0.72, 0.79, 0.88, and 0.42, respectively. These findings suggest that genetic factors play a role in modifying the effect of genes for aortic disease as seen in the higher concordance for aortic event among MZ twins compared to sibling pairs. Incomplete concordance among MZ twins also indicates a role for the unique environment in altering age of onset. These findings have clinical significance in predicting disease risk in twins and sibling pairs and understanding the sources of variability in age of onset of aortic disease.

602T

Obscurin variants in patients with left ventricular noncompaction. *T.J. Rowland[1], S.L. Graw[1], M.E. Sweet[1], M. Gigli[2], M.R.G. Taylor[1], L. Mestroni[1].* 1) Cardiovascular Institute and Adult Medical Genetics Program, University of Colorado Denver Anschutz Medical Campus, Aurora, CO; 2) Cardiovascular Department, "Ospedali Riuniti," University of Trieste, Trieste, Italy.

Left ventricular noncompaction (LVNC) is a rare type of cardiomyopathy. In our patient population, we identified a possible association between LVNC and variants in the obscurin gene (*OBSCN*). Obscurins are giant proteins (≈700 to 900 kDa) involved in sarcomere structure and play key roles in myofibrillo-genesis and cytoskeletal arrangement through interaction with several other binding partners. While disrupting these interactions can have severe consequences for normal striated muscle function, obscurin's pathogenic involvement in cardiomyopathies is unclear. The association of *OBSCN* missense variants with more common cardiomyopathies in two previous clinical studies, combined with suggestions of a functional cardiac role in limited animal studies, made obscurin an intriguing target for exploration in our cardiomyopathy cohort. Using the Illumina TruSight One Sequence Panel, which queries 4,813 genes associated with clinical phenotypes, we identified and confirmed four probands with *OBSCN* frameshift or splicing variants (four variants total) in our population of 335 cardiomyopathy patients. Three of these probands have *OBSCN* frameshift variants, and the remaining one has a splicing variant. Interestingly, while the majority of patients analyzed had dilated cardiomyopathy (DCM) (325 out of 335 [97.0%]), only one of the four *OBSCN* probands had DCM. The other three probands had LVNC, which was rare in our population (10 out of 335 [3.0%]), giving an odds ratio of 139 [CI 13-1506] for the association between an *OBSCN* variant and LVNC. All four *OBSCN* variants identified localize to the C-terminal end of obscurin-B-like isoform and occur upstream of the fibronectin type-III 4 and protein kinase 2 domains, which the frameshift variants are predicted to eliminate. The earliest variant occurs upstream of the protein kinase 1 domain. We screened all four probands for variants in 54 other known cardiomyopathy-related genes and no pathogenic variants were detected. Affected family members were unavailable for segregation analysis of the *OBSCN* probands. Our findings suggest a strong correlation between *OBSCN* frameshift and splicing variants, all clustering to the C-terminal end of the same isoform group, with the occurrence of the rare LVNC phenotype.

603F

Reassessment of cardiomyopathy gene and variant pathogenicity using 7,855 clinical cases and 60,706 reference samples. *K.L. Thomson[1,2], R. Walsh[3,4], J.S. Ware[3,4], B.H. Funke[5,6], J. Woodley[2], K.J. McGuire[2], F. Mazzarotto[3,4], E. Blair[7], A. Seller[2], J.C. Taylor[8,9], E.V. Minikel[10,11], D.G. MacArthur[10,11,12], M. Farrall[1,8], S.A. Cook[3,13,14], H. Watkins[1,8,9], Exome Aggregation Consortium.* 1) Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom; 2) Oxford Medical Genetics Laboratory, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom; 3) National Heart and Lung Institute, Imperial College, London, United Kingdom; 4) NIHR Royal Brompton Cardiovascular Biomedical Research Unit, Royal Brompton Hospital, London, United Kingdom; 5) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Massachusetts, 02139, USA; 6) Department of Pathology, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 7) Department of Clinical Genetics, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom; 8) The Wellcome Trust Centre for Human Genetics,Oxford,United Kingdom; 9) NIHR Biomedical Research Centre, Oxford, United Kingdom; 10) Analytical and Translational Genetics Unit, Massachusetts General Hosptial, Boston, MA 02114, USA; 11) Broad Institute of MIT and Harvard, MA 02142, USA; 12) Department of Medicine, Harvard Medical School, Boston,USA; 13) National Heart Centre Singapore, Singapore 169609, Singapore; 14) Duke-National University of Singapore, Singapore 169857.

Introduction: Recent population studies have cast doubt on the pathogenicity of variants previously reported in Mendelian disease genes and the validity of some gene:disease relationships. In the clinical laboratory, this has led to more variants being classified as variants of uncertain significance (VUS); these inconclusive results reduce the clinical utility of testing and increase the risk of false positive diagnosis. The challenges of variant interpretation are particularly well illustrated by inherited cardiomyopathies (CMs), which are among the most common serious Mendelian disorders. Using data from CM cohorts and the Exome Aggregation Consortium (ExAC), we show how new opportunities for large–scale comparison of rare variation can enable us to verify the genes and variant types that can be reliably interpreted in a clinical setting. **Methods:** Data from 7855 cases with Hypertrophic Cardiomyopathy (HCM), Dilated Cardiomyopathy (DCM) or Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) were obtained from two clinical laboratories. 20 HCM, 46 DCM and 8 ARVC genes were evaluated. Rare variant frequency (minor allele frequency [MAF] $<1\times10^{-4}$ in ExAC) was assessed in clinical cases and 60,706 ExAC samples. Statistical analyses were performed to compare rare variant frequency between cohorts. **Results:** In most well-established CM genes a significant excess of rare variation was found in cases. In addition, our results suggest that in these key genes, a significant proportion of variants currently classified by the clinical laboratories as VUS, are likely to be disease causing. However, in many other genes, including some reported as important causes of a particular CM, no significant difference in rare variant frequency was found. This indicates that novel rare variants in these genes cannot be reliably interpreted. Also, our findings suggest that many previously reported variants in these genes are false positives and that some published gene:disease pairs may not be valid. **Conclusions:** Robust assessment of rare variant frequency is essential to evaluate the genes and variants implicated in rare diseases. Large collaborative datasets of cases, and importantly reference samples, provide unprecedented power for such assessment. These approaches, applicable across a range of Mendelian diseases, will improve selection of genes for clinical test panels, reduce uncertainty in interpretation and increase the clinical utility of testing.

Titin-truncating variants, a common incidental finding, are penetrant in the general population and may predispose the heart to fail. *J.S. Ware[1,2,3], A. de Marvao[2], S. Schafer[4], R. Walsh[1,3], T. Dawes[2], P.J.R. Barton[1,3], N. Hubner[5], D. O'Regan[2], S.A. Cook[1,2,3,4,6].* 1) National Heart & Lung Institute, Imperial College London, UK; 2) MRC Clinical Sciences Centre, Imperial College London, UK; 3) NIHR Royal Brompton Cardiovascular Biomedical Research Unit, Royal Brompton Hospital & Imperial College London, UK; 4) National Heart Centre Singapore, Singapore; 5) Cardiovascular and Metabolic Sciences, Max-Delbrück-Center for Molecular Medicine, Berlin, Germany; 6) Duke-National University of Singapore, Singapore.

Dilated cardiomyopathy (DCM) is a frequent cause of heart failure and a common indication for heart transplantation. DCM has a strong genetic basis, with variants that truncate the sarcomeric giant protein titin the commonest genetic cause (TTN-truncating variants, TTNtv, in up to 1 in 4 cases). However, rare variants in titin are cumulatively common: rare missense variants have a prevalence >50% and truncating variants 1-2% in the general population, and it is not known whether these are have physiological or disease relevance. First, we re-examined *TTN* transcripts in the human heart, and identified a subset of variants that do not impact the predominant cardiac isoforms. These variants are not associated with DCM. Stringent assessment of allele frequencies further identified a tranche of variants that, though rare (<1:1000), remained implausibly common in reference samples to cause disease. These were typically splice-disrupting, and we speculate may be rescued by alternative splice sites or in-frame exon-skipping. After excluding such variants, the prevalence of rare TTNtv predicted to influence the heart is ~0.4% in reference samples.   We characterised the heart of healthy volunteers in great detail and determined TTNtv status. Volunteers with TTNtv had significantly increased cardiac chamber dimensions and reduced contractility on conventional cardiac MRI, while ultra-high resolution 3D MRI coupled with atlasing techniques had increased power to demonstrate regional differences in structure and function. Effect sizes of TTNtv on the hearts of healthy volunteers were large with regression Beta values ranging from 4-15% and of a magnitude that may be expected to affect clinical outcomes.   We generated rat models carrying TTNtv, to dissect disease mechanisms. Young heterozygous mutant animals had normal cardiac function, but a distinct metabolic phenotype (mTORC activation and altered fatty acid metabolism) suggestive of an adaptive compensated state at baseline. Examining cardiac function *ex vivo*, mutant hearts had reduced reserve and failed under mechanical stress. We have previously demonstrated that TTNtv in humans are associated with peri-partum cardiomyopathy, similarly suggesting that TTNtv predispose to failure under haemodynamic stress.   Approximately 30,000,000 people world-wide carry TTNtv that are associated with cardiac remodelling and DCM, and TTNtv in the general population may predispose otherwise healthy individuals to heart failure.

605T

Identification of a second gene mutated in capillary malformation–arteriovenous malformation (CM-AVM2). *M. Amyere[1], N. Revencu[2], E. Pairet[1,2], R. Helaers[1], M. Baselga[3], M. Cordisco[4], W. Chung[5], J. Dubois[6], J.P. Lacour[7], L. Martorell[8], J. Mazereeuw-Hautier[9], R. Pyeritz[10], J.B. Mulliken[11], L. Boon[1,12], M. Capillary Malformation–Arteriovenous Malformation (CM-AVM) is an autosomal dominant disorder manifesting multifocal CMs together with high risk for fast-flow vascular malformations, especially in the head and neck. We have detected *RASA1* heterozygous loss-of-function mutations in about 50% of screened families. This suggests genetic locus heterogeneity. We performed a genome-wide linkage study in a large family with autosomal dominantly inherited CMs without a *RASA1* mutation, and identified a locus on Chr7. Whole exome sequencing was performed including an additional 9 blood samples of patients from 7 unrelated families. Subsequently, a candidate-gene was screened by targeted massively parallel sequencing for mutations in 365 patients with CMs associated or not with fast-flow vascular malformations. A damaging mutation was identified in 5 out 8 families. Moreover, targeted massive parallel sequencing unravelled mutations in an additional 49 families with CMs with/without fast-flow vascular malformations. In total, 54 mutations were identified: 50% were non-sense, frame-shift, or splice site mutations, and 50% were substitutions predicted to strongly impact protein function. Expression studies of selected variants demonstrated loss of protein function. Mutations were identified altogether in 103 individuals: > 95% had capillary malformations, usually multifocal, and 20% an associated fast-flow vascular malformation. The cutaneous capillary malformations in these patients are more telangiectatic than in CM-AVM, and thus a clinical distinction can be possible. We suggest to call this new entity CM-AVM2. As the fast-flow lesions can cause severe morbidity and even mortality, it is important to recognize for entities.

606F

Origin of the *KRIT1* common Hispanic founder mutation causing cerebral cavernous malformation type 1. *L. Pawlikowska[1,2], H. Choquet[1], C.E. McCulloch[3], A. Akers[4], L. Morrison[5], H. Kim[1,2,3].* 1) Center for Cerebrovascular Research, Dept of Anesthesia, Univ California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, Univ California, San Francisco, CA; 3) Dept of Epidemiology and Biostatistics, Univ California, San Francisco, CA; 4) Angioma Alliance, Durham, NC; 5) Depts of Neurology and Pediatrics, Univ New Mexico, Albuquerque, NM.

   Objective: Familial cerebral cavernous malformation type 1 (CCM1, MIM116860) is an autosomal dominant disease caused by mutations in *KRIT1* (krev-interaction trapped 1, *CCM1*), and characterized by multiple brain lesions that can lead to intracerebral hemorrhage, seizures, and neurological deficits. The high prevalence of the disease in families of Mexican-American heritage is due to a founder effect caused by the *KRIT1 c.1363C>T,* p.Q455X "common Hispanic mutation" (CHM) inherited from a shared ancestor. Genealogic studies in large CCM1-CHM families have traced this mutation to a likely shared ancestor from Spain. We investigated the geographic origin of the *KRIT1* CHM founder mutation using haplotype analysis. **Methods:** We focused on a 7q region of 0.66Mb flanking the *KRIT1* gene, including 31 single nucleotide polymorphisms (SNPs). Genotypes were extracted from the Affymetrix Axiom Genome-Wide LAT 1 Human Array for CCM1-CHM subjects and Illumina Human1M or Affymetrix SNP 6.0 data for HapMap controls. Haplotype estimation and association testing were performed in Haploview v4.2 in 189 Hispanic CCM1-CHM patients enrolled in the Brain Vascular Malformation Consortium CCM study, and 474 healthy controls (165 European, 86 Mexican, 137 Chinese and 87 African ancestry subjects) from the International HapMap Project. Linkage disequilibrium (LD) structure using pairwise correlation (r^2) was examined in populations and used to determine haplotype boundaries. **Results:** The LD structure of the region surrounding *KRIT1* differed among different control groups. As expected, the CCM1-CHM cohort shared much longer haplotypes around the CHM locus than did controls, consistent with their shared ancestry and familial relationships. We identified a shared haplotype spanning 525kb around the *KRIT1* gene consisting of 16 genetic markers (CHM underlined, TGACGCATCATTAATA). The corresponding ancestral haplotype, TGACGCATCATCAATA was found in 22% of Mexican, 26% of European, 19% of Chinese and 7% of African control chromosomes. **Conclusions**: The CCM1 common Hispanic founder mutation (*KRIT1 c.1363C>T,* p.Q455X) arose on a haplotype that is common among both European and Mexican controls. We are performing further analysis utilizing longer haplotypes, Native American controls and local genetic ancestry prediction algorithms to identify the ancestry of the CHM haplotype.

607W

Genetic testing and diagnoses within a cardiovascular connective tissue clinic. *G. MacCarrick[1], J.P. Habashi[1], H.C. Dietz III[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 2) Howard Hughes Institute, Chevy Chase, Maryland, USA.

   Many genetics clinics find themselves evolving to specialty clinics, utilizing the expertise of their attending physicians; this is especially true in cardiac genetics. We sought to review the demographic, diagnosis and genetic testing data from a busy cardiovascular connective tissue clinic to examine the utilization of genetic testing in this setting. Data from 530 unique patients seen in one year by two cardiologists with genetics specialty and one genetic counselor was reviewed. The average patient age was 25.1 years, with 295/235 M:F ratio. 61% of patients were from out of state, with 88.5% Caucasian ethnicity. The most common diagnoses seen were Marfan syndrome (28%), aortic aneurysm/dissection (18%), Loeys-Dietz syndrome (13%) and ascending aortic aneurysm +/- bicuspid aortic valve (7%). Out of 55 patients referred for possible Marfan or Loeys-Dietz syndromes based on skeletal findings only, 1 had aneurysmal disease leading to a Loeys-Dietz diagnosis. Nine patients came with variants of unknown significance (VUS) previously detected, seeking greater expertise in interpretation of results. Of 42 patients with aortic aneurysm or dissection on which aortopathy panel testing was pursued, 9 (21%) had positive results (6 *FBN1*, 4 *TGFBR1/2*, 2 *ACTA2*, 1 *TGFB2*) and 12 had one or more VUS. There were no positive panel results in 6 patients with isolated arterial dissections including coronary artery dissections. A total of 62 aortopathy panels were sent out through clinic, with additional panel testing including: 3 Ehlers-Danlos, 1 Noonan, 1 Stickler. Single gene testing included: 8 *FBN1*, 2 *COL3a1*, and 6 familial mutations. SNP arrays were pursued in only 3 patients presenting with intellectual disability, and 6 clinical whole exomes were pursued with no positive results. 6 patients with ectopia lentis (ECL) without aneurysm were evaluated; consideration of exome slice for ECL genes was considered, but found to be cost-prohibitive. In patients with Marfan syndrome, 60% had molecular diagnoses; 40/95 of these positive tests were sent out through their care at our institution. In summary, in the cardiovascular connective tissue clinic, aortopathy panels continue to offer great appeal for a streamlined diagnostic approach with seemingly low burden of VUS contrasted with significant positive impact in individualized medical care based on diagnosis.

608T

Is the common *Cerebral Cavernous Malformation 2* **exon 2-10 deletion due to a founder in the US population?** *M. Detter[1,2], A. Akers[3], D. Marchuk[1].* 1) Molecular Genetics and Microbiology, Duke University, Durham, NC; 2) Medical Scientist Training Program, Duke University, Durham, NC; 3) Angioma Alliance, Norfolk, VA.

Cerebral cavernous malformations (CCMs) are clusters of dilated blood vessels that occur predominately within the central nervous system. These ectatic vessels are prone to hemorrhage and patients present clinically with headache, focal neurologic deficits, seizure, stroke, and death. The prevalence of CCMs is estimated to be 0.5% of the general population. Mutations within three genes, *KRIT1* (*CCM1*), *MGC4607* (*CCM2*), and *PDCD10* (*CCM3*), have been identified as contributing to the pathogenesis of CCMs in both the sporadic and heritable forms of disease. Previous work in our lab identified a 77.6-kb deletion of *CCM2* exon 2-10 shared among 8 probands who were negative for mutations detected through sequence analysis. In order to distinguish between this shared deletion occurring multiple time within the population or as the result of a founder effect, we determined microsatellite and SNP haplotypes within 650-kbs proximal and 1410-kbs distal to the deletion. Haplotype analysis revealed a variation at the microsatellite 140kb distal to the deletion site. The results of this study suggest either multiple independent deletion events or a founder effect with subsequent recombination within the 140kb region between the deletion and varying microsatellite. To further investigate a potential founder effect, our current study has recruited a new cohort of 12 unrelated American families known to harbor the *CCM2* exons 2-10 deletion. By DNA sequence analysis of the 5-kb regions proximal and distal to the deletion point, we are performing a full SNP haplotype analysis of the region flanking the deletion. Complete sequencing of the 10-kb of DNA immediately adjacent to the deletion will provide more statistical power to determine the presence of a founder within the US population of CCM patients. While the identification of a founder effect within this population would be an interesting result, different SNP haplotypes would also be provocative. This deletion is known to occur through recombination of an *AluSx* sequence in intron 1 and an *AluSg* sequence distal to exon 10. Different SNP haplotypes would highlight the stochastic nature of this recombination event that results in an identical 77.6-kb deletion shared among unrelated families.

609F

Haplotype analyses of CYP2C19*2 and CYP2C19*17 genetic polymorphisms in clopidogrel non-responsiveness after percutaneous coronary intervention with stent implantation. *F. Saydam[1], I. Degirmenci[2], A. Birdane[3], M. Ozdemir[4], C. Ozbayer[5], N. Ata[3], H. Gunes[2].* 1) Department of Medical Biology and Genetics, Recep Tayyip Erdogan University Faculty of Medicine, Rize, Turkey; 2) Department of Medical Biology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Turkey; 3) Department of Cardiology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Turkey; 4) Department of Pharmacology, Eskişehir Osmangazi University Faculty of Medicine, Eskişehir, Turkey; 5) Department of Midwifery, Dumlupınar University Kütahya School of Health, Kütahya, Turkey.

Dual antiplatelet medication with aspirin and clopidogrel is currently recommended strategy for patients undergoing percutaneous coronary intervention (PCI) with stent implantation. However, emerging non-responsiveness to clopidogrel often results in fatal stent thrombosis. Previous findings suggest that the CYP2C19*2 polymorphism is associated with non-responsiveness to clopidogrel and the CYP2C19*17 polymorphism enhances antiplatelet activity of clopidogrel. We therefore aimed to analyze the haplotypes of these polymorphisms in clopidogrel non-responsiveness. Antiplatelet activity of clopidogrel activity was measured by the VerifyNow P2Y$_{12}$ assay in blood samples collected from patients that took a standard dose of clopidogrel (75 mg/day) for at least 7 days. 243 responder and 104 non-responder patients underwent PCI with stent implantation are included in our study. The CYP2C19*2 (c.681G>A) and CYP2C19*17 (c.-806C>T) polymorphisms are genotyped using the Sequenom MassARRAY system. The genotype frequencies for each polymorphism were in good agreement with the predicted Hardy–Weinberg equilibrium values. Haplotypes with a frequency of <0.03 were excluded. Only frequencies of the A-T haplotype were <0.03 in our study group. The comparison of the G-T haplotype frequencies between the responder and non-responder group did not reveal any significant difference. The A-C haplotype was significantly associated with non-responsiveness to clopidogrel (OR=2.855, 95%CI: 1.868–4.364, *P*<0.001). Conversely, the G-C haplotype was associated with responsiveness to clopidogrel (*P*=0.002). Our findings suggest that the A-C haplotype has a 2.8-fold increased risk and the G-C haplotype enhances antiplatelet activity of clopidogrel. Checking the A-C haplotype as a pharmacogenetics test for risk patients will make treatment effective.

610W

Mechanism of priapism in a mouse model of Fabry disease. *J. Shen[1], E. Arning[1], X. Meng[1], M. Wight-Carter[2], T. Day[1], T. Bottiglieri[1], R. Schiffmann[1].* 1) Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX; 2) Animal Resources Center, UT Southwestern Medical Center, Dallas, TX.

Fabry disease is caused by deficient activity of lysosomal enzyme α-galactosidase A. Fabry disease exhibits broad range of clinical manifestations including cardiovascular diseases and renal insufficiency. Nitric oxide (NO) pathway dysregulation was thought to contribute to vasculopathy in this disease. Fabry disease is one of a few diseases that are associated with priapism, an abnormal prolonged painful erection of the penis. The pathophysiology of priapism in Fabry disease is not well understood. Our goal was to investigate underlying mechanism of priapism in Fabry disease using a mouse model. We found that Fabry mice develop priapism in an age-dependent manner with onset of symptoms at approximately 15 months of age. Wild type (WT) controls with the same genetic background had very low frequency of priapism (0.5% (1/207)). Compared to normal controls, expression of plasminogen activator inhibitor-1, which plays important roles in progression of fibrosis, was significantly upregulated in Fabry mouse penile tissues, suggesting that Fabry disease promotes penile fibrosis. Plasminogen abnormality has been found in children with Fabry disease (2007; 104: 2873). Expression of neuronal nitric oxide synthase (nNOS), but not endothelial and inducible NOS, was significantly increased in Fabry mouse penis. The nNOS upregulation was controlled at transcription level. It has been suggested that excess adenosine and reduced gene expression and activity of phosphodiesterase-5A (PDE5A), the cGMP-specific esterase, contribute to priapism in mouse models of sickle cell disease and NOS-deficient conditions. There was no significant change in tissue adenosine level and PDE5A expression level in Fabry mouse penis compared to WT controls. In conclusion, our findings suggest that increased nNOS expression and NO production may contribute to priapism in Fabry disease. Furthermore, nNOS was also upregulated in Fabry mouse heart, suggesting that nNOS-mediated NO dysregulation is a general pathogenic mechanism in Fabry disease.

611T

Loss-of-function mutations in *NONO* can cause an X-linked form of syndromic left ventricular non-compaction. *D.A. Scott[1,2], A. Hernandez-Garcia[1], M. Azamian[1], V.K. Jordan[2], B.J. Kim[1], M. Starkovich[1], J. Zhang[1], L.-J. Wong[1], S.A. Darilek[1], A.M. Breman[1], Y. Yang[1], J.R. Lupski[1,3,4,5], A.K. Jiwani[6], B. Das[7], S.R. Lalani[1], A.D. Iglesias[8], J.A. Rosenfeld[1], F. Xia[1].* 1) Department of Molecular & Human Genetics, Baylor College Medicine, Houston, TX 77030; 2) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030; 4) Department of Pediatrics, Baylor College Medicine, Houston, TX 77030; 5) Texas Children's Hospital, Houston, TX 77030; 6) Department of Pediatrics, University of Texas Medical Branch, Galveston, TX 77555; 7) Department of Pediatrics, Children's Medical Center, UT Southwestern Medical Center, Dallas, TX 75235; 8) Department of Pediatrics, Columbia University, New York, NY 10027.

Left ventricular non-compaction (LVNC) is a distinct form of cardiomyopathy characterized by deep intertrabecular recesses in hypertrophied segments of left ventricular myocardium. LVNC can present as an isolated finding, in association with congenital heart defects, or as part of a genetic syndrome. The non-POU domain containing, octamer-binding gene (*NONO*) is located on chromosome Xq13.1 and encodes a member of a small family of RNA and DNA binding proteins that includes SFPQ and PSPC1. Members of this family form homo- and hetero-dimeric complexes that perform a variety of tasks involved in RNA synthesis, transcriptional regulation and DNA repair. Loss-of-function mutations in *NONO* have been described as a cause of intellectual disability in males but not as a cause of LVNC or congenital heart defects. By searching a clinical database of over 6,000 individuals referred for exome sequencing and over 60,000 individuals referred for copy number variant (CNV) analysis, we identified two Hispanic males with LVNC, atrial and ventricular septal defects, developmental delay and intellectual disability, who harbored *de novo*, loss-of-function mutations in *NONO*. We also identified a Hispanic male infant with developmental delay, congenital brain anomalies and severe LVNC requiring cardiac transplantation, who inherited a single-gene deletion of *NONO* from his asymptomatic mother. Features commonly observed in males with *NONO* loss-of-function alleles included abnormalities of the corpus callosum and relative macrocephaly. We conclude that loss-of-function mutations in *NONO* can cause an X-linked form of syndromic LVNC associated with congenital heart defects, global developmental delay and intellectual disability.

612F

Pseudoxanthoma elasticum (PXE): Dysregulation of local ATP metabolism and treatment with a tissue non-specific alkaline phosphatase (TNAP) inhibitor. *S.G. Ziegler[1], C.R. Ferreira[2,3], E. Gallo MacFarlane[1], R.C. Riddle[4], R. Tomlinson[4], C. Ma[5], E. Sergienko[5], A.B. Pinkerton[5], J.L. Millan[5], W.A. Gahl[2], H.C. Dietz[1,6].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Division of Genetics and Metabolism, Children's National Health System, Washington, DC; 4) Department of Orthopaedic Surgery, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Sanford-Burnham-Prebys Medical Discovery Institute, La Jolla, CA; 6) Howard Hughes Medical Institute, Chevy Chase, MD.

   Biallelic mutations in *ABCC6* cause PXE, characterized by calcification in the eyes, skin, and vessels. While the function of ABCC6 in PXE remains elusive, the mechanisms of related ectopic calcification disorders are better understood. Generalized arterial calcification of infancy is caused by biallelic mutations in *ENPP1*, which encodes an enzyme that converts ATP to AMP and pyrophosphate (PPi), a major inhibitor of tissue calcification. AMP is further degraded to adenosine and inorganic phosphate by CD73, encoded by *NT5E*; biallelic mutations in *NT5E* cause calcification of joints and arteries. We reasoned that a test for genetic interaction in mouse models of ectopic calcification might inform the pathogenesis of PXE. *Enpp1*[-/-] and *Abcc6*[-/-] mice showed fibrous capsule calcification of the vibrissae (an early marker of ectopic calcification) at 15 weeks of age, while *Nt5e*[-/-] mice calcified after one year. *Abcc6*[-/-] mice with one mutated *Enpp1* or two defective *Nt5e* alleles showed accentuated calcification with strong statistical evidence for synergy. Additionally, ABCC6, ENPP1, and CD73 exhibited regulatory interactions; human fibroblasts with biallelic *ABCC6* mutations had increased ENPP1 and decreased CD73 activity. Taken together, these data suggest that ABCC6 participates with ENPP1 and CD73 in ATP metabolism. *ABCC6* mutant cells exhibited a calcification phenotype in culture, suggesting a cell-autonomous defect and opposing the prevailing hypothesis that PXE results from failed liver secretion of an endocrine inhibitor of peripheral calcification. Moreover, a conditional *Abcc6*-targeted mouse revealed that liver-specific deletion failed to recapitulate the calcification phenotype produced by ubiquitous *Abcc6* deletion. Given their ability to recapitulate pathogenic events, PXE patient fibroblasts emerged as a viable model for investigating therapies. Under osteogenic conditions, *ABCC6* mutant cells had increased expression and activity of TNAP, an enzyme that degrades PPi. A novel, selective, and orally bioavailable TNAP inhibitor robustly attenuated calcification in PXE patient cells and in *Abcc6*[-/-] mice. A parsimonious model suggests that ENPP1 serves to generate PPi from ATP, while ABCC6 and CD73 cooperate in the further catabolism of AMP to adenosine, which normally represses TNAP expression. Perturbation of this pathway limits the bioavailability of PPi and hence results in calcification inferring broad therapeutic relevance for TNAP inhibitors.

613W

Case report: Two likely pathogenic mutations one in *MYH7* and one in *TTN* in a 12 year old girl with hypertrophic cardiomyopathy with restrictive phenotype. *L.M. Sigsworth[1], M.J. Bock[1], J.A. Gold[1,2].* 1) Loma Linda University , Loma Linda , CA; 2) University of California, Irvine, CA.

   Introduction: Hypertrophic cardiomyopathy (HCM) is a common form of cardiomyopathy, which may present at any age. Most cases of HCM are thought to occur due to single gene mutations. This case study explores the rare occurrence of a patient with early onset severe HCM who possesses mutations in two different genes, leading to HCM. **Case:** The patient is a 12-year-old Hispanic female who initially presented with dyspnea and changes in vision when running the mile during physical education class. Physical exam: grade 3/6 mid-systolic ejection murmur. Her cardiac silhouette was unremarkable. Echocardiogram showed severe circumferential left ventricular hypertrophy with a mid-cavitary gradient and an ejection fraction of 60-65%. She has a pulmonary capillary wedge pressure of 24 mmHg by catheterization. A family history was noncontributory. **Management and Outcome:** The patient was then transferred to Loma Linda Children's. She was clinically diagnosed with HCM with a restrictive phenotype and was seen by pediatric genetics. A SNP chromosomal microarray showed a 234 kB duplication at 10q24.32. The duplicated interval involves six known genes (*BTRC*, *DPCD*, *POLL*, *MIR3158*-2, *MIR3158*-1, and *FBXW4*). *BTRC* and *FBXW4* are partially duplicated and not associated with HCM. The cardiomyopathy panel revealed mutations in MYH7 on chromosome 14 (OMIM #192600) (cDNA change:c.5258A>G) (amino acid change :pGlul753Gly), which is is likely pathogenic. MYH7 encodes for the beta-myosin gene in the heavy chain of the sarcomere. The in-silico analysis suggests this may affect protein function. The TTN mutation on chromosome 2 (OMIM #613765) (cDNA change:c.46759G>A) (amino acid change: p.Ala15587Thr). This is a novel mutation, predicted to affect protein function.
Discussion: MYH7 is the most common mutation that causes hypertrophic cardiomyopathy (Kaski 2009). TTN is more commonly reported to cause dilated cardiomyopathy (Itoh-Satoh 2002, Neiva-Sousa 2015). TTN has been reported to cause HCM (Satoh 1999). A unique aspect of this patient's presentation is the early onset of late stage HCM. Researchers have reported a "dose effect" for double mutation carriers of cardiomyopathy mutation variants (Bales 2016). This is another case that shows a possible "double-dose effect" leading to a more severe phenotype. Whether or not her duplication is significant will depend on the results of her parents testing. Other family members could develop late onset HCM with one gene mutation.

614T

A genomic exploration to explain Glatiramer Acetate's adverse cardiovascular effects. *I. Braenne[1,2,3], C. Willenborg[1], L. Zeng[4,5], J. Erdmann[1,3], H. Schunkert[4,5], CARDIoGRAM Consortium, CARDIoGRAMplusC4D Consortium.* 1) IIEG, University of Luebeck, Luebeck, Germany; 2) Public Health Genomics, University of Virginia, Charlottesville, VA 22908; 3) DZHK (German Research Center for Cardiovascular Research), Partner site Hamburg/Luebeck/Kiel, Germany; 4) Deutsches Herzzentrum Muenchen, Technische Universitaet Muenchen, Muenchen, Germany; 5) DZHK (German Research Center for Cardiovascular Research), Partner site Muenchen, Germany.

   Aims: Glatiramer acetate (GA), which is used in the treatment of multiple sclerosis, is reported to show multiple coronary artery related adverse effects including increased blood pressure, hypercholesterolemia and coronary artery disease. Here, we study the genes affected under GA treatment to identify the disturbed genetic mechanisms underlying the adverse effect and at the same time identify new CAD risk genes. **Methods:** We identified genes and gene products reported to interact with GA using a drug gene interaction database. We traced the association signal in 200-kb region around the genomic position of these genes in around 60,000 cases and 123,000 controls and validated our findings in a second meta-analysis consisting of additional ~20,000 cases and ~ 80,000 controls. **Results:** Four genes were reported to interact with GA, but only TGFB1 shows association with CAD in our analysis. We identified presumably five independent new CAD loci within the TGFB1 region. The lead SNP, rs12459996, was genome-wide significantly associated with CAD in our extended meta-analysis (p=1.58×10^{-12}). The other four assumed sub loci showed p-values ranging from 1.63×10^{-7} to 6.89×10^{-7}. The five loci show significant additive effect. **Conclusion:** Studying genes reported to interact with Glatiramer acetate, we identified the interaction with TGFB1 as the one that presumably increases the risk of CAD under treatment. TGFB1 is also a new CAD risk gene, not reported for CAD previously. Hence, indirectly, we identify a new CAD gene in this study.

615F

The genomics of ELITE endurance athletes. *D. Waggott[1], M. Mattsson[1,2], M. Wheeler[1], E. Ashley[1].* 1) Stanford University, Stanford, CA., Select a Country; 2) Karolinska Institute.

   Health exists as a spectrum from disease to some outlier physiological optimum. To date most molecular genetic research has focused on disease states and less on extreme health populations. We hypothesize that interrogating outlier elite endurance athletes, with strict physiological eligibility criteria, will inform cardiovascular research through the identification of complementary pathways and therapeutic targets. Eligibility criteria for the ELITE study (Exercise at the Limit - Inherited Traits of of Endurance http://med.stanford.edu/elite.html) required a lifetime VO2max, which measures maximal oxygen consumption during peak aerobic exercise, at a threshold estimated to be attainable in less than 1 in 50,000 people (men 80ml/kg/min; women 65ml/kg/min). VO2max is reported to have substantial genetic influence (h2~0.5) and is correlated with endurance sport performance along with work efficiency. Several well documented cases of athletic outliers have been tied to rare genetic variants including the Finnish cross country skier Mäntyranta (*EPOR*) and Priscilla Lopes-Schliep (*LMNA*). In the later, the same domain of the LMNA gene is related to rare forms of muscular dystrophy. Additionally, adaptive hypoxia variations have been identified in high altitude populations in Tibet (*EPAS1*), Andes and Ethiopia. To date we have sequenced 268 ELITE participants using clinically enhanced exomes and run 550 samples on high density multi-ethnic SNP chips. Preliminary analysis has focused on a combination of rare variant curation and common variation association. Rare variation curation included prioritization of LOF variants within candidate genes related to oxygen transport, muscle physiology and metabolism (i.e. *PPARA, PPARGC1A, RYR2, ACTN3, MSTN*). Global gene screening was accomplished using in silico functionally weighted burden testing. Common variant association (the largest GWAS of its kind) has been used to support rare variant findings and identify non-coding and structural variant association signals. We believe that our methodology of combining rare LOF variants with common variation association in a population with extreme endurance physiology will systematically identify pleiotropic genes with both protective and pathogenic features similar to role of *PCSK9* and LDL levels. .

616W

Whole exome sequencing of a restrictive cardiomyopathy family: Rare variant vs polymorphisms. *M. Kapoor[1], S. Das[1], A. Biswas[1], B. Murry[1], S. Seth[2], B. Bhargava[2], V. Scaria[3], S. Sivasubbu[3], V. Rao[1].* 1) Anthropology, Delhi University, Delhi, India; 2) Department of Cardiology, AIIMS, New Delhi; 3) CSIR-IGIB, New Delhi.

Cardiomyopathies are a disease of complex nature with genetic heterogeneity. Restrictive cardiomyopathy (RCM) is complex genetic disorder, in which incidence is still unknown. Genetic heterogeneity is a marked characteristic of cardiomyopathies which cannot be defined with single driver mutation to cause diverse phenotypes. Polymorphism could be considered in sarcomere genes as a cumulative effect to cause diverse phenotypes with same driver mutations. With emergence and continued upgrading in next generations sequencing technologies provide a cost effective path for geneticist. Here, we tried to explain one rare mutation and two candidate gene polymorphism as a cause of restrictive cardiomyopathy with genetic heterogeneity and phenotypic plasticity. The study was ethically approved and written consent was taken from patient and family members. On the basis of clinical severity, early age of onset and worst prognosis, patient with parents (trio) was selected for whole exome sequencing. Good quality DNA is processed for library preparation, capture and sequencing on illumina HiSeq 2500. Segregation of rare variant F764Y in MYH7 and two polymorphisms R25529H and R23473H in TTN is found. Rare mutation is present on highly conserved region of the genes, susceptible to cause protein damage known to cause cardiomyopathies. This 764 residue in MYH7 resides in converter region, acts as a flexible joint in myosin which during contractile cycle undergo conformational changes. So, substitution of a tyrosin at this position of phenylalanine might cause the change in polarity causing disturbance in the transmitted movement causing diminished efficiency of contractile function. Rare variant is present in neck region of MYH7 and two polymorphisms are present on Fibronectin type III region of TTN protein. Protein-protein interaction of TTN and MYH7 in the contraction and relaxation mechanism of heart muscle could explain the phenotypic plasticity leading to stiffness of heart muscle as the main characteristics of restrictive cardiomyopathy rather than dilated cardiomyopathy as earlier reported. These kinds of protein-protein interaction of polymorphism and driver mutation in different gene should be consider and validated through in-vitro or in-vivo techniques to elucidate final pathway causing phenotypic plasticity and genetic heterogeneity among cardiomyopathy cases.

617T

Associations between cysteine-rich protein 1 (CRIP1) expression and blood pressure. *C. Müller[1,2], A. Jagodzinski[1,2], K.J. Lackner[3,6], T. Münzel[7,6], I. Hermanns[5], P.S. Wild[4,5,6], S. Blankenberg[1,2], T. Zeller[1,2].* 1) Department of General and Interventional Cardiology, University Heart Center Hamburg, Hamburg, Germany; 2) DZHK (Deutsches Zentrum für Herz-Kreislauf-Forschung e.V.), partner site Hamburg/Kiel/Luebeck, Germany; 3) Department of Clinical Chemistry and Laboratory Medicine, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany; 4) Preventive Cardiology and Preventive Medicine, Center for Cardiology, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany; 5) Center for Thrombosis and Hemostasis, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany; 6) DZHK (German Center for Cardiovascular Research), partner site RhineMain, Mainz, Germany; 7) Center for Cardiology I, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany.

Gene expression of cysteine-rich protein 1 (intestinal) (*CRIP1*) is associated with systolic (SBP) and diastolic blood pressure (DBP) in monocytes (Rotival et al. Plos Genet. 2011) and whole blood cells (Huan et al. Plos Genet. 2015) of large population-based cohorts. Until today, the role of *CRIP1* in hypertension is unknown. The aims of our study were to study longitudinal expression changes of CRIP1 protein and mRNA in a BP-lowering clinical trial and to determine cross-sectional associations between *CRIP1* mRNA and subclinical phenotypes of cardiovascular disease in a large population-based study. In the BP-lowering clinical trial TeamSta, 406 hypertensive patients were included and treated for 6 months with antihypertensive treatment. At baseline visit and 6-months follow-up, BP was measured and *CRIP1* mRNA was quantified in peripheral blood mononuclear cells by qPCR. Differential gene expression after treatment was estimated by linear mixed models and adjusted for sex and age. In the population-based Gutenberg Health Study (GHS), gene expression was measured using Illumina HT12 v3 BeadChips (n = 1285). Plasma renin activity was assessed by LIAISON Direct Renin Assay. Interventricular septal thickness (IVSD), left ventricular posterior wall thickness (LVPW), left ventricular hypertrophy (LVH) and left ventricular mass (LVM) were selected as subclinical phenotypes. Associations between *CRIP1* mRNA and plasma renin activity, SBP or subclinical phenotypes were calculated by linear regression and adjusted for sex and age. After hypertensive treatment, the mean SBP was decreased by 11.5 mmHg in TeamSta subjects. *CRIP1* mRNA was significantly reduced in all patients (p = 5.6×10^{-14}). In GHS, *CRIP1* mRNA was significantly elevated with SBP in all individuals (n = 1285, p = 1.0×10^{-19}), and after excluding subjects receiving antihypertensive treatment (n = 941, p = 3.6×10^{-13}). Increased *CRIP1* mRNA associated with IVSDd (p = 1.9×10^{-3}), LVPWd (p = 1×10^{-4}), LVH (p = 5.2×10^{-3}) and LVM (p = 9×10^{-4}). Plasma renin activity negatively associated with *CRIP1* mRNA expression in monocytes (p = 8.3×10^{-4}). *CRIP1* mRNA levels were significantly changed in relation to BP and intervention in a clinical trial. In addition, monocytic *CRIP1* mRNA associated with left ventricular hypertrophy and renin plasma activity in a large population cohort.

618F

Targeted sequencing of genes related to LDL cholesterol in patients with peripheral arterial disease. *M. Safarova[1], E. Austin[1], D. Schaid[2], I. Kullo[1].* 1) Department of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN.

   Objectives. Peripheral arterial disease (PAD) is most commonly due to atherosclerosis and is associated with significant morbidity and mortality. Low-density lipoprotein cholesterol (LDL-C) is an independent risk factor for PAD; however, whether genes related to LDL-C are associated with PAD is not known. We, therefore, tested whether: 1) genomic regions known to be associated with LDL-C are associated with PAD, and 2) these associations remain significant after adjustment for LDL-C. **Methods.** PAD cases were defined as a resting/post-exercise ankle-brachial index (ABI) ≤0.9 or ≥1.4 and/or history of lower extremity revascularization, and no history of CHD at the time of recruitment. Controls were subjects with normal ABI or no history of PAD. We performed targeted sequencing of 10 genes (*ABO, APOB, APOC1, APOE, LDLR, LPA, PCSK9, PDGFD, SORT1, TRIB1,* including coding regions, 2 kb upstream and 1kb downstream*)* identified by GWAS to harbor variants associated with LDL-C, using Illumina HiSeq 2000 (read depth ≥30). **Results**. Following quality control of the sequence data, 1470 PAD cases (mean ± SD, 69 ± 11 years, 62% men, LDL-C, 120 ± 43 mg/dL) and 1558 controls (60 ± 11 years, 56% men, LDL-C, 125 ± 36 mg/dL) were available for analysis. In 645 individuals on a statin at the time of recruitment, we imputed LDL-C levels by assuming a 25% reduction in LDL-C on therapy. Using the adaptive sum of powered score (aSPU) global association test and adjusting for age and sex, *APOE*, *APOB* and *APOC1* (all, P ≤ 0.01) were associated with LDL-C but not with PAD, whereas *ABO*, *PCSK9* and *SORT1* (all, P < 0.001) were associated with PAD but not with LDL-C. After additional adjustment for LDL-C these genes remained significantly associated with PAD. **Conclusion**. This study provides novel data on the association of LDL-C-related genes with the presence of PAD. In our study sample, *PCSK9*, *SORT1* and *ABO* were associated with PAD despite a lack of association with LDL-C. Further research is warranted to investigate whether non-lipid-related effects of *ABO, PCSK9* and *SORT1* mediate these associations and, therefore, help identify novel therapeutic targets for PAD.

619W

Integrated whole genome sequencing and transcriptome study identifies rare mutations in atherosclerosis and thrombosis pathways in a case of severe restenosed atherothrombosis. *A.M. Veerappa[1], S.M. Dinesh[2], N.B. Ramachandra[1], D. Sameer[3], J. Shah[4].* 1) Department of Genetics and Genomics, University of Mysore, Mysore, Karnataka, India; 2) NUCSER, KS Hegde Medical Academy, Nitte University, Mangalore-575 018, India; 3) Department of Cardiology, Apollo Hospitals, Ahmedabad-382428, India; 4) Dept of Cardiology, HCG Multi Speciality Hospital, Ahmedabad-380 006, Gujarat, India.

   The globally debated 34-year-old male case with rare severe restenosed atherothrombosis was presented to us with 8 clogged arteries resulting in myocardial infarction, ischaemic stroke, type 2 diabetes and hypertension. This study assessed the possible cause for severe restenosed atherothrombosis in the present case recruited. We performed whole genome sequencing (WGS) and transcriptome profiling and disease pathway analysis. Here we report the consequences of novel and rare damaging mutations in *LRP6, APOBR*, *APOH*, *ACAT1*, *ITGAM* and *STAB2* on the cellular pathways resulting in disease. Overlaying the transcriptome profile on mutant genes resulted in the disruption of several processes such as LDL uptake, clearance, inflammation and thrombosis. Enrichment analysis of the dysregulated genes showed significant elevations in inflammatory processes and cardiovascular diseases. Integrative analysis of WGS and transcriptome profiling identified mutations in rare genes, and these were specifically involved in causal processes of Endothelial Dysfunction, Reverse Cholesterol Transport, Plaque Development, Inflammation and Plaque Rupture, and Thrombosis. The findings indicate Atherosclerosis/Atherothrombosis to be a highly heterogenous disease and the conclusions of this study will help in better understanding of the significant contributions of genetics towards the etiology of this disease.

620T

Homozygous *TPM1* mutation in a familial pediatric dilated cardiomyopathy. *K. Al Harbi[1], K. Thangaraj[2], A.M. Abdallah[3], S. Justin Carlus[1].* 1) Pediatrics Department, College of Medicine, Taibah University, Al-Madinah, Saudi Arabia; 2) Centre for Cellular and Molecular Biology, Hyderabad, India; 3) West Midlands Regional Genetics Laboratory, Birmingham Women's NHS Foundation Trust , Birmingham , UK.

Cardiomyopathies represent the second largest group of patients in sudden cardiac death (SCD) victims, next to coronary artery disease. Cardiomyopathy's causal pathology usually lies in the genes that are responsible for generating the mechanical properties of the heart.   Methods-We sought to identify the genetic basis of severe, non-syndromic Dilated cardiomyopathy (DCM) diagnosed in a Saudi family with 2 out of 3 children affected with DCM and 1 affected with Patent ductus arteriosus (PDA). Their parents displayed no phenotypic evidence of DCM on screening by echocardiography. We applied targeted sequencing and custom data analysis and interpretation pipelines to identify pathogenic base substitutions and insertions and deletions in 181 genes associated with cardiomyopathies. Our sequencing panel covered coding exons, exon-intron boundaries and known variants in intronic regions of target genes.   Results: Genetic analysis revealed a homozygous missense mutation in TMP1 gene (c.7G>A, p.Gly3Arg) in all three affected individuals. This gene is a member of the tropomyosin family of highly conserved, widely distributed actin-binding proteins involved in the contractile system of striated and smooth muscles and the cytoskeleton of non-muscle cells. Mutations in this gene are associated with DCM, hypertrophic cardiomyopathy (HCM) and Left ventricular noncompaction.   Conclusion: Using targeted sequencing strategy we have successfully identified a likely pathogenic variant within the TMP1 gene and provided evidence that TMP1 is a risk gene for DCM.

621F

Factor analysis of clustered cardiovascular risk in adult Punjabi female population. *V. Bains[1], B. Doza[1,2], K. Kaur[1].* 1) Human genetics, guru nanak dev university, Amritsar, India; 2) Director, Aligarh Muslim University off-campus, Murshidabad, West Bengal.

Cardiovascular Disease (CVD) is a abnormal functioning of heart or blood vessels. Hypertension, hyperlipidemia and heart failure are among the most commonly seen cardiovascular disease. Metabolic syndrome including hypertension, elevated triglycerides, increased abdominal fat, low HDL and elevated fasting blood glucose increases the risk of CVD even further. The objective of the present study was to determine significant cardiovascular risk among obese and non-obese adult Punjabi females. A total of 200 females (aged 21-37 years) were recruited from Amritsar region of Punjab with 100 obese and 100 normal females. Principal component factor analysis (PCFA) was applied to extract orthogonal components from anthropometric and physiometric variables. Association between components were explained by factor loadings. PCA was performed with varimax rotation to reduce 14 intercorrelated variables into three and four independent factors for the obese and non obese females respectively. The three factors explained 74.73% of total variance among obese females and four factors explain 73.98% among non-obese females. Factor 1 was loaded (>0.5) with high BMI, WC, WHR, Bicep skinfold and SBP among both the obese and non-obese females. Hip circumference, tricep skinfold and subscapular skinfold for obese females and age, DBP, MBP and pulse rate had maximum loadings on factor 2 for obese females while hip circumference, tricep skinfold and subscapular skinfolds had highest loadings for non obese females. The anthropometric variables such as weight, BMI, WC, WHR and bicep skinfolds were grouped together on factor 1 among both the obese and non-obese adult females. Physiometric variables SBP, DBP, MBP and pulse rate are grouped together on factor 1 for obese females and factor 2 for non-obese females. Hence, this may be interpreted from present analysis that both the anthropometric and physiometric varibles are equally important indicator for the development of CVD among both the obese and non-obese adult females. Further common greater communality estimates (>0.75) found on weight, WC, HC, tricep skinfolds, DBP and MBP among both the obese and non-obese females shows that these parameters may be consider as good predictors of CVD.   .

The impact of genetic variation on doxorubicin-induced cardiotoxicity.
J.D. Blischak[1,2], D.A. Knowles[3,4], C.K. Burrows[1], K.W. Patterson[1], C. Ober[1], J.K. Pritchard[3,5,6], Y. Gilad[1]. 1) Department of Human Genetics, University of Chicago, Chicago, IL, USA; 2) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL, USA; 3) Department of Genetics, Stanford University, Stanford, CA, USA; 4) Department of Radiology, Stanford University, Stanford, CA, USA; 5) Department of Biology, Stanford University, Stanford, CA, USA; 6) Howard Hughes Medical Institute, Stanford University, CA, USA.

Doxorubicin, a commonly prescribed cancer drug, has cardiotoxic side effects in a subset of patients. The ability to predict who will experience these cardiotoxic side effects would enable physicians to prescribe optimal dosage regimens for each patient. To investigate the genetic basis of doxorubicin-induced cardiotoxicity, we developed an *in vitro* cardiomyocyte model. We obtained 46 immortalized lymphoblastoid cell lines (LCLs) derived from blood samples collected from adults unselected with respect to cardiovascular disease. We reprogrammed these LCLs into induced pluripotent stem cells (iPSCs) and differentiated the resulting iPSCs into cardiomyocytes. We then treated the cardiomyocytes with variable doses of doxorubicin and measured the extent of cardiac damage by i) assessing levels of cardiac troponin, a clinical cardiac stress marker, and ii) sequencing RNA to identify gene expression changes. Incorporating previously available genotype data, we identified response expression quantitative trait loci (response eQTLs), i.e. genetic variants associated with gene expression levels only pre- or post-treatment with doxorubicin. Next we trained a classifier using the response eQTLs as the input to predict the extent of cardiac damage in the *in vitro* model as measured via cardiac troponin. Our results provide insight into the mechanisms of doxorubicin-induced cardiotoxicity and provide a framework for the incorporation of patient genotypes in determining personalized doxorubicin dosage.

A role for the non-sarcomeric protein WTIP in hypertrophic cardiomyopathy.
H. De Jong[1], F.E. Dewey[2], F. Lan[2], R. Lui[2], A. Erbilgin[2], M.T. Wheeler[2], S.P. Cordero[3], A. Werdich[4], R.S. Chen[1], S. Pan[2], Y. Kim[2], K. Bommakanti[2], J.M. Bos[6], F. Haddad[2], V. Froelicher[2], M. Ackerman[6], R.S. Vasan[5], C. McCrae[4], J.C. Wu[2], M. Snyder[1], E.A. Ashley[1,2]. 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Medicine, Stanford University, Stanford, CA; 3) Training program in biomedical informatics, Stanford University, Stanford, CA; 4) Department of Medicine, Harvard University, Boston, MA; 5) Department of Medicine, Boston University, Boston, MA; 6) Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN.

Hypertrophic cardiomyopathy (HCM [MIM 192600]), a common cause of sudden death in young people, is an inherited condition characterized by a thickening of the left ventricular wall of the heart. While many cases of HCM are caused by variants in genes that encode the cardiac sarcomere, a large proportion of cases have an unknown mechanism. Using exome sequencing and identity-by-descent analysis, we identified a putatively causal novel variant in Wilms Tumor Interacting Protein (WTIP [MIM 614790]) in a three-generation HCM kindred. Induced pluripotent stem cell-derived cardiomyocytes from family members with this variant recapitulated the hypertrophic phenotype. In neonatal rat ventricular myocytes, shRNA knockdown of WTIP increased phenylephrine-induced hypertrophy. An association between the genomic region surrounding *WTIP* and left ventricular thickness in a large population cohort also indicates a role for WTIP in complex forms of hypertrophy. Together, these results suggest a novel non-sarcomeric mechanism for HCM.

624F

Genetic risk factors of arterosclerosis in Turkish Cypriot population. *M.C. Ergoren[1,4], E. Ozerkman[2], A. Bostanci[2], S.G. Temel[3], G. Mocan[1].* 1) Medical Biology, School of Medicine, Near East University, Nicosia, Cyprus; 2) Medical Genetic Laboratory, Near East University Hospital, Near East University, Nicosia, Cyprus; 3) Histology and Embryology, School of Medicine, Near East University, Nicosia, Cyprus; 4) Experimental Health Sciences Research Centre, Near East University, Nicosia, Cyprus.

Genetic variation is a rich source of knowledge for cardiovascular disease because many, if not all, cardiovascular disorders are highly heritable. Genetic risk scores are a useful tool for examining the cumulative predictive ability of genetic variation on cardiovascular diseases arterosclerosis. Important considerations for creating genetic risk scores include the choice of genetic variants, biochemical parameters, and ethnicities. The questions still remain about the ultimate clinical utility of the genetic risk score, further investigation in high-risk populations and new ways to combine genetic risk scores with traditional risk factors may prove to be fruitful. To investigate the arterosclerosis genetic risk score profile, we compared 200subjects with a cardiac problem and 200 without; we based on HapMap, 1000 genome and dbSNP datas and picked previously identified 36 different SNPs on 24 different genes that are suggested to have association with arterosclerosis for different populations. This study is the first analysis of the highest SNP coverage that shown the association of genetic variants with arterosclerosis in North Cyprus. Our data is the first data shown the association of all 24 gene and 36 polymorphism to arterosclerosis and thus these data are demonstrating the cardio-genetic profile of North Cyprus. North Cyprus has a unique mixture of allele distribution for each SNP to the other close by country neighbors. Thus, SNP-SNP interactions and also their relation with biochemical pathways might play critical role for developing genetic related diseases like CVD, metabolic syndromes etc. To conclude, this study will help for understanding the genetic profile of arterosclerosis in the Island and also will be great source and useful tool for prevention of arterosclerosis.

625W

RNA sequencing of human atrial tissue implicates members of the *CLDN* **gene family in atrial fibrillation.** *A. Isaacs[1,2,3], J. Winters[1,4], A. Witten[5], S. Zeemering[1,4], E. Bidar[6], B. Maesen[6], J. Maessen[1,6], H. Crijns[1,7], M. Stoll[1,2,3,5], U. Schotten[1,4], CATCH-ME Consortium.* 1) CARIM School for Cardiovascular Diseases, Maastricht University, Maastricht, Netherlands; 2) Maastricht Centre for Systems Biology (MaCSBio), Maastricht University, Maastricht, Netherlands; 3) Dept. of Biochemistry, Maastricht University, Maastricht, Netherlands; 4) Dept. of Physiology, Maastricht University, Maastricht, Netherlands; 5) Dept. of Genetic Epidemiology, Institute for Human Genetics, University of Muenster, Germany; 6) Dept. of Cardiothoracic Surgery, Maastricht University, Maastricht, Netherlands; 7) Dept. of Cardiology, Maastricht University, Maastricht, Netherlands.

Atrial fibrillation (AF), a complex, multifactorial disease, is the most common form of arrhythmia, imposing substantial burdens on health care systems, and predisposing patients to adverse outcomes, such as stroke and heart failure. Next-generation RNA sequencing is a valuable tool for elucidating genes, pathways, and variants that either play a role in disease etiology or are sensitive markers of disease and/or progression. In the current pilot of an ongoing study, right atrial tissue biopsies were obtained for 35 patients during open-heart procedures performed at Maastricht University Medical Centre (19 sinus rhythm (SR), 8 paroxysmal AF (ParAF), 8 persistent AF (PersAF)). Messenger RNA was extracted from these samples and directional, paired-end libraries were prepared (NEBNext Ultra Directional RNA Library Prep Kit) and sequenced (Illumina NextSeq 500). The well-known Tuxedo Suite was used to perform sequence alignment and feature identification, quantification, and differential expression. Differential expression analysis was used to compare the three groups (SR, PersAF, and ParAF); results were considered significant if non-zero expression was observed in each group, the effect in fold-change was ≥ 2, and the experiment-wide false discovery rate was ≤ 0.05. 52 genes met these criteria for the SR vs. ParAF comparison, 102 for SR vs. PersAF, and 121 for ParAF vs. PersAF. There were also substantial intersections of genes between comparisons (SR vs. ParAF ∩ SR vs. PersAF = 12, SR vs. ParAF ∩ ParAF vs. PersAF = 18, and SR vs. PersAF ∩ ParAF vs. PersAF = 56). One gene, a member of the claudin family, was differentially expressed in all three pairwise comparisons; of note, this gene was also identified as having differential isoform expression in each of the three analyses. A second member of this gene family was differentially expressed in two comparisons (SR vs. PersAF and ParAF vs. PersAF), while a third was significant in the ParAF vs. PersAF analysis (and nominally significant for the other two). Claudin proteins are crucial for the formation and maintenance of tight junctions. Family members are often co-expressed and create complexes; these play critical roles in permeability to sodium and potassium ions, among others, polarity, and signal transduction. Continuing ascertainment and sequencing of patients will allow for a much more fine-grained and sensitive analysis of the role of atrial tissue expression, including claudins, in AF.

eQTL analysis of megakaryocytes (MKs) derived from induced pluripotent stem cells (iPSCs). *K. Kammers[1], M.A. Taub[1], I. Ruczinski[1], J. Martin[2], L.R. Yanek[2], A. Frazee[1], Y. Gao[3], D. Hoyle[3], N. Faraday[2], D.M. Becker[2], L. Cheng[3], Z.Z. Wang[3], J.T. Leek[1], L.C. Becker[2], R.A. Mathias[2].* 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) The GeneSTAR Research Program, Johns Hopkins School of Medicine, Baltimore, MD; 3) Division of Hematology and Institute for Cell Engineering, Johns Hopkins School of Medicine, Baltimore, MD.

Understanding the biology of platelet aggregation is important to prevent inappropriate vascular thrombosis. GWAS studies have identified common variants associated with platelet aggregation, but because they are intronic or intergenic, their biological link to platelet function is unclear. To explore potential function of genetic variants in this context, we have produced pluripotent stem cells (iPSCs) from mono-nuclear cells in subjects from our parent platelet aggregation studies, and then derived megakaryocytes (MKs), the precursor cells for anucleate platelets, from the iPSCs to determine patterns of gene expression in the MKs related to specific genetic variants. For 198 MK cell lines we generated genotype data on the Illumina 1M GWAS array with 1,003,451 SNPs, and RNA-seq data from extracted non-ribosomal RNA. To estimate transcript expression, we aligned and assembled raw RNA-seq reads with the Tuxedo pipeline and conducted statistical downstream analyses in R using the Ballgown and Matrix eQTL packages. In particular, we present necessary statistical considerations that include transformation and filtering of the genomic data sets as well as adjustments for known and unknown batch-effects in the statistical models. We show that failing to make such adjustments can result in spurious apparent associations between genotype and gene expression. Including iPSC-derived MKs on 108 European American (EA) and 90 African American (AA) subjects, we identify a total of N=7,190 and N=525 cis-eQTLs in the two racial groups (q<0.05), respectively. Given unequal capture of common variation on GWAS arrays between African and European ancestry subjects as represented here, we rely on a distance-based replication scheme to look for eQTL replication between the two groups (replication at a distance of 5kb). Of the 7,190 cis-eQTLs discovered in the EAs, 328 were replicated in AAs (q<0.05), and of the 525 cis-eQTLs discovered in the AAs, 261 were replicated in the EAs (q<0.05). A high number of the detected cis-eQTLs (38%) are unique to MKs compared to 44 other tissue types that are reported in the latest version of the GTEx Project. We are currently performing integrative analysis by including the eQTL signatures in our GWAS for platelet aggregation phenotypes to identify potential mechanisms of action for previously identified GWAS loci, and to identify additional GWAS signals that fail stringent Bonferroni thresholds in the absence of prior functional relevance.

627F

Combining conventional risk factors and genetic variants to predict the risk of hypertension in Taiwanese population using Taiwan Biobank. *C.W. Lin[1,2], C.Y. Shen[1,2].* 1) Taiwan Biobank, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Hypertension is a common complex disorder and results from multiple genetic and environmental risk factors and their complex interactions. Proper lifestyle modification could prevent and delay the onset of hypertension in individuals at high risk, thus it is particularly important to develop risk prediction tools for the use in population-base screening and prevention programs. This study aimed to construct a risk assessment model, combining conventional risk factors and genetic variants, to predict the risk of hypertension in Taiwanese population. We used data from health cohort of Taiwan Biobank, which provide phenotypic information regarding lifestyle patterns, dietary habits, environmental exposure histories, health status, physical examinations, and biochemistry measurements of 53,613 subjects (stage 1) and whole-genome genotypic information of 14,432 unrelated subjects using TWBv1.0 chip (653,291 single nucleotide polymorphisms, SNPs, specifically for the Han Chinese in Taiwan) (stage 2). We built a conventional risk model, including age, sex, alcohol consumption, family history of hypertension, body mass index, fasting plasma glucose, triglyceride and microalbumin in stage 1, and the area under the receiver operating characteristic curve (ROC-ACU) was 0.855. Twenty-six SNPs, each of which reflected a genetically independent locus, were found to be associated with the risk of prevalence hypertension in stage 2. The genetic risk model based on genetic risk score incorporated 26 SNPs was significantly associated with prevalence of hypertension (Odds ratio=1.96, 95% confidence interval=1.80-2.13, P<0.001), and the AUC-ROC was 0.623. Though, the addition genetic risk model into conventional risk model slightly improves the ROC-AUC from 0.855 to 0.873, the magnitude of this increase was significant (P<0.001). A prediction model that includes both conventional risk factors and genetic variants could increase the predictive power and helps to classify individuals into risk subgroups for prevention programs.

628W

Family based whole exome sequencing in left-sided heart defects. *K.L. McBride[1256], D. Corsmeier[13], G.A. Zender[12], S.M. Fitzgerald-Butt[18], L. Kelly[14], B. Kelly[13], J. Fitch[13], C.C. Askwith[57], G.E. Herman[1456], H. El-Hodiri[1456], V. Garg[12568], P. White[1356].* 1) Nationwide Children's Hospital, Columbus, OH; 2) Center for Cardiovascular Research; 3) Center for Microbial Pathogenesis; 4) Center for Molecular and Human Genetics; 5) College of Medicine, Ohio State University; 6) Department of Pediatrics; 7) Department of Neuroscience; 8) The Heart Center.

Congenital heart disease (CHD) involving the left side of the heart (left-sided lesions–LSLs) constitute 10% of all CHD but a disproportionate amount of CHD morbidity and mortality. LSLs (aortic stenosis, aortic coarctation, hypoplastic left heart) demonstrate a strong genetic component, but few specific disease genes have been identified. Specifically, case-control whole exome sequencing (WES) studies of non-syndromic CHDs are able to identify likely causative variants in only a few percent. We hypothesized that a family-based approach may be more successful at finding disease genes than case-control designs. A total of 21 multiplex LSL families (2 – 5 affected individuals) were recruited. Linkage analysis and WES were performed to identify segregating possible pathogenic variants. WES data was filtered by segregating, rare variants (freq<0.001) with *in silico* prediction of pathogenicity. High priority candidate genes based on biological role were functionally tested. Three families harbored predicted pathogenic variants in genes previously implicated in CHD, including *MATR3, MCTP2,* and *NOTCH1*. Two additional families had variants with functional consequences in novel CHD genes. A variant in *NRP2* was studied by morpholino knock-down in Xenopus. The knockdown phenotype of ventricular hypoplasia and dextrocardia was rescued by wild-type human *NRP2*, but not the *NRP2* variant. A variant in *BMP10* demonstrated decreased protein expression and excretion in cell based assays. Several other candidates did not show functional effects. A variant in the potassium channel gene, *KCNJ2*, had normal electrophysiological properties in Xenopus oocyte studies, while a variant in a downstream target of *NOTCH1, HEY1,* had normal transactivation in cell based luciferase assays. Many families had multiple plausible candidates, thus burden studies were performed using Ingenuity Pathway Analysis by comparing these 21 families to 21 control families of similar structure. Rare variants in genes important in heart development were significantly over-represented. The use of multiplex families results in a higher yield for identifying likely pathogenic variants (5/21) than case-control designs, but bottlenecks exist in rapid functional screening of variants to identify true pathogenic changes. While non-coding variants may be causal in families without exonic changes, the genetics of CHD, even in those families with apparent Mendelian inheritance, is likely complex and oligogenic. .

629T

HUNTing for genetic causes of atrial fibrillation. *J.B. Nielsen[1,2], W. Zhou[2,3], L. Fritsche[3,4], E.M. Schmidt[3], M. Lin[1,2], M.B. Elvestad[4], C.M. Brummett[5], O.L. Holmen[4,6], C.R. Abecasis[1,3], K. Hveem[4,7], C.J. Willer[1,2,3].* 1) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, Michigan; 2) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan; 3) Department of Bioinformatics and Computational Medicine, University of Michigan, Ann Arbor, Michigan; 4) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 5) Department of Anesthesiology, University of Michigan, Ann Arbor, Michigan; 6) St. Olavs Hospital, Trondheim University Hospital, Trondheim, Norway; 7) Department of Medicine, Levanger Hospital, Nord-Trøndelag Health Trust, Levanger, Norway.

Atrial fibrillation (AF) is a common cardiac arrhythmia and a major risk factor of stroke, heart failure, and death. Despite an estimated heritability of ~60%, only a few loci have so far been identified as genetic risk factors of AF in the population. We undertook an array-based genome-wide association study (~600,000 markers with enrichment for coding variants) in individuals from the ethnically homogeneous HUNT study, a community-based health-survey in Norway. The cohort included 5,584 individuals with and 55,426 without AF. We identified one novel susceptibility locus for AF at chromosome 2 (leading SNP rs3731746, p.Thr17571Lys, MAF = 0.18, OR = 1.19, 95% CI 1.12 – 1.26, P-value = 1.9×10^{-9}) that was replicated in an independent hospital-based US cohort of 964 AF cases and 5,487 controls matched on age sex and inferred ancestry (OR = 1.15, P-value = 0.04). The novel locus comprised several highly correlated missense variants situated in the A and M-band of titin (TTN), the largest human protein and responsible for the passive elasticity of heart and skeletal muscle. Protein-truncating variants in TTN have been previously linked to dilated cardiomyopathy, and dilated cardiomyopathy is a risk factor for AF, so we performed a sensitivity analysis by conditioning on cardiomyopathy. This revealed results very similar to the unconditioned analysis, indicating a mechanism that does not act through overt cardiomyopathy. In addition to the novel locus, we confirmed three known loci for AF (PITX2, NEURL, and ZFHX3). Association tests, including burden tests, based on imputation of another ~15 million markers are currently ongoing. In conclusion, we have identified a novel locus for AF at TTN, a strong biological candidate for structural remodeling of the myocardium, that could help improve our understanding of this clinically important cardiac arrhythmia.

Identifying candidate microRNA biomarkers for hemodynamic stability in patients with mild ischemic stroke or transient ischemic attack. *A.P. Pilbrow[1], P. Allan[2,3], J. Faulkner[4], T. O'Donnell[2], J. Lanford[5], B. Woolley[6], D. Lambrick[7], L. Stoner[6], Y-C. Tzeng[2,3].* 1) Christchurch Heart Institute, University of Otago Christchurch, Christchurch, New Zealand; 2) Centre for Translational Physiology, University of Otago Wellington, Wellington, New Zealand; 3) Department of Surgery and Anaesthesia, University of Otago, Wellington, New Zealand; 4) Department of Sport and Exercise, University of Winchester, Winchester, United Kingdom; 5) Department of Neurology, Wellington Hospital, Wellington, New Zealand; 6) School of Sport and Exercise, Massey University, Wellington, New Zealand; 7) Faculty of Health Sciences, University of Southampton, Southampton, United Kingdom.

Background. Biomarker discovery for stroke has proved difficult due to the slow release of proteins across the blood-brain barrier. However, recent studies suggest that microRNAs (small RNAs that regulate gene expression) can move across the blood-brain barrier. Interestingly, both microRNAs and markers of hemodynamic stability (blood pressure variability, BPV; cerebral blood flow variability, CFV; cerebral autoregulation, CA) may have utility as prognostic markers in stroke. This study aimed to test associations between plasma microRNA levels and hemodynamic stability parameters in patients recently diagnosed with mild ischemic stroke or transient ischemic attack. **Methods**. We measured plasma levels of 372 microRNAs in 10 male patients (mean age ± standard deviation, 71.4 ± 8.9 years) with mild ischemic stroke (n = 5) or transient ischemic attack (n = 5) at 1 week (baseline) and 14 weeks after hospital admission, using real-time PCR (Exiqon). Fluctuations in blood pressure and cerebral artery blood flow were measured in the affected brain hemisphere by spectral power analysis. Cerebral autoregulation was determined by wavelet phase synchronization analysis. Associations between plasma microRNA levels and markers of hemodynamic stability at baseline were tested with Pearson correlation. Changes in microRNA levels over 14 weeks were analyzed with paired t-tests. **Results**. Of the microRNAs tested, 82 were detectable in the majority of patients. At baseline, levels of four microRNAs, let-7d-3p, miR-18b-5p, miR-26a-5p and miR-451a, were strongly correlated with CFV (r = 0.93, -0.89, -0.88 and -0.79 respectively, p < 0.05). Levels of miR-126-5p were negatively correlated with worse CA (r = -0.76, p = 0.03). Of these microRNAs, only let-7d-3p differed between baseline and 14 weeks, with median levels 8-fold higher at 14 weeks (p = 0.033). **Conclusions**. Our data suggest that let-7d-3p, miR-18b-5p, miR-26a-5p and miR-451a may be candidate biomarkers for CFV in patients with mild ischemic stroke or transient ischemic attack. Moreover miR-126-5p may be a marker for poor cerebrovascular control in these patients.

631W

Familial case of antithrombin-III deficiency caused by new mutation in the *SERPINC1* **gene.** *M.E. Polyak, E.V. Zaklyazminskaya.* Petrovsky Russian Research Centre of Surgery, Moscow, Abricosovsky lane, 2.

Introduction. Inherited deficiency of antithrombin-III is relatively rare (1:10000) autosomal-dominant disorder leading to a high risk of venous thromboembolism. Plasmatic levels of AT-III are usually less than 50% from normal values in the most of patients. Mutations in the *SERPINC1* gene may lead to Quantitative (type I) and Qualitative (type II) types of AT-III deficiency by different molecular mechanisms. Usually mutations leading to haploinsufficiency lead to AT-III type I. Many of known missense mutations cause AT-III type II, with normal levels of dysfunctional protein. **Materials and methods**. We observed a 29 y.o. female proband with a history of venous thrombosis at the age of 18. Father and grandmother have had thromboembolic events. The level of AT-III was measured with routine methods; mutation screening in *SERPINC1* gene was performed by bi-directional Sanger sequencing. Resources PolyPhen2, SIFT, NetGene2, and Splice Site Predictor were used for *in silico* characterization of mutant protein. **Results**. New VUCS p.W221S in *SERPINC1* gene was detected in proband and her father, and was absent in healthy sister. This variant is absent in "1000 Genomes" and other available databases. Both PolyPhen2 and SIFT resources characterize p.W221S as probably damaging. No changes in splicing were detected using open resources. The residual AT-III levels in our patients were significantly decreased up to 44-48% (AT-III type I). **Conclusion**. We assume that novel p.W221S variant is disease-causing mutation for AT-III type I mutation. Examples of missense mutations causing quantitative are previously described. The possible pathogenic mechanism could affect post-translational processing of AT-III protein (folding, intracellular transport, or excretion). .

Gene expression analysis of megakaryocytes (MKs) derived from induced pluripotent stem cells (iPSCs) shows platelet-related signature of CD41+CD42a+ percentage. *M.A. Taub[1], K. Kammers[1], I. Ruczinski[1], J. Martin[2], L.R. Yanek[2], A. Frazee[1], Y. Gao[3], D. Hoyle[3], N. Faraday[2], D.M. Becker[2], L. Cheng[3], Z.Z. Wang[3], J. Leek[1], L.C. Becker[2], R.A. Mathias[2].* 1) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 2) The GeneSTAR Research Program, Johns Hopkins School of Medicine, Baltimore, MD; 3) Division of Hematology and Institute for Cell Engineering, Johns Hopkins School of Medicine, Baltimore, MD.

Platelet aggregation in blood on ruptured or eroded atherosclerotic plaques may initiate harmful cardiovascular events. As the precursor of anucleate platelets, the megakaryocyte (MK) is an important cell type in understanding platelet aggregation genetics. However, MKs are hard to collect in large numbers due to invasive sampling procedures. Our group has generated induced pluripotent stem cells (iPSCs) from peripheral blood mononuclear cells and differentiated these iPSCs into MKs. As part of a larger study on heart disease genetics, we generated transcript expression data (RNA-seq) on these samples. As previously described by our group, a marker of relevance in the derivation of MKs from iPSCs is percent CD41+CD42a+ megakaryoblasts (CD41/42%) in the differentiated MK cell pellet. We see a wide range in the CD41/42% in the final pellets used in our -omics approaches. To understand the influence of this variability in cell-differentiation stageon gene expression, we performed differential expression (DE) analysis to relate transcript abundance to CD41/42% in 198 iPSC-derived MK cell lines from 108 European American and 90 African American samples in the GeneSTAR Study. RNA-seq was performed on extracted non-ribosomal RNA. We generated gene and transcript expression values with the Tuxedo pipeline, and conducted downstream analyses in R using the Ballgown package. We transformed and filtered the expression data, and adjusted for known and unknown batch-effects in our models. We calculated DE as a function of CD41/42% and did gene ontology (GO) analysis on the results, separately for transcripts with positive and negative associations between expression and CD41/42%. We identified N=13761 (q<0.05) transcripts showing DE by CD41/42%. Limiting our analysis to N=10701 transcripts with positive association between expression and CD41/42%, of which 7889 showed significant DE, significant GO results (q<0.05) include many categories directly related to platelet function, including platelet activation, blood coagulation, platelet degranulation, and platelet aggregation. These results indicate CD41/42% is an important marker of MK cell differentiation in our setting, and is an important co-variable in the downstream analysis of iPSC-derived MK transcriptomic signatures.

Sequencing identifies new variants and new genes for carotid intima-media thickness in Dominican Republicans. *L. Wang[1,2], N. Dueker[1], A. Beecham[1], S.H. Blanton[1,2], T. Rundek[1,3], R.L. Sacco[1,2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) John T. McDonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Neurology, Epidemiology and Public Health, University of Miami, Miami, Fl.

Carotid intima-media thickness (cIMT) is a subclinical marker for cardiovascular diseases (CVD). We have been using cIMT as a precursor phenotype to reduce heterogeneity in genetic studies of CVD. Previously, we reported a quantitative trait locus (QTL) on chromosome 14q for cIMT in Dominican families and identified *PRIMA1, FOXN3,* and *CCDC88C* as candidate genes via genotyping informative common variants (CVs). Herein, we sought to extend our efforts with next-generation sequencing. We sequenced all exons within the QTL, as well as introns and flanking regions of *PRIMA1, FOXN3* and *CCDC88C* in 116 individuals from 7 Dominican families with evidence for linkage at the QTL (LOD>0.1). 561 unrelated Dominicans from Northern Manhattan Study (NOMAS) with exome-chip genotyping and imputation to 1000-genome references were used for validation. For CVs (minor allele frequency [MAF]≥5%), single variant analysis using the Quantitative Transmission-Disequilibrium test (QTDT, for families) and linear regression (for NOMAS) were performed. For rare variants (RVs, MAF<5%), we performed gene-based tests using the Family SNP-set Kernel Association Test (Fam-SKAT, for families) and SKAT-O (for NOMAS). CVs in *PRIMA1* and the *SPATA7-PTPN1-*ZC3H14-*EML5-TTC8* gene cluster displayed the most robust evidence for association (P<0.005 in families and P<0.05 in NOMAS). Consistent with previous findings, the strongest association with CVs was found in *PRIMA1* (P=8x10[-5] in families, P=0.01 in NOMAS). Interestingly, the top marker is not in linkage disequilibrium (r^2<0.01) with the previous top marker (P=3x10[-4] in families, P=0.1 in NOMAS). Gene-based test suggested that RV is not a major mechanism for *PRIMA1* to contribute to cIMT (P=0.7 in both datasets). In contrast, gene-based test on exonic RVs found evidence for association in 4 genes within the 5-gene cluster (P<0.05). To further evaluate exonic RVs in the 5-gene cluster, we combined them in a gene-set-based analysis and used Combined Annotation-Dependent Depletion (CADD) to prioritize RVs. We found that the evidence for association is enriched in RVs with CADD>10 (N=15, P=0.003) compared to RVs with CADD<10 (N=31, P=0.02) in the family dataset. Our data demonstrate a complicated genetic architecture of cIMT that could not be appreciated in our previous studies: multiple independent CVs in *PRIMA1* and exonic RVs in new candidate genes. Future studies are needed to understand the contribution of these genes and variants to cIMT.

Many novel genetic loci associated with blood pressure are identified from a GWAS in UK Biobank. *H.R. Warren[1,2], E. Evangelou[3,4], C.P. Cabrera[1,2], H. Gao[3], I. Tzoulaki[3], M.R. Barnes[1,2], M.J. Caulfield[1,2], P. Elliott[3], UKB-CMC BP working group and ICBP, CHARGE+, T2D-GENES, GoT2DGenes, ExomeBP, and CHD Exome+ Consortia.* 1) Clinical Pharmacology, William Harvey Research Institute, Barts and The London School of Medicine, Queen Mary University of London, London, UK; 2) NIHR Cardiovascular Biomedical Research Unit, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 3) Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, London, UK; 4) Department of Hygiene and Epidemiology, University of Ioannina Medical School, Ioannina, Greece.

High blood pressure (BP) is a major risk factor for cardiovascular disease (CVD). Many BP-associated genetic loci have previously been identified, but together only explain a small percentage of the total trait variance. The UK Biobank (UKB) cohort provides a unique opportunity to perform the largest ever GWAS of BP within a single study. We have analysed systolic BP, diastolic BP & pulse pressure traits from 140,886 unrelated Europeans from UKB across ~73 million genotyped and imputed autosomal variants. Using UKB for discovery, with replication in independent study meta-analyses (N~200k), we have identified and validated ~110 novel genetic loci. Amongst the new variants, we have found rare or low-frequency variants with larger effect sizes on BP than common variants, and some exonic missense variants. Conditional analyses have been used to determine multiple independent signals within novel loci. Many of the novel BP-associated loci are also associated with hypertension (HTN). Lookups in non-European ancestries, despite lower power, suggest some novel loci are also associated in other populations, e.g. Hispanics. Integrative bioinformatics analyses have found eQTL associations and strong evidence of plausible biological function for many novel genes, as well as an enrichment of pathways implicated in CVD, and an over-representation of genes affected by anti-HTN drugs. Integration with NMR metabolomics data has detected significant downstream associations across different plasma spectral regions and for a range of lipoprotein fractions. UKB's deep imputation coverage and large sample size enables the assessment of all previously reported BP loci. As well as confirming prior findings, we have validated additional independent variants at many known BP regions, which remain significant after conditioning on known SNPs. Results for specific mutations within genes published for monogenic HTN disorders show that, despite lower power, some of these rare variants also have nominally significant associations with large effects on BP at a population level. Our large discovery yield illustrates the benefits of UKB data and our functional results show promise for identifying potential causal genes impacting HTN mechanisms, which will increase our understanding of the genetic risk and underlying biology for HTN.

Integration of genetics and transcriptomics to identify missing heritability for platelet aggregation. *L.R. Yanek[1], K. Kammers[2], M.A. Taub[2], J. Martin[1], N. Faraday[1], I. Ruczinski[2], Y. Gao[3], D. Hoyle[3], Z. Wang[3], L. Cheng[3], D.M. Becker[1], J. Leek[2], L.C. Becker[1], R.A. Mathias[1].* 1) GeneSTAR Research Program, School of Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) Division of Hematology and Institute for Cell Engineering, School of Medicine, Johns Hopkins University, Baltimore, MD.

Background: Missing heritability in GWAS studies is a common occurrence. Variants with lower effect sizes are routinely missed for failure to cross stringent significance thresholds required for the millions of SNPs tested. The argument for inclusion of functional relevance in the re-evaluation of these SNPs with marginal significance has gained favor in the era of Next Generation Sequencing enabling the rapid integration of genetic and transcriptomic data. Methods: GeneSTAR (Genetic Study of Atherosclerosis Risk) is an ongoing family-based study which includes platelet function assessment before and after 2 weeks of aspirin (ASA). We performed GWAS on platelet function separately in 1094 European American (EA) and 773 African American (AA) participants, adjusting for age, sex, population stratification, and family structure. In a subset (N=90 AAs and N=108 EAs) with induced pluripotent stem cell-derived megakaryoctyes (MKs), we performed RNA sequencing with the Illumina HiSeq 2500 platform. Samples were processed through TopHat for alignment, Cufflinks/Cuffmerge for assembly, and Tablemaker and Ballgown for analysis. Expression quantitative trait loci (eQTL) analyses were run separately in EAs and AAs, adjusting for age, sex, batch, CD41/42 (an index of MK differentiation), and population stratification and expression principal components. Results: In one exemplary phenotype, post-ASA aggregation to ADP 2uM, GWAS identified several loci that did not cross the traditional 5×10^{-8} threshold of significance but were suggestive with p-values between 10^{-5} and 10^{-7}. eQTL analysis in MKs identified 7,190 *cis* eQTLs in EAs and 525 *cis* eQTLs in AAs (q<0.05). By integrating the eQTL analysis with the GWAS results, we found that SNPs in a region of Chr 20 with suggestive evidence regulate the expression of *CPNE1* in MKs. rs761825 is the lead SNP in *CPNE1* with GWAS p-value in EAs $p=6.73 \times 10^{-6}$, in AAs p=0.702; eQTL $p=1.28 \times 10^{-5}$ in EAs, p=0.23 in AAs. Discussion: Leveraging the eQTL analysis with our GWAS data, we now identify a novel locus that may regulate platelet aggregation. Interestingly, *CPNE1* encodes a calcium-dependent membrane-binding protein, and has been reported to interact with mitogen activated protein kinases that are known to be important to platelet activation. We are repeating this analysis with additional platelet aggregation phenotypes and will present results from several integrated analyses.

Mutation spectrum and clinical polymorphism in Russian patients with left ventricular non-compaction. *E.V. Zaklyazminskaya[1,3], M.E. Polyak[1], E.A. Mershina[2], V.E. Sinitsin[2], A.A. Bukaeva[1], O.V. Blagova[3], L.B. Mitrofanova[4], N.P. Kotlukova[5], Ju. Lutokhina[3], A.G. Shestak[1], S.L. Dzemeshkevich[1,3].* 1) Petrovsky Russian Research Centre of Surgery, Moscow, Russian Federation; 2) Research Centre of Nuclear Imaging and Computerized Tomography; 3) Sechenov First Moscow State Medical University; 4) Federal Almazov North-West Medical Research Centre; 5) 7th Moscow City Children Hospital.

   Introduction. Left ventricular non-compaction (LVNC, MIM#300183**)** is a cardiomyopathy characterized by prominent trabeculation in the left ventricular apex, lateral wall and ventricular septum. It is not completely clear if LVNC represents a distinct clinical entity, cardiac embryogenesis disruption or a variant of clinical appearance of other types of cardiomyopathies (dilated and/or hypertrophic). Mutation spectrum, genotype-phenotype correlations, clinical polymorphism and natural course of LVNC are still to be elucidated. **Materials and methods**. Clinical and genetic evaluation of patients was performed in accordance with Helsinki Declaration. Fifty four patients with LVNC were included into the target group. Clinical and instrumental evaluation had included physical examination, familial history taking, resting ECG and 24-hours Holter monitoring ECG, Echo-cardiography, cardiac MRI or computer tomography, and myocardial biopsy (by indication); anti-myocardial antibodies measurement. The genetic study was performed by massive parallel sequencing (IonTorrent PGM) of 28 genes with following Sanger sequencing for all under covered regions. **Results**. Clinical group of LVNC patients included 28 males and 26 females. Five patients were diagnosed before 1y.o.. In the adult group (49 patients) the mean age was 41 y.o.. The follow-up period was from 6 months up to 60 months. Most of LVNC patients had decreased cardiac contractility and heart failure of different degree; 5 probands had undergone orthotopic heart transplantation. The vast majority of patients have had apparent signs of other cardiomyopathies beside LVNC: left ventricular hypertrophy, dilated cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy; 1 patient had neuromuscular disorder. The common feature was inflammation (myocarditis). Rhythm disturbances were found in >50% of patients. The autosomal-dominant mode of inheritance was the most frequent in familial cases, though sporadic cases were also present. We had identified pathogenic/potentially pathogenic genetic variants in 18% of probands tested. Two mutations were detected in two probands who underwent the heart transplantation. Most of mutations were detected in *MYH7* and *MyBPC3* genes. **Conclusion**. Most of LVNC patients have concomitant cardiomyopathy, arrhythmias and/or myocarditis. Isolated LVNC scarcely exists. Mutations in *MYH7* and *MyBPC3* genes are the most frequent finding in Russian patients with LVNC. .

   Introduction: The Brugada syndrome (BrS) is an inherited cardiac disorder associated with ST-segment elevation in the right precordial leads and a high risk for sudden cardiac death (SCD). Although rare variants in *SCN5A* (encoding the major cardiac Na-channel isoform) are found in ~20% of cases, the genetic basis of the disorder remains largely unresolved. In a previous genome-wide association study (GWAS) on 312 patients with BrS, we had identified 3 common haplotypes predisposing to the disorder: two at the *SCN5A-SCN10A* locus and one near the *HEY2* gene. Here we aimed to identify additional common SNPs modulating the susceptibility to BrS and/or SCD. Results: By extending the GWAS to a set of 877 index cases of North-Western European ancestry versus 2,833 ancestry-matched controls, we confirmed the 3 previously reported association signals at the *SCN10A*, *HEY2* and *SCN5A* loci. Conditional analysis on SNPs at the *SCN5A-SCN10A* locus revealed 2 additional independent association signals located between the *SCN5A* and *SCN10A* genes. The cumulative effect of the 5 loci on disease susceptibility reached an odds ratio >50 in the presence of ≥ 8 risk alleles versus ≤ 2. Conclusions: Our novel findings further reinforce the predominant involvement of the *SCN5A-SCN10A* locus in the disease and prompt a reevaluation of the genetic architecture of the BrS for refinement of patient care. We are currently investigating whether additional SNPs are associated with the BrS phenotype or with arrhythmia symptoms by typing additional patients. Long QT syndrome is characterized by prolongation of the QT interval on electrocardiogram and associated with a high risk of sudden death. To date, mutations in 15 LQTS-susceptibility genes have been implicated. However, the genetic cause for approximately 20-25 % of LQTS patients remains elusive. We sought to add new channelopathy genes data to the existing knowledge of genetic mutations underlying LQTS to both expand our understanding of its genetic basis and assess the value of genetic testing in clinical decision-making. We screened for 68 cardiac arrhythmia genes among 92 unrelated LQT cases (9,66±5,602, 53 male and 8,69±5,676, 39 female) from Turkey. Cardiac symptoms were present in 52% of LQTS patients. Mean age of onset was 7,368±4,982. Mean QTc interval was 480,14±57,335. Targeted sequencing on ion PGM using Custom Panel revealed that known 15 LQT gene variants (79) acounted for 40,5% of the cases, while the remaining gene variants (116) accounted for 59,5% of the cases. 168 missense, 11 splice site, 4 frameshift, 6 inframe deletions, 2 nonsense and 4 UTR variants have been identified in the study. 39 (20%) of these variants were novel, 26 (%13,35) of these variants were reported as pathogenic/probably pathogenic, 40 (%20,5) of these had conflicting interpretations of pathogenicity, 64 (%32,8) of these were classified as unknown significance/nonidentified/untested and the remaining 26 (%13,35) were reported as benign/likely benign in public databases. Family segregations investigated 7 de-*novo* missense variants in *KCNQ1, CACNA1C, RYR1, CALM2* and *SCN5A* genes. While 7 patients were carrying only one pathogenic variant (3 *KCNQ1*, 1 *SCN5A*, 1 *KCNH2*, 1 *GDP1L* and 1 *CALM2*), the other pathogenic mutations (in *KCNQ1, SCN5A, KCNE1, CACNA1C, RYR2, JUP, LMNA, GPD1L, CASQ2* genes) were together with at least one other channelopathy variants. Any suspicious variant has not be detected in the remaining 10 (10,9%) patients. Age of onset was higher in those noncarriers (10,3±4,11 years) when compared to ≥ 1 variant carriers (6,90±5,00 years) (t test, p>0,05). It must be emphasized that the genetic complexity of cLQTS, currently makes it necessary to screen the other cardiac genes besides 15 LQT genes before the molecular-genetic workup is finished. We believe our findings will be an anchor point for finding novel pathogenesis of this disorder. Acknowledgements: Inherited arrhythmia panel project is supported by grant from SANTEZ (0253. STZ.2013-2), Turkey.

Genetic determinants of thrombin generation and clot lysis time: Results of a targeted exome sequencing study. *H.G. de Haan[1], C. Kabrhel[2], T.P. Baglin[3], F.R. Rosendaal[1,4,5], A. van Hylckama Vlieg[1].* 1) Clinical Epidemiology, Leiden University Medical Center, Leiden, Netherlands; 2) Emergency Medicine, Massachusetts General Hospital, Channing Network Medicine, Harvard Medical School, Boston, USA; 3) Cambridge Haemophilia and Thrombophilia Centre, Addenbrooke's Hospital, Cambridge University Hospitals National Health Service Foundation Trust, Cambridge, United Kingdom; 4) Einthoven Laboratory of Experimental Vascular Medicine, Leiden University Medical Center, Leiden, The Netherlands; 5) Thrombosis and Hemostasis, Leiden University Medical Center, Leiden, The Netherlands.

Background: The thrombin generation (TG) potential and clot lysis time (CLT), which represent the ability to form and dissolve a clot, respectively, are well-established risk factors for venous thrombosis. Despite the heritability of these traits, few genetic determinants have been identified. Exploring the role of protein coding variants could provide insight into the genetic architecture and biology underlying these traits. **Aims**: We aimed to identify novel genetic determinants of TG and CLT using targeted exome sequencing. **Methods**: We included 296 controls (without venous thrombosis) from two population-based, case-control studies on venous thrombosis (MEGA and THE-VTE). Individuals were selected using the following criteria: European ancestry, no surgery or malignancy, no natural anticoagulant deficiency, and no factor V Leiden or prothrombin 20210A carriership. Targeted sequencing was performed of the coding regionsand boundaries of 740 genes involved in thrombosis and hemostasis or closely related pathways. We investigated the association of 3,002 low-frequency, common (minor allele frequency (MAF) >1%) variants with CLT and four parameters of TG: endogenous thrombin potential, peak height, time-to-peak, and lag time. Linear regression models were adjusted for age, sex, country of the study, and additionally for oral contraceptive use in the TG analyses. To account for multiple testing, we calculated false discovery rates (FDR). **Results:** We identified a common synonymous variant in *COL4A1* which was associated with time-to-peak (c.1815T>C, MAF=6.7%, β=0.65 per z-score increase, P=$1.92*10^{-5}$, FDR=6.2%). *COL4A1* encodes a major component of the type IV collagen of the basement membrane, and it is a highly replicated locus for cerebro- and cardiovascular disease risk. CLT and three of the TG parameters showed no association with any of the genetic variants observed, with the lowest FDR (22%) observed for an association between CLT and a missense variant in *TLR5*. **Conclusions:** We identified a variant in *COL4A1* as a novel determinant of time-to-thrombin peak. Replication and functional studies are warranted to further unravel the implication of *COL4A1* in TG and, potentially, venous thrombosis risk. We did not identify any variants associated with either CLT or three of the four TG parameters, which is likely attributable to our small sample size.

Exome sequencing in venous thromboembolic disease identifies mutation burden in *PROS1*, *STAB2* and *SERPINC1*. *K. Desch[1], M. Halvorsen[2], A.B. Ozel[3], M. Germain[4], D. Tregouet[4], P.H. Reitsma[5], J. Li[3], D. Goldstein[2], D. Ginsburg[3].* 1) Pediatrics and Communicable Disease, University of Michigan, Ann Arbor, MI; 2) Institute for Genomic Medicine, Columbia University, New York, NY; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) INSERM, UMR_S 937; Institute of Cardiometabolism And Nutrition (ICAN), Université Pierre et Marie Curie Paris 6, Paris F-75013, France; 5) Leiden University Medical Center, Leiden, Netherlands.

　　Deep vein thrombosis and pulmonary embolism, collectively referred to as venous thromboembolism (VTE [MIM 188050]), are the third leading cause of cardiovascular death in the United States. Genetic factors account for 50-60% of VTE risk and a recent meta-analysis of genome-wide association studies confirmed that common variants in *F5* (MIM 612309), *ABO* (MIM 616093), and seven other loci are associated with VTE. Rare mutations in the anticoagulant genes *PROC* (MIM 176860), *PROS1* (MIM 612336) and *SERPINC1* (MIM 107300) have been linked to VTE in family studies. In order to identify new genetic variants altering the risk for VTE, we performed exome sequencing in 373 unrelated individuals of European ancestry with unprovoked VTE and compared results to a previously sequenced control cohort of 5784 unrelated Europeans. To avoid variant calling bias, only SNVs from exons with less than 5% difference in the average percentage of bases covered at least 10x between cases and controls were included, removing 11,813 of 188,689 intervals. To find variants associated with risk of VTE, we used an emerging framework for a "collapsing" analysis on genes. We defined qualifying variants on the basis of annotation and minor allele frequency, and in the dominant model, cases and controls were scored on the basis of having one or more qualifying variant in each gene. Tests under the dominant model were performed via a Fisher's exact test for a total of 17,395 CCDS genes. Strikingly, ranked by p-value, the top three genes were *PROS1* (P= 3.34E-08), *STAB2* (P=1.65E-05), and *SERPINC1* (P=3.21E-05). We detected 15 qualifying variants in 373 cases and 56 qualifying variants in 5784 controls in *STAB2*. This gene encodes Stabilin-2, which is a transmembrane glycoprotein scavenger receptor. Common variants at *ABO* are associated with VTE and are also known to regulate von Willebrand Factor (VWF) and coagulation Factor VIII (F8) plasma levels. Common variants in *STAB2* are also associated with VWF/F8 levels in a large GWAS and with VTE risk in a smaller candidate gene study, suggesting that haploinsufficiency for Stabilin-2 may increase VTE risk through elevated levels of VWF/F8. Although replication and functional testing of these findings is warranted, this study demonstrates the utility of collapsing analyses using WES data to identify multiple loci harboring an excess of rare variants in individuals with a common complex disease trait.

641T

Common and rare variants in previously identified linkage region on chromosome 12p associated with left ventricular mass in Dominican families. *N.D. Dueker[1], S. Guo[1], A. Beecham[1], L. Wang[2], S.H. Blanton[2], C. Dong[3], D. Cabral[3], T. Rundek[3], R.L. Sacco[2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami - Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Neurology, Epidemiology and Public Health, Miller School of Medicine, University of Miami, Miami, FL.

　　Increased left ventricular mass (LVM), an intermediate phenotype for cardiovascular disease (CVD), is predictive of CVD and stroke. Using families from the Dominican Republic, we have previously shown LVM to be heritable and found evidence for linkage to 12p. For our current study, we aimed to further characterize the QTL by sequencing the 1 LOD unit down region on 12p in ten extended families from the Dominican Republic with evidence for linkage to LVM (family specific LOD score > 0.1). Using these data, we tested 5,477 CVs (minor allele frequency [MAF] ≥5%) using the QTDT test. Gene-based analyses were performed to test rare variants (RVs; MAF<5%) in 181 genes using the family-based sequence kernel association test. A sample of 618 unrelated Dominicans from the Northern Manhattan Study (NOMAS) with Illumina Exome Array data was used for replication analyses. In our analysis of CVs, no significant associations were observed. However, among the top CVs, rs12299972 (p=7.0x10^-4), an intronic variant in *SLC38A1*, was associated with increased LVM and showed evidence for replication in NOMAS (p=0.02). Exonic RVs in *SLC38A1* also showed moderate association in the families (p=0.07) and NOMAS (p=0.06) suggesting that both common and rare variants in *SLC38A1* may be involved in LVM. Exonic RV analyses identified an additional candidate gene, *PKP2*, which was our most strongly associated gene (p=0.005) with suggestive evidence for replication in NOMAS (p=0.10). This association remained in the families and was even stronger in NOMAS sample, when analyses were restricted to non-synonymous variants (p<0.05 in both samples). *PKP2* encodes plakophilin 2, a protein found in desmosomes, which are protein structures in cell membranes that maintain adhesion between neighboring cells. Desmosomes are found in tissues that experience mechanical stress such as the myocardium. Desmosomal genes, including *PKP2*, have been implicated in arrythmogenic right ventricular cardiomyopathy and recently, arrhythmogenic left ventricular cardiomyopathy as well, making *PKP2* an excellent candidate gene for LVM. In conclusion, re-sequencing of our previously identified QTL identified common and rare variants within two candidate genes, *SLC38A1* and *PKP2*, to be associated with LVM. Future studies are necessary to elucidate the role these variants play in the pathogenesis of increased LVM.

642F

Genome-wide association study and linkage study for histidine-rich gly-coprotein levels in a healthy young cohort. *A. Ozel[1], K. Desch[2], D. Sieme-niak[3], D. Ginsburg[1,3], J.Z. Li[1].* 1) Department of Human Genetics, University of Michigan- Ann Arbor; 2) Department of Pediatrics, University of Michigan- Ann Arbor; 3) HHMI, Department of Human Genetics, University of Michigan- Ann Arbor.

Through its inhibition of Factor XIIa, histidine-rich glycoprotein (HRG) regulates the intrinsic pathway of blood coagulation. HRG has a domain structure that facilitates interactions with multiple ligands, potentially contributing to pleotropic roles in coagulation, immunity and angiogenesis. We performed genome-wide association studies in a healthy sibling cohort of 1,152 subjects (in 489 sibships), focusing on the European subset (n = 940), and a second healthy cohort of 2,304 individuals (in 72 sibships) of Irish descent (Desch et al., 2012). HRG plasma levels were determined by AlphaLISA using a polyclonal HRG antibody. Heritability (h^2) was estimated as 69% (using *Merlin-Regress*), consistent with results from intra-class correlation (66%) and *GCTA* (60%). Common variants at *HRG* on chromosome 3 showed significant association with HRG plasma levels (P < 5.0E-8). The top candidate SNP was rs9898(T) (+14% /minor allele, MAF = 0.33, P = 6.6E-115), a non-synonymous variant located at the exon 5 of the *HRG* gene. Meta-analysis of the two cohorts confirmed the signals on chromosome 3, with best p-value of 6.2E-348 with the same effect direction. These SNPs collectively explained 47% of the variation in the HRG levels. Rs9898(T) was also detected in a previously published genome-wide study of activated partial thromboplastin time (aPTT) suggesting that altered HRG levels are a major influence in the variance of the aPTT coagulation test. Linkage analysis using the sibling subset of the two cohorts identified significant signals at three intervals: a ~ 0.6 cM interval on 3q28 (LOD=11.1, permutation P < 0.05), which is near the *HRG* gene; a ~ 0.7 cM interval on 2q37.1-2q37.2 (LOD=4.2, permutation P < 0.05); and a ~ 2.7 cM interval on 18q21.1 (LOD=2.6, permutation P < 0.05). The three peaks in the linkage analysis explained 2.5 % of the variation in the HRG levels. To our knowledge, this is the first genome-wide study investigating histidine-rich glycoprotein level variation in a healthy population. These results provide new insight into the genetic control of circulating HRG levels, and may aid the clinical interpretation of aPTT levels. Furthermore, linkage analysis revealed loci undetected in association studies suggesting allelic heterogeneity at specific genes in these three linkage intervals.

643W

Copy number variants implicate cardiac function and development pathways in earthquake-induced stress cardiomyopathy. *M.A. Kennedy[1], C.J. Lacey[2], K. Doudney[3], P.G. Bridgman[4], P.M. George[3], R.T. Mulder[2], J.J. Zarifeh[5], B. Kimber[2], M. Cadzow[6], M.A. Black[6], T.R. Merriman[6], K. Lehnert[7], V. Bickley[3], J.F. Pearson[8], V. Cameron[9].* 1) Dept Pathology, University of Otago, Christchurch, Christchurch, New Zealand; 2) Department of Psychological Medicine, University of Otago, Christchurch, New Zealand; 3) Molecular Pathology Laboratory, Canterbury Health Laboratories, Canterbury District Health Board, Christchurch, New Zealand; 4) Department of Cardiology, Christchurch Hospital, Christchurch, New Zealand; 5) Psychiatric Consultation Service, Christchurch Hospital, Canterbury District Health Board, Christchurch, New Zealand; 6) Department of Biochemistry, University of Otago, Dunedin, New Zealand; 7) School of Biological Sciences, University of Auckland, Auckland, New Zealand; 8) Biostatistics and Computational Biology Unit University of Otago, Christchurch; 9) Department of Medicine, University of Otago, Dunedin, New Zealand.

The pathophysiology of stress cardiomyopathy (SCM), also known as Takotsubo cardiomyopathy, is poorly understood. SCM can occur sporadically, often in association with a stressful event, but case clusters are also well known to occur after major natural disasters. There is some evidence for familiality in this condition, and we have examined three possible models for an underlying genetic predisposition to SCM. Our primary study cohort consists of 28 women who suffered SCM as a result of two devastating earthquakes that struck the city of Christchurch, New Zealand, in 2010 and 2011. To seek possible underlying genetic factors we carried out exome analysis, Cardio-MetaboChip analysis and array comparative genomic hybridization on these subjects. The most striking finding from these analyses was the observation of an extraordinarily high rate of rare, heterogeneous copy number variants (CNV) of uncertain clinical significance (in 13/28 subjects). Several of these CNVs clearly impacted on genes of cardiac relevance including *RBFOX1*, *GPC5*, *KCNRG*, *CHODL*, and *GPBP1L1*. There is no physical overlap between the CNVs, and the genes they impact do not fall into a clear pathophysiological pathway. However, the recognition that SCM cases display a high rate of unusual CNV, and that SCM predisposition may therefore be associated with these CNVs, offers a novel perspective and a new approach by which to understand this problematic and enigmatic condition.

A novel family with an unreported p.Glu768Lys *TNNI3K* mutation and atrial or junctional tachycardia. *J. Delanne[1], G. Laurent[2], J. Thevenon[1,4], C. Bonnet[3], S. Falcon-Eicher[3], C. Thauvin-Robinet[1,4], Y. Duffourd[4], T. Jouan[4], A. Baurand[1], C. Jacquot[1], N. Jean[1], L. Faivre[1].* 1) Centre hospitalier universitaire de Dijon, centre de génétique, 14 rue Paul Gaffarel BP 77908 21079 DIJON Cedex, Dijon, France; 2) Centre hospitalier universitaire de Dijon, service de cardiologie, 14 rue Paul Gaffarel BP 77908 21079 DIJON Cedex, Dijon, France; 3) Centre hospitalier universitaire de Dijon, service de cardiologie pédiatrique, 14 rue Paul Gaffarel BP 77908 21079 DIJON Cedex, Dijon, France; 4) Centre hospitalier universitaire de Dijon, laboratoire de génétique chromosomique et moléculaire, 14 rue Paul Gaffarel BP 77908 21079 DIJON Cedex, Dijon, France.

    Mutations within the Troponin I-interacting kinase (TNNI3K) gene have been reported in two families only. The mutations are associated with familial dilated cardiomyopathy and abnormal cardiac conduction disease comprising variable atrial arrhythmias. Using Whole Exome Sequencing (WES) in the two most distant relatives of a 5-patient, 3-generation family with an unrecognized abnormal cardiac rhythm phenotype, we identified a novel heterozygous TNNI3K mutation. The five patients presented with palpitations that revealed supraventricular tachycardia (SVT) qualified as congenital Junctional Ectopic Tachycardia (JET) for two of them, and undetermined SVT with or without multifocal zones in the other three. To date, none of the patients has developed dilated cardiomyopathy, but one patient has a moderately dilated aorta and another one has mitral incompetence. The mutation (chr1: g.74957901G>A; c.2302G>A; p.Glu768Lys) cosegregated with the affected family members, and was reported as probably pathogenic according to the prediction scores (SIFT: 0.002; Polyphen2: 0.983). Reverse phenotyping supported the implication of this gene in this familial phenotype. This is another example of the power of next generation sequencing and reverse phenotying in identifying the cause of unrecognized phenotypes. The description of further cases will be helpful for a better delineation of the phenotype associated with TNNI3K mutations.

645F

Whole exome sequencing in the Framingham Heart Study identifies rare variation in *HYAL2* that influences platelet aggregation. *J.D. Eicher[1,2], M.H. Chen[1,2], A. Pitsillides[2], H. Lin[3], N. Veeraraghavan[4], J.A. Brody[5], G.A. Metcalf[6], D.M. Muzny[6], R.A. Gibbs[6], E. Boerwinkle[6,7], L.A. Cupples[2,8], A.D. Johnson[1,2].* 1) Population Sciences Branch, Framingham Heart Study, NHLBI, NIH, Framingham, MA; 2) The Framingham Heart Study, Framingham, MA; 3) Section of Computational Biomedicine, Department of Medicine, Boston University School of Medicine, Boston, MA; 4) Rady Children's Institute for Genomic Medicine, San Diego, CA; 5) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, WA; 6) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 7) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 8) Department of Biostatistics, Boston University School of Public Health, Boston, MA.

    Inhibition of platelet reactivity is a common therapeutic strategy in the secondary prevention of cardiovascular disease. Genetic and environmental factors influence inter-individual variation in platelet reactivity. Identifying genes that contribute to platelet reactivity can reveal new biological mechanisms and possible therapeutic targets. Unfortunately, platelet reactivity data are not widely available in large cohorts. The Framingham Heart Study represents one of the largest population-based cohort studies with collected platelet reactivity assays against a wide range of agonists and doses. In this investigation, we performed whole exome sequencing to identify rare coding variation associated with platelet reactivity in the European ancestry Framingham Heart Study. We conducted both single variant and gene-based association tests against measures of platelet reactivity to collagen, ADP, and epinephrine agonists in up to 1,211 individuals. Single variant tests revealed no significant associations ($p<1.44\times10^{-7}$), though we observed a suggestive association with variants in *MRVI1*, which was previously associated with platelet reactivity (rs11042902, $p=1.95\times10^{-7}$). Using gene-based association tests of rare and low-frequency variants, we found significant associations of *HYAL2* with increased ADP-induced aggregation ($p=1.07\times10^{-7}$) and *GSTZ1* with increased epinephrine-induced aggregation ($p=1.62\times10^{-6}$). *HYAL2* also showed suggestive associations with increased epinephrine-induced aggregation ($p=2.64\times10^{-5}$). The rare variants in the *HYAL2* gene-based association included a missense variant (N357S) at a known N-glycosylation site and a nonsense variant (Q406*) that removes a glycophosphatidylinositol (GPI) anchor from the resulting protein. These variants suggest that improper membrane trafficking of HYAL2 influences platelet reactivity. We also observed suggestive associations of *AR* ($p=7.39\times10^{-6}$) and *MAPRE1* ($p=7.26\times10^{-5}$) with ADP-induced reactivity. Expression of these associated genes was confirmed in an independent platelet RNA-seq sample. Our study demonstrates that gene-based tests and other grouping strategies of rare variants are powerful approaches to detect associations in population-based analyses of complex traits not detected by single variant tests, and several new genetic factors that influence platelet reactivity.

646W

Increase burden of rare variants in known genes to cause familial thoracic aortic aneurysms and dissections in patients with early age onset of aortic dissections. *D. Guo[1], E. Regalado[1], S. LeMaire[2], S. Prakash[1], S. Wallace[1], E. Hostetler[1], R. Zhao[1], J. Smith[3], M. Bamshad[3], D. Nickerson[3], X. Liu[4], D. Milewicz[1].* 1) Department of Internal Med, Univ Texas/Houston Med Sch, Houston, TX; 2) Cardiovascular Surgery, Texas Heart Institute at St. Luke's Episcopal Hospital, Houston, TX 77030, USA; 3) Department of Genome Sciences, University of Washington, Seattle, WA 98195, USA; 4) Department of Epidemiology & Disease Control, Univ Texas/Houston School of Public Health, Houston, TX.

Thoracic aortic dissections (TAD) are associated with a high degree of morbidity and medical expenditure in survivors. Clinical management can be initiated to prevent deaths due to aortic dissection if genetic and clinical predictors can be used to justify the risk of surgical repair of an aneurysm. Up to 20% of thoracic aortic aneurysm and dissection patients have a family history of disease (FTAAD) and fourteen FTAAD genes have been identified for this disorder. To identify genetic factors that predispose to patients with early age onset of sporadic TAD (ESTAD), we performed exome assay on DNA samples from 374 patients with ESTAD. Exclusion criteria are: age onset of dissection more than 55 years old and individuals with a known genetic syndrome (such as Marfan syndrome) or FTAAD. Exome results showed that burden of mutations (n = 32) and rare missense variants with unknown significant function (VUS) (n = 75) in known FTAAD genes was significantly increased in ESTAD patients compared to those of the ESP European American (ESP-EA) cohort (http://evs.gs.washington.edu/EVS/) with p < 0.0001, respectively. In additional, genomic copy number variants of known FTAAD genes were identified in four of the ESTAD patients. In clinical practice, it is important to evaluate the functional input of rare missense VUS in known FTAAD genes to the pathogenesis of TAAD, which are routinely identified by genetic diagnosis lab. To investigate these variants, we performed bioinformatics analyses to evaluate the input of these variants to protein function. The rare missense VUS that were identified in proteins (n = 6), such as ACTA2 and LOX, which barely have missense variants in the general population or that were located at the critical domains (n = 6), such as kinase domain of TGFBR1 or TGFBR2 kinase or calmodulin-binding domain of MYLK, which were the locations of majority known mutations for FTAAD, have higher damaging or conservation scores than rare missense variants (n = 351) identified in ESP-EA cohort and have similar scores compared to missense mutations in known FTAAD genes reported (n = 1155). In summary, increased burden of mutations or rare missense VUS in known FTAAD was increased in ESTAD cohort than that of ESP-EA cohort. Combination of bioinformatic analyses of rare missense VUS and their domain locations is potentially to be used to predict functional input of these variants to the pathogenesis of TAAD.

647T

Whole exome sequencing in 161 sudden infant death syndrome (SIDS) cases with a focus on cardiovascular and metabolic genetic diseases. *J. Neubauer[1], M.R. Lecca[2], G. Russo[2], C. Bartsch[3], A. Medeiros-Domingo[4], W. Berger[5,6,7], C. Haas[1].* 1) Institute of Forensic Medicine, University of Zurich, Zürich, Switzerland; 2) Functional Genomics Center Zurich (FGCZ), University of Zurich / ETH Zurich, Zurich, Switzerland; 3) University of Zurich, Zurich, Switzerland; 4) Department of Cardiology, Inselspital, University Hospital Bern, Switzerland; 5) Institute of Medical Molecular Genetics, University of Zurich, Schlieren, Switzerland; 6) Center for Integrative Human Physiology (ZIHP), University of Zurich, Zurich, Switzerland; 7) Neuroscience Center (ZNZ), University and ETH Zurich, Zurich, Switzerland.

Sudden infant death syndrome (SIDS) is described as the sudden and unexplained death of an apparently healthy infant younger than one year of age. The cause of death remains unexplained after a complete autopsy, review of the circumstances of death and the clinical history. Although the incidence rate of SIDS drastically decreased in the last years, SIDS is still one of the leading causes of postneonatal infant death in developed countries. The occurrence of SIDS is described by a triple risk model involving (1) a critical developmental period, (2) exogenous stress factors, and (3) a vulnerable infant. Genetic studies in SIDS cohorts indicate that 10-15% of SIDS cases might be explained by genetic cardiac diseases, not detectable during conventional forensic autopsy examination. Post-mortem genetic testing by using next generation sequencing (NGS) approaches represents an efficient and rapid technology to further investigate unexplained death cases and might help to elucidate pathogenic mechanisms in cases without a conclusive cause of death. Here, we report the results of a whole exome-sequencing (WES) study in 161 European SIDS infants with a primary focus on 193 genes associated with cardiovascular or metabolic diseases. SureSelect (Human All Exon V5 + UTRs, Agilent) exome capture was followed by sequencing on the Illumina HiSeq2500 platform. The average on-target coverage was 90.2% at ≥ 20x. Pathogenicity of variants was assigned according to a scoring scheme based on the type of variant, *in silico* protein predictions, and minor allele frequencies in European control populations. Potentially causative variants were detected in 26% of the SIDS cases. The majority of infants had variants with likely functional effects in genes associated with channelopathies (11%), followed by cardiomyopathies (9%), and metabolic diseases (1%). Although lethal arrhythmia represents the most plausible and likely cause of death, the majority of SIDS cases still remains elusive and might be explained by a multifactorial event triggered by a combination of different genetic and environmental risk factors. To our knowledge, this is the first WES study in a large SIDS cohort. Since WES is not substantially more expensive than a targeted NGS approach, it represents an unbiased screening of the exome, which would help to investigate different pathogenic mechanisms within the genetically heterogeneous SIDS cohort and to identify new candidate genes in sudden infant death.

648F

Familiality of statin intolerance and characteristics of members of high risk statin intolerance pedigrees. *S. Knight[1,2], H.T. May[1], J. Carlquist[1,2], J.B. Muhlestein[1,2], K.U. Knowlton[1], B.D. Horne[1,2].* 1) Intermountain Medical Center, Murray, UT; 2) University of Utah, Salt Lake City, UT.

Background: With the introduction of new PCSK-9 inhibitor drugs, a new option is available for patients with statin intolerance (SI) to lower their low-density lipoprotein cholesterol (LDL-C). However, PCSK-9 drug costs require careful targeting of those who will benefit the most. Objectives: To determine the familiality of SI, identify pedigrees with a high rate of SI, and determine differences in clinical and demographic characteristics for SI patients with and without a familial component. Methods: Intermountain Healthcare patients with SI (determined using medication allergy/intolerance electronic report), and pedigree records in the Intermountain Genealogy Registry (IGR) were studied (n=2556). Familiality of SI was tested using the genealogy index of familiality (GIF). GIF is the average pairwise kinship coefficient (multiplied by 100,000). Significance of GIF was assessed using empirical distributions from 1000 age and sex matched IGR control pts without SI. To be high risk for SI, pedigrees had to have an SI rate >5 times all IGR pedigrees. Sex, age, race, LDL-C, and comorbidities were compared between high- and low-SI pedigrees. Results: The GIF for SI was 0.71 (controls GIF: 0.60; GIF ratio=1.17, p=0.065). A total of 23 high-risk pedigrees were identified; the average rate of SI was 2.4% (IQR: 2.2% to 3.3%) with all having 4-6 SI cases. Median familial relative risk of SI was 6.2 (IQR: 5.8, 7.8). Patient characteristics are not significant different after correction for multiple comparisons (Table). Conclusions: A trend for evidence of a familial component to SI was found and several high risk pedigrees were identified. Clinical and demographic characteristics were not different. While these factors would not be effective to use to identify SI pts with a familial etiology, further identification of SI indicators is needed.

	SI pts in high risk pedigree (n=96)		SI pts not in high risk pedigrees (n=2460)		p-value
Male	56	58.30%	1207	49.10%	0.08

649W

Genome-wide gene-environment interaction analysis identifies genetic signals associated with cardiometabolic phenotypes and physical activity in Hispanic Americans: The Insulin Resistance Atherosclerosis Family Study (IRASFS). *C. Gao[1,2,3], J. Keaton[1,2,4], F. Hsu[5], H. Okut[2], J. Rotter[6], Y. Chen[6], K. Taylor[6], C. Langefeld[3,5], L. Wagenknecht[7], D. Bowden[2,4,8], N. Palmer[2,4,8].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 4) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Biostatistical Sciences; Wake Forest School of Medicine, Winston-Salem, NC; 6) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute, Harbor-UCLA Medical Center, Torrance, CA; 7) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 8) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC.

Despite the recent success of genome-wide association studies (GWAS) in identifying genetic variants regulating metabolic phenotypes, a substantial proportion of the heritability remains unexplained. Gene-environment interactions are a potential tool to explain the missing heritability. In this study, up to 822 Hispanic Americans from IRASFS were chosen for a genome-wide interaction analysis with 12 cardiometabolic phenotypes using physical activity score acquired by questionnaire. Interaction and joint (main+interaction effects) analyses were performed using SOLAR. The top signal was rs183130 (MAF=28%), located upstream of the cholesteryl ester transfer protein gene (*CETP*), with high density lipoprotein (HDL). This association was characteristic of GWAS results and driven by a main effect (P_{Main}=3.04E-10) with no interaction (P_{Int}=0.16). Among novel signals, SNP rs3735602 (MAF=45%) located downstream of the dihydrolipoamide dehydrogenase gene (*DLD*) was strongly associated with triglyceride levels (TG) and driven by an interaction effect (P_{Int}=1.08E-07) while no main effect was observed (P_{Main}=0.41). This suggests a complex function of *DLD*: the minor allele (C) has a protective effect in carriers with low physical activity with the opposite effect in the high physical activity group, i.e. compared to non-carriers, the homozygous C allele carriers have 35% less and 45% more TG in low and high physical activity groups, respectively. Interestingly, DLD performs mechanistically distinct functions, i.e. the homodimeric form functions as a dehydrogenase regulating energy metabolism and the monomer as a protease. These distinct functions may be responsible for its complex effects. Additionally, intronic SNP rs57556257 (MAF=9%) in cysteine rich transmembrane BMP regulator 1 gene (*CRIM1*) was strongly associated with disposition index (DI), a measure of crosstalk modulating glucose homeostasis pathways, in the joint analysis (P_{Joint}=5.95E-08). The signal exhibited main and interaction effects (P_{Main}=2.44E-07, P_{Int}=1.01E-02), suggesting the genetic effect is partially dependent on physical activity. *CRIM1* encodes a transmembrane protein containing an insulin-like growth factor-binding domain. In conclusion, genome-wide interaction analysis of physical activity indicates that the inclusion of environmental factors allows for the identification of additional genetic signals contributing to variation in cardiometabolic phenotypes.

A three-way interaction among maternal and fetal variants contributing to congenital heart defects. *M. Li[1], J. Li[2], C. Wei[3], Q. Lu[4], X. Tang[2], S. Macleod[2], C. Hobbs[2].* 1) Department of Epidemiology and Biostatistics, School of Public Health, Indiana University at Bloomington, Bloomington, IN; 2) Department of Pediatrics, University of Arkansas for Medical Sciences; 3) Department of Epidemiology and Biostatistics, University of North Texas Health Science Center; 4) Department of Epidemiology and Biostatistics, Michigan State University.

Congenital heart defects (CHDs) develop through a complex interplay between genetic variants, epigenetic modifications, and maternal environmental exposures. Genetic studies of CHDs have commonly tested single genetic variants for association with CHDs. Less attention has been given to complex gene-by-gene and gene-by-environment interactions. In this study, we applied a recently developed likelihood-ratio Mann-Whitney (LRMW) method to detect joint actions among maternal variants, fetal variants, and maternal environmental exposures, allowing for high-order statistical interactions. All subjects are participants from the National Birth Defect Prevention Study, including 623 mother-offspring pairs with CHD affected pregnancies and 875 mother-offspring pairs with unaffected pregnancies. Each individual has 872 single nucleotide polymorphisms encoding for critical enzymes in the homocysteine, folate, and trans sulfuration pathways. By using the LRMW method, three variants (fetal rs625879, maternal rs2169650, and maternal rs8177441) were identified with a joint association to CHD risk (nominal P-value = 1.13e-07). These three variants are located within genes BHMT2, GSTP1, and GPX3, respectively. Further examination indicated that maternal SNP rs2169650 may interact with both fetal SNP rs625879 and maternal SNP rs8177441. Our findings suggest that the risk of CHD may be influenced by both the intragenerational interaction within the maternal genome and the intergenerational interaction between maternal and fetal genomes.

Cardiovascular comorbidity influence genetic association studies results. *O.A. Makeeva[1,2], A.A. Sleptsov[1], E.V. Kulish[1], V.V. Markova[1], O.L. Barbarash[2], A.M. Mazur[3], E.B. Prokhorchuk[3], N.N. Chekanov[3], V.A. Stepanov[1], V.P. Puzyrev[1,4].* 1) Institute of Medical Genetics, Tomsk, Russian Federation; 2) Institute of Complex Issues of Cardiovascular Problems, Kemerovo, Russia; 3) Genoanalitika, Moscow, Russia; 4) Siberian State Medical University, Tomsk, Russia.

Comorbidity or a combination of several diseases in one individual is a common phenomenon. However, the genetic background for the non–random disease combinations is not fully understood. More data is needed to investigate the genetic profile of patients burdened with several diseases (polypathia, disease conglomerates) and its comparison with the profile of patients with single diseases. Our association study featured three groups of patients with various combinations of cardiovascular disorders and a control group of relatively healthy individuals. Patients were selected as follows: presence of only one disease, ischemic heart disease (IHD); a combination of two diseases, IHD and arterial hypertension (AH); and a combination of several diseases, including IHD, AH, type 2 diabetes mellitus (T2DM), and hypercholesterolemia. Genotyping was performed using the "My Gene" genomic service (www.i–gene.ru). About 1,400 polymorphic genetic variants and their associations with the studied phenotypes were analyzed. A total of 14 polymorphic variants were associated with the phenotype "IHD only," including those in the genes *APOB, CD226, NKX2–5, TLR2, DPP6, KLRB1, VDR, SCARB1, NEDD4L,* and *SREBF2*, as well as several intragenic variants. A total of 13 markers were associated with the "IHD and AH" phenotype, including variants in the *BTNL2, EGFR, CNTNAP2, SCARB1,* and *HNF1A* genes, and 6 intragenic polymorphisms. 14 variants were associated with a combination of several cardiovascular diseases (CVD), including in the *TAS2R38, SEZ6L, APOA2, KLF7, CETP, ITGA4, RAD54B, LDLR,* and *MTAP* genes, along with three intragenic polymorphisms. The *SCARB1* rs4765623 was common marker for the "IHD only" and "IHD and AH" phenotypes; rs663048 in SEZ6L and intragenic rs6501455 were common for the "IHD and AH" phenotype and a combination of several diseases (syntropy); there were no common genetic markers for the "syntropy" and "IHD only" phenotypes. Classificatory analysis of the relationships between the associated genes and metabolic pathways revealed that lipid–metabolizing genes are involved in the development of all three studied CVD phenotypes whereas immunity response genes are specific to the "IHD only". The study demonstrates that comorbidity presents an additional challenge for association studies of common diseases: the genetic profile of combined forms of pathology can be different from those for isolated forms of a disease.

Utilizing the strength of pedigree-based study design to identify novel tissue plasminogen activator loci. *N. Zwingerman[1], V. Truong[1], M. Wilson[2], P. Wells[3], P.E. Morange[4], D.A. Trégouët[5], F. Gagnon[1]. 1) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 2) Genetics and Genome Biology Program, Peter Gilgan Centre for Research and Learning, Toronto, Canada; 3) Department of Medicine, Faculty of Medicine, University of Ottawa, Ottawa, Canada; 4) INSERM, UMR_S 1062, Nutrition Obesity and Risk of Thrombosis, Marseille, France; 5) INSERM, UMR_S 1166, Team Genomics and Pathophysiology of Cardiovascular Diseases, Paris, France.*

Tissue Plasminogen Activator (tPA) is a serine protease that mediates the conversion of plasminogen to plasmin, the major enzyme responsible for endogenous fibrinolysis. In some populations, elevated tPA levels are associated with thrombotic outcomes. tPA plasma levels are highly heritable, with estimates as high as 67%. A mega-GWAS implicated 3 genes involved in tPA regulation that collectively explain only ~1% of tPA variance. Rare genetic variants with large effect size could underlie the unaccounted tPA variation. A pedigree-based study in a founder population is an efficient design to test for co-segregation of putative rare variants. To identify rare genetic variants associated with tPA plasma levels. The study sample consists of 4 extended French-Canadian pedigrees ascertained on a single proband with venous thromboembolism, with complete data of 178 individuals. We used an iterative Bayesian oligogenic joint linkage and segregation analysis to conduct a genome-wide linkage scan of microsatellite markers with tPA levels, followed by a variance-component approach to validate findings in a hypothesis-testing framework. Then an association analysis, using a linear mixed regression model adjusted for relatedness and covariates was used, to test for association between single nucleotide polymorphisms (SNPs) and tPA plasma levels in the identified linkage region. The significance threshold was determined by estimating the effective number of tests, accounting for the LD structure in the region. Both linkage analysis approaches identified a genome-wide significant signal on chromosome 11q14 region (LOD score=3.51; $\log_{10}$(BF)=2.56, p=0.001) and 15q25 region (LOD score=3.16; $\log_{10}$(BF)= 1.61, p=0.0012). There were 3,286 and 2,170 genotyped SNPs in the linkage regions common to both approaches on chromosome 11 and 15 respectively, corresponding to a significance threshold of $2.89e^{-5}$ and $4.17e^{-5}$. Nine and two genotyped SNPs met the significance thresholds respectively. Imputed SNP data in the regions were analyzed for refinement, which identified the strongest associations with rare variants in this region (top imputed SNP: $p=3.48e^{-7}$, MAF=0.11 vs to MAF=0.039 in population). Linkage analysis followed by genetic association testing in pedigrees identified a novel regions of interest for tPA level variation, providing new insights on tPA determinants.

653T

Protein-altering and regulatory genetic variants near *GATA4* implicated in bicuspid aortic valve. *C.J. Willer[1], W. Zhou[1], J. Jiao[1], J.B. Nielsen[1], M. Mathis[1], M. Heydarpour[2], G. Lettre[3,4], L. Folkersen[5,6], S. Prakash[7], C. Schurmann[8], M. Lin[1], M. Othman[1], J. Kitzman[1], A. Boyle[1], S. Ganesh[1], G. Abecasis[1], K. Eagle[1], R.J.F. Loos[8], P. Eriksson[5], J-C. Tardif[3,4], C.M. Brummett[1], D. Milewicz[7], S. Body[2], B. Yang[1], BAVCon Consortium. 1) University of Michigan, Ann Arbor, MI; 2) Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Montreal Heart Institute, Montreal, Quebec, Canada; 4) Université de Montréal, Montreal, Quebec, Canada; 5) Karolinska University hospital Solna, Karolinska Institutet, Stockholm, Sweden; 6) Technical University of Denmark, Copenhagen, Denmark; 7) University of Texas Health Science Center at Houston, Houston, TX; 8) 12.The Charles Bronfman Institute for Personalized Medicine, The Icahn School of Medicine at Mount Sinai, New York, NY.*

Individuals with bicuspid aortic valve (BAV), a heritable congenital heart defect, have substantially increased risk of complications of the valve and aorta. To identify the underlying causes of BAV, we performed a genome-wide association scan of 466 non-syndromic BAV cases and 4,660 age, sex, and ethnicity-matched controls, with replication in an additional 1,360 cases and 8,205 controls. We genotyped samples with the Illumina Human CoreExome array with 498,075 markers. We identified association with a non-coding variant (rs6601627, OR = 1.90, 95% CI 1.62 – 2.23, $p=3x10^{-15}$) 151kb from the cardiac-specific transcription factor, *GATA4*, and near-significance for protein-altering p.Ser377Gly in *GATA4* (rs3729856, OR = 1.31, 95% CI 1.19 – 1.45, $p=1x10^{-7}$). These variants were determined to be independent by conditional analysis. This locus allowed investigation of both protein-coding and non-coding regulation of an important cardiac transcription factor and its involvement in a congenital heart defect. We identified chromatin interaction loops in K562, using ChIA-PET data and Hi-C data, between associated variants and a region in the large 40kb intron of GATA4. To investigate the role of GATA4 in aortic valve development, *GATA4* was interrupted by CRISPR Cas9 and single guide RNA (sgRNA) in induced pluripotent stem cells (iPSCs) from donors with normal tri-leaflet aortic valve. The disruption of *GATA4* significantly impaired the transition from endothelial cells into mesenchymal cells, a critical step in heart valve development. In summary, we report the first genome-wide significant association with BAV which identified non-coding variants near GATA4, and a missense variant within *GATA4*. We demonstrate that disruption of *GATA4* in iPSC impairs the differentiation from endothelial to mesenchymal cells, confirming that at this locus *GATA4* is likely the functional gene increasing risk of BAV.

654F

Sequence data processing and analysis of 18,000 human genomes in the NHLBI TOPMed sequencing program. *T. Blackwell[1], G. Abecasis[1], K. Barnes[2], J. Blangero[3], E. Burchard[4], A. Weiss[17], J.G. Wilson[5] on behalf of the NHLBI TOPMed Program.* 1) TOPMed Informatics Research Center, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) University of Colorado, Denver; 3) University of Texas Rio Grande Valley School of Medicine; 4) University of California, San Francisco; 5) Jackson Heart Study, University of Mississippi Medical Center; 6) Massachusetts General Hospital; 7) Broad Institute; 8) New York Genome Center; 9) National Heart, Lung and Blood Institute, NIH; 10) Department of Biostatistics, University of Washington, Seattle; 11) Department of Biostatistics, Harvard School of Public Health; 12) Johns Hopkins University Medical School; 13) Brown University, Providence RI; 14) University of Maryland Medical School; 15) Northwest Genomics Center, University of Washington, Seattle; 16) Framingham Heart Study, Boston University; 17) Brigham and Women's Hospital, Boston; 18) University of Pittsburgh.

The National Heart Lung and Blood Institute's Trans-Omics for Precision Medicine (TOPMed) initiative aims to stimulate discovery of the fundamental mechanisms that underlie heart, lung, blood and sleep disorders by combining whole genome sequence and other omics data with existing high quality phenotype information. The first two years of the project will generate deep whole genome sequence data for >60,000 diverse samples (including a majority of samples with non-European ancestries that are traditionally under-represented in genomic research) and represent a collaboration between diverse groups of scientists, 6 genome sequencing centers, a project data coordination center, an informatics resource center and staff at the National Institutes of Health and the National Center for Biotechnology Information (NCBI). Here we describe efforts to integrate sequence data across participating studies and sequencing centers. This is being carried out at the project's Informatics Research Center (IRC). Currently >18,500 samples from 10 year 1 studies have been sequenced to an average sequencing depth of 37.8x (after duplicate removal), resulting in 98.9% of the genome covered at depth 10 or greater. An initial data freeze with 10,597 sequenced individuals yields 142 million SNPs and 10.2 million short indels, of which 44.3% and 38.7% are singletons, respectively. Each individual carries a non-reference allele at between 3.5 and 4.5 million sites, depending on ethnicity. Deep sequencing, PCR-free sample prep, and harmonized data processing allow us to achieve <0.2% difference in SNP variant calls when the same sample is sequenced at different sites. Although more differences are observed for indel polymorphisms, these are concentrated in low complexity regions of sequence, such as short tandem repeats. Compact file formats and efficient processing allow analysis at this scale. A primary goal of the project is to allow investigators exploring diverse study designs and phenotypes to benefit from access to high-quality sequence data and analysis. There are also many opportunities to be had from combined analysis of the sequence data to be generated by the project, including a diverse catalog of genetic variation, a potential resource of controls for genetic association studies, and an imputation reference panel. We discuss some of these opportunities and associated logistical and technical challenges, as well as opportunities for any scientist to access project results.

655W

GWAS to 30X genomes: Evolution of sequencing in the ARIC cohort to reveal the genetic architecture of complex traits. *G.A. Metcalf[1], A. Morrison[2], B. Yu[2], X. Liu[2], S. White[1], H. Doddapaneni[1], J. Hu[1], W. Salerno[1], D.M. Muzny[1], R.A. Gibbs[1], E. Boerwinkle[1,2].* 1) Baylor College of Medicine, Houston, TX; 2) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

The Atherosclerosis Risk in the Community (ARIC) study is a flagship project seeking to identify susceptibility genes underlying well-replicated GWAS findings for heart, lung, and blood diseases and their risk factors in combined analyses with the larger Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium. Early efforts involved DNA sequencing via a multiplexed DNA capture approach targeting a 2.2 Mb region of the genome. While informative, analyses were limited to the loci selected from the GWAS findings and thus biased towards common variants. As sequencing platforms improved, more comprehensive applications of whole exome sequencing (WES) and low pass (6X) genomes became affordable. To date, the HGSC has accumulated sequences from 15K WES 5K low pass whole genome samples spanning 5 longitudinal cohort studies with extensive phenotypic and clinical data. To promote novel discoveries for rare coding variants, we jointly analyzed the ARIC and CHARGE data for multiple biomedical traits. Single variant tests of common variants and gene-based tests of rare variants were evaluated for each trait and ancestry separately, followed by multiethnic meta-analyses. Functional annotation of SNVs, genes and regulatory elements was integrated to increase power to detect true phenotype-genotype association using our custom annotation pipeline, WGSA. These data have fueled considerable analytical work in collaboration with the CHARGE consortium, forming the foundation for discovery of novel genes/loci influencing a number of chronic disease risk factors. Recently we conducted a fixed effects meta-analysis of WES data in 14,770 participants for 13 hematology traits in European Americans (EA) and African Americans (AA). Discovery analyses revealed 5 novel, significant gene-based test results and 3 novel, significant single variant associations. For example, a low frequency (MAF=0.009) novel single synonymous variant in GFI1B (rs150813342) was associated with platelet count in EAs (P=4.72x10-8). Generation and analysis of 30X WGS data is underway using the Illumina HiSeq X in an effort to identify coding and non-coding regions in relation to complex quantitative traits, specifically those regions influencing the human serum metabolome and its association with CVD. By focusing on proximal measures of physiologic processes we will optimize the size of a gene's effect relative to corresponding risk factor level or disease endpoint.

656T

Common variants of *ZFPM2* are associated with non-syndromic bicuspid aortic valve. *S. Prakash[1], M. Heydarpour[2], D. Guo[1], D. Milewicz[1], S. Body[2], BAVCon Investigators.* 1) Internal Medicine/Medical Genetics, University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Background: Bicuspid aortic valve (BAV) is the most common congenital heart defect, but the genetic causes are largely unknown. Approximately one-third of BAV patients develop ascending aortic aneurysms and 1-2% develop acute aortic dissections (TAAD). We hypothesized that common autosomal variants predispose to BAV and TAAD and performed a GWAS of BAV cases who were referred for surgical repair to Brigham and Women's Hospital (average age 55 years, 26% female, 44% TAAD, 46% aortic stenosis). Methods: 480 patients of European ancestry with BAV were genotyped using Illumina Omni-2.5 arrays and compared separately with two sets of unselected dbGAP genotypes: the Health and Retirement Study (HRS, phs000428, n=12,845) and Smoking Cessation (SmokCes, phs000404, n=1,525) cohorts. Association tests were carried out using logistic regression, adjusting for gender and principal components. Candidate regions were imputed against 1000 Genomes Phase 3 using shapeit and impute2 and meta-analyzed using PLINK. Results: After removal of cryptically related individuals and population outliers, a total of 447 BWH cases, 9,428 HRS controls and 935 SmokCes controls were available for analysis. The maximum genomic inflation factor was 1.03. The strongest association signals for both the BWH-HRS and the BWH-SmokCes comparisons were observed on chromosomes 7 and 8 and did not overlap with previously reported loci for BAV. A total of 12 genotyped SNPs in the *ZFPM2* gene in 8q23.1 were positively associated with BAV (OR=1.46), but not TAAD, with a minimum genotyped *P*-value of 1×10^{-7} (rs16873287) and minimum imputed *P*-value of 9×10^{-8} (rs12676726). The same haplotype block was associated with BAV in a meta-analysis combining two other cohorts with BAV and TAAD or Turner syndrome ($P=8 \times 10^{-5}$, OR=1.38). *ZFPM2* encodes a transcription factor that interacts with Gata4, was implicated in cardiac outflow tract development and is mutated or affected by rare CNVs in patients with tetralogy of Fallot. In a separate cohort of 765 elderly patients who were ascertained for sporadic TAAD (average age 63, 15% BAV), neither top SNP was significantly associated with BAV (OR=1.02), but one rare deletion of *ZFPM2* was identified in a subject with BAV. Additional replication studies with cohorts that were primarily ascertained for BAV are ongoing. Conclusion: These observations support previous data that common variants affecting cardiac developmental genes may also contribute to BAV. .

657F

A genome-wide association study of >27,000 cases and controls for coronary artery disease in a multiethnic cohort. *M. Verbanck[1], V.W. Setiawan[2], N. Zubair[3], A.C. Morrison[4], P.S. de Vries[4], L. Hindorff[5], C. Haiman[2], R. James[5], L. Le Marchand[6], U. Peters[3], C.L. Wassel[7], K.E. North[8], R.J.F. Loos[1], T. Matise[9], C. Avery[8], C. Kooperberg[3], R. Do[1] on behalf of the PAGE Study.* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) University of Texas Health Science Center, Houston, TX; 5) National Institute on Minority Health and Health Disparities, National Institutes of Health, Bethesda, MD; 6) University of Hawaii Cancer Center, Honolulu, HI; 7) University of Vermont College of Medicine, Burlington, VT; 8) University of North Carolina, Chapel Hill, NC; 9) Rutgers University, Piscataway, NJ.

Coronary artery disease (CAD) is one of the leading causes of death worldwide. Large-scale genetic studies of CAD have successfully identified common genetic variants associated with CAD. However, these genetic studies have been performed mostly in European ancestry populations. To test whether genetic variants are associated with complex traits and disease in non-European populations, the National Institute of Health's Population Architecture using Genomics and Epidemiology (PAGE) consortium has generated a meta-cohort comprising approximately 50,000 U.S. participants of African, Hispanic, Asian, Native Hawaiian and Native American ancestry. These individuals were genotyped using the 1.7M SNP Multi-Ethnic Genotyping Array (MEGA), a custom-built array designed specifically to include genetic variation from diverse ancestry populations. From the meta-cohort, we identified 5,432 CAD cases and 21,911 controls. Cases were defined by myocardial infarction (MI) and/or revascularization, in addition to CAD-related death. Controls were defined as not having any evidence of CAD/MI. We performed an initial genome-wide association analysis, using logistic regression under an additive model, after adjustment for age, sex and the first 10 principal components of genetic ancestry, on autosomal variants with a minor allele frequency ≥1%. We identified two sub genome-wide significant SNPs in two loci (CYP46A1; CAMK1D; $P<6 \times 10^{-7}$). Both SNPs are rare in European populations (MAF=0.002 and MAF=0.01 respectively) and are in regions that do not have genome-wide significant SNPs in the CARDIOGRAM+C4D study. Future plans include replication of the top associated SNPs in additional samples, refining the association analysis by examining ancestry-specific effects and fine-mapping using imputation data from the Haplotype Reference Consortium panel. We will present findings of these plans, and describe advantages and challenges with analyzing genetic data in multi-ethnic populations.

658W

Pleiotropic effects of Coxib, a phenotype rescue study *in-silico* **and** *in-vivo***.** *K. Vishnolia[1,2], I. Braenne[1,2], H. Schunkert[3,4], J. Erdmann[1,2].* 1) IIEG, University of Luebeck, Luebeck, Germany; 2) DZHK (German Research Center for Cardiovascular Research), Partner site Hamburg/Luebeck/Kiel, Germany; 3) Deutsches Herzzentrum Muenchen, Technische Universitaet Muenchen, Muenchen, Germany; 4) DZHK (German Research Center for Cardiovascular Research), Partnersite Muenchen, Germany.

   Aim: Cyclooxygenase 2 inhibitors (Coxibs) are used in the treatment of chronic pain relief and are known to cause severe side-effects such as Myocardial infarction (MI) and Hypertension. Due to the severe side-effects, coxibs are under scrutiny and several Coxibs have been withdrawn from the market. Coxibs are reported to interact with several gene and gene products either down-stream the prostaglandin synthesis pathway or through other pathways. It is likely, that some of these drug genes interactions influence the increased risk of MI or hypertension. **Results:** In an *in-silico* analysis, we studied the genes representing molecular targets of coxibs to search for genomic signals for coronary artery disease (CAD) risk. We screened for association with CAD in 84.813 cases and 202.543 controls. With this approach, we identified four candidate genes, VEGFA, MMP9, CACNA1E and BCAR1. To examine the role of these genes with regard to the side effects that occur under coxib treatment, we next performed *in-vivo* studies in Zebrafish larvae. The four human genes, VEGFA, MMP9, CACNA1E and BCAR1 are conserved genes and found as homologue genes in Zebrafish genome. Four days post fertilized Zebrafish larvae when treated with coxibs, we identified significantly increased blood pressure compared to control treatment. In parallel, the mRNA expression levels of all four genes was observed to be significantly lower after coxib treatment, validating our *in-silico* prediction. To verify whether the -due to Coxibs- altered gene expression influenced the blood pressure we next repeated the experiment but this time supplementing coxibs with a second drug. **Conclusion:** The hypothesis is that a second drug with an opposite effect on one or all four genes will restore the normal levels, and that we can rescue the phenotype accordingly. This study gives new insights in the mechanisms underlying the severe side effects of coxibs and how we can explore the potential clinical relevance of off-target drug effects.

659T

Antihypertensive drug response in *APOL1* **risk allele carriers and non-carriers in African-Americans using electronic medical record data.** *G. Galarneau[1], G.N. Nadkarni[1], E.P. Bottinger[1,2], R.J.F. Loos[1], R. Do[1].* 1) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Berlin Institute of Health, Berlin, Germany.

   Genetic variants forming the *APOL1* risk allele have been associated with kidney disease in individuals of African ancestry (Genovese, G. *et al*. *Science*, 2010). We recently showed that the *APOL1* risk allele was also associated with increased systolic blood pressure (SBP) in young African-Americans (Galarneau et al. Abstract #514 ASHG 2015). Since studies have shown that the response to blood pressure-lowering therapies depends on genotype, drug target and mechanism of action, we hypothesized that *APOL1* carrier status might exhibit differences in the SBP response to antihypertensive classes. We extracted data from the electronic medical record (EMR) of 5,204 African-Americans from the Mount Sinai Bio*Me* Biobank and identified a total of 3,035 events of first prescription of an antihypertensive class of which we could assess class-specific drug response (no more than one class being newly prescribed, but concurrent usage of other antihypertensive classes was permitted to increase power). We used for replication an independent set of 1,623 African-Americans from the Bio*Me* Biobank. We defined the pre-prescription SBP as the mean SBP during the three months prior to prescription and the post-treatment SBP as the mean SBP during the three months after the prescription. The outcome variable was defined as the decrease in outpatient SBP following the prescription of a specific antihypertensive class. Overall, this decrease ranged from 1.4-10.2 mmHg in the different antihypertensive classes. We tested the association of the *APOL1* risk allele with SBP antihypertensive response by performing a linear regression with sex, age, body-mass index and total number of antihypertensive classes prescribed as covariates. Three of the ten antihypertensive classes studied were statistically significant (p<0.05) (aldosterone antagonists, beta blockers and loop diuretics). Among these three, the class of aldosterone antagonists replicated in the replication cohort (p=0.009). Carriers of the *APOL1* risk allele had a significantly better response (12.5 vs 0.9 mmHg decrease in SBP) to aldosterone antagonists compared to non-carriers. These results can potentially lead to new paradigms of blood pressure-lowering treatment in *APOL1* carriers.

660F

A phenome-wide scan detects pleotropic effect of LY96 on new-onset atrial fibrillation and diabetes after coronary artery bypass grafting surgery. *Y.J. Li[1,2], R. Huang[2], W. Qi[1,2], M.V. Podgoreanu[3], M.D. Kertai[3].* 1) Department of Biostatistics and Bioinformatics, Duke Univ Med Ctr, Durham, NC; 2) Duke Molecular Physiology Institute, Duke Univ Med Ctr, Durham, NC; 3) Department of Anesthesiology, Duke Univ Med Ctr, Durham, NC.

Using a genome-wide approach, we previously identified genetic variants in the Lymphocyte antigen 96 (*LY96*) gene that were associated with a reduced risk for postoperative atrial fibrillation (POAF) in patients who underwent coronary artery bypass graft (CABG) surgery. The encoded protein for the *LY96* gene is the toll-like receptor 4 coreceptor LY96. Functional activation of toll-like receptor 4 has been shown to be associated with increased inflammation and oxidative stress. As POAF is one of the most common complications after CABG surgery, occurring 25% to 40%, we sought to further understand the pleiotropic effects of LY96 gene related to health condition of CABG patients in the Pegassus cohort by taking the advantage of the rich electronic medical record data available in these patients. A total of 863 patients with available postoperative ICD-9 codes and LY96 genotype data were investigated. We mapped the ICD-9 codes to PheWAS codes for the disease classification (https://phewas.mc.vanderbilt.edu/). To ensure reasonable sample sizes of cases and controls, we limited our analyses on PheWAS codes with incidence rates between 18% and 80%. Single nucleotide polymorphisms (SNPs) in LY96 analyzed were from Illumina Human610-Quad BeadChip. Logistic regression model was used to test the association between SNP and each phenotype with age and gender adjusted. The phenotypes meeting $p < 0.05$ were included in the multivariate-genotype analysis using TATES to determine the pleotropic effect of the LY96 variants across the targeted phenotypes. A total of 2621 postoperative ICD-9 codes available after the surgery date were surveyed, which mapped to 1259 PheWAS codes. The incidence rates of PheWAS codes range from 0.00113 to 0.9887, where 18 PheWAS codes met our filtering criteria for further analyses. Five SNPs in LY96 presented consistent association with type 2 diabetes mellitus (T2DM). The incidence rate of T2DM was 40.6% in our dataset, but only 12% of patients have both POAF and T2DM. Particularly, our previous reported POAF SNP rs10504554 (OR=0.48, $p=2.97 \times 10^{-5}$) is associated with T2DM (OR=1.36, p=0.024) and tobacco use disorder (OR=1.37, p=0.029). Multivariate-genotype association analysis across these three phenotypes remains significant ($p=8.91 \times 10^{-5}$). By adopting the PheWAS approach, we provide new evidence of the role of LY96 variants on other comorbidities in CABG patients.

661W

Distribution of *CAPN10* gene haplotypes according to clinical and biochemical parameters related to hypertension. *A.G. Castro-Martínez[1], J. Sánchez-Corona[1], A.G. García-Zapién[1], G. Ramírez-López[2], S. Fonseca-Reyes[3], M.C. Morán-Moguel[1], S.E. Flores-Martínez[1].* 1) División de Medicina Molecular, Centro de Investigación Biomédica de Occidente, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México; 2) Unidad de Investigación Epidemiológica y en Servicios de Salud del Adolescente, Instituto Mexicano del Seguro Social, Tonalá, Jalisco, México; 3) Instituto de Investigación Cardiovascular, Nuevo Hospital Civil de Guadalajara, Guadalajara, Jalisco, México.

The present study was aimed to analyze the distribution of haplotypes derived from four *CAPN10* gene variants (SNP-44, SNP-43, indel-19 and SNP-63) according to clinical and biochemical parameters related to hypertension, because it has been described that calpain 10, which is encoded by the *CAPN10* gene, is involved in the secretion and insulin action and has also been reported its association with metabolic disorders related to hypertension. **Methods.** The study included 189 patients with hypertension and 97 normotensive subjects. Measurements of anthropometric parameters and biochemical estimations were performed. SNP-44 (rs2975760, IVS3 g.4841 T>C), SNP-43 (rs3792267, IVS3 g.4852 G>A) and SNP-63 (rs5030952, IVS13 g.16378 C>T) were identified by PCR-RFLP and the indel-19 variant (rs3842570, IVS6 g.7920 ins/del 32-bp) by gel based detection of PCR products-length differences. Chi-squared tests, with Fisher's correction when necessary, were applied to compare haplotype frequencies between patients with hypertension and normotensive subjects. In the hypertensive patients, haplotype distribution was compared according to clinical and biochemical parameters related to hypertension using the non-parametric Mann–Whitney U test, and the contribution of each haplotype to the risk of developing hypertension was determined by multivariate logistic regression analysis. **Results.** Haplotype frequencies did not differ significantly between patients with hypertension and normotensive subjects. However, in hypertensive patients, when analyzing the distribution of haplotypes according to systolic pressure, diastolic pressure, BMI, glucose, insulin, HOMA, and lipid profile (cholesterol, triglycerides, LDL, HDL), statistically significant difference was observed for the diplotype 1121/2111 regarding the systolic pressure (OR=0.186, CI=0.040-0.864; p=0.032) and the diplotype 1221/2111 with LDL levels (OR=0.117, CI=0.015-0.934; p=0.043). **Conclusion.** The results suggest that the diplotype 1121/2111 is associated with decrease of systolic pressure, and the diplotype 1221/2111 with a decrease in LDL levels in our study group.

662T

Genetic analysis of 1968 WHO Group 1 Pulmonary Arterial Hypertension (PAH) patients enrolled in the National Biological Sample and Data Repository for PAH (PAH Biobank). *M. Pauciulo, K. Lutz, C. Winslow, A. Walsworth, A. Gygi, M. Barve, A. Reponen, L. Martin, H. He, W. Nichols.* Division of Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH.

The PAH Biobank was established to build a resource of biological specimens, clinical data and genetic data available to the PAH research community to further our understanding of the pathogenesis of this potentially fatal disease. Information on the resource and access to the samples and data can be found at www.pahbiobank.org. To date, 2,308 patients have been enrolled from 32 Enrolling Centers across the U.S. Blood samples collected at the Enrolling Centers are shipped overnight to the PAH Biobank. Blood is processed to store plasma and serum, extract DNA and RNA, and prepare immortalized cell lines. DNA sequencing is performed using the Illumina TruSeq Custom Amplicon system to interrogate the coding sequences/intron-exon junctions of *BMPR2*, *ALK1*, *ENG*, *CAV1*, *KCNK3*, *EIF2AK4*, and *SMAD9*. Genotyping of >4.3 million SNPs is done using the Illumina HumanOmni5 Beadchip. MLPA is performed to identify exonic deletions/duplications of *BMPR2*, *ALK1*, and *ENG*. Genetic analysis has been completed in 1,968 patients including 951 IPAH, 889 APAH, 67 FPAH, and 47 Drugs and Toxins PAH. 445 distinct variants occurred 11,639 times. 176 distinct synonymous and intronic variants occurred 9,438 times. The remaining 269 coding variants were observed 2201 times. This included 26 nonsenses in 42 patients, 51 ins/dels in 366 patients, and 11 splice site variants in 15 patients. 181 missenses occurred 1178 times. 74 missenses are predicted to be pathogenic/suspected pathogenic with 47 classified as variants of unknown significance. Of the 368 distinct coding/splice variants, 123 were in *BMPR2* with 98 predicted to be pathogenic or suspected pathogenic. 63 of the remaining 245 coding variants are predicted to be pathogenic or suspected pathogenic and spread across *ALK1* (15), *ENG* (11), *CAV1* (6), *SMAD9* (11), *KCNK3* (4), and *EIF2AK4* (15). MLPA identified 21 exonic insertion/deletions in *BMPR2* (19), *ALK1* (1) and *ENG* (1). The PAH Biobank is a powerful resource available to the PAH research community. This is the largest consecutively enrolled PAH cohort for which genetic analysis has been completed to date. While mutations have been identified in several genes, *BMPR2* remains the gene with the most pathogenic variants. Stratification of the cohort based on these genetic analyses could enable the identification of additional, novel genes and/or modifier genes affecting disease severity/penetrance in those harboring pathogenic or suspected pathogenic mutations in previously identified genes.

663F

Metabolic and transcriptomic fingerprints of menopausal hormone therapy in Finnish women. *A. Joensuu[1,2], J. Kettunen[3,4,2], M. Jauhiainen[2], A.J. Kangas[3], P. Soininen[3,4], A. Jula[5], V. Salomaa[2], J. Eriksson[6], M. Ala-Korpela[3,4,7], M. Perola[1,2,8], K. Auro[1,2,9].* 1) National Institute for Health and Welfare, Helsinki, Finland; 2) Department of Health, National Institute for Health and Welfare, Helsinki, Finland; 3) Computational Medicine, Faculty of Medicine, University of Oulu & Biocenter Oulu, Oulu, Finland; 4) NMR Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, Kuopio, Finland; 5) National Institute for Health and Welfare, Turku, Finland; 6) Department of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland; 7) Computational Medicine, School of Social and Community Medicine & Medical Research Council Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 8) University of Tartu, Tartu, Estonia; 9) Helsinki University Central Hospital, Department of Gynecology and Obstetrics, Helsinki, Finland.

Background: Menopause influences the health of all middle-aged women. Hormone therapy (HT) is commonly used to treat menopausal symptoms, but the effect of HT on cardiovascular disease (CVD) risk is under strong debate. The analysis of metabolic and transcriptomic profiles of HT users and non-users introduces novel information on factors affecting disease risk. **Methods:** We studied 4146 non-pregnant, non-lipid medicated 40-70-year-old women from four Finnish population cohorts, FINRISK 1997, DILGOM, HBCS and Health2000. Levels of 74 serum metabolites were quantified using an NMR platform. Metabolites were individually treated as dependent variables in linear regression corrected for age and fasting. HT users (N=1017) were studied against a) premenopausal (pre-MP, N=1362) and b) postmenopausal (post-MP, N=1759) women independently in each cohort and results were combined with random effects meta-analysis. The transcriptomic effects of HT use was studied against postmenopausal age-matched women in 74 DILGOM participants. **Results:** The metabolic profiles of pre-MP women and HT users are very similar: $p<0.05$ Bonferroni corrected differences were seen in only three metabolites; monounsaturated fatty acids, the ratio of monounsaturated fatty acids to total fatty acids and histidine. On the contrary, a clear atherogenic shift was demonstrated when comparing HT users and post-MP women: levels of 42 of the 74 studied metabolites differed. Levels of VLDL, IDL and LDL subclasses were higher and HDL subclasses lower in post-MP women. Also levels of serum cholesterol, triglycerides, apoB-100, omega-3 and 6 fatty acids, the amino acids glutamine, glycine, isoleucine and tyrosine as well as glucose, albumin and the degree of glycoprotein acetylation were clearly higher in post-MP women. The transcriptomic results support the metabolomics findings; levels of 194 transcripts differed ($p<0.01$) between HT and post-MP women, and DAVID annotation analysis reveals genes involved in the GO Biological processes Generation of precursor metabolites and energy and Regulation of gene expression, epigenetic as well as Steroid biosynthetic process and Steroid metabolic process enriched in these transcripts. **Conclusions:** Our results provide the first metabolome-wide population-based knowledge on using HT. The data demonstrate that HT usage is associated with a metabolic profile similar to that of premenopausal women, and compatible with a cardio-protective effect.

664W

Chamber-specific miRNA expression profiles of the human heart. *Y. Kakimoto[1], M. Tanaka[2], H. Kamiguchi[2], H. Hayashi[2], E. Ochiai[1], M. Osawa[1].* 1) Department of Forensic Medicine, Tokai University School of Medicine, Isehara, Japan; 2) Support Center for Medical Research and Education, Tokai University, Isehara, Japan.

The human heart contains two characteristic muscles: the ventricular myocardium and the atrial myocardium. The ventricular myocardium plays a central role in contraction to pump blood out from the heart to the entire body, whereas the atrial myocardium mainly serves as the source and target of neurohumoral signals. Gene expression analyses have shown that some mRNAs are specifically expressed in certain human cardiac chambers; however, chamber-specific miRNA expression signatures remain unclear. We performed deep sequencing of miRNA in 4 pairs of human left atria (LA) and left ventricles (LV) under normal physiological conditions. Of the total 19,830,155 reads generated from 8 libraries, 17,939,353 (90.5%) could be aligned to the human genome sequence, of which 6,975,989 reads (35.2%) were mapped to known miRNA sequences. In total, 1,134 mature miRNAs were identified and miR-1 was found to be the most abundant miRNA in both chambers, representing 21% of the miRNAs in the LA and 26% of the miRNAs in the LV. Twenty-five miRNAs were differentially expressed between the LA and the LV; 14 miRNAs were upregulated in the LA and 11 were upregulated in the LV. Subsequent real-time PCR of the miRNAs of 9 pairs of LA and LV validated the chamber-specific miRNA expression patterns. Notably, the miR-208 family members showed prominent chamber specificity in their expression; miR-208a-3p and miR-208a-5p were abundant in the LA, whereas miR-208b-3p and miR-208b-5p were preferentially expressed in the LV. miR-208a is encoded within an intron of the α-cardiac myosin heavy chain (α-MHC) gene (*MYH6*) and miR-208b is encoded within an intron of the β-cardiac myosin heavy chain (β-MHC) gene (*MYH7*), both of which are located on human chromosome 14. In the human heart, α-MHC is mainly expressed in the atrium, whereas β-MHC is extensively expressed in the fetal ventricle and moderately expressed in the adult ventricle. It is known that genetic deletion of miR-208a induces atrial fibrillation and the expression of ventricular miR-208b increases under cardiac stress, which is caused by conditions such as hypertrophy and ischemia. The anatomical expression profiles of the miR-208 family members support their chamber-specific functions in the human heart. The findings of this study might enhance our understanding of cardiac miRNAs and various heart diseases.

665T

An essential splice site mutation in *flt1* protects against early-stage atherosclerosis in zebrafish larvae. *M. den Hoed[1], M.K. Bandaru[1], L. Conrad[1], A. Emmanouilidou[1], P. Ranefall[2], C. Wählby[2], A. Larsson[3], E. Ingelsson[1,4].* 1) Department of Medical Sciences, Molecular Epidemiology, SciLifeLab, Uppsala University, Sweden; 2) Department of Information Technology, Division of Visual Information and Interaction and SciLifeLab, Uppsala University, Sweden; 3) Department of Medical Sciences, Biochemical structure and function, Uppsala University, Sweden; 4) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA 94305, USA.

Objective: Genome-wide association studies (GWAS) identified 56 loci that are associated with the risk of coronary artery disease (CAD). For most loci the causal genes are currently unknown. We previously showed that: 1) CAD-associated loci are also associated with early-stage atherosclerosis; 2) zebrafish larvae are a promising model system for high-throughput, largely image-based screens of early-stage atherosclerosis. We now aim to identify causal genes in GWAS-identified loci for CAD using zebrafish model systems. **Methods**: Bioinformatics analyses identified *CXCL12*, *COL4A1* and *FLT1* as positional candidate genes in CAD-associated loci. Zebrafish orthologs were identified and heterozygous carriers of nonsense (sa1516 in cxcl12b; fh336 in col4a1) or essential splice site (sa1504 in flt1) mutations were crossed into transgenic backgrounds with fluorescent markers on macrophages (Tg:mpeg1-mCherry) and neutrophils (Tg:mpo-EGFP). After an in-cross of transgene positive heterozygous carriers, offspring were (over)fed on a normal or cholesterol-supplemented diet from 5 to 10 days post-fertilization. At 10 days, larvae were soaked in a lipid-staining dye, followed by imaging the vasculature with an automated positioning system, fluorescence microscope and CCD camera. Atherogenic traits were subsequently quantified using a custom-written image analysis pipeline in ilastik, CellProfiler and ImageJ. After imaging, whole-body total cholesterol and triglyceride levels were assessed enzymatically and larvae were genotyped using KASP technology. Multilevel mixed models were used to assess the effect of each mutation (additive model) on atherogenic traits, while adjusting for diet, time-of-imaging and batch (random factor). **Results**: In data from up to 258 larvae, each additional copy of sa1504 in flt1 resulted in 0.3±0.1 SD less vascular lipid deposition (P=6E-5) and co-localization of lipids and macrophages (P=1E-2), without effects on total cholesterol or triglyceride levels (P>0.1). No effects were identified for mutations in col4a1 and cxcl12b (N up to 344 and 291, respectively). **Discussion**: Our results represent the first mutant model demonstrating that flt1 plays a role in early-stage atherosclerosis, implying that *FLT1* is the culprit for CAD in the 13q12 locus. *COL4A1* and *CXCL12* remain the most promising candidates in their respective loci. The lack of effect for these genes in our screen may reflect genetic redundancy, genetic adaptation and/or a late onset effect.

666F

The I-PICC Study: Protocol for a point-of-care randomized controlled trial of statin pharmacogenetics in a learning healthcare system. *S.J. Miller[1], R.E. Ferguson[1,2], J.M. Gaziano[1,3,4], R.C. Green[3,4,5,6], J.L. Vassy[1,3,4].* 1) VA Boston Healthcare System, Jamaica Plain, MA; 2) Boston University School of Public Health, Boston, MA; 3) Brigham and Women's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Partners HealthCare Personalized Medicine, Cambridge, MA; 6) Broad Institute of MIT and Harvard, Cambridge, MA.

   Background: The pharmacogenetic (PGx) association between *SLCO1B1* rs4149056 and simvastatin myopathy is well validated, but the clinical utility of its implementation in patient care is unknown. Here we describe the protocol of the I-PICC Study (Implementing Pharmacogenetics in Clinical Care), a randomized controlled trial (RCT) of *SLCO1B1* genotyping in primary care. Design/Results: The I-PICC Study is enrolling 400 statin-naïve primary care and women's health patients across the Veteran Affairs Boston Healthcare System. Eligible patients are aged 45-70 and have elevated risk of cardiovascular disease (CVD) according to American College of Cardiology/ American Heart Association (ACC/AHA) guidelines. Primary care providers (PCPs) are also research subjects and consent via electronic health record (EHR) alerts. To model PGx genotyping at the point of care, we are enrolling patients when their PCPs order cholesterol testing, indicating a moment of clinical decision-making about CVD risk. Given this design, we discussed with the institutional review board options for patient consent that minimize PCP burden, including 1) waiving consent and allowing PCPs themselves to enroll patients; 2) mailing letters to eligible patients at study launch, giving them the chance to contact the staff to opt out of enrollment but otherwise be considered consented; and 3) mailing letters and requiring patients to contact staff expressly to opt in to enrolling. A consented patient is then enrolled only if and when their PCP co-signs an order for *SLCO1B1* testing, performed on a blood sample already collected in clinical care. Enrolled patients are randomized to have their PCPs receive results through the EHR immediately (PGx+) vs. after 1 year (PGx-). We will query clinical and pharmacy data for 1-year outcomes: myopathy and concordance with Clinical Pharmacogenetics Implementation Consortium (CPIC) simvastatin guidelines (drug safety) and cholesterol levels and concordance with ACC/AHA guidelines (CVD risk reduction). We are validating a natural-language processing algorithm for myopathy and have 80% power to detect a 15% difference in the proportions meeting CPIC and ACC/ AHA guidelines. Discussion: A point-of-care RCT, the I-PICC Study eliminates the need for separate study visits or blood draws while minimizing the burden to participating PCPs. Such studies pose special challenges for balancing human subjects protection with trial efficiency in a learning healthcare system.

667W

Genetic variants associated with statin-induced changes in gene expression in human lymphoblastoid cell lines. *E. Theusch, R.M. Krauss, M.W. Medina.* Children's Hospital Oakland Research Institute (CHORI), Oakland, CA.

   Statins are widely prescribed to lower plasma low-density lipoprotein cholesterol levels. They also have pleiotropic effects seemingly unrelated to their cholesterol-lowering properties, but the mechanisms are poorly understood. Though statins reduce cardiovascular disease risk overall, statin efficacy varies, and some people experience adverse side effects while on statin treatment.   To identify potential genetic modulators of clinical statin response, we looked for genetic variants associated with statin-induced changes in gene expression (differential eQTLs or deQTLs) in lymphoblastoid cell lines (LCLs) derived from participants of the Cholesterol and Pharmacogenetics (CAP) 40 mg/day 6 week simvastatin clinical trial. We exposed CAP LCLs to 2 μM simvastatin or control buffer for 24 hours and performed polyA-selected, strand-specific RNA-seq. Statin-induced changes in gene expression from 259 European ancestry or 153 African American ancestry LCLs were adjusted for potential confounders prior to association with genotyped and imputed genetic variants within 1 Mb of each gene's transcription start site.   From the meta-analysis of the two ancestral populations, we identified deQTLs for 7 genes (*TBC1D4*, *MDGA1*, *TDRD12*, *SERPINB1*, *GATM*, *GLUL*, and *DTD1*) that had unadjusted p-values under 5.8×10^{-9} (a conservative threshold based on 13,955 genes tested and 1 million independent markers per genome). deQTLs for another 4 genes (*CHI3L2*, *OAS3*, *OAS1*, and *DFNA5*) were identified in the European ancestry subset alone.   The lead deQTLs for *OAS3* and *OAS1* were in strong linkage disequilibrium (LD; $r^2 > 0.9$) and, unlike most of the other deQTLs identified, were not strong eQTLs for endogenous gene expression levels in our data. They were also in more modest LD ($r^2 > 0.8$) with a known *OAS1* splice site mutation and were strongly correlated with endogenous, but not statin-induced changes in, *OAS1* splicing in our data.   *OAS1* and *OAS3* are interferon-induced genes that play major roles in antiviral response. Interestingly, *OAS1* has been a target of intense natural selection in humans. This could explain why most *OAS1/3* deQTL variants are common (35% MAF) in Europeans but rare (2% MAF) in Africans and why there was no *OAS1/3* deQTL signal observed in the CAP African Americans. There is some epidemiological evidence that statins are protective against certain viruses, thus supporting future investigation of whether antiviral activity of statin treatment varies by *OAS1/3* deQTL genotype.

Swedegene: Genome-wide association study of ACE inhibitor-induced cough in Sweden. *M. Wadelius[1], N. Eriksson[1,2], T. Axelsson[1], Q-Y. Yue[3], P.K.E. Magnusson[4], P. Hallberg[1].* 1) Department of Medical Sciences and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Uppsala Clinical Research Center, Uppsala, Sweden; 3) Medical Products Agency, Uppsala, Sweden; 4) Swedish Twin Registry, Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

   Background: Angiotensin-converting enzyme (ACE) inhibitors are used to manage hypertension and heart failure. Treatment is usually successful, but a substantial number of patients experience drug intolerance in the form of persistent dry cough. Candidate gene studies have tested the association between cough and genes in the bradykinin pathway, but findings have been inconsistent. A recent genome-wide association study (GWAS) of patients with cough induced by ACE inhibitors identified associations with intronic SNPs in the potassium channel gene *KCNIP4* on chromosome 4 [1].   **Method**: We performed a GWAS on 124 patients with ACE inhibitor-induced cough and 4890 population controls collected by the Swedish adverse drug reaction bio-bank Swedegene (www.swedegene.se). Cases and controls were genotyped using the Illumina arrays HumanOmni2.5 and HumanOmniExpress 700K. After quality control, the merged genotyped set contained 600 000 single nucleotide polymorphisms (SNPs). After phasing and imputation at the Michigan Imputation Server that uses the software Eagle and Minimac3 with the Haplotype Reference Consortium panel, the dataset contained 8.6 million SNPs. We corrected for principal components 1-4. The genome-wide significance p-value threshold was set to p <5 E-08 to correct for multiple testing.   **Results:** ACE inhibitor-induced cough was significantly associated with SNPs on chromosomes 1, 3, 12 and 14 at a genome-wide level. The minor allele frequencies ranged from 0.04 to 0.09 in cases and 0.01 to 0.02 in controls. The strongest association was with rs36058006 located in an intergenic region on chromosome 1 (odds ratio 6.93 [95% confidence interval 3.65, 13.17], p = 3.42 E-09). The second strongest signal came from rs115510347, an intronic SNP in *KCNMB2* on chromosome 3 (odds ratio 6.25 [95% confidence interval 3.37, 11.59], p = 6.31 E-09). There was no association with the previously identified gene *KCNIP4* on chromosome 4 (p=0.982).   **Conclusion:** We found novel associations between ACE inhibitor-induced cough and uncommon SNPs that need to be replicated. One of the interesting associations was with the potassium channel gene *KCNMB2*. The association between cough induced by ACE inhibitors and another potassium channel gene, *KCNIP4,* was not replicated [1].   **Reference:** 1. Mosley, J.D., et al., *A genome-wide association study identifies variants in KCNIP4 associated with ACE inhibitor-induced cough.* Pharmacogenomics J, 2016; **16**(3): 231-7.

Genetic variants in the lipoprotein (a) gene and atherothrombosis in Mexican population. *L.I. López-Salazar[1], E.A. Hernández-Tobías[1], R. Camacho-Mejorado[1], G. Noris[2], C. Santana[2], R. Gómez[1].* 1) Departamento de Toxicología, Cinvestav-IPN, Mexico City, Mexico; 2) Laboratorio Biología Molecular Diagnóstica, Querétaro, México.

   Atherothrombosis (ATT) is a complex disease that involves atherosclerotic lesions disruption and clot formation causing myocardial infarction and stroke. Therefore, ATT is the major cause of death worldwide. ATT is a highly heritable and polygenic condition with differential ethnic-susceptibility. Consequently, genetic variants in candidate genes could act as potential predictors. Lipoprotein (a) gene (*LPA*) has been related to cholesterol levels, pro-thrombotic effects and inflammation, all of them related to ATT development. Hence, the aim of the present study was to evaluate the contribution of three SNPs (rs9457951, rs10455872 and rs3798220) in *LPA* to ATT development in Mexican population.   204 cases and 204 controls were genotyped using real-time PCR through TaqMan assays. In addition, a genomic control (n=300) was included to reduce the spurious associations because Mexican population is an admixed one. An ancestral control (n=140) was also included (Mazahuas, Me'Phaas and Nahuas). Population genetic parameters were calculated through Arlequin software.   A nuance association between rs9457951-GC and hypercholesterolemia (*P*=0.02) was found. In addition, the genotype CC in rs3798220 showed important differences when Mexican populations (Mestizo) were compared to worldwide populations from 1000 genomes (0.08 *vs.* ≤ 0.0001, respectively). This finding was reinforced to compare with Native American populations, which exhibited the highest frequencies of this genotype (0.37 in Nahuas, 0.26 in Me'Phaas and 0.30 in Mazahuas). Hardy-Weinberg equilibrium was found in all populations. However, Mazahuas exhibited important but not significant homozygous excess (F_{is} = 0.345).   Our results suggest a possible contribution of Amerindian ancestry to ATT development, given that rs3798220-CC genotype has been related to cardiovascular risk. Further, heterozygous genotype in rs9457951 might be associated with hypercholesterolemia. Nevertheless, further studies increasing sample size should be realised to confirm these findings.

   Statement of purpose: Genetic variation can be used to study causal relationships between biomarkers and diseases. We have identified new common and rare genetic variants associated with cardiovascular-related protein levels (protein quantitative trait loci; pQTLs). We functionally annotated these pQTLs, predicted and experimentally confirmed a novel molecular interaction and determined which pQTLs are associated with diseases and physiological phenotypes.   **Methods and results:** As part of a larger case/control study of VTE, serum levels of 51 proteins implicated in cardiovascular diseases were measured in 330 individuals from the Tromsø Study. Exonic genetic variation near each protein's respective gene (*cis*) was identified using sequencing and arrays. Using single site and gene-based tests, we identified 27 genetic associations between pQTLs and the serum levels of 20 proteins: 14 associated with common variation in *cis*, of which six are novel (i.e. not previously reported); seven associations with rare variants in *cis*, of which four are novel; and six associations in *trans*. Of the 20 proteins, 13 were associated only with single sites, five with only rare variation, and two with both single site and rare variation. *cis*-pQTLs for kallikrein and F12 also show *trans* associations for proteins (uPAR, kininogen) known to be cleaved by kallikrein as well as with NTproBNP. We experimentally demonstrate that kallikrein can cleave proBNP (NTproBNP precursor) *in vitro*. Nine of the pQTLs have previously identified associations with 17 diseases and/or physiological phenotypes. To further validate these findings and identify novel associations, we have performed and are currently analyzing un-targeted mass spectrometry on plasma from an additional 160 individuals in the Tromsø Study.   **Conclusions:** We have identified *cis* and *trans* genetic variation associated with the serum levels of 20 proteins and utilized these pQTLs to study molecular mechanisms underlying diseases and/or physiological phenotypes.

   Introduction: Preeclampsia is a potentially severe and clinically heterogeneous vascular pregnancy disease characterized by systemic inflammation, endothelial dysfunction and often impaired placental development. Hemeoxygenase-1 gene (*HMOX-1*) encodes the HO-1 protein, a stress response enzyme with antioxidant and anti-inflammatory functions. The promoter region of *HMOX-1* contains a regulatory GT_n microsatellite repeat, which long version is associated with reduced *HMOX-1* expression. We have previously shown that pregnant women with the long repeat are at higher risk of developing late-onset, less severe form of preeclampsia. In this study, our aim was to investigate whether fetal genotype of the repeat also affects mother's preeclampsia risk. **Materials and methods:** We genotyped the GT_n repeat in cord blood DNA from 609 preeclamptic and 745 non-preeclamptic pregnancies from the Finnish Genetics of Preeclampsia Consortium cohort using DNA fragment analysis. **Results:** The long allele of the repeat was associated with preeclampsia (p=0.041, OR 1.18, 95% CI 1.00-1.38) and early-onset preeclampsia (p=0.026, OR 1.39 (1.03-1.86)). Moreover, the long genotype was associated with preeclampsia (additive model: p=0.024, OR 1.51 (1.05-2.16); dominant model: p=0.031, OR 1.45 (1.03-2.03)), early-onset preeclampsia (additive model: p=0.041, OR 2.08 (1.03-4.21)) and severe preeclampsia (additive model: p=0.021, OR 1.62 (1.07-2.44); dominant model p=0.021, OR 1.58 (1.07-2.33)). Based on interaction analysis the effect of child's genotype is independent of the mother's genotype. **Conclusions:** Maternal and fetal *HMOX-1* risk alleles seem to predispose to two preeclampsia subphenotypes. Decreased HO-1 level may affect endothelial adaptation to pregnancy and placental development, two mechanisms central in the development of preeclampsia.

672F

The effect of *NR3C1* and *VDR* polymorphisms on stable warfarin doses in patients with mechanical cardiac valves. *H. Kim[1], Y. Cho[1], B. Yi[1], H. Gwak[2], K. Lee[1].* 1) College of Pharmacy, Chungbuk National University, Cheongju, Republic of Korea, South Korea; 2) College of Pharmacy & Division of Life and Pharmaceutical Sciences, Ewha Womans University, Seoul.

   Background It is widely recognized that genotype significantly influences pharmacokinetics and pharmacodynamics of warfarin and contributes to the interpatient variability in warfarin dose requirements. The aim of this study was to evaluate the effects of polymorphisms of CYP2C9 transcription factor genes, NR3C1 and VDR, on stable warfarin doses in Korean patients with mechanical heart valves. METHODS Two hundred and four patients were enrolled including patients who had mechanical heart valve prosthesis and maintained a stable warfarin dose with INR of 2.0-3.0 for three consecutive times. In order to investigate the influences of genetic polymorphisms on the inter-individual variability of daily warfarin dose requirements, 17 single nucleotide polymorphisms (SNPs) were genotyped; VKORC1 (rs9934438), CYP2C9 (rs1057910), CYP4F2 (rs2108622), NR3C1 (rs41423247, rs1800445, rs56149945, rs10052957, rs6198, rs33388, rs6196, rs244465), and VDR (rs1544410, rs11568820, rs731236, rs757343, rs7975232, rs2228570). Statistical analyses were conducted to evaluate the effects of NR3C1 and VDR allelic variations on stable warfarin doses. RESULTS VDR SNP combination of rs7975232 and rs2228570 showed significant associations with stable warfarin doses, along with VKORC1, CYP2C9 and CYP4F2 polymorphisms. Patients with the combination of GT,TT/CT,CC genotypes of VDR rs7975232/rs2228570 required significantly higher warfarin stable doses (5.79 ± 2.02 mg) than those with the other combined genotypes (5.19 ± 1.78 mg). Multivariate analysis showed that VDR rs7975232/rs2228570 contributed to the overall warfarin dose variability by 1.7% out of 42.9% in total.   CONCLUSION This study demonstrated that stable warfarin dose is associated with VDR SNPs in combination as well as VKORC1, CYP2C9, and CYP4F2 .

Identification of novel heart failure plasma biomarkers using the Hybrid Mouse Diversity Panel (HMDP) cardiac transcriptome data. *A. Huertas-Vazquez[1], M. Seldin[1], P. Gupta[1], J. Hsiao[1], G. Stolin[1], A. Lusis[1,2,3], J. Wang[1].* 1) Department of Medicine/Division of Cardiology, David Geffen School of Medicine, University of California, Los Angeles 650 Charles E. Young Drive South. Room A2-237 CHS; 2) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles; 3) Department of Microbiology, Immunology and Molecular Genetics, University of California, Los Angeles.

   Heart Failure (HF) is a heterogeneous condition characterized by a large number of pathological abnormalities with vast differences in outcomes. HF occurs in over 6 million people in the US and it is projected that at least 8 million will have HF by 2030. Therefore, the discovery of novel biomarkers for more accurate and predictive risk assessment remains a priority. The purpose of the study was to identify novel plasma biomarkers for HF by using cardiac transcriptome data. We carried out cardiac transcriptome profiling using Illumina arrays among 100+ mouse strains from the Hybrid Mice Diversity Panel (HMDP), including both, controls and mice sustaining chronic heart injury due to systemic isoproterenol (ISO) treatment. We identified differentially expressed genes using the statistical package LIMMA implemented in R. For further validation, we performed Western blots to evaluate whether the differentially expressed cardiac transcripts were also differentially abundant at the plasma protein level in C57BL/6J mice under control or ISO treatment for 3 weeks. We observed an enrichment for genes known to be involved in HF including *Lgals3*, P=9.73 X 10-22 (galectin-3) and *Timp1*, 1.01 X 10-22 (TIMP metallopeptidase inhibitor 1) as well as newly identified proteins, including rgs1 (regulator of G-protein signaling 1). Based on known transcript abundances in the HMDP, we observed the expected differences in plasma protein expression for LGALS3 and RGS1 between control and ISO treated mice over 3 weeks of ISO treatment. Our findings showed the promise and feasibility of novel biomarker discovery using mice raised in a controlled environment from the HF-HMDP cardiac transcriptome data. The contribution of identified proteins in HF human samples is under investigation.

Gene-alcohol interactions identify novel blood pressure loci in African Ancestry using 1000G imputations: The CHARGE Gene-Lifestyle Interactions Working Group. *M.F. Feitosa[1], A.T. Kraja[1], T. Winkler[2], A.R. Bentley[3], M. Brown[4], K. Schwander[5], Y.J. Sung[5], S.K. Musani[6], S.M. Tajuddin[7], K. Lohman[8], M. Richard[9], T. Bartz[10], N. Franceschini[11], X. Guo[12], E. Fox[6], S.L.R. Kardia[13], C. Rotimi[3], M. Fornage[8], M.A. Province[1], A. Morrison[4] on behalf of the CHARGE Gene-Lifestyle Interactions Working Group.* 1) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, St. Louis, MO; 2) Department of Genetic Epidemiology, University of Regensburg, Regensburg, Germany; 3) Center for Research on Genomics and Global Health, NHGRI, NIH, Bethesda, MD; 4) Department of Epidemiology, Human Genetics, and Environmental Sciences, University of Texas Health Science Center, Houston, TX; 5) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 6) Department of Medicine, University of Mississippi Medical Center, Jackson, MS; 7) Laboratory of Epidemiology and Population Sciences, National Institute on Aging, National Institutes of Health, Baltimore, MD; 8) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 9) Brown Foundation Institute of Molecular Medicine, University of Texas Health Science Center, Houston, TX; 10) Department of Epidemiology, University of Washington, Seattle, WA; 11) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 12) Department of Pediatrics, LABioMed at Harbor-UCLA Medical Center, Torrance, CA; 13) Department of Epidemiology, University of Michigan School of Public Health, Ann Arbor, MI.

Genetic and lifestyle factors and their interactions contribute to the risk for hypertension. Heavy alcohol consumption is associated with high blood pressure (BP) and cardiovascular disease; however, it remains controversial whether light-to-moderate consumption is beneficial or harmful. We performed two genome-wide meta-analyses of SNP-alcohol interactions using two exposure types: current drinker (Yes/No) and, among drinkers, if light (1-7 drinks/week) or heavy (8-more drinks/week) consumption. Our analyses included 21,417 individuals (11,224 non-drinkers and 10,193 current drinkers) from 12 African Ancestry studies. We conducted SNP-alcohol interaction associations on systolic, diastolic, mean arterial, and pulse BPs. Studies calculated the joint 2 degree of freedom test for each SNP and SNP-alcohol interaction effects. We applied study- and meta-based genomic control adjustments. SNP results are reported if: (*a*) minor-allele count >10; (*b*) df>20 (compound statistic for allele frequency, N exposed, imputation quality); (*c*) >50 individuals alcohol-exposed and >5,000 N individuals, (*d*) >2 studies for each SNP, and (*e*) meta-heterogeneity p >0.1. Besides replicating several known BP loci, we identified 18 novel loci for BP (p<5E-08): eight interacting with light-heavy alcohol (*KCNMB2, USP15, DNAJC3, ZMAT4, TACC2, TUSC1, LOC100996669, SP100*), and ten interacting with current alcohol consumption (*CHRM2, LINGO2, PTPRE, GALNT18, FAT3, PCDH9, LDLRAD4, FAM19A2, LINC00689, TCF21*). Our findings show that *CHRM2* (Cholinergic-Receptor, Muscarinic 2) and *LINGO2* (Leucine Rich Repeat And Ig Domain Containing 2), which have been reported in association with alcohol dependence, also interact with alcohol consumption influencing BP. Associations have also been reported with diabetes, glucose metabolism (*ZMAT4, TACC2, LINGO2, GALNT18, FAT3*), heart disease (*TUSC1, TCF21, CHRM2*), angiotensin II receptor blocker response (*TCF21*), neurological psychiatric disorders (*CHRM2, KCNMB2, PTPRE, ZMAT4, GALNT18, FAT3*), and calcium or potassium channel mediation (*FAT3, PTPRE, KCNMB2, CHRM2, PCDH9*). Bioinformatics from GeneGO analyses showed enrichment for urinary tract (p_{FDR}=6.4E-11), heart rhythm (p_{FDR}=2.2E-09) and personality disorders (p_{FDR}=2.1E-07). These findings identify both novel and previously known BP genes which demonstrate significant interactions with alcohol consumption which may provide insights into mechanisms of high BP, therapeutic interventions, and novel drug targets.

675F

Rare coding variants associated with blood pressure in ~16,000 individuals of African ancestry. *P. Nandakumar[1], D. Lee[1], M.A. Richard[2], F. Tekola-Ayele[3], B.O. Tayo[4], E. Ware[5,6], Y.J. Sung[7], B. Salako[8], A. Ogunniyi[8], C.C. Gu[7], M.L. Grove[9], M. Fornage[2], S. Kardia[5], C. Rotimi[3], R.S. Cooper[4], A.C. Morrison[10], G. Ehret[1,11], A. Chakravarti[1].* 1) McKusick - Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Institute of Molecular Medicine and Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 3) Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Department of Public Health Sciences, Stritch School of Medicine, Loyola University Chicago, Maywood, IL; 5) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 6) Institute for Social Research, University of Michigan, Ann Arbor, MI; 7) Division of Biostatistics, Washington University School of Medicine in St. Louis, St. Louis, MO; 8) Department of Medicine, University of Ibadan, Ibadan, Nigeria; 9) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX, USA; 10) Department of Epidemiology, Human Genetics, and Environmental Sciences, University of Texas Health Science Center at Houston, Houston TX; 11) Department of Specialties of Medicine, Geneva University Hospitals, Geneva, Switzerland.

Genome-wide association studies (GWAS) of blood pressure (BP) have implicated common variants at ~80 loci for systolic (SBP) and diastolic (DBP) pressure across multiple populations, but the specific genes involved are unknown. This study focuses on identifying these and other specific genes associated with BP traits in individuals of African ancestry using eight cohorts (AADM, ARIC, CARDIA, GenNet, GENOA, HUFS, HyperGEN, LUC) genotyped on the Illumina HumanExome BeadChip v1.0 (n=247,870 variants) or v1.1 (n=242,901). Data quality control yielded a final set of 15,914 individuals and 170,540 variants for analysis. Fixed-effects meta-analyses were performed with the seqMeta R package for SBP and DBP, each adjusted for age, age-squared, sex, BMI and the first 10 principal components of ancestry from each cohort. These analyses include single variants analyzed by frequency class (common: MAF≥0.05, low frequency: 0.01≤MAF<0.05 and rare: MAF<0.01), gene-based analysis with SKAT and the T1 burden test on variants with MAF<0.01, and those considered "damaging" (intronic splice, NMD-compatible stop-gain, and conserved missense (phyloP>4)), multiple test corrected by the Bonferroni method. **Results**: Associations of rare variants in *COL6A1* (rs150432347, SBP, P=1.19 x 10^{-7}), encoding a collagen VI protein providing structural support in the heart, and *SLC28A3* (rs11568416, SBP, P=8.92 x 10^{-8}), encoding a sodium-dependent nucleoside transporter which may regulate vascular tone, were identified, with 19 and 6 copies across the six cohorts, respectively. Further, associations of rare variants with 2 to 15 carriers in each of *SEL1L3, KRBA1, YOD1, CRYBA2, GAPDHS,* and *AFF1* were identified for SBP and DBP. The T1 burden test on damaging variants identified two significant associations: *CCDC13* (SBP, P=3.54 x 10^{-7}), a centriolar satellite protein playing a role in primary ciliogenesis, relevant to the poor functioning of cilia resulting in weak vascular tone characteristic of polycystic kidney disease; the *QSOX1* gene (DBP, P=3.86 x 10^{-6}) encodes a sulfhydryl oxidase enzyme involved in vascular smooth muscle cell migration and proliferation *in vitro*. These results suggest credible candidate genes for BP regulation in African-ancestry individuals.

676W

Relationship between C-reactive protein serum concentration and the 1846 C>T polymorphism in elderly patients with Acute Coronary Syndrome from Western Mexico. *G.L. Reynoso Villalpando[1,2,3], J.R. Padilla Gutierrez[1,2], A. Valdez Haro[1,2,3], F. Casillas Muñoz[1,2,3], H.E. Flores Salinas[4], J.F. Muñoz Valle[1,2], Y. Valle[1,2].* 1) GENETICS, UNIVERSIDAD DE GUADALAJARA , Guadalajara , Jalisco, Mexico; 2) Instituto de Investigacion en Ciencias Biomedicas; 3) Doctorado en Genetica Humana, Centro universitario de Ciencia Salud, Guadalajara; 4) Unidad Medica de alta especialidad, Centro Medico Nacional de Occidente, Guadalajara.

  Background: C-reactive protein (CRP) is an inflammation biomarker and risk predictor in cardiovascular disease. Variants of the *CRP* gene are associated with serum protein concentration. Current evidence supports a relationship between elevation on CRP concentration and genetic polymorphisms thus increasing risk of Acute Coronary Syndrome (ACS). We evaluate the association between the 1846C>T (rs1205) polymorphism with CRP protein concentration in ACS. Methods: A total of 300 controls and 300 patients with ACS from Western Mexico were included. Genotyping was performed with polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP). High sensitivity CRP concentration (hsCRP) was measured by immunoturbidimetry. For IL-6 measurement we used the Quantikine Human IL-6 Immunoassay (Quantikine ELISA, R&D), a solid phase sandwich ELISA, according to manufacturer instruction. Results: Serum CRP concentration was increased in patients (19.80 mg/L) compared with controls (4.10 mg/L, p=<0.0001). By clinical spectrum, ST-segment elevation myocardial infarction had increased CRP concentration than unstable angina patients (21.8 vs 5.9 mg/L, p=<0.0001). The 1846C>T *CRP* polymorphism was not associated with ACS. However, T/T carriers had lower CRP concentration than C/C (2.5 *vs* 5.1 mg/L, p=0.032) in CG. IL-6 showed a low positive correlation with CRP concentration in ACS and controls (r=0.20-0.44, p<0.05). Conclusion: ACS patients had higher cardiovascular risk as denoted their increased CRP levels. CRP concentration seems to be related with ACS severity. The 1846C>T polymorphism is not a susceptibility genetic marker to ACS in western Mexico population. However, the allele 1846T is associated with lower CRP concentration regardless disease.

677T

Multiple independent variants at the *MCPH1/ANGP2T* locus influence circulating concentrations of serum angiopoietin-2. *S. Salimi[1], K. Ryan[2], V. Thomeas[3], T. Dave[2], J.R. O'Connell[2], J. Perry[2], A.R. Shuldiner[2], M.L. Maitland[3], B.D. Mitchell[2].* 1) Department of Epidemiology and Public Health, University of Maryland School of Medicine; 2) Department of Medicine, Division of Endocrinology, University of Maryland School of Medicine; 3) The University of Chicago Medicine.

  Background Angiopoietin-2 (Ang-2) is an endothelium-derived growth factor and the concentration of Ang-2 [Ang-2] measured in circulation is a candidate biomarker for multiple cardiovascular pathophysiologic processes. To elucidate the underlying genetic determinants of variation in [Ang-2], we performed a genome-wide association (GWA) analysis of serum [Ang-2] in 1,172 healthy Old Order Amish individuals. **Methods:** Subjects were genotyped on the Affymetrix 500K/6.0 platforms and imputed to the 1000G reference panel. Following GWAS, we performed sequential conditional analysis at associated loci to explore whether multiple SNPs contributed independently to residual variation in [Ang-2] after accounting for age, sex, and body mass index. We then identified all SNPs in high linkage disequilibrium with these SNPs and annotated their potential effects on gene function using ROADMAP Epigenomics. **Results:** The heritability of serum [Ang-2] was 0.38, $p < 4×10^{-12}$. On initial GWA analysis, rs2440393, at the *MCPH1/ANGPT2* overlapping locus, was significantly associated with [Ang-2] ($p=3.47×10^{-8}$) with a minor allele frequency of 0.06. This SNP had a 5-fold enrichment in Amish compared to European Caucasians from 1000G. Conditional analysis revealed a total of 3 SNPs at this locus (rs2440393, rs17625642, rs1968586) to be independently associated with [Ang-2] at $p < 0.001$, and these collectively accounted for 20% of the residual variation in [Ang-2]. These SNPs are in high linkage disequilibrium (LD) ($r^2 > 0.8$) with 46, 8 and 2 other SNPs, respectively. The rs2440393 and rs17625642 variants are in high LD with SNPs that are enriched enhancers in 25 and 31 tissues, respectively. The rs2440393 variant was associated with expression levels of multiple genes expressed in peripheral blood monocytes, including *FER, RMND5A, and RNF215* and *DEFA4*. **Conclusion:** Our results suggest that 20% of the variation of serum [Ang-2] is accounted by at least three independent signals at the *MCPH1/ANGPT2* locus. These variants are independently in high LD with numerous other tissue–specific putative functional SNPs with enhancers and DNase activities.

678F

Causal inference of platelet reactivity on cardiovascular disease risk: A Mendelian randomization study. *C. Song, A.D. Johnson, CHARGE Consortium Stroke Working Group.* Framingham Heart Study, Framingham, MA.

Background: Antiplatelet medication, *e.g.*, aspirin, is widely used in the prevention and treatment of cardiovascular disease. However, population studies report conflicting results for the association between variation in baseline platelet reactivity and incident cardiovascular disease (CVD). In this study, we aimed to understand the causal influence platelet reactivity on arterial CVD, including coronary heart disease (CHD) and ischemic stroke using a Mendelian randomization (MR) approach. Methods: Platelet reactivity was determined via platelet rich plasma measures of light transmission aggregometry in the Framingham Heart Study Offspring cohort. Measures included lag time in aggregation to collagen (Type 1 calf skin), and a range of ADP and epinephrine doses. ADP and epinephrine threshold concentrations (EC50) were the minimal concentration of each agonist to produce a >50% aggregation response. We selected the top locus for each platelet reactivity trait from the largest genome-wide association study (GWAS; Johnson et al. *Nat Genet* 2010). Then, we created genetic risk scores for each trait using SNPs from the same locus with low-to-moderate linkage disequilibrium (LD; $r^2 < 0.5$). We used these genetic risk scores as instrumental variables (IV), correcting for LD, in MR analyses. The association between IVs and platelet reactivity traits were obtained from the Framingham Offspring study while the association between IVs and CVD outcomes were obtained from previous Consortia GWAS. We then tested whether elevated platelet reactivity was associated with higher CVD risk by MR using summary statistics. Results: Our results show that shorter collagen lag time, which indicates increased platelet reactivity, had a causal effect on CHD risk [Odds ratio (OR) =2.53; P-value =0.007], but not significant on ischemic stroke risk [OR =2.23; P-value =0.630]. Decreased threshold concentrations of ADP or epinephrine indicate increased platelet reactivity and also showed a similar trend of influence on CHD. Conclusion: Our study indicates that increased platelet reactivity is a causal risk factor for arterial CVD, in line with therapeutic treatment strategies. This highlights potential clinical utility of platelet reactivity tests in early detection of CVD risk, though defining a precise test remains a significant future challenge. Further study is ongoing to understand the causal influence of platelet reactivity on venous CVD.

A gene-by-environment interaction study of peripheral arterial disease identifies novel loci. *N.R. van Zuydam[1,2], M. de Andrade[3], A.I. Stilby[4], E. Vlachopoulou[5], E. Ahlqvist[6], E. Dahlström[7], V. Salomaa[8], A.P. Morris[1,9], C.N.A Palmer[2], J.C. Hopewell[4], H.M. Colhoun[2], I.J. Kullo[3], GoLEAD and SUMMIT.* 1) Wellcome Trust centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Medical Research Institute, University of Dundee, UK; 3) College of Medicine, Mayo Clinic, Rochester MN, USA; 4) CTSU, Nuffield Department of Population Health, University of Oxford, Oxford, UK; 5) University of Helsinki, Finland; 6) Lund University, Malmö, Sweden; 7) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, Helsinki University Central Hospital, Helsinki, Finland; 8) National Institute for Health and Welfare, Helsinki, Finland; 9) Institute of Translational Medicine, University of Liverpool, Liverpool, UK.

Peripheral arterial disease (PAD) affects ~200 million people world-wide and is associated with increased mortality. PAD is a complex, heritable disease (21-58%) that is strongly influenced by environmental factors such as smoking and diabetes. Disease mechanisms remain poorly understood but genetic association studies may provide insights into disease pathology. We aimed to identify novel loci and to assess known loci for PAD over all, and in the context of smoking and diabetes. PAD was defined as atherosclerosis of the lower limbs and controls had no history of PAD. We combined summary statistics from 1000G imputed or CardioMetabochip genotypes, derived from subjects of European ancestry, in a fixed-effects inverse-variance weighted meta-analysis. We performed 3 separate meta-analyses: 1) All subjects (7,942 cases and 176,594 controls); 2) Diabetes stratified (3,228 cases/21,013 controls with diabetes and 4,714 cases /135,581 controls without diabetes); and 3) Smoking stratified (5,759 cases/85,854 controls from ever smokers and 1,782 cases /88,692 controls from never smokers). We tested loci for interaction with diabetes and smoking status. We identified novel loci, at genome-wide significance ($p < 5 \times 10^{-8}$), associated with PAD in all subjects (rs10850034, OR[95%CI]=1.18[1.11-1.24], $p=2 \times 10^{-11}$, near *HECTD4*) and in non-smokers (rs10894808, OR[95%CI]=1.43[1.31-1.55], $p=2 \times 10^{-8}$, $phet=2 \times 10^{-7}$) near *B3GAT1*. Rs10850034 is a proxy for rs11066301 ($r^2=0.97$), a locus associated with haemoglobin concentrations and haematocrit ($p=8 \times 10^{-12}$). Rs10894808 is an eQTL for *B3GAT1* in lung and pituitary tissues ($p < 3 \times 10^{-8}$). We detected associations for known PAD loci: rs10738610 (OR[95%CI]=1.16[1.12-1.21], $p=5 \times 10^{-16}$), in the 9p21.3 region; rs951266 (OR[95%CI]=1.13[1.09-1.17], $p=2 \times 10^{-8}$), an eQTL for *CHRNA5* in a range of tissues including tibial nerve and skeletal muscle ($p < 2 \times 10^{-13}$); and rs10455872 (OR[95%CI]=1.31[1.24-1.39], $p=2 \times 10^{-12}$), near *LPA*. We present the largest genetic study of PAD that identifies two novel loci, one specific to non-smokers with evidence of a smoking interaction, and strengthens the association of three known loci. Some loci are linked to gene expression, pointing to potential effector transcripts for experimental follow-up.

680T

Gene, gender, environment interactions between serum homocysteine and rs1801133 polymorphisms of methylenetetrahydrofolate reductase (MTHFR). *X. Xu[1], J.C. Lovejoy[1,2], A.T. Magis[1].* 1) Arivale Inc., 710 2nd Avenue, Suite 410, Seattle, WA, 98104; 2) Institute for Systems Biology, 401 Terry Ave N, Seattle, WA 98109.

  Background: MTHFR is the rate-limiting enzyme in S-adenosyl-methionine biosynthesis and regeneration cycle, catalyzing the re-methylation of homocysteine to methionine. Hyperhomocysteinemia leads to endothelial cell injury and blood vessel inflammation, which greatly increases the risk of cardiovascular events. Genetic mutations in *MTHFR* are the most commonly known inherited risk factor for elevated homocysteine levels. The aim of this study was to assess the effect of MTHFR variants on homocysteine levels, and to explore potential interaction patterns. **Methods and Results:** 656 individuals (51.4% females, 94.2% whites, average age: 51.3 years, body mass index-BMI: 26.3 kg/m^2) were recruited from the general population in Seattle, WA, and were offered standard lifestyle intervention (i.e., exercise and nutritional counseling) beginning July 2015. Serum homocysteine level was measured up to 3 times (T1, T2, T3) over a 12-month period (average time interval: 6-month). Significant decreases were observed following supplementation with active methyltetrahydrafolate (MTHF) (T1: 10.8 umol/L, T2: 10.0 umol/L, T3: 9.8 umol/L, p<0.01). *MTHFR* rs1801133 C/T was detected by qPCR, with genotype frequency of TT 10.2% and CT 42.2% in the cohort. Generalized estimating equation accounting for within-individual correlations over time was used to examine the relationships and interactions, adjusted for age, BMI and lab vendor. No main effect of *MTHFR* genotype on homocysteine level was found. However, a significant gene-by-gender interaction was observed (p<0.01). In males, TT homozygotes had lower homocysteine level than CT+CC group (i.e., T1: 11.0 vs. 12.1 umol/L). Whereas, female TT homozygotes had significantly higher level than women carrying one or no T allele (i.e., T1: 10.1 vs. 9.6 umol/L). Further longitudinal analysis identified a gene-by-environment interaction pattern (rs1801133*time^2, p<0.01). Compared to CC group, T-carriers exhibited a faster decrease with MTHF supplementation from T1 to T2. Additionally, a gender-gene-environment interaction (rs1801133*gender*time) also occurred (p<0.01), with males carrying T-alleles exhibited the largest-trajectory of homocysteine change from T1 to T3. **Conclusion:** We observed significant gene, gender, environment interactions between *MTHFR* rs1801133 variation and homocysteine levels, which seems to affect trajectories in participants exposed to lifestyle interventions.

681F

Copy number variants in the nuclear genome and mitochondrial copy number. *N. Pankratz[1], J. Lane[1], D. Arking[2], R. Longchamps[2].* 1) Dept Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 2) Mckusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

  Introduction: Mitochondrial DNA copy number (mtDNA CN), which is a surrogate measure of mitochondrial function, declines with age and is associated with multiple traits and outcomes, including all-cause mortality. Heritability estimates for mtDNA range from 35-65%, indicating that these levels are under genetic control. In the present study, we have performed a genome-wide association study in the ARIC study to search for copy number variants (CNVs) that are associated with mtDNA CN. Methods: A raw estimate for mitochondrial copy number (mtDNA CN) was obtained from the median log R ratio (LRR) of mitochondrial markers on the Affymetrix 6.0 SNP array. To correct for batch effects, total amount of nuclear DNA, and sample quality, we performed a principal component analysis (PCA) of LRR on select autosomal markers and regressed out the most informative PCs. This method has been implemented in Genvisis (http://www.genvisis.org), and there is evidence that it may be more accurate than qPCR derived estimates. Estimates were further adjusted for age, sex, study center, and smoking status before being inverse normalized. Nuclear copy number variants (CNVs) were typed in the 9,312 samples of European Ancestry that had high quality intensity data (standard deviation of LRR < 0.35 and call rate > 0.96). CNVs were called on PC-corrected LRRs using PennCNV, filtered down to a high quality set of large (>200kb) variants using Genvisis, and underwent genome-wide segmental analyses using PLINK. Results: While no region reached genome-wide significance, the top two ranking genes (*TFB1M* and *MTHFD2*) are both known to localize to the mitochondria. A large duplication surrounding the *TFB1M* gene, which is known to be involved in mitochondrial biogenesis, led to a mtDNA CN estimate that was 3.0 SD above the population mean. Conclusions: The genetic mechanisms influencing mtDNA CN are not well known, however genome-wide analyses such as these may shed some light on the genetic factors influencing this trait. Since deleting or duplicating a gene will often lead to a powerful loss of function or gain of function, these events are likely rare due to natural selection, and therefore a genome-wide significant association might only be achieved through the meta-analysis of a hundred thousand samples.

682W

Exome-wide association analysis of cardiac structural traits in a large healthcare provider organization identifies genetic heterogeneity underlying left ventricular structure and overlapping genetic architecture with cardiomyopathy genes. *J.H. Chung[1], J. Robishaw[2], C. O'Dushlaine[1], R. Metpally[2], H.L. Kirchner[2], N.A. Manus[2], D. Hartzel[2], A. Lopez[1], J. Penn[1], J.D. Overton[1], J.G. Reid[1], A.R. Shuldiner[1], A. Baras[1], I. Borecki[1], O. Gottesman[1], V. Mehra[2], F.E. Dewey[1].* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

Understanding the genetic architecture of human cardiac structure can aid in the treatment of diseases related to abnormal structure and function, such as cardiomyopathy (CM). Previous studies of left ventricular (LV) structure have identified several candidate loci but were limited to common variants which may not be causal. Whole exome sequencing could reveal causal protein-coding variation. We performed an exome-wide association study (EXWAS) in a large clinical population with echocardiographic traits in the Regeneron Genetics Center-Geisinger Health System DiscovEHR study. We analyzed 6 LV traits from echocardiographic data captured in electronic health records in 10,639 individuals without ischemic heart disease. Association tests were performed for single variants with minor allele count ≥ 10 using linear mixed models adjusted for age, height, sex, systolic blood pressure, ancestry, and genetic relatedness. We also performed gene-burden association of rare (minor allele frequency [MAF] ≤ 0.01) predicted loss-of-function (pLOF) variants for all genes with ≥ 4 pLOF carriers. We found 6 variants in 5 genes and 11 variants in 11 genes with exome-wide (P ≤ 1E-7) and suggestive (P ≤ 1E-6) association, respectively. The top locus was rs75431703, a synonymous variant in *PLEKHG4B*, associated with LV mass (P = 6.7E-11, β = 106.5 ± 16.3g, MAF = 7E-4). We also found rs2234962, a missense variant in *BAG3* found to be protective for dilated cardiomyopathy (DCM), associated with LV internal diameter (LVIDd) (P = 3.3E-08, β = -0.064 ± 0.013cm, MAF = 0.2). Gene-burden analysis found 3 and 8 genes with gene-wise (P ≤ 1E-6) and suggestive (P ≤ 1E-5) associations, respectively. The top finding was for *SPON2*, an extracellular matrix protein, with interventricular septum thickness (P = 4.2E-8, β = 0.536 ± 0.098cm). pLOFs in TTN, a cardiac structural protein implicated in DCM, were associated with LVIDd (P = 1.0E-07, β = 0.26 ± 0.05cm). Overall, there was a high degree of genetic heterogeneity with 14/17 variants and 10/11 genes associated with a single trait, most of which were novel. In the largest EXWAS of cardiac structural traits to date, we found exome-wide significant associations with 6 variants and 3 genes with LV structure; two of which were in familial CM genes. These results suggest a high degree of genetic heterogeneity underlying cardiac structure in humans, and shared genetic architecture between rare coding variation in large populations and familial CM.

683T

Rare Variants in Fox-1 homolog A (*RBFOX1*) are protectively associated with blood pressure. *K.Y. He[1], H. Wang[1], B.E. Cade[2,3], P. Nandakumar[4], A. Giri[5], E.B. Ware[6,7], J. Haessler[8], J. Liang[1], J.A. Smith[7], N. Franceschini[9], C. Kooperberg[8], T.L. Edwards[5], S.L.R. Kardia[7], X. Lin[10], A. Chakravarti[4], S. Redline[2,3,11], X. Zhu[1].* 1) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Division of Sleep and Circadian Disorders, Brigham and Women's Hospital, Boston, MA; 3) Division of Sleep Medicine, Harvard Medical School, Boston, MA; 4) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 5) Division of Epidemiology, Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 6) Biosocial Methods Collaborative, Institute for Social Research, University of Michigan, Ann Arbor, MI; 7) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI; 8) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 9) Department of Epidemiology, UNC Gillings School of Global Public Health, Chapel Hill, NC; 10) Department of Biostatistics, Harvard T.H. Hypertension is a risk factor for cardiovascular diseases and the most important risk factor for stroke. Family studies suggest that hypertension related traits are heritable. Many genome-wide association studies (GWAS) have identified common blood pressure (BP) variants; however, each variant only accounts for a small amount of variation in BP. In particular, many BP variants identified by large, powerful genome-wide association studies do not overlap with the linkage evidence observed from family studies. In this study, we performed linkage analysis using 517 individuals in 130 European families from the Cleveland Family Study (CFS) who have been genotyped by Illumina OmniExpress Exome array. The largest linkage peak was observed on chromosome 16p13 (MLOD=2.81) for systolic blood pressure (SBP). Follow-up conditional linkage and association analyses in the linkage region identified multiple rare, coding variants in *RBFOX1* to be protectively associated with SBP. In a 17-member CFS family, carriers of a missense variant rs149974858 are normotensive even though their BMIs were extremely high (average BMI=60). Gene-based association of rare variants using SKAT-O showed significant association with SBP (p-value=0.00403) and DBP (p-value=0.0258) in the discovery data set and the association was further observed in large independent European replication cohorts (N=57,234, p-value=0.013 for SBP, 0.0023 for PP). These rare exonic variants are not polymorphic in African ancestry populations and they may contribute to the hypertension disparity between African Americans and European Americans. *RBFOX1* is expressed in multiple brain tissues, as well as the atrial appendage and left ventricle in the heart, and skeletal muscle tissues, which are highly related to blood pressure. Our study showed that associations of rare, functional variants could be detected using family information with blood pressure traits in the discovery family data.

Venous thromboembolism (VTE) is the collective term for deep vein thrombosis (DVT) and its life-threatening complication pulmonary embolism (PE). Between 300,000-600,000 Americans are diagnosed with VTE every year, and it has been suggested that 60,000-100,000 Americans die of VTE annually. Observational studies have shown an association between obesity and venous thromboembolism (VTE) but it is not known if observed associations are causal, due to reverse causation or confounding bias. We leveraged information from two recent genome-wide association studies (GWAS) of childhood and adult body mass index (BMI) to explore the causal relationship between childhood and adult obesity and adult VTE. Using a two-sample Mendelian Randomization (MR) approach, we assessed the associations of 15 childhood BMI single nucleotide polymorphisms (SNPs) and 95 adult BMI SNPs in a VTE study comprising 7,507 cases and 52,632 controls. We observed a significant association between genetically predicted childhood BMI as defined by a composite risk score and VTE (OR: 1.30, 95% CI: 1.03-1.63 per s.d. increase in childhood BMI, p=0.02). The overall association between genetically predicted adult BMI and VTE was 1.59 per s.d. increase in adult BMI (95% CI: 1.30-1.93, p=5.8x10⁻⁶). We reran the analysis including only the 75 SNPs found to be genome-wide significant in European ancestry individuals only and observed a similar association (OR=1.58, 95% CI: 1.28-1.95 per s.d. increase in BMI, p=2.02x10⁻⁵). In sensitivity analysis, we removed 10 SNPs that have been associated with both childhood and adult BMI, leaving five SNPs for childhood BMI and 90 SNPs for adult BMI. After removal of the overlapping SNPs, the childhood BMI-VTE association was no longer apparent (OR= 1.17, 95% CI: 0.74-1.87 per s.d. increase in BMI, p=0.50), whereas the results for adult BMI remained largely unchanged (OR=1.54, 95% CI: 1.21-1.96 per s.d. increase in BMI, p=0.0005). Thus, our overall results supporting a causal link between childhood BMI and VTE should be interpreted with caution, but it is possible that the lack of association observed when removing adult BMI SNPs is due to low statistical power. In summary, our results show evidence for a causal association between higher BMI and VTE, lending support to previous observational studies.

685W

Defining updated risk profiles by linking contemporary cohorts with historical cohorts based on shared genetics. *J.D. Mosley[1], S.L. Van Driest[1,2], Q.S. Wells[1], C.M. Shaffer[1], T.L. Background: Longitudinal studies have identified and validated many risk factors for chronic diseases, and management of these factors has led to declines in morbidity and mortality. Limitations of longitudinal studies include long latencies and high costs. We hypothesized that we could use genetic correlations, which quantitate the shared genetic architectures of phenotype pairs, to efficiently define updated risk profiles for a contemporary cohort using risk factors measured in a historical prospective study. **Methods:** We used 37 baseline risk factors measured in the Atherosclerosis Risk in Communities (ARIC) study (n=7,716 European ancestry subjects) and cases and controls for type 2 diabetes (T2D) (1,321 cases and 6,395 controls) and ischemic heart disease (IHD) (5,114 cases and 8,789 controls) from a contemporary electronic health record (EHR) data set (n=19,093 EAs). We measured pairwise genetic correlations (rG) between the ARIC and EHR phenotypes using linear mixed models and compared these rG estimates to hazard ratio estimates for longitudinal outcomes of incident T2D and IHD within the ARIC population. **Results:** For T2D, the rG estimates were strongly correlated with hazard ratio estimates (Pearson's correlation [r]=0.8), indicating that the EHR and ARIC T2D phenotypes have similar risk profiles. The linear correlation between these measures was weaker when comparing the EHR to ARIC IHD phenotype (r=0.6), suggesting that the phenotypes have differing risk profiles. The EHR IHD phenotype was most strongly genetically correlated with ARIC metabolic risk factors including total-to-HDL cholesterol ratio (rG=-0.44, p=0.005), HDL (rG=-0.48, p=0.005), systolic blood pressure (rG=0.44, p=0.02) and triglycerides (rG=0.38, p=0.02). We measured genetic correlations between these 4 ARIC IHD risk factors and 158 EHR-derived diagnoses, and found they were significantly genetically correlated with T2D and atherosclerotic and hypertension-related disease. **Conclusions:** Genetic correlations measured across populations were linearly correlated with longitudinal hazard ratio estimates for T2D and IHD. For IHD, contemporary treatment and prevention efforts in the EHR population should target hypertensive and metabolic disease. Linking outcomes from EHR data sets with biomarkers from epidemiological cohorts using genetic correlations will facilitate the identification of risk factors without decades of follow-up.

686T

Missense variant in *GDF15* explains 3.7-5.3% of the variance in GDF-15 in two large CV outcome trials. *N. Eriksson[1], A. Johansson[2], B.J. Barratt[3], R.C. Becker[4], A. Budaj[5], E. Background: Growth differentiation factor 15 (GDF-15) is an independent prognostic biomarker for cardiovascular events and major bleeding during antithrombotic treatment. Whether there is a causal association between GDF-15 and clinical outcomes is still unknown. Genetic markers located in *GDF15* are associated with altered circulating GDF-15 concentrations. In this meta-analysis, we assess the genetic effects on GDF-15 in 19,910 patients from two large cardiovascular outcome trials. **Methods:** GWAS was performed in 10,013 patients from the PLATelet inhibition and patient Outcomes study (PLATO, ClinicalTrials.gov number, NCT00391872) and 10,788 patients from the Stabilization of Atherosclerotic Plaque by Initiation of Darapladib Therapy trial (STABILITY, ClinicalTrials.gov number, NCT00799903). Genotype data was generated on the Illumina HumanOmni2.5 and OmniExpressExome arrays. In total 9,448 patients from PLATO and 10,462 patients from STABILITY passed QC and had GDF-15 measurements available at baseline. Imputation was performed using 1000 genomes as reference. GWAS analyses of GDF-15 were performed study wise using PLINK, adjusted for established cardiovascular risk factors and genetic principal components and meta-analyzed using PLINK. Analyses were performed sequentially adjusting for each genome-wide significant variant until no signals were left. **Results:** Overall the median (interquartile range) level of GDF-15 was 1528 (1139 – 2144) in PLATO and 1248 (909 – 1814) ng/L in STABILITY. Within each study we identified three independent genome-wide significant SNPs associated with log(GDF-15). All were within or close to the *GDF15* gene on chromosome 19 with the top hit in PLATO being rs17725099 (PLATO beta=0.161, p=1.47×10^{-107}, STABILITY beta=0.187, p=3.06×10^{-158}). Combining the GWAS results in a meta-analysis pinpointed the missense variant rs1058587 (beta=0.179, p =2.36×10^{-270}) in *GDF15* as the driving variant of the top signaling cluster of SNPs. Follow-up analyses adjusting for rs1058587 gave additional signals. The top hit SNP rs1058587 explained 3.7% and 5.3% of the variation in log(GDF-15) and the increase in median GDF-15 from the major genotype C/C to the minor G/G was 36% (1406 to 1918 ng/L) and 48% (1121 to 1663 ng/L) in PLATO and STABILITY, respectively. **Conclusion:** We identified a missense SNP affecting GDF-15 concentrations. The SNP explained up to 5.3% of the variance in GDF-15 and may be suitable for future Mendelian randomization analyses.

Functional enrichment analysis of genome-wide association study identifies novel pathways influencing blood pressure in African Americans. *J. Liang, COGENT-BP Consortium of African Ancestry.* Wolstein Research BLDG, Rm 1306, Case Western Reserve University, Cleveland, OH.

Blood pressure (BP) is a highly heritable trait influenced by many biological pathways and functional categories encoded in the genome. Individuals of African ancestry share a disproportionate burden of hypertension and its complications compare to other ethnic groups in the U.S. To better understand the biological pathways and functional categories of the genome, we performed meta-analyses of BP genome-wide association studies (GWAS) of 31,968 individuals of African ancestry from 21 studies using high density imputed genotypes from the 1000 Genomes Project for gene discovery. We further explored genetic contributions of BP traits with respect to the functions involved. We used the Meta-Analysis Gene-Set Enrichment variaNT Association (MAGENTA) software on the GWAS data from systolic BP (SBP), diastolic BP (DBP), pulse pressure (PP) and hypertension (HTN) to identify GSK3 pathway ($P_{GWAS-GSEA}$ =1.2×10^{-3} for SBP), Th1/Th2 immune pathway ($P_{GWAS-GSEA}$ =1.6×10^{-3} for DBP) and SHH pathway ($P_{GWAS-GSEA}$ =2.1×10^{-3} for HTN) using the BIOCARTA database, and membrane depolarization ($P_{GWAS-GSEA}$ =6.0×10^{-4} for DBP), regulation of BP ($P_{GWAS-GSEA}$ =6.0×10^{-4} for SBP) and histone deacetylation ($P_{GWAS-GSEA}$ =7.0×10^{-4} for PP) using the GOTERM database, as the most significantly enriched biological pathways. Functional annotation and cell-type group enrichment analysis were performed using a stratified LD score regression method by partitioning heritability from GWAS summary statistics of the four BP traits while accounting for linkage disequilibrium among markers. For functional categories enrichment, super enhancer (P_{Enrich} = 6.6×10^{-6} for DBP), enhancer (P_{Enrich} = 3.8×10^{-4} for SBP) and H3K27ac (P_{Enrich} = 9.0×10^{-4} for HTN) are significantly enriched passing the multiple test threshold. For cell types enrichment analysis, immune (P_{Enrich} = 1.4×10^{-9} for DBP), kidney (P_{Enrich} = 2.4×10^{-6} for DBP) and cardiovascular (P_{Enrich} = 2.3×10^{-5} for SBP) are the three most significantly enriched systems. Our findings from analyzing pathway and functional elements enrichment using African American BP GWASs data suggest novel pathways for BP regulation in a highly susceptible population to hypertension.

688W

Meta-analysis of genome-wide association studies in different ethnicities identifies new loci regulating Factor VII, Factor VIII and von Willebrand factor. *M. Sabater-Lleal[1], P.S. de Vries[2], J. Marten[3], J.E. Huffman[4], C.J. O'Donnell[4], N.L. Smith[5,6], CHARGE Hemostatic Working Group.* 1) Cardiovascular Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 3) MRC Human Genetics Unit, IGMM, University of Edinburgh, Edinburgh, United Kingdom; 4) National Heart, Lung, and Blood Institute, Framingham, MA; The Framingham Heart Study, NHLBI Population Sciences Branch, Framingham, MA; 5) Seattle Epidemiologic Research and Information Center, Veterans Affairs Office of Research and Development, Seattle, WA; 6) University of Washington, Seattle, WA.

  Background: Coagulation Factors VII (FVII), VIII (FVIII) and von Willebrand factor (vWF) are relevant proteins in hemostasis that have been strongly associated to risk of thrombosis and hemorrhagic disorders. In the present study we aim to identify novel loci regulating plasma levels of FVII, FVIII and vWF by meta-analyzing GWAS results from up to 46,232 individuals of different ethnicities.**Methods:** All cohorts performed linear regression analysis according to an additive model of inheritance between genome-wide 1000 Genomes imputed SNPs (about 14 million markers after filtering) and phenotype levels, with adjustments for age, sex, and ancestry-informative principal components. Case/control status, family structure and other cohort-specific covariates were added when necessary. Individuals of European, African, Asian, and Hispanic ancestry were included, and separate analyses were run for each ethnicity.**Results:** We identified significant associations with vWF at loci near *ABO, vWF, STXBP5, STAB2, SCARA5, TCN2, FCHO2, TAB1, HLA-C, STX2, CLEC4M, SYNGR1, ST3GAL4, SLC39A8, DAB2IP, PXK, GIMAP7, C2CD4B,* and *OR13C5,* the first 9 representing overlapping loci between the FVIII and vWF phenotypes. Among these, *FCHO2, SYNGR1/TAB1, ST3GAL4/KIRREL3, BANK1/SLC39A8* (near *NFKB1), DAB2IP, HLA* region*, PXK, GIMAP* gene cluster, and *C2CD4B* represent novel findings. Three novel loci, located near *SOX17* gene and two non-coding RNA respectively, were uniquely associated with FVIII. For FVII levels, loci containing *F7, PROC, GCKR, MS4A5A* and *ADH4* represented replications of previously described loci, whereas 2 loci were novel, near *REEP3* and *TBL2.***Conclusions:** Our study represents the largest meta-analysis to unravel genetic determinants of FVII, FVIII and vWF and identify novel genetic determinants regulating plasma levels of these proteins. Our preliminary results show limited relevance of rare variation in the regulation of these phenotypes. Functional characterization of the novel loci regulating these proteins might reveal interesting new therapeutic targets for thrombosis and bleeding disorders.

Genotype-phenotype in Marfan syndrome patients with causative mutations from the 6 cysteines in the 43 cbEGF-like domains in fibrillin-1 (FBN1). *J.A. Aragon-Martin[1], D. Akinfenwa[1], Y. Isekame[1], C.S. Gracias[1], Y.B.A. Wan[1], P. Mazadza[1], T. Thayalacumar[1], G. Arno[2], A. Chandra[3], D.G. Charteris[4], A. Saggar[5], M. Jahangiri[6], M.T. Tome Esteban[1], A.H. Child[1].* 1) Cardiovascular Sciences Research Centre, St George's University of London, London, England, United Kingdom; 2) Institute of Ophthalmology, University College London, London, United Kingdom; 3) Southend University Hospital, Southend on Sea, United Kingdom; 4) Vitreoretinal Surgery, Moorfields Eye Hospital, London, United Kingdom; 5) Clinical Developmental Sciences, St George's University of London, London, United Kingdom; 6) Department of Cardiothoracic Surgery, St. George's Healthcare NHS Trust, Cranmer Terrace, London SW17 0RE, United Kingdom.

  Background: Marfan syndrome (MFS) is an autosomal dominant connective tissue condition (OMIM #154700) that is phenotypically heterogeneous [cardiovascular (Thoracic Aortic Aneurysm – TAA), ocular (Ectopia Lentis – EL), skeletal (Scoliosis)] and is reported to be due to mutations in the *FBN1* gene. Through out the FBN1 protein there are 43 cbEGF-like domains, which contains 6 highly conserved cysteine residues that form disulphide bonds between themselves: C1-C3, C2-C4 and C5-C6. Calcium ions play a key role in the stability of these domains and increase resistance to proteolysis degradation. Methods: Patients (n=101) with mutations in one of the 6 cysteine residues in any of the 43 cbEGF-like domains were entered in the study. Clinical data was obtained from the Marfan clinic at St George's Hospital and the genotypes from the *FBN1* mutation-screening database in Sonalee Laboratory. A genotype-phenotype database was created with this data. Results: This study found that MFS phenotypes may arise due to mutations in any of the 6 cysteine residues: – C1 showed Skeletal (82%), EL (65%), TAA (47%); – C2 showed Skeletal (75%), TAA (69%), EL (38%); – C3 showed TAA (57%), EL (50%), Skeletal (50%); – C4 showed TAA & EL (56%), Skeletal (44%); – C5 showed TAA (79%), Skeletal (71%), EL (57%); – C6 showed Skeletal (94%), EL (83%), TAA (61%); – C1^C3 showed Skeletal (68%), EL (58%), TAA (52%); – C2^C4 showed Skeletal & TAA (64%), EL (44%); – C5^C6 showed Skeletal (84%), EL (72%), TAA (69%); – C1_C6 showed Skeletal (89%), EL (74%), TAA (54%). Data showed that phenotypes found in cysteine residues of the cbEGF-like domains were Skeletal (73%), TAA (61%), EL (59%). Females were more likely to have Skeletal (58%) or EL (64%) phenotypes than men TAA (52%) phenotypes. Conclusions: Not counting skeletal phenotypes, the study shows a strong genotype-phenotype relationship with mutations in C1 & C6 with EL and C2 & C5 with TAA. When combining data from C1^C3 + C5^C6 the strongest association was with EL & C2^C4 with TAA. This maybe due to the proximity of C1^C3 + C5^C6 to the calcium binding region and it could have less influence in a TAA phenotype. The different phenotypes arising from mutations in the cysteine could be due to a random assembly of these bonds in the protein. Instability of the calcium binding region due to mutations in cysteine from cbEGF-like domains are more likely to express an EL than a TAA phenotype, but the risk of TAA is till very high.

Genetic correlation of cardiovascular and metabolic traits with anthropometric measures in the Busselton Health Study. *G. Cadby[1], P.E. Melton[1], N.S. McCarthy[1], J. Hui[2,3], J. Beilby[2,3], A.W. Musk[2,4,6], A.L. James[2,5,6], J. Hung[6,7], J. Blangero[8], E.K. Moses[1].* 1) The Curtin UWA Centre for Genetic Origins of Health and Disease, Curtin University and The University of Western Australia, Western Australia; 2) Busselton Population Medical Research Institute Inc, Western Australia; 3) PathWest Laboratory Medicine WA, Western Australia; 4) Department of Respiratory Medicine, Sir Charles Gairdner Hospital, Western Australia; 5) Department of Pulmonary Physiology and Sleep Medicine, Sir Charles Gairdner Hospital, Western Australia; 6) School of Medicine and Pharmacology, The University of Western Australia, Western Australia; 7) Department of Cardiovascular Medicine, Sir Charles Gairdner Hospital, Western Australia; 8) South Texas Diabetes and Obesity Institute, The University of Texas Rio Grande Valley, Texas.

Anthropometric measures genetically correlated with cardiovascular (CVD) and metabolic traits may provide insight into their pathways and aetiologies. Using subjects from the Busselton Health Study (n=4671), we employed empirically derived identity by descent (IBD) measures to estimate the genetic correlation between CVD and metabolic traits (HDL-C, LDL-C, triglycerides, insulin, total cholesterol, coronary heart disease and diabetes) and anthropometric measures (BMI, waist-hip ratio, weight, and abdominal, arm, thigh, calf and neck circumferences). IBD estimates were derived from genome-wide data using LDAK and genetic correlations were calculated in GCTA. Transformed residuals (after adjustment by age and sex) were used in all analyses. For significantly associated genetic correlations, anthropometric measures were also adjusted by BMI to determine whether the correlation was independent of obesity. We used the false discovery rate to correct for multiple testing, with q≤0.05 considered statistically significant. Diabetes was genetically correlated with BMI (r_g=0.59) and abdominal circumference (r_g=0.63). Coronary heart disease was genetically correlated only with arm circumference (r_g=0.55). HDL, triglycerides and insulin were genetically correlated with BMI (HDL r_g=-0.29; triglycerides r_g=0.28; insulin r_g=0.57), waist-hip ratio (HDL r_g=-0.38; triglycerides r_g=0.42; insulin r_g=0.57) and circumference of the abdomen (HDL r_g=-0.33; triglycerides r_g=0.42; insulin r_g=0.77) and arm (HDL r_g=-0.29; triglycerides r_g=0.31; insulin r_g=0.57). LDL and total cholesterol were not genetically correlated with any anthropometric measure. After adjustment for BMI, three genetic correlations remained statistically significant: waist-hip ratio and triglycerides (r_g=0.26); waist-hip ratio and HDL (r_g=-0.23); abdominal circumference and insulin (r_g=0.26). These results reveal that the genetic correlation between CVD and metabolic traits and anthropometric measures are largely due to the role of obesity. However, central adiposity, rather than obesity, remains genetically correlated with these traits, indicating possible pleiotropic genes that affect both central adiposity and CVD and metabolic traits.

691W

Pharmacogenetics of time to Acute Coronary Syndrome recurrence (PhACS): A UK cohort study. *P. Yin[1], A. Jorgensen[1], A. Morris[1], R. Turner[2], R. Fitzgerald[2], R. Stables[3], A. Hanson[2], M. Pirmohamed[2].* 1) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom; 2) Department of Molecular & Clinical Pharmacology, University of Liverpool, United Kingdom; 3) Liverpool Heart and Chest Hospital, United Kingdom.

Coronary heart disease is a major global public health burden. It is a recurrent disease that is treated by multiple drugs, including aspirin, clopidogrel, statins, beta-blockers, ACE inhibitors and aldosterone antagonist. There is significant inter-patient variability in the response to cardiovascular drugs, which may have a heritable basis. We have therefore undertaken a genome-wide association study to identify loci associated with response to cardiovascular drugs in 1470 patients recruited to a UK prospective pharmacogenetic study of acute coronary syndrome (ACS). Index hospital admission was defined non-ST elevation acute coronary syndrome. Patients were treated with a range of cardiovascular drugs and followed up prospectively for up to 5 years from hospital discharge. Despite treatment, approximately 14% of patients had recurrence of ACS during the following up, defined by myocardial infarction (MI), stroke or cardiovascular death. We began by considering clinical risk factors for response to cardiovascular drugs (time to recurrence of ACS) in a Cox proportional hazard regression framework. Several risk factors were nominally related (p<0.05): age (p=1.3x10^{-14}), body mass index (p=0.015), prior MI (p=2.1 x10^{-8}), ACE inhibitor use pre-admission (p=0.0049), and aldosterone antagonist use (p=0.0058). Patients were genotyped using the Illumina Omni Express array. After quality control, the genotype scaffold was imputed up to the 1000 Genomes Phase I reference panel (all ancestries, March 2012 release). We tested for the association of SNPs with time to event under an additive dosage model after adjusting for the clinical factors identified above and principal components to account for population structure. We identified a genotyped intronic variant (rs2660044) in the *CTNNA3* gene with strong evidence of association: minor allele frequency 0.15, hazard ratio (95% confidence interval) 2.47 (1.67-3.65), p=3.4 x10^{-7}. This gene encodes a protein that plays a role in cell-cell adhesion in muscle cells. Mutations in this gene are associated with arrhythmogenic right ventricular dysplasia, familial 13. Our study highlights that variants mapping to *CTNNA3* are associated with response to cardiovascular drugs in ACS recurrence time. .

Genetic factors predicting Lp-PLA₂ activity and their association with cardiovascular-related mortality and morbidity. *M.K. Siddiqui[1], G. Kennedy[2], F. Carr[1], A. Doney[1], C.N.A. Palmer[1].* 1) Molecular and Clinical Medicine, University of Dundee, Dundee, United Kingdom; 2) Immunoassay Biomarker Core Laboratory, Ninewells Hospital & Medical School Dundee, United Kingdom.

Lipoprotein-associated phospholipase A₂ (Lp-PLA₂), is a vascular-specific, proinflammatory enzyme that is known to increase the risk of CVD events and stroke. Chu *et al.* conducted a meta-analysis of genome-wide association studies across the CHARGE consortium and JUPITER study to identify genetic variants associated with the mass and activity of the enzyme. We sought to replicate the findings in a cohort of 7,000 Scottish Caucasian individuals in the GoDARTS study for whom Lp-PLA₂ activity levels had been measured. We replicate one of five loci associated with Lp-PLA₂ mass and eight of nine loci associated with Lp-PLA₂ activity, with the ninth variant showing borderline significance ($p = 0.07$). Notably, the variants in *PLA2G7* (rs1362931, $\beta = 3.24$, $P = 4 \times 10^{-5}$) and *APOC1-APOE* (rs7412, $\beta = -7.4$, $P = 2 \times 10^{-10}$ and rs445925, $\beta = -5.0$, $P = 1.6 \times 10^{-6}$) were strongly associated with Lp-PLA₂ activity in models adjusted for BMI, age, sex and smoking status, similar to the original study. In context of Lp-PLA₂'s role in cardiovascular health, we decided to examine the impact of these variants on related mortality and morbidity. We classified statin users who were subsequently hospitalized due to an ischemic event or coronary artery disease or had the same events recorded as their cause of death, as having statin failure. We find the variant in *PLA2G7* is associated with this outcome, both cross-sectionally and longitudinally. In the highest quartile of Lp-PLA₂ levels homozygous carriers of the variant (T/T) had 1.7 times the hazards of having statin failure compared to homozygous carriers of the ancestral allele (p value = 0.035).

693F

Fine-scale genetic population structure and genetic risk for coronary artery disease in Finland. *S. Kerminen[1], I. Surakka[1], A-P. Sarin[1], E. Tikkanen[1], G. Hellenthal[2], A. Havulinna[3], M. Perola[3], V. Salomaa[3], S. Ripatti[1], M. Pirinen[1].* 1) Institute for Molecular Medicine Finland, Helsinki, Finland; 2) University College London, London, UK; 3) National Institute of Health and Welfare, Helsinki, Finland.

Finland is known for its relatively small founder population and strong genetic isolation, which have made it a valuable source for genetic studies of diseases and traits. Previous studies of Finnish population structure have reported genetic differences between South-West (SW) and North-East (NE) Finland and a similar division can be seen, e.g., in the incidence of coronary artery disease (CAD). Here we refine the current knowledge of the genetic structure in Finland and study whether it explains regional differences in the incidence of CAD. We identify Finnish population structure by applying haplotype-based methods ChromoPainter and fineSTRUCTURE to 2376 such individuals from the FINRISK Study survey of 1997 whose both parents were born close to each other. The high-level population structure reveals where exactly the previously undetermined "genetic border" between SW and NE Finland lies and shows strong similarities both to the known history of inhabitation of Finland and to the geographic incidence of CAD. At a lower-level, we identify several geographically clustered genetic populations which correspond well to detailed dialectal regions. To study the possible impact of the genetic structure to the regional differences in CAD, we generate two genetic risk scores: (1) lead-SNP score using 153 independent lead SNPs and (2) polygenic score using 53,000 LD-pruned SNPs with p-value below 0.05 from CARDIoGRAMplusC4D Consortium. Among the genetically identified subpopulations, our lead-SNP score for CAD yields an odds ratio of 1.11 ($p = 0.025$) between NE region of Kainuu and SW Finland possible explaining some of Kainuu's 1.8 fold incidence in CAD compared to SW Finland. The geographic distribution of our polygenic score also clearly reflects the observed incidence: the highest genetic risk is found from East and the lowest from the SW. The results demonstrate that the haplotype-based methods can detect unprecedented details of population structure in Finland reflecting population history and dialect patterns. The similarity between distributions of genetic risk scores and incidence of CAD suggests that some of the regional differences in risk of CAD are genetic.

694W

Using big data to interpret genomes with medical records for therapeutic target discovery. *R. Chen.* Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Millions of individuals have been sequenced or genotyped and linked with medical records, providing an exciting opportunity for therapeutic target discovery. My lab has been using a resilience approach to learn from success instead of failure, and analyzed hundreds of thousands of genomes with electronic medical records to drive target discovery for childhood Mendelian diseases, Alzheimer's disease, and cardiovascular traits. I will describe how we analyzed 589,305 genomes and identified 13 genetic super heroes who carry fully penetrant childhood Mendelian diseases but are healthy in our recent resilience project, and how we decoded individuals who carry APOE e4/e4 risk variants but are resilient for Alzheimer's disease. I will further describe how we analyzed individuals who have a loss of gene but carry favorable cardiovascular traits, identified potential therapeutic targets to lower fasting glucose levels, and validated the effects in mice.

695T

A reference-agnostic and rapidly queryable NGS read data format allows for flexible analysis at scale. *N. Shekar[1], W.J. Salerno[2], A.C. English[2], A. Mangubat[1], J. Bruestle[1], E. Boerwinkle[2,3], R.A. Gibbs[2].* 1) Spiral Genetics, Seattle, WA; 2) Baylor College of Medicine, Human Genome Sequencing Center, Houston, TX; 3) University of Texas Health Science Center, Human Genetics Center, Houston, TX.

In identifying the complement of genetic variants that are associated with complex disease, larger sample sizes increase power. Studies such as the Alzheimer's Disease Sequencing Project and the CHARGE Consortium where samples are collected from a range of centers show heterogeneous data, requiring informatics that can additively scale to thousands of samples and analytics that go beyond identifying small variants in NGS data. At scale, the challenge of evaluating SNPs, indels and SVs becomes the "N+1" problem of incrementally adding samples without having to perpetually reevaluate petabytes of population read data stored in BAM files. The Biograph™ Analysis Format (BAF) is a method of indexing NGS data that extends the Burrows Wheeler Transform to allow for multiple paths, effectively creating a read overlap graph of the data. A BAF of HiSeq X 30x WGS data is 20 Gb, 80% smaller than the original BAM. Generated from the BAM in 14 hours, the BAF can be queried up to 200,000 times a second. Multiple BAFs can be combined, resulting in a file size of approximately 10GB per individual. With multi-individual BAFs, query time grows less than linearly with the number of individuals. For example, with 30,000 putative SV sites to be queried, SV-typing these sites across 10,000 HiSeq X WGS samples in BioGraph Analysis Format would require less than 100 TB of storage (for all the read data), 16 CPU hours, and 10 minutes (using 100 machines). Additionally, the data are reference-agnostic, so variants can be called against any reference or against the read graph of any other set of individuals, dramatically reducing the time for data harmonization. Further, information is divided such that the "read overlap graph" created from all the individuals is separate from the information indicating that path through the graph for each individual. This allows a search for a particular variation of interest directly from the read data remotely and rapidly, without the opportunity to reveal the exact individual(s) from that the variant originates. Because the data are essentially a read overlap graph, it is possible to accurately characterize SVs by traversing the graph from a particular location or search for a particular sequence associated with the SV. So, fast querying of small files with reasonable compute requirements provides an N+1 solution for SNPs, indels and SVs. We describe how the BAF API allows users to construct specific queries for a range of applications.

696F

Rare variants in the non-coding sequence and plasma lipids: An analysis of deep, whole genome sequence data in 2,255 Estonians. *S. Zekavat[1,2,3], P. Natarajan[1,2,4], A. Ganna[1,5,6,7], J. Ernst[8,9,10,11], A. Metspalu[12], B. Neale[1,5,6], T. Esko[1,12], S. Kathiresan[1,2,4].* 1) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 2) Center for Human Genetic Research and Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA, 02114, USA; 3) Department of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, 02139, USA; 4) Department of Genetics, Harvard Medical School, Boston, MA 02115, USA; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston 02114, MA, USA; 6) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 7) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm 171 77, Sweden; 8) Bioinformatics Interdepartmental Program, University of California, Los Angeles, CA, USA; 9) Departments of Biological Chemistry and Computer Science, University of California, Los Angeles, CA, USA; 10) Eli and Edythe Broad Center of Regenerative Medicine and Stem Cell Research at UCLA, CA, USA; 11) Jonsson Comprehensive Cancer Center, University of California, Los Angeles 12 Molecular Biology Institute, University of California, Los Angeles, CA 90095, USA; 12) Estonian Genome Center, University of Tartu, Tartu 51010, Estonia.

Plasma lipids are heritable risk factors for coronary heart disease. Common DNA sequence variants in non-coding regions (analyzed individually) and rare mutations in coding regions (analyzed after collapsing by gene) are known to contribute to variability in plasma lipids. High-coverage whole genome sequences (WGS) allow for detection of rare variants in non-coding regions. The analysis of such variants poses considerable challenges due to issues of power and insufficient knowledge of non-coding functional interpretation with WGS. In 2255 Estonians whole-genome sequenced with mean coverage 30X, we evaluated consequences of individual variants and rare (MAF <1%) variants aggregated within functional units. We defined three functional units: 1) protein-coding regions of a gene; 2) annotated enhancer regions of HepG2 liver cells linked to genes by gene expression data (Ernst et al. Nature 2011); and 3) annotated promoter and enhancer regions of HepG2 liver cells within 20kb of the transcription start site (TSS) at DNAse hypersensitive sites (from Roadmap and ENCODE). We limited our analyses to 301 genes previously associated with plasma lipids by large-scale GWAS. Single variant analyses recapitulated known associations: *APOE* rs7412 for LDL-C (p = 3.2e-70), *CETP* rs7205804 for HDL-C (p = 7.4e-14), *LPA* rs74617384 for Lp(a)-Ch (p=3.9e-60), *LPL* rs115849089 for TG (p=2.3e-8), and *APOA5* rs3741298 for TG (p=3.9e-8). Gene-based analyses of rare null protein-coding variants identified previously reported associations: *LDLR*, *APOB* for LDL-C (p = 1.9e-23 and 2.4e-7, respectively). Across 31.5M non-coding variants, we observed 12,443 rare variants (MAF < 1%) at HepG2 promoters and enhancers within 20KB of the TSS of 301 lipid genes. Non-coding burden analyses demonstrated suggestive association (p<0.05) at many lipid genes. Non-coding burden analyses of rare variants in enhancers linked to genes showed suggestive association at *R3HDM2* and *FAM117B* for LDL-C; *LIPG* and *APOA4* for HDL-C; and *VEGFA*, *HIST1H1B*, *ARHGEF15*, and *ABCG5* for triglycerides. Non-coding burden analyses of rare variants in promoters and enhancers near transcription start sites showed suggestive association at *NF1*, *SBNO1*, *APOA5*, and *APOE* for LDL-C; *SERINC3*, *ABCG5*, *NBEAL2*, *LRP4*, and *ANGPTL3* for HDL-C; and *PLCB3*, *HIST1H1B*, *APOB*, *SERBP1*, *FADS1*, and *SLC22A18AS* for triglycerides. Rare variants grouped within regulatory functional units may impact blood lipid variation; replication of these results is ongoing.

697W

Evaluation of coronary artery disease risk loci as targets of current and prospective drugs. *V. Tragante do O[1], F. Asselbergs[1,2,3].* 1) Heart & Lungs, University Medical Center Utrecht, Utrecht, Utrecht, Netherlands; 2) Durrer Center for Cardiogenetic Research, ICIN-Netherlands Heart Institute, Utrecht, The Netherlands; 3) Faculty of Population Health Sciences, Institute of Cardiovascular Science, University College London, London, UK.

Genome-wide association studies (GWAS) have so far identified around 60 loci associated with coronary artery disease (CAD) and myocardial infarction (MI). Only a few of these loci are currently targets of on-market medications. Here, we systematically evaluated these risk loci for their druggability, either theoretically (with databases of small molecules) or based on known and predicted interactions (with databases of drug-gene interactions), including their potential side effects. Our results show that dozens of drugs potentially target pathways affected by CAD/MI associated loci. These drugs can be grouped for predominantly treating neoplastic disorders, blood and blood forming organs and the cardiovascular system. However, 80% of pathways affected by CAD/MI loci are not targeted by any drug. The overlap of indications and side effects of the drugs that target these genes evidence diabetes and hypertension as the main risk factors for CAD/MI. After filtering for undesired side effects, we discuss the possibilities of atrasentan, imatinib and tocilizumab as candidates for repurposing for treatment of CAD/MI.

698T

Haplotype phasing of key cardiac disease genes at genome and transcriptome levels using long-read sequencing technologies. *A. Dainis[1], E. Tseng[2], T. Clark[2], T. Hon[2], M. Wheeler[3], E. Ashley[1,3].* 1) Genetics, Stanford University, Stanford, CA; 2) Pacific Biosciences, Menlo Park, CA; 3) Cardiovascular Medicine, Stanford University, Stanford, CA.

Cardiac diseases, including hypertrophic cardiomyopathy (HCM [MIM 192600]), can be caused by rare genetic mutations. While current clinical sequencing strategies have ever improving power to find these disease-causing mutations, mutation detection often lacks additional information about the haplotype or chromosome of origin of these mutations. Without this information, critical knowledge about the disease-causing genes, including resolution of compound heterozygotes, is lost. Haplotype phasing using short-read sequencing often requires additional sequencing of close family members or inferential phasing using common genetic variants, a process which may provide poor resolution for rare mutations. New long-read sequencing technologies, including Pacific Biosciences SMRT Sequencing and Oxford Nanopore MinION Sequencing, can allow us to capture multiple SNPs in a single sequencing read, reducing the need for familial sequencing or inferential phasing. We present the results of sequencing multiple cardiac disease related genes, including *MYH7* (MIM 160760) and *MYBPC3* (MIM 600958), using three long-read haplotyping strategies: gene-specific gDNA capture and sequencing using PacBio SMRT sequencing, targeted-primer cDNA sequencing using PacBio SMRT sequencing, and tiling amplification of gDNA for Oxford Nanopore sequencing. We compare all three methods for ease and efficiency, sequencing error-rates, and downstream analysis. These three haplotyping strategies may lend themselves best to their own individual problems: when rapid haplotyping is needed, a tiling gDNA strategy on the MinION may be preferred, but when economical sequencing of many genes is required, a capture strategy using PacBio may be the best course of action.

699F

Label-free quantitative proteomic profiling of discordant monozygotic twin blood serum identifies Fibulin-1 as a candidate biomarker for ischaemic stroke. *N. Vadgama[1], R.C. Lovering[2], D. Lamont[3], J. Hardy[1], J. Nasir[4].* 1) Instituite of Neurology, University College London, London, United Kingdom; 2) Institute of Cardiovascular Science, University College London, London, United Kingdom; 3) College of Life Sciences, University of Dundee, Dundee, United Kingdom; 4) Molecular & Clinical Sciences Research Institute, St. George's University of London, United Kingdom.

Background: Stroke is a common disorder with significant morbidity and mortality, and complex aetiology involving both environmental and genetic risk factors. Although some of the major risk factors for stoke, such as smoking and hypertension, are well-documented, the underlying genetic and detailed molecular mechanisms remain elusive. Thus, identification of biomarkers may contribute to the clinical diagnosis of stroke. **Methods**: We performed a comparative proteomic analysis of blood serum of monozygotic twins discordant for ischaemic stroke using a label-free proteomics method to identify qualitative and quantitative differences at the protein level. To explore the biological processes associated with the differentially expressed proteins, we performed pathway analysis and Gene Ontology classification using g:Profiler. **Results**: MS/MS data for candidate peptides were exported to the MASCOT database for comparison to known peptides. Proteins were identified and quantified with high confidence (MASCOT ion score of 35 and $p<0.05$) and reimported into Progenesis software for further filtering. 190 proteins were identified in the plasma and a functional analysis was performed on those which were differentially expressed. These proteins were classified according to biological function and canonical pathway. The categories overrepresented in the affected twin related to vesicle mediated transport (n=12), response to stress (including wound heading) (n=16), protein activation cascade (including complement activation) (n=11), and beta-amyloid clearance (n=2). Further, the expression of Fibulin-1, an extracellular matrix protein in cardiovascular tissues, was consistently up-regulated in both replicate datasets of the affected twin. **Conclusion**: The identification of cellular pathways enriched in ischaemic stroke as well as the up-regulation of Fibulin-1 sheds new light on the underlying disease-causing mechanisms at the molecular level, which could lead to the development of new drug targets and biomarkers in the future.

700W

The gut microbiome associates with lifetime cardiovascular disease risk profile among Bogalusa Heart Study Participants. *T.N. Kelly[1], L.A. Bazzano[1,2], N. Ajami[3], H. He[1], J. Zhao[1], J. Petrosino[3], A. Correa[4], J. He[1,2].* 1) School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA; 2) School of Medicine, Tulane University, New Orleans, LA; 3) The Alkek Center for Metagenomics and Microbiome Research, Baylor College of Medicine, Houston, TX; 4) University of Mississippi Medical Center, Jackson, MS.

   With growing evidence for a critical role of the gut microbiome in energy harvest, glucose and lipid metabolism, and systemic inflammation, a potential influence of this supraorganism on cardiovascular health has been hypothesized. The objective of the current analysis was to examine the association between the gut microbiome and lifetime cardiovascular disease (CVD) risk profile among 57 Bogalusa Heart Study (BHS) participants with the highest and 55 with the lowest lifetime burdens of CVD risk factors. Lifetime CVD risk profile was estimated using a z-score based data reduction technique that leveraged fasting plasma glucose, systolic blood pressure, and low-density lipoprotein cholesterol values collected from an average of 9 study visits obtained over 33 years of follow-up. 16S rRNA sequencing was conducted on microbial DNA extracted from stool samples of the BHS participants. Alpha diversity, including measures of richness and evenness, and individual genera were tested for associations with lifetime CVD risk profile. Multivariable regression techniques were employed to adjust for age, gender, and race (Model 1), and additionally body mass index (Model 2). Increases in microbial richness, but not evenness, were associated with decreased odds of high lifetime CVD risk profile. In Model 1, odds ratios (95% confidence intervals) for each standard deviation increase in richness, measured by the number of observed operational taxonomic units, Chao 1 index, and abundance-based coverage estimator, were 0.62 (0.39, 0.99), 0.61 (0.38, 0.98), and 0.63 (0.39, 0.99), respectively. Associations were consistent in Model 2. Eight microbial taxa associated with lifetime CVD risk profile in Model 1 including: *Alloprevotella* ($P=2.96 \times 10^{-6}$), *Paraprevotella* ($P=6.48 \times 10^{-4}$), *Prevotella 7* ($P=7.95 \times 10^{-5}$), *Catenibacterium* ($P=1.82 \times 10^{-4}$), *Megamonas* ($P=4.18 \times 10^{-5}$), *Tyzzerella* ($P=4.39 \times 10^{-4}$), *Tyzzerella 4* ($P=1.51 \times 10^{-4}$), and *Enterobacter* ($P=6.41 \times 10^{-8}$). Five additional microbial taxa were identified by Model 2 including: *Coprococcus 2* ($P=1.38 \times 10^{-4}$), *Megasphaera* ($P=1.38 \times 10^{-4}$), *Ruminococcus* ($P=5.01 \times 10^{-4}$), *Thalassospira* ($P=3.44 \times 10^{-4}$), and *Methanobrevibacter* ($P=1.20 \times 10^{-4}$). Findings from this study suggest that increased microbial richness but not evenness are associated with lower lifetime CVD risk. Thirteen taxa also associated with lifetime CVD risk. These cross-sectional data add to the accumulating evidence that microbiota may play an important role in CVD risk.

Transcriptome signatures and structural variations in clinical subtypes of congenital heart disease (CHD) based on next generation sequencing technologies. *Y. Liu[1], A. Desai[1], K. Nguyen[1], X. Chang[1], E. Goldmuntz[2], H. Hakonarson[1].* 1) Center for Applied Genomics CAG, The children's hospital of philadelphia CHOP, Philadelphia, PA; 2) Division of Cardiology The Children's Hospital of Philadelphia CHOP, Philadelphia, PA.

   Congenital heart disease (CHD) constitutes defects in the structure of the heart and the great vessels that is present at birth. CHD is among the most common birth defects with approximately 9 out of 1000 newborns affected and it's the leading cause of birth defect-related deaths. Clinically, there are multiple subtypes of CHD. However, previous genetic studies have usually treated different clinical subtypes of CHD as a single identity or focused on individual subtypes without comparison between them. In this study, we observed transcriptome differences among 4 common CHD subtypes of 13 tissue types based on 145 genomic RNA-seq samples from 118 individuals. We uncovered differentially expressed genes (DEGs) between conotruncal cardiac defects (CTD) and left ventricular outflow tract obstruction (LVOT) defects that involve genes related to embryonic organ development processes/vascular processes, and these expression profiles were distinct from those observed for heterotaxy (Het) and atrial septal defect (ASD), which involved genes regulating energy processes such as oxidative phosphorylation. The differentially expressed genes did not show tissue specificity but gene expression levels in general were different among different cardiac tissues. To further explore the potential underlying causes for the DEGs, whole exome sequencing (WES) was performed from blood-derived DNA samples for those 118 individuals. Using multiple filters, recurrent CNV regions were detected for some of the CHD subtypes. Overall, we identified 8 transcriptome signature genes of differential expression impact: *C5orf46, ODF2L, MAP7D3, PSIP1,CLGN, ABI3BP, CCDC88A*, and *AGPS*, based on integrative analysis of DGEs, gene module networks, and CNVs. Those signature genes were further validated using 3D protein structure modeling. Acknowledgment: We thank the PCGC consortium for providing access to the data used for this study.

Analysis of the human kidney transcriptome reveals transcriptional regulation of genes crucial for blood pressure regulation. *C. Mercado[1], X. Wang[1], M. Bell[1], G. Roberts[2], Y. Chang[1].* 1) Medicine, University of Maryland, Baltimore, Baltimore, MD; 2) University of Maryland, Baltimore County, Baltimore, MD.

Serine/threonine kinases (WNK1, WNK4, SPAK, OSR1) and cation co-transporters (NKCC2, NCC) are members of a multi-kinase network that determines renal Na$^+$ reabsorption and blood pressure (BP) regulation. Environmental stressors such as hypovolemia activate WNK kinases to phosphorylate SPAK and OSR1, which in turn phosphorylate NKCC2 and NCC, allowing for the influx of extracellular Na$^+$ and Cl$^-$ into renal epithelial cells to restore blood volume. Rare mutations in these genes cause monogenic forms of hyper- and hypotension, which are well characterized in mouse models. While post-translational regulation of these proteins has been well established, regulation of these genes at the transcript level is not completely understood. In this study, we performed RNA-seq of the human kidney transcriptome, complemented with 5' and 3' RACE, to uncover pre- and post-transcriptional regulation of several genes in this pathway. First, *STK39* encodes for Ste20-related proline alanine rich kinase (SPAK), which phosphorylates and activates cation co-transporters. Variants within *STK39* are associated with susceptibility to essential hypertension, and SPAK null mice are hypotensive and mimic Gitelman syndrome (GS), a rare monogenic salt-wasting human disorder. In mice, SPAK activity is determined by the nephron segment-specific expression of full length SPAK and truncated SPAK isoforms with impaired kinase function. In humans, we identified N-terminally truncated *STK39* transcripts transcribed with human-specific promoters not found in mice. The relative abundances of these alternative isoforms are also distinct from rodent models, suggesting differential regulation of Na$^+$-reabsorption between humans and mice. Second, *SLC12A3* encodes for the thiazide-sensitive Na$^+$/Cl$^-$ cotransporter (NCC), and rare mutations in this gene cause GS. *SLC12A3* undergoes alternative splicing (AS) and alternative polyadenylation at multiple sites. AS within the final exon leads to an exon-exon junction >50 nucleotides downstream of the termination codon and generates a potential substrate for nonsense-mediated decay (NMD). By suppressing NMD, we demonstrated that *SLC12A3* transcript abundance is partially determined by a mechanism termed "regulated unproductive splicing and translation" (RUST). In summary, genes in this pathway are under complex pre and post-transcriptional regulation, resulting in the differential expression of alternative transcripts that may contribute to the fine-tuning of BP control.

Molecular characterization of pediatric restrictive cardiomyopathy from integrative genomics. *T.N. Rindler[1], R.B. Hinton[1], N. Salomonis[1], S.M. Ware[2].* 1) Pediatrics, Cincinnati Children's Hospital, Cincinnati, OH; 2) Pediatrics and Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN.

Pediatric restrictive cardiomyopathy (RCM) is a genetically heterogeneous heart muscle disease with limited therapeutic options. RCM cases are largely idiopathic; however, even within families with a known genetic cause for cardiomyopathy, there is striking variability in the disease severity. Although accumulating evidence suggests a strong role for regulation of both gene expression and alternative splicing in the development of dilated cardiomyopathy (DCM), there have been no detailed molecular characterizations of the underlying pathways dysregulated by RCM. By applying RNA-Seq to a cohort of pediatric RCM patients and comparing to other forms of adult cardiomyopathy and controls, we have identified transcriptional differences highly common to all examined cardiomyopathies, as well as those unique to RCM. RCM-selectively induced transcripts include a number of known and novel G-protein coupled receptors linked to calcium handling and contractile regulation. An in-depth comparison of alternative splicing revealed splicing difference shared among cardiomyopathy subtypes as well as splicing events linked solely to RCM. Genes identified with altered alternative splicing implicate direct regulation by the DCM splicing factor, RBM20. In conclusion, we present the first comprehensive report on the molecular pathways dysregulated in pediatric RCM including shared and unique pathways identified in comparison to other subtypes of cardiomyopathy. Analyses identify RBM20 as a potential mediator of alternative splicing dysregulation and demonstrate that disruption of the alternative splicing patterns in pediatric RCM is in the inverse direction as occurs in DCM.

Assessing chromatin marks to unveil the pleiotropic mechanisms of 122 loci associated with blood pressure. *D. Hemerich[1,2], J. Pei[3], M. Harakalova[1], T. Lumbers[4], T. Treibel[4], J. van den Velden[5], I. Ifimov[6], B. Boukens[6], C. Cheng[3], H. Kerstens[7], M. Mokry[8], J.C. Moon[4], J. Moore[9], P.B. Munroe[10], V. Tragante[1], F.W. Asselbergs[1,4,11].* 1) University Medical Center Utrecht, Utrecht, Utrecht, Netherlands; 2) CAPES Foundation, Ministry of Education of Brazil, Brasília, Brazil; 3) Department of Nephrology, UMC Utrecht, Utrecht, Netherlands; 4) Institute of Cardiovascular Science, UCL, London, UK; 5) Department of Physiology, VU UMC, Amsterdam, Netherlands; 6) Department of Biomedical Engineering, WUSTL, USA; 7) Princess Máxima Center for Pediatric Oncology, Department of Research, Utrecht, Netherlands; 8) Department of Pediatrics, Wihelmina Children's Hospital, Utrecht, Netherlands; 9) Department of Biostatistics and Epidemiology, Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, USA; 10) Clinical Pharmacology, William Harvey Research Institute, Queen Mary University of London, London, UK; 11) Durrer Center for Cardiogenetic Research, ICIN-Netherlands Heart Institute, Utrecht, Netherlands.

   Background: High blood pressure (BP) is a major risk factor for cardiovascular disease and premature death, that can lead to a variety of outcomes (aneurysm, left ventricular hypertrophy, stroke, kidney failure or coronary artery disease, for instance). To better understand how BP-associated variants influence different phenotypes, we aim at assessing to which extent regulatory elements are affected by 122 BP-associated loci in different tissues. **Materials and Methods**: We tested the phenotypic cell-type specificity of the 122 independent single nucleotide polymorphisms (SNPs) and vicinity ($r^2 > 0.8$) with H3K27ac peaks across 48 datasets of different tissues (43 from public sources, and 5 recently generated in-house from myocardial biopsy tissues). Statistical significance was evaluated by permuting 10,000 matched sets of SNPs not associated with the phenotype to calculate a 95th-percentile threshold as cell-type specificity score, resulting in specific tissues, best scoring (BS) SNPs and their respective index SNPs influencing each specific tissue. We intersected both sets of index and BS SNPs with 342 datasets of DNase data. Both DNase and H3K27ac are marks of active transcription. We used 43 datasets on H3K27me3, a histone mark known to silence genes, for comparison. **Results**: The most significant cell-types were right ventricle (RV) ($p=3\times10^{-4}$), kidney ($p=3\times10^{-3}$), both public ($p=0.01$) and in-house ($p=4\times10^{-3}$) datasets of left ventricle, aorta ($p=0.02$) and adrenal gland, both adult ($p=0.02$) and fetal ($p=0.05$), all tissues related to possible different outcomes induced by BP. The intersection of the two sets of BS (74) and index (63) SNPs with DNase data showed that 45 BS SNPs (60,8%) caused 2998 overlaps with peaks, while 19 index SNPs (30,1%) implicated 616 overlaps, a 4.8 fold enrichment. A similar rate was observed with H3K27ac peaks in the most significant tissue, RV, with 23 overlaps by 23 BS SNPs (31,1%) and 4 by 4 Index SNPs (6,3%) (fold enrichment=5.7). When testing intersection with peaks of an opposite mark (H3K27me3), 21 Index SNPs (33,3%) had 147 overlaps, while 33 BS SNPs (44,6%) had 222, a fold enrichment of only 1.5. **Conclusion**: These preliminary results point to an enrichment of BP-related SNPs with chromatin marks, highlighting variants in LD that may play a causal role. Further analysis may help clarify the mechanisms through which these SNPs affect genes, resulting in different outcomes.

705F

Plasma levels of miR-19a, miR-26a and miR-584 are associated with severity of coronary artery disease in Turkish men. *N. Coban[1], D. Pirim[2], A.F. Erkan[3], F. Guclu Geyik[1], B. Ekici[3], N. Erginel Unaltuna[1].* 1) Department of Genetics, Institute for Experimental Medicine, Istanbul University, Istanbul, Turkey; 2) Department of Molecular Biology and Genetics, Mus Alparslan University, Mus, Turkey; 3) Department of Cardiology, Medical Faculty, Ufuk University, Ankara, Turkey.

   MicroRNAs (miRNAs) have been shown to be associated with various physiological and pathological conditions, including inflammation and cardiovascular disease, but little is known about their relationship with the presence of coronary artery disease (CAD) and disease severity. We hypothesized that particular miRNAs may be differentially expressed in patients with severe coronary artery disease (SYNTAX score ≥33). In order to test the hypothesis, ninety nine patients with angina or acute myocardial infarction who underwent coronary angiography were recruited and divided into 2 groups: normal coronary arteries (coronary lesion with ≤30% stenosis) and critical disease (≥1 coronary lesion with ≥70% stenosis). Of the 99 total subjects, 57 were diagnosed as having CAD. Blood samples were drawn before coronary angiography. Gensini and SYNTAX scores and myocardial blush grade (MBG) were assessed. MiRNA expression profiles were analyzed by using the Agilent's miRNA microarray system in selected 4 male patients with proven severe atherosclerotic CAD (SYNTAX score ≥33) and 4 without CAD. MiRDB target prediction tool was utilized to identify miRNA target genes involved in atherosclerosis pathway for differently expressed miRNAs. Expressions of selected miRNAs were analyzed by using real-time PCR in 57 patients with CAD and of 42 healthy controls. Microarray results indicate that miR-584 was significantly down-regulated in male patients compared to non-CAD group (fold change>1.5, *p*<0.05). In addition, among CAD patients with three-vessel disease, higher SYNTAX scores were significantly associated with higher levels of miR-19a and miR-26a (fold change>1.5, *p*<0.05). Based on miRDB target prediction scores, we identifed *ABCA1, ADM and PHACTR1* genes were strong candidates (target score≥93) for miR-19a, miR-26a and miR-584, respectively. Currently, expression profiles of miR-19a, miR-26a, and miR-584 are being analyzed by qRT-PCR in 57 patients with CAD and of 42 healthy controls including male and female subjects. Lower plasma levels of miR-584 and higher levels of miR-19a and miR-26a were significantly associated with the presence as well as severity of CAD in Turkish men. Plasma miR-584, miR-19a and miR-26a could be potential biomarkers for CAD, and thus may be utilized in predicting CAD risk and its severity in patients presenting with chest pain.

RNA sequencing analyses reveal eight miRNA/mRNA pairs that may mediate the effects of cocaine in cardiovascular disease. *C.M. Dong, W. Zhu, H.L. Wang, G.C. Sartor, M. Bao, A.J. Griswold, C.R. Wahlestedt.* University of Miami, Miami, FL.

Introduction: Cocaine abuse is a significant risk factor for cardiovascular (CV) mortality and morbidity. The molecular mechanisms underlying the cocaine effects, however, remain elusive. **Goal:** MicroRNAs (miRNAs) are short, noncoding RNAs that bind to the 3'-UTR of the target mRNA, resulting in translational repression or degradation. This study aimed to identify miRNA/mRNA pathways that may mediate cocaine's effects in the CV system. **Methods:** C57BL/6 mice were treated daily with cocaine (20mg/kg body weight, ip injection), cocaine methiodide (CM, a cocaine analogue that does not enter the CNS), or saline for consecutive 10 days. Total RNA was extracted from the aortas (n=3) and subjected to HTSeq-based small RNA sequencing and RNA sequencing containing >41,000 probes. Gene expression profiles between treatment groups (fold changes ≥2) were analyzed, and candidate genes were validated by qRT-PCR. Putative pathways were identified by Gene Ontology and KEGG pathways analyses. miRNA's target mRNAs were predicted using miRDB. The relationship between miRNAs and mRNAs were determined by co-transfection of HEK293 cells using wt and mutant candidate gene 3'UTRs. **Results:** When compared to saline treatment, 8 miRNAs were downregulated by both cocaine and CM, and 4 miRNAs were upregulated by both treatments. Relative to saline, 48 genes were upregulated by both cocaine and CM, and 267 genes were downregulated by both agents. MiRNA prediction analysis revealed 2070 genes to be targets for the 4 upregulated miRNAs, and 3205 genes to be targets for the 8 downregulated miRNAs. Superimposition of the dataset from miRNA prediction with the RNAseq data revealed 71 genes predicted to be targets of the 4 upregulated miRNAs showed decreased expression (anti-correlation) in cocaine and CM-treated aortas, whereas 18 genes predicted to be the targets of the 8 downregulated miRNAs showed increased expression by cocaine and CM. Based on their relevance to cellular physiology and CV diseases, we ranked 8 top miRNA/mRNA pairs and established causal relationship between the miRNAs and their target genes. **Conclusions:** Cocaine appears to affect the homeostasis and functional integrity of the aortas by affecting the expression of miRNAs and their target genes. Further functional analyses of the candidate pathways in vitro and in vivo will lead to the discovery of novel molecular targets for intervention for cocaine-induced CV toxicities.

707T

Interpretable deep learning approaches to understand the genetic and regulatory basis of coronary artery disease. *P. Greenside, J. Israeli, C. Miller, M. Pjanic, T. Quertermous, A. Kundaje.* Stanford University, Stanford, CA.

The majority of genetic variants associated with coronary artery disease (CAD), such as those identified through genome-wide association studies, are enriched in non-coding regulatory elements that are preferentially active in CAD-relevant cell types. However, deciphering causal variants and the context-specific regulatory mechanisms through which they manifest their effects remain key challenges. To address these issues, we present a deep learning framework to learn context-specific de-novo sequence features that can accurately predict transcription factor (TF) binding from ChIP-seq experiments and chromatin accessibility dynamics from ATAC-seq experiments in coronary artery smooth muscle cells in healthy, stimulated and diseased states. We develop a novel method for efficiently computing feature importance in deep neural networks to highlight binding sites of individual TFs, homotypic and heterotypic sequence grammars with spatial constraints and important nucleotides in flanking sequences of chromatin accessible regulatory elements. We focus our study on the TCF21 transcription factor in the context of these dynamic accessibility profiles as TCF21 binding events are highly enriched for statistically significant CAD-associated variants. We discover a novel cis-regulatory grammar involving TCF21 and previously unidentified cofactors that is highly predictive of chromatin accessibility changes across normal and diseased states. Finally, we use our model to score and identify putatively causal non-coding CAD-associated variants and obtain novel hypotheses about the regulatory mechanisms through which they disrupt intermediate molecular phenotypes.

Cigarette smoking changes CpG methylation and thus increases the expression of *GPR15* **- A potential candidate gene for plaque development?**
T. Haase[1,2], J. Krause[1,2], C. Mueller[1,2], J. Stenzig[2,3], C. Roethemeier[1], P. Wild[4,5,6], S. Blankenberg[1,2], T. Zeller[1,2]. 1) University Heart Center Hamburg, Hamburg, Germany; 2) DZHK (German Center for Cardiovascular Research), partner site Hamburg/Kiel/Lübeck, Germany; 3) Department of Experimental Pharmacology and Toxicology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; 4) Preventive Cardiology and Preventive Medicine, Center for Cardiology, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany; 5) Center for Thrombosis and Hemostasis, University Medical Center of the Johannes Gutenberg-University Mainz, Mainz, Germany; 6) DZHK (German Center for Cardiovascular Research), partner site Rhine-Main, Mainz, Germany.

   Purpose Cigarette smoking increases the risk for cardiovascular disease. Differentiation of monocytes to proinflammatory macrophages is an important step in plaque development, but the mechanisms remain not fully understood. *GPR15*, coding for the G protein-coupled receptor 15, is an interesting new cardiovascular candidate gene as the CpG locus cg19859270 within the *GPR15* gene has been identified to be hypomethylated in smokers. The aim of this study was to analyze the connection between smoking, *GPR15* and plaque development.   **Methods** To determine the effect of changes in smoking over time, monocytic *GPR15* mRNA expression was measured by qPCR in smokers (n=179), ex-smokers (n=369) and never-smokers (n=480) from the population-based Gutenberg Health Study at baseline and five-year follow-up. The methylation status of the *GPR15* cg19859270 locus was determined in PBMCs from 262 subjects by bisulphite conversion and high resolution melting and mRNA expression was measured by microarray. To evaluate the role of *GPR15* in plaque development, monocytes from 4 smokers and 5 never-smokers were differentiated *in vitro* into proinflammatory macrophages and *GPR15* expression was measured by qPCR.   **Results** Monocytic *GPR15* expression was significantly higher in smokers compared to ex- (p<0.001) and never-smokers (p<0.001). Ex-smokers had significantly higher *GPR15* expression levels than never-smokers up to ten years after quitting (p<0.001). Smoking initiation between baseline and follow-up (n=17) led to an increase in *GPR15* expression, whereas smoking cessation resulted in decreased *GPR15* expression (n=42, p<0.001). In PBMCs, the correlation between smoking and *GPR15* expression (p<0.0001) was associated with cg19859270 hypomethylation (p<0.05). Likewise, smoking cessation was linked to cg19859270 methylation as well as reduced *GPR15* expression (p<0.05). In macrophages, *GPR15* expression was significantly lower compared to monocytes in smokers (p<0.001) and never-smokers (p<0.01).   **Conclusion** This is the first longitudinal study showing that smoking changes *GPR15* expression, mediated by changes in DNA methylation. Whether *GPR15* plays a role in cardiovascular disease development needs to be further analyzed.

709W

Epigenome-wide association study for myocardial infarction identified a DNA methylation site on the loci related to atrial fibrillation and ischemic stroke. *M. Nakatochi[1], S. Ichihara[2], K. Yamamoto[3], T. Matsubara[4], M. Yokota[5].* 1) Statistical Analysis Section, Center for Advanced Medicine and Clinical Research, Nagoya University Hospital, Nagoya, Japan; 2) Graduate School of Regional Innovation Studies, Mie University, Tsu, Japan; 3) Department of Medical Biochemistry, School of Medicine, Kurume University, Kurume, Japan; 4) Department of Internal Medicine, School of Dentistry, Aichi Gakuin University, Nagoya, Japan; 5) Department of Genome Science, School of Dentistry, Aichi Gakuin University, Nagoya, Japan.

   Aims Development of myocardial infarction (MI) depends on environmental and genetic factors. To investigate epigenetic basis for MI, we performed an epigenome-wide association study for MI in an elderly Japanese. We also explored DNA methylation (DNAm) sites associated with single nucleotide polymorphisms (SNPs) related to cardiovascular disease (CVD). *Methods* 192 case subjects with MI and 192 control subjects were enrolled, and whole-blood DNA samples were obtained from them. Genome-wide DNAm profiles for their DNA samples were obtained by analysis with an Infinium HumanMethylation450 BeadChip. Genome-wide SNPs were genotyped using Illumina HumanOmniExpress-12 BeadChip. Unassayed genotypes were imputed using the 1000 Genome Project phase 3 reference panel. From measured and imputed genotypes, we extracted genotypes of 145 SNPs reported to be associated with the CVD including MI. First, the association of MI with DNAm status was performed with a general linear model, and then the association of DNAm status with CVD-associated SNPs was assessed. *Results* Three DNAm sites showed genome-wide significant associations with MI. Out of these DNAm sites, one DNAm site, which indicated most significant association ($\beta = 0.018 \pm 0.003$, $p = 3.96 \times 10^{-10}$), is located within the *ZFHX3* gene. Also, we identified 228 combinations of CVD-associated SNP and DNAm site that showed significant association ($p < 1 \times 10^{-8}$). The above DNAm site was not included in the combinations. *Conclusions* We identified three DNAm sites significantly associated with MI. Out of these, one DNAm site is located within the *ZFHX3* gene. Although SNPs in *ZFHX3* on 16q22 has been reported to be associated with atrial fibrillation and ischemic stroke, there is no report that *ZFHX3* was associated with MI. Our results suggest a novel insight that the development of MI was caused by changes in DNAm within *ZFHX3* via a different pathway with SNPs in *ZFHX3*.

710T

GWAS candidate gene for coronary artery disease *TCF21* **interacts with the aryl-hydrocarbon receptor to modify coronary smooth muscle cell response to pro-atherogenic stimuli.** *M. Pjanic[1], J.B. Kim[1], O. Sazonova[1], T. Nguyen[1], T. Wang[1], C.L. Miller[1], L. Maegdefessel[2], U. Hedin[2], T. Quertermous[1].* 1) Department of Medicine, Cardiovascular Institute, Stanford University, Stanford, CA; 2) Karolinska Institute, Stockholm, Sweden.

Genome-wide association studies (GWAS) for coronary artery disease (CAD) have discovered and validated 48 loci genome-wide and recent 1000-Genomes based meta-analyses have discovered additional 8 loci with significant association, however, detailed follow-up studies on the mechanisms of association are still scarce. Here we analyze the relationship of two transcription factors, TCF21, one of the lead GWAS candidate genes for CAD, and AHR, aryl hydrocarbon receptor, which previously was not implicated as fundamental for the atherosclerotic process. We show that both the predicted and in-vivo ChIP-Seq binding sites for TCF and AHR colocalize in the human genome with over 400 predicted sites and 119 ChIP-Seq sites directly overlapping. TCF and AHR-ARNT predicted binding sites longitudinal phasing was observed near the transcription start sites, outlining the position of +1 nucleosome. AHR-ARNT matrix was highly enriched in both TCF21 ChIP-Seq peaks and ATAC-Seq open chromatin regions in human coronary artery smooth muscle cells (HCASMC), implicating the role of AHR in this important vascular cell type. Co-expression modules of TCF21 and AHR showed high degree of connectivity. Separation of rotationally phased and unphased predicted binding sites for TCF and AHR resolved the roles of direct and indirect TCF-AHR interactions, and implicated as highly-modulated various inflammatory, interleukin and cytokine related processes, while ChIP-Seq co-localization of TCF21 and AHR/ARNT emphasized the role of calcium related processes. We performed TCF21 overexpression analysis in HCASMC and obtained GO ontologies that recapitulate in vivo pathophysiology of the atherosclerotic vessel wall, and a set of chronic inflammatory ontologies was established with the colocalization of TCF21 and AHR ChIP-Seq sites as well as with the binomial testing of GWAS SNP overrepresentation. We experimentally confirmed that TCF21 binds to and regulates AHR gene expression in HCASMC, as well as to elements near AHR downstream genes, such as CYP1A1, using reporter assays. The functional relevance of AHR pathway in HCASMC is confirmed using AHR ligands TCDD and oxidized LDL. Finally, we show that AHR is elevated in atherosclerotic arteries using laser capture microdissection in mice in vivo and in human ex vivo. In conclusion, we extend GWAS results to functional assays and show that TCF21 and AHR functional connectivity provides a novel mechanism for diseased coronary vessel wall biology.

711F

Effect of lipoprotein (a)-associated genetic variants on plasminogen levels and fibrinolysis. *X. Wang[1,2], C. Hong[1], H. Wang[1], J. Lewis[1], Y. Zhu[1], X. Chu[3], J. Backman[1], Z. Hu[1], P. Yang[4], C. Still[3], G. Gerhard[3,5], M. Fu[1].* 1) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, baltimore, MD; 2) Department of Orthopedic Surgery, Second Affiliated Hospital of Chongqing Medical University, Chongqing 400010, China; 3) Geisinger Obesity Institute, Geisinger Clinic, Danville. PA 17822, USA; 4) Department of Obstetrics, Gynecology & Reproductive Sciences, University of Maryland School of Medicine, Baltimore, MD 21201, USA; 5) Penn State Institute for Personalized Medicine, Penn State College of Medicine, Hershey, PA 17033, USA.

Two genetic variants (rs3798220 and rs10455872) in the apolipoprotein (a) gene (*LPA*) have been implicated in cardiovascular disease (CVD), presumably through their association with Lipoprotein (a) (Lp(a)) levels. While Lipoprotein (a) (Lp(a)) is recognized as a lipoprotein with atherogenic and thrombogenic characteristics, it is unclear whether or not the two Lp(a)-associated genetic variants in the *LPA* gene are also associated with markers of thrombosis (i.e. plasminogen levels and fibrinolysis). In the present study, we genotyped the two genetic variants in 2919 subjects of the Old Order Amish (OOA) and recruited 146 subjects according the carrier and non-carrier status for rs3798220 and rs10455872, and also matched for gender and age. We measured plasma Lp(a) and plasminogen levels in OOA subjects, and found that the concentrations of plasma Lp(a) were 2.62 and 1.73 fold higher in minor allele carriers of rs3798220 and rs10455872, respectively, compared with non-carriers ($P = 2.04 \times 10^{-17}$ and $P = 1.64 \times 10^{-6}$, respectively). By contrast, there was no difference in plasminogen concentrations between carriers and non-carriers of rs3798220 and rs10455872. Furthermore, we observed no association between carrier status of rs3798220 or rs10455872 with clot lysis time. Finally, plasminogen mRNA expression in liver samples derived from 76 Caucasian subjects was not significantly different between carriers and non-carriers of these two genetic variants. Our results provide further insight into the mechanism of action behind two genetic variants previously implicated in CVD risk and show that these polymorphisms do not modulate plasma plasminogen levels and fibrinolysis.

Cocaine may induce hypertension and aortic stiffness via the miR-30c-5p-Me1-NADPH oxidase-ROS pathway. *W. Zhu, H.L. Wang, G.C. Sartor, J.Q. Wei, M. Bao, C.T. Pierce, C.R. Wahlestedt, C.M. Dong.* University of Miami, Miami, FL.

   Introduction: Cocaine abuse is a significant risk factor for hypertension (HTN) and vascular aging/aortic stiffness. It is known that cocaine stimulates sympathetic nervous system by inhibiting catecholamine reuptake at sympathetic nerve terminals; however, this has not been shown to be the major mechanism of action in cocaine-induced HTN. Using RNA sequencing, we have demonstrated that cocaine treatment results in altered expression of microRNAs and target genes that segregate into eight molecular pathways. One of them is the microRNA-30c-5p (miR-30c)—malic enzyme 1 (Me1)—NADPH oxidase—reactive oxygen species (ROS) pathway. Me1 is a cytosolic protein important for oxidation-reduction and ROS production. **Goal:** Our goal was to establish if the miR-30c—Me1—NADPH oxidase—ROS axis mediates, at least in part, the effects of cocaine in cardiovascular disease (CVD). **Methods:** C57BL/6 mice were treated daily with cocaine (20mg/kg body weight, ip injection), cocaine methiodide (CM, a cocaine analogue that does not enter the CNS), or saline for consecutive 10 days. Blood pressure (BP) and pulse wave velocity (PWV) for aortic stiffness were obtained. miR-30c and Me1 expression was determined by qRT-PCR and/or immunohistochemistry. The causal relationship between miR-30c and Me1 was established using lusiferase assay with wild type (wt) and mutant Me1 3'UTR (disrupting the binding sites for miR-30c) in HEK293 cells. ROS production was detected by dihydroethidium (O_2^-), chloromethyl-2',7'-dichlorofluorescein diacetate (H_2O_2), and aminophenyl fluorescein ($ONOO^-$). **Results:** When compared with saline treatment, BP and PWV were significantly increased by cocaine and CM over the entire treatment course. Cocaine and CM also caused downregulation of Me1 and upregulation of miR-30c expression in the aortas, resulting in increased O_2^-, H_2O_2, and $ONOO^-$ production. Importantly, transfection of miR-30c dose-dependently inhibited the luciferase activities of wt Me1 3'UTR, whereas miR-30c had no effects on the luciferase activity of the mutant Me1 3'UTR, indicating that miR-30c directly interacts with Me1 3'UTR, suppressing Me1 expression and leading to enhanced ROS production. **Conclusions:** Our data indicate that cocaine may induce HTN and aortic stiffness in mice via, at least in part, the miR-30c—Me1—NADPH oxidase—ROS pathway. Further characterization of this pathway *in vivo* may lead to the development of novel therapeutic strategies to combat drug abuse-related CVD.

Integration of allele-specific chromatin signatures with GWAS findings to localise functional variation for complex traits. *A.J.P. Smith[1,3], F. Drenos[2,3], K. Li[1,3], J.A. Cooper[3], J. Palmen[3], P.B. Munroe[1], P. Deloukas[1], P.J. Talmud[3], S.E. Humphries[3].* 1) Clinical Pharmacology, Queen Mary University of London, London, United Kingdom; 2) School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 3) Institute of Cardiovascular Sciences, University College London, London, United Kingdom.

   Genome-wide association studies have found many loci associated with complex diseases and traits. These studies usually identify SNPs that are proxies for the causal variant due to strong linkage-disequilibrium (LD) that is present in the human genome. Fine-mapping may aid in the reduction in the number of potential causal variants, particularly in conjunction with trans-ethnic fine-maping studies, but this may still not identify the functional variant. The majority of GWAS associations occur outside of coding regions and are therefore likely to have roles in modulating gene regulation. We previously developed a high-throughput method, termed FAIRE-gen, to localize potential causal variants using FAIRE-enrichment of open chromatin followed by allelic quantification using fine-mapping genotyping chips. Allelic imbalance in heterozygotes following enrichment of accessible chromatin can identify variants that influence chromatin structure and therefore regulatory potential. To address the localization of functional regulatory variants, we have integrated allele-specific chromatin signatures with public eQTL databases and regulatory annotation projects (ENCODE and Roadmap Epigenomics) with GWAS-associated variants using the GWAS catalog and 1000 Genomes Project to examine those in strong LD. Variants demonstrating potential for functionality using these tools were examined using *in vitro* methods, and revealed strong potential for effects on transcription factor binding and reporter gene expression. Using this methodology we demonstrate the identification of potentially functional variants for cardiovascular and autoimmune traits.

A study of the effect of dietary behaviour on DNA methylation in children in the Avon Longitudinal Study of Parents and Children (ALSPAC). *M. Ward[1,2], T. Gaunt[1,2], C. Relton[1,2,3].* 1) Medical Research Council Integrative Epidemiology Unit, University of Bristol, Bristol, U.K; 2) School of Social and Community Medicine, University of Bristol, Bristol, U.K; 3) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, U.K.

Background: Previous studies have found evidence of associations between DNA methylation and various aspects of diet, including fruit and vegetable, alcohol, B vitamin and protein intake and general nutritional status [1, 2]. Methods: We investigated the relationship between DNA methylation derived from peripheral blood and dietary patterns in 7 year old children in ALSPAC. Dietary patterns were quantified using principal components generated from a food frequency questionnaire [3]. The study identified three distinct dietary patterns: 'junk', 'traditional' and 'health conscious'. We performed epigenome-wide association analyses (EWASs) on those three dietary principal components, adjusting for age, sex and BMI. Findings: CpG sites with p-values below a Bonferroni-corrected threshold of $p<1.04e-7$ were observed for the 'junk' and 'health conscious' principal components, with smallest p-value around 5e-17. No CpG sites reached this threshold for the 'traditional' principal component. Interpretation and future research: We have found evidence of associations between DNA methylation and dietary patterns in children. We plan to perform two-sample Mendelian randomisation [4] to investigate whether the observed associations between diet and DNA methylation represent causal relationships. References: [1] Haggarty P. Genetic variation influences the gene expression response to hypoxia and oxidative stress in human iPSC-derived cardiomyocytes. *M.C. Ward[1], N.E. Banovich[1], D.A. Knowles[2], A. Mitrano[1], J.K. Pritchard[3,4,5], Y. Gilad[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Computer Science, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University, Stanford, CA; 4) Department of Biology, Stanford University, Stanford, CA; 5) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

The basis for complex polygenic diseases such as cardiovascular disease (CVD) is not fully understood, however the importance of non-coding regions has been highlighted. Myocardial infarction, a prevalent sub-class of CVD, is caused by oxygen deprivation leading to damage of heart tissue (ischaemia). Re-oxygenation by reperfusion can result in further damage, however the severity of ischaemia-reperfusion (I/R) injury is known to differ between individuals. To develop an understanding of the genetic determinants underlying this difference in phenotypic outcome, we have established an *in vitro* I/R model in induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs). iPSCs from 15 genotyped Yoruba HapMap individuals were differentiated into *TNNT2* positive iPSC-CMs and maintained under normoxic and aerobic metabolism-promoting culture conditions. To mimic I/R injury, iPSC-CMs under normoxia (condition A) were subjected to hypoxia (B) followed by short (C)- and long-term (D) re-oxygenation. Global gene expression levels were determined by RNA-seq. A total of 5982 genes are differentially expressed between all four oxygen conditions combined and this includes, both genes known to be involved in the hypoxic and oxidative stress response pathways such as *VHL* and *TET1*, as well as novel targets. The secretion of the cell damage marker, lactate dehydrogenase (LDH), indicates that re-oxygenation of oxygen-deprived iPSC-CMs is cytotoxic, and that there is inter-individual variation in the degree of response. A combined analysis of gene expression levels and LDH release identifies co-expressed modules of genes associated with overall cell stress and highlights the role of the autophagy gene *GABARAPL2*. In order to map genetic loci associated with the gene expression response, recently developed methods were used to identify expression quantitative trait loci (eQTLs) from a small sample size. Over 500 genes with a putative *cis* eQTL in at least one condition were identified, as well as a number of genes with response eQTLs - i.e. eQTLs with a difference in effect size between conditions. These data suggest the importance of genetic variation in mediating the variable gene expression, and subsequent cellular stress response to hypoxia and oxidative stress in a disease-relevant cell type.

716T

Transcriptome analysis of human explanted hearts identifies cardio-myopathy-specific mechanisms. *M. Sweet[1], A. Cocciolo[2], D. Slavov[1], S.L. Graw[1], K. Jones[1], L. Mestroni[1], M.R.G. Taylor[1].* 1) Cardiovascular Institute and Adult Medical Genetics Program, University of Colorado, Aurora, CO; 2) Ospedali Riuniti and University of Trieste, Trieste, Italy.

Cardiomyopathies are diverse in their genetic and phenotypic architecture but have been proposed to evolve via a "final common pathway" towards heart failure. The goal of this study was to use RNA-sequencing (RNA-seq) and pathway analysis to identify differentially regulated pathways in 42 samples of left ventricular heart tissue from cardiomyopathy patients. We identified differentially expressed genes between ischemic cardiomyopathy (ICM, n=14) and dilated cardiomyopathy (DCM, n=28) as well as between DCM sub-phenotypes, arrhythmogenic DCM (aDCM, n=13) and non-arrhythmogenic DCM (naDCM, n=15). Pathway analysis was performed using Ingenuity Pathway Analysis (IPA). Between ICM and DCM, 878 genes were differentially expressed ($p < 0.05$, $q < 0.05$). Pathway analysis showed enrichment for mTOR signaling ($p = 4\times10^{-13}$), epithelial adherens junction remodeling ($p = 3\times10^{-10}$), and Rho signaling ($p = 1\times10^{-7}$) with functional enrichment in immune response ($p = 7\times10^{-7}$). These results agree with previous models of chronic myocardial infarction that demonstrate increased mTOR signaling, which is known to aid in myocardial remodeling, and inflammatory response to the site of myocardial injury, which requires immune cell motility via Rho signaling and infiltration via cell-cell junction remodeling. Sub-phenotyping of the DCM samples into patients with and without a history of ventricular tachycardia revealed 280 genes differentially expressed between aDCM and naDCM ($p < 0.05$, $q < 0.20$). Pathway analysis demonstrated downregulation of oxidative phosphorylation ($p = 1\times10^{-13}$) and genes involved in muscle contraction ($p = 3\times10^{-5}$) in aDCM versus naDCM. These results suggest that aDCM patients may have reduced ATP production and contractility, which could contribute to arrhythmogenesis as compared to naDCM. More broadly, these results suggest that a 'final common pathway' model may need to be amended based on biological differences among DCM sub-phenotypes in advanced heart failure.

717F

Endothelial activating *KRAS* mutations in brain arteriovenous malformation. *S. Nikolaev[1,2], S. Vetiska[3], X. Bonilla[1], S. Antonarakis[1], J. Fish[4], I. Radova-novic[3].* 1) HUG, Geneva, geneva, Switzerland; 2) Service of Genetic Medicine, University Hospitals of Geneva, Switzerland; 3) Department of Fundamental Neurobiology, Krembil Neuroscience Institute, University of Toronto, Canada; 4) Department of Laboratory Medicine and Pathology, Toronto General Research Institute, University of Toronto, Canada.

Brain Arteriovenous Malformations (BAVMs) are focal developmental disorders of the brain vasculature with a prevalence of about 1 in 100'000 people and are a leading cause of hemorrhagic stroke in young adults and children. A BAVM is composed of entangled and morphologically abnormal vascular channels. In order to reveal the genetic cause of sporadic BAVMs we have performed deep exome sequencing of 27 BAVMs and 18 matching blood samples. In the majority of BAVMs we have detected recurrent putative somatic mutations p.G12D and p. G12V at low variant allele frequency (VAF) varying between 0.9% and 4.2%. Droplet Digital PCR (ddPCR) for these and other KRAS driver mutations in 32 BAVM patients (including 27 EXOME-sequenced) confirmed all predicted KRAS variants and revealed new ones totaling to 75% of patients (15 p.G12D, 8 p. G12V and 1 p.Q61H). No KRAS mutations were detected in normal blood neither with the exome sequencing no with ddPCR. Endothelial and smooth muscle cell cultures from 3AVMs with KRAS mutations and from 3 normal brain vessels were established using CD31 and SMA markers, respectively. KRAS mutations from DNA and RNA sequencing were detected with VAFs 2.8 – 9.3 times higher than in original BAVMs in endothelial but were absent in smooth muscle or normal brain endothelial cells cultures. Moreover we show that KRASmut transfected HUVEC cell lines and AVM endothelial cells exhibit higher levels of phospho-ERK, but not phospho-AKT or phospho-p38 MAPK, as compared to normal endothelial cells. Lastly we demonstrate on HUVEC cells lines that VEGF stimulation results in high pospho-ERK, however treatment with Ras inhibitor Farnesyl transferase prevents ERK phosphorylation. This work reveals the causative mutations and proposes the mechanistic explanation for BAVM, thus categorizing this disease as a new type somatic RASopathies.

Genetic analysis of transcription factors, *GATA4* and *NKX2-5* in patients with non-syndromic congenital heart defect from India. *R. Dixit[1], A. Kumar[2], B. Mohapatra[1].* 1) Dept of Zoology, Institute of Science, Banaras Hindu University, Varanasi, Uttarpradesh, India; 2) Dept of Pediatrics, Institute of medical Sciences, Banaras Hindu University, Varanasi, Uttarpradesh, India.

Congenital Heart Disease (CHD) is the leading cause of infant morbidity and mortality, occurring approximately in 1% of all live births. Transcription factors are known to govern heart development. Among them NKX2-*5* (MIM: 600584) and *GATA4* (MIM: 600576) are two critical cardiac specific transcription factors, those are most frequently associated with mutations in familial as well as sporadic CHD cases. Over past couple of decades around 74 mutations in *NKX2-5* and 69 mutations in *GATA4* have been identified globally. However no such studies have been conducted in Indian population so far and etiology of these defects in India is not precisely known. Therefore, in present study we sought to find the association of mutations in *NKX2-5* and *GATA4* among CHD patients from India and validating the observed variants by *in silico* and *in vitro* methods. These genes were sequenced in 280 CHD patients and 200 controls (400 chromosomes). Functional significance of observed genetic variants was analyzed by *in silico* (Polyphen, SIFT and Mutation Taster) and *in vitro* (western blotting, luciferase assay and immunostaining) approaches. By Sanger sequencing in *GATA4*, 5 novel sequence variants (c.23C>A; p.A8D, c.25G>A; p.A9T, c.383A>T; p.E128V, c.397A>T; p.S133C and c.682T>A; p.W228R) and 4 known variants (c.223G>T; p.A75S, c.1073G>C; p.S358T, c.1220C>A; p.P407Q and c.1064C>G; p.T355S) were identified in 20 CHD cases (7.1%). Simultaneously, *NKX2-5* revealed 3 novel non-synonymous genetic variants (c.182C>G; p.A61G, c.391G>A; p.E131K and c.443C>A ; p.A148E) and 2 known variants (c.284G>T; p.R95L and c.739C>G; p.P247A) in 5 CHD cases (1.78%). None of these were found in 200 ethnic matched controls (400 Chromosomes). *In silico* predictions showed that the mutated amino acid residues were conserved across the species and also predicted to be disease causing by various *in silico* tools. The mutant proteins showed *in vitro* functional deficits demonstrated by western blot, immunocytochemistry and transactivation assay of downstream ANF and cActin promoter activity. This study further expands the mutational spectrum of these two widely studied transcription factors, where novel mutations affecting the protein's function are identified in 25 (8.9%) non-syndromic CHD patients from Indian cohort. *In vitro* studies provide strong evidence of their role in disease pathology and encourage us to conduct more detailed animal model studies for understanding the molecular basis of disease mechanism.

719T

***SOX7* deficiency impairs embryonic vasculogenesis and epithelial-to-mesenchymal transition during atrioventricular endocardial cushion development.** *A. Hernandez-Garcia[1], M. Wat[1], R. Udan[2], A. Renwick[2], Z. Yu[1], C.A. Shaw[1], M. Dickinson[2], D.A. Scott[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030.

SOX7 is located on chromosome 8p23.1 in a region that is commonly deleted in individuals with complex cardiovascular malformations. SOX7 is highly expressed in vascular endothelial cells and in the endocardium but its role in these cells remains unclear. To determine if SOX7 plays a critical role in cardiovascular development, we generated standard and conditional *Sox7* knockout mice. *Sox7[-/-]* embryos die around E11.5 with signs of cardiac failure including pericardial edema and failure of vasculature remodeling. The same phenotype was observed when *Sox7* was ablated in endothelial cells using Tie2-Cre transgenic mice. Immunohistochemistry studies revealed normal levels of apoptosis and an increased level of endothelial cell proliferation in the absence of SOX7. Transcriptome analysis carried out at E8.5, revealed a set of genes involved in vasculogenesis whose expression is decreased in the absence of SOX7 including *Gja4*, *Gja5*, *Ptrf*, *Hey1*, *Dll4* and *Cxcr4*. We then investigated the role of SOX7 during endocardial cushion development. *Sox7[-/-]* embryos at E10.5 had markedly hypocellular endocardial cushions with severely reduced numbers of mesenchymal cells. This suggests a possible defect in epithelial-to-mesenchymal transition (EMT). These embryos also had hypoplasia of ventricular trabeculae. Rare *Sox7[-/flox]*;Tie2-Cre embryos that were recovered at E15.5 had pericardial effusions, vascular hemorrhage and ventricular septal defects. Our results suggest that SOX7 is an important regulator of vascular development and most likely plays a key role in the regulation of endothelial cell proliferation and specification. Our studies also suggest that SOX7 has an essential role in regulating atrioventricular canal and septal development and may act in a cell autonomous fashion to regulate EMT in the endocardium.

720F

LRP6 mutation causes coronary artery disease by activating noncanonical Wnt signaling. *R. Srivastava, J. Zhang, G.W. Go, A. Narayanan, T.P. Nottoli, A. Mani. Yale University, New Haven, CT.*

Mutations in Wnt signaling coreceptor LRP6 have been linked to coronary artery disease (CAD) in humans. Mice carrying *LRP6^R611C* mutation exhibit loss of vascular smooth muscle cell (VSMC) differentiation and aortic medial hyperplasia. *LRP6^R611C* mice on high-fat diet display dramatic obstructive CAD and exhibit accelerated atherosclerotic burden on LDLR knockout background. Pathway analysis showed that impaired LRP6/canonical Wnt activity leads to enhanced non-canonical Wnt signaling, diminishes TCF7L2 expression and increases activation of PDGF signaling. Hence, LRP6 mutations are on one hand loss of function mutations in the canonical and a gain of function mutations in the noncanonical Wnt signaling pathways. Strikingly, Wnt3a administration to *LRP6^R611C* mice improved LRP6 activity, reduced noncanonical Wnt activity, led to TCF7L2-dependent VSMC differentiation, and rescued post-carotid-injury neointima formation. Paradoxically, excess Wnt signaling has been also associated with diverse vascular diseases. Accordingly, wild-type mice administered with Wnt3a exhibited reduced VSMC differentiation and increased post carotid injury neointima formation. These changes were similarly associated with loss of LRP6 activity, reduced TCF7L2 expression and activation of noncanonical Wnt in VSMC. These findings indicate that Wnt3a maintains a delicate balance between canonical and non-canonical Wnt to sustain vascular health, while its excess availability or lack of response to its physiological levels can cause a range of vascular diseases. Our findings identify the underlying pathophysiogical processes that link altered Wnt signaling to diverse vascular diseases and identify new targets for their pharmacological therapy.

721W

PRDM6 mutations impair histone methylation and underlie nonsyndromic patent ductus arteriosus. *N. Li[1], E. Smith[1], M. Bahjati[2], H. Lynch[3], R. Lifton[1,4], A. Mani[1,4]. 1) Cardiovascular Research Center, Department of Internal Medicine, Yale University, New Haven, CT; 2) Isfahan University of Medical Sciences, Isfahan, Iran; 3) Department of Preventative Medicine, Creighton University School of Medicine,Omaha, NE; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT.*

Nonsyndromic patent ductus arteriosus (PDA) is one of the most common congenital heart defects (CHD), which is occasionally inherited as an autosomal dominant disorder with incomplete penetrance. Using combined genome-wide linkage analysis and whole-exome sequencing (WES), we identified independent mutations in PRDM6, a vascular smooth muscle cells (VSMC)-specific histone methyltransferase that transcriptionally suppresses contractile proteins. In vitro assays showed that the mutations cause loss of function either by intracellular redistribution of the protein and/or by alteration of its methyltransferase activities. Wild-type embryonic ductus arteriosus (DA) initially exhibited high expression levels of PRDM6, which rapidly declined postnatally to increase the number of VSMCs necessary for ductus contraction increased. This dynamic change suggests that PRDM6 plays a key role in maintaining VSMCs in an undifferentiated stage in order to promote their proliferation and that its loss of activity results in premature differentiation and impaired remodeling of the DA. PRDM6 knock out mice die prenatally from abnormal vascular development, which prompted generation of conditional KO mice to model the human disease. Our findings identify PRDM6 mutations as underlying genetic causes of nonsyndromic isolated PDA in humans and as a target for treatment of vascular disorders that alter vascular remodeling.

722T

Genome-wide association study of modifiers for tetralogy of Fallot in 22q11DS identifies variants in the *GPR98* locus on 5q14.3. *T. Guo[1], G. Repetto[2], D. McDonald McGinn[3], J. Chung[1], A. A total of 65% of 22q11.2 deletion syndrome (22q11DS, velo-cardio-facial/DiGeorge syndrome) patients have congenital heart disease (CHD), including aortic arch and/or intracardiac malformations. Some of the most serious anomalies include tetralogy of Fallot (TOF) or persistent truncus arteriosus (PTA). We hypothesized that common genetic variants could serve as modifiers of CHD risk, or subtypes of CHD. We performed a GWAS on 1,512 22q11DS subjects using Affymetrix 6.0 microarrays. Imputation was performed based on the 1000 Genome Project data and 6.5 M SNPs were retained for analysis. Logistic regression was used to adjust the first three principal components to assess associations in a discovery cohort of 798 cases and 491 syndromic controls. The controls had 22q11DS but had a normal heart and aortic arch as determined by echocardiography. Findings were validated in a second cohort of 223, 22q11DS subjects from a Chilean population (106 cases and 90 controls). Meta analysis of the two cohorts was performed and none of the loci reached genome wide significance (5×10^{-8}) between cases with CHD and controls. However, six loci reached a p value with suggestive association (1×10^{-5}); they are variants at 5q14.3 (*GPR98*), 4q32.3 (*SPOCK3*), 6p12.1 (*GLYATL3*), 8q24.3 (*ZC3H3*) and 14q24.3 (*POMT2*) and 16q22.3 (close to *PSMD7*). We then examined subtypes of CHD and found a GWAS significant SNP (3.19×10^{-8}) in an intron of *GPR98* with TOF. Variants in another intron of *GPR98* showed suggestive association with PTA ($p=1.81 \times 10^{-6}$). The *GRP98* locus is within 2 Mb of *MEF2C* (Myocyte-specific enhancer factor 2C), which is the closest functional gene known to affect heart development. This data indicates that variants in the 5q14.3 region may alter risk to subtypes of CHD in 22q11DS.

723F

The haploinsufficiency of *Csk* increases blood pressure by modulating sodium resorption and plasma volume. *J. Kang[1], S. Kim[1,2], J. Lim[1], S. Hwang[2], B. Oh[1].* 1) Biochemistry and Molecular Biology, Kyung Hee University, Seoul, South Korea; 2) Department of Chemical Engineering, HanKyong National University, Gyeonggi-Do, South Korea.

Blood pressure is a complex trait regulated by an orchestrated network of physiological pathways that involve modulation of vascular tone, heart rate, and blood volume. The *CSK* locus (15q24) is associated with blood pressure in human samples from various ethnic groups. it was recently reported that the deficiency of the *Csk* gene increases blood pressure through Src, a target protein of the Csk. In this manuscript we have investigated the signaling mechanisms of high blood pressure in *Csk* heterozygote mice. We have shown that high blood pressure in *Csk* heterozygote mice was decreased not only by PP2, an Src inhibitor, but also by losartan, an angiotensin II receptor inhibitor. To determine whether hypertension in *Csk* heterozygotes might be associated with a change in the heart rate or plasma volume, we measured both the heart rate and the plasma volume respectively by observing the electrocardiogram and by using Evans blue dilution in *Csk* heterozygote and wild-type mice. The plasma volume was significantly increased in the *Csk* heterozygote compared to the wild-type while the heart rate was not significantly different between two groups. The increased plasma volume was decreased by treatment of PP2 and losartan. Consistent with the plasma volume, the plasma sodium level was increased in the *Csk* heterozygote compared to the wild-type while the plasma potassium level was not changed in *Csk* heterozygotes. Interestingly, the plasma sodium level was significantly decreased only by PP2, but not by losartan. Our results suggest high blood pressure in *Csk* heterozygotes is induced by increased plasma volume and sodium level that are primarily controlled by the Csk/Src signaling pathway.

724W

Cytogenetic analysis of chromosomal abnormalities in patients with Myelodysplastic Syndrome from Central Brazil. *C.L. Ribeiro[1,2], I.P. Pinto[1,2], D.M.C. Cunha[2], I.B. Minasi[2,3], A.D. da Cruz[1,2,3,4], C.C. da Silva[1,2,3,4,5].* 1) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Pontifical Catholic University of Goias, Genetics Master's Program, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory (LaGene), Secretary of Goias State for Public Health (SES), Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Brazil.

   Myelodysplastic Syndrome (MDS) is a group of heterogeneous clonal hematopoietic disorders characterized by ineffective myeloid differentiation, dysplasia, karyotypic abnormalities, increased risk for progression to acute leukemia, and frequent progression to acute myeloid leukaemia. MDS incidence has risen dramatically in recent years and is associated with advanced age, shorter telomeres, cancer chemotherapy with alkylating agents, radiation, and inherited syndromes related to abnormalities in DNA repair. Cytogenetic abnormalities are identified in greater than 50% of MDS. Chromosomal analysis can help better determine prognosis and classifying the MDS in different risk groups. The aim of this study was to identify cytogenetic alteration in blood marrow using the karyotype analysis in 10 patients with MDS from the public health service in Central Brazil. Conventional cytogenetics analysis by GTG banding using the software IKAROS® (Metasystems Corporation, Germany) showed a diversity of structural and numerical chromosomal alteration. The cytogenetic abnormalities at diagnosis were identified in 40% of the patients, including deletion at 17p chromosome, trisomy at 21 chromosome, monosomy at X chromosome, gain in the heterochromatic region at 1 chromosome, and polyploid cells. The p53 gene, located at 17p13.1 region, encodes a tumor suppressor protein that responds to diverse cellular stresses to regulate expression of target genes, thereby inducing cell cycle arrest, apoptosis, senescence, DNA repair, or changes in metabolism. Mutations in this gene are associated with a variety of human cancers, and may be involved in the process of neoplastic transformation of hematopoietic cells. On the other hand, the trisomy of the 21 chromosome has been observed in low percentage of cases of MDS, usually in the advanced stages with rapid transformation leukemic. The other chromosomal alterations identified could be intrinsically related to the neoplastic process and could represent both the cause and the consequence of ineffective hematopoiesis in MDS. Cytogenetic analyses are presumed to be strongly predictor of clinical outcome in MDS. Furthermore, the comprehension of pathogenetic mechanisms of MDS can contribute to a better understanding of biological events involved in the initiation, progression and promotion of this disease and help to determine the prognosis, collaborating with an effective, early and individualized treatment.

Aneuploidy detection using multiplex ligation-dependent probe amplification (MLPA), in bone marrow from pre-B ALL patients. *A. Vazquez-Reyes[1,4], L. Bobadilla-Morales[1,2], C. Barba-Barba[2], G. Macías-Salcedo[2], J.R. Corona-Rivera[3], F. Sánchez-Zubieta[5], A. Corona-Rivera[1,2].* 1) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo "Instituto Dr. Enrique Corona", CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) Unidad de Citogenética, Hematología y Oncología Pediátrica, División de Pediatría, Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 3) Servicio de Genética División de Pediatría, Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 4) Doctorado en Ciencias en Biología Molecular en Medicina, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 5) Hematología y Oncología Pediátrica, División de Pediatría, Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México.

   Acute lymphoblastic leukemia (ALL) is a malignancy from T cell and B cell progenitors that proliferate in bone marrow, blood and other organs. Three-quarters of the affected patientswith ALL, show numerical or structural chromosomal alterations, which are important factors in leukemogenesis. The numerical alterations are determined by the golden standard: the karyotype. Nevertheless, there is a new molecular technique that can be used to determine the numerical alterations in ALL: MLPA. The Multiplex Ligation-dependent Probe Amplification (MLPA), is a method based in the multiplex PCR, that detects abnormal changes in copy number of ~45 different genomic DNA sequences. There are studies that have used this technique to detect chromosomal gain or losses in products of conception, copy number alterations in adult malignancies, and partial or complete deletions of genes involved in pre-B ALL. However, there are no studies that have used the MLPA technique to assess chromosomal gains and losses in patients with pre-B ALL. The preliminary aim of this study is to identificate aneuploidy for the first time using the MLPA technique and correlates the results with the routine karyotype analysis from LLA pre-B patients. We analyzed 15 bone marrow samples from children diagnosed with pre-B ALL, from the Unidad de Citogenética, Servicio de Hematología Oncología Pediátrica, Nuevo Hospital Civil "Dr. Juan I. Menchaca". The DNA extraction was carried out using the QIAmp© DNA Blood Mini Kit. The chromosomal gains and/or losses were detected by the SALSA MLPA P036 Subtelomeres Mix 1 probemix, using the MLPA technique. Finally, the MLPA results were correlated with the karyotype results, using the Pearson's correlation test. We analyzed 5 samples from pre-B ALL children with normal ploidy and 10 children with aneuploidy. The chromosomal number detected by MLPA and karyotype matched in 5/5 samples with normal ploidy (r^2=1.000, p<0.05); and the results from MLPA and karyotype matched in 7/10 samples with aneuploidy (r^2=0.8330, p<0.05). In the present study, MLPA technique was capable to detect 7/10 samples with aneuploidy and 5/5 samples with normal ploidy. Preliminary results suggest that MLPA could be a useful tool to aneuploidy identification in children with pre-B ALL, in order to establish a better treatment and a better prognosis.

726F

Over expression of IQGAP1 in patients with mutations in the Armadillo region of APC gene can be a marker of incidence of metastatic Colon Cancer. *H. Azimi[1,3,4], A. Razavi[1,3,8], S. Ghavimi[2], N. Anderson[3,4], J. Brown[1,4], S. Emamian[5], S. Singh[1,6], A. Kolahi[7], A. Afsari[2], R. Jaasbi[8].* 1) Genetic Informatic, GenomicsOnCall, Washington, DC; 2) Howard University Hospital, Department of Medicine, Washington, DC; 3) PsychoGenome, Ottawa, ON, Canada; 4) Carleton University, Department of Integrated Sciences Ottawa, ON, Canada; 5) Indiana University, Bloomington, IN; 6) Howard University School of Medicine, Washington, DC; 7) Shahid Beheshti University School of Medicine, Tehran, Iran; 8) Islamic Azad University, Department of Genomic and Genetics, Iran.

　Background: A large proportion of mutations occurring in patients with colon cancer involve genes encoding proteins of the APC, WNT, EGFR and p53 pathway. The involvement of the majority of these mutations in colon cancer progression is not well known. Next Generation Targeted Exome Sequencing (NGTES) of patients with metastatic colorectal carcinogenesis (mCRC) will lead to the discovery of specific driver mutations that are important in this process. **Objective:** To evaluate patients with mCRC for expression of IQGAP1 and investigate if different mutation sites on the APC protein correlate with the higher incidence of metastasis. **Method:** A total of 100 patients (48 males and 52 females) with mCRC (T2-T3) and matched normal were obtained from the CRC database held at Psychogenome Laboratories in Ottawa, Canada. The age range was from 38 to 92 with a mean of 68. Real-time reverse transcriptase PCR was conducted on frozen tissues of mCRC. Next Generation Targeted Exon Sequencing (Ion Torrent) was performed to analyze mutations in the APC genes of all patients. Results were matched with exon sequencing data of patients with no mCRC [100 patients (53 male and 47 female)] Stage 1 and 2 CRC between age of 43 and 86 with median age of 65. Results were compared to TCGA and published known mutations, COSMIC, dsSNP and false positive was driven out by parallel sequencing by using MuTect. **Result:** Overall 120 different mutations (12 novel and 108 known) were found. There were 48 non-synonymous mutations, 35 synonymous, 12 frameshift, and 25 stop-gain mutations. In mCRC patients with overexpression of IQGAP1, the majority of mutations were in Exon 4 and 5 with 88% of mutations occurring at ARM region of APC protein, between ARM and first 15AA repeat region. Samples that did not have overexpression of IQGAP1 with no mCRC had 15% of mutations in the ARM and 15AA repeat region compared to those who had mCRC. **Conclusion:** Using NGTES, we examined the expression of IQGAP1 in mCRC tissue and found that IQGAP1 levels highly correlate with the degree of malignancy and metastasis in CRC patients. We found that patients with mutations in the ARM region of APC, leading to an upregulation of IQGAP1, have a worse prognosis compared with patients with mCRC with fewer or no mutations in the same region. This is the first Next Generation Sequence analysis of patients with mCRC that has shown an upregulation of IQGAP1 with a majority of the mutations occurring in the ARM region of APC.

Development and validation of a clinical bioinformatics pipeline for comprehensive pediatrics cancer panels. *K. Cao[1], F. Chang[1,2], C. Wu[1], F. Lin[1], M. Li[1,2], M. Sarmady[1].* 1) Pathology, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Dept. of Pathology & Laboratory Medicine, University of Pennsylvania, Philadelphia PA.

　Molecular tumor profiling has been increasingly utilized by oncologists to guide clinical decision making. Next generation sequencing (NGS) has emerged as the method of choice to analyze a wide range of genes known to be associated with various cancers. We have recently launched multiple NGS panels targeting childhood cancers including 13 hereditary cancer panels (128 genes), one hematological cancer panel (99 genes), and one solid tumor panel (237 genes). Development of bioinformatics pipelines that can accurately and efficiently transform numerous genetic alterations in the raw data to a few clinically meaningful somatic/germline variants is an essential component of genomic profiling. To support the cancer diagnostic needs, we have designed, implemented and validated a clinical bioinformatics pipeline for the cancer panel analysis.　Fastq files generated by MiSeq sequencer are first aligned to GRCh37 (hg19) assembly. Variants are called by five variant calling tools to maximize the detection rate. Raw variants are pre-filtered using strand ratios and allele fractions. Variants called by different tools are then merged, annotated and filtered using multiple public, commercial, and in-house databases. Copy number variations (CNVs) and loss of heterozygosity (LOH) are called by using our home-brew software that integrates multiple tools (e.g. VarScan and CNVKit) together. CNVs and LOH calls are calculated and visualized using NGS reads and pre-selected SNPs built in the panels.　To assess the performance of our pipeline, we validated the pipeline using replicates of five cancer cell lines with serial dilutions, three known positive and ten clinical samples for each of the three panels. Our results showed 100% concordance to that of commercially available pipelines on variants with ≥5% allele frequency for somatic and 10% for hereditary panels. Our pipeline allows analyzing multiple samples in parallel, which greatly increases analysis efficiency. To evaluate reproducibility of the pipeline, three libraries were prepared using HapMap sample NA12878. Our results showed 100% intra- and inter-run reproducibility for all panels.　In summary, we have developed a comprehensive bioinformatics pipeline for variant and CNV calling, annotation and filtering for our custom-designed cancer NGS panels. The validation results demonstrate 100% accuracy and reproducibility of the pipeline in identifying cancer associated mutations and CNVs with increased efficiency.

Implementing molecular barcode counting into a comprehensive integrated targeted sequencing portfolio and bioinformatics pipeline. *E. Lader, Z. Wu, S. Tian, Q. Jiang, Y. Wang, J. DiCarlo.* Qiagen Biological Research Center, 6951 executive way, Frederick MD 21703.

We recently completed the development of a comprehensive targeted sequencing portfolio making use of random molecular barcoding and an integrated bioinformatics package which makes use of a machine learning algorithm for mutation calling. These applications include targeted somatic mutation and in/del detection in DNA, fusion transcripts and other mutations and rearrangements (both known and novel) in RNA, high throughput targeted quantitive RNA expression analysis, and miRNome profiling. For RNA and miRNA quantification and characterization, molecular barcoding allows extremely accurate and unbiased quantification of a few to up to thousands of targets simultaneously. For mutation, rearrangement, and fusion calling, we employ a combination of single primer extension and molecular barcoding to achieve extremely uniform coverage and high sensitivity mutation detection, even in challenging FFPE and biofluid samples. The highly integrated sample to insight workflow and analysis package, and flexibility of panel design.

Neuroblastoma with *MYCN* amplification and ALL pre-B with 46,XY,t(4;11). Case report. *S. Brukman[1,5], H. Romo-Rubio[4], L. Bobadila-Morales[1,2,3], G. Macias-Salcedo[2], A. Marquez-Mora[2], M.C. Almodovar-Cuevas[2], R. Corona-Rivera[1,2,3], F. Sanchez-Zubieta[4], A. Corona-Rivera[1,2].* 1) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo, CUCS, Universidad de Guadalajara; 2) Unidad de Citogenética, Servicio de Hemato-Oncología Pediátrica, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca". Guadalajara, Jalisco, México; 3) Servicio de Genética División de Pediatría, Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 4) Hematología y Oncología Pediátrica, División de Pediatría, Hospital Civil "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 5) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Common childhood malignancies include leukemias (30-40%), brain tumors (20%) and lymphoma (12%) followed by neuroblastoma (NB)(1). Acute lymphoblastic leukemia (ALL) and ALL pre-B cell represent 80-85%; the most frequent cytogenetics abnormalities are hyperdiploidy-25% and MLL-5%. The most common extracranial cancer in childhood is Neuroblastoma, with approximately 15% of deaths during childhood. The amplification of the *MYCN* oncogene locus on 2p24-25, occurs in approximately 25% of primary NB, and it is a biologic marker for an unfavorable prognostic in patients. The finding toghether of this two neoplasic abnormalities in the same patient is unusual. The objective is present a case of patient with two different primary cancer tumor with their respective laboratory diagnostics. **Clinical report:** 23 months old male, at 1 year old presented stiffness in lower limbs, MRI reported spinal cord compression by tumor diagnosed as Neuroblastoma in Biopsy report. Immediately start treatment with radiotherapy and chemotherapy. 11 months after treatment presented weakness, hematomas in lower libs, hyporexia and fever; leukocytosis of 222,200 10^3/μL, lymphocytes 83% and platelets 12.4×10^3. FISH positive for *MYCN* gene amplification: nuc ish(MYCN amp)[100]. In bone marrow aspirate was found 100% of blastic lymphocytes L1 by FAB, inmunophenotype Pre-B (CD19, CD79, MLL+), Karyotype: 46,XY,t(2;?)(q36;?),t(4;11)(q21;q23)[3]/46,XY[5]. FISH: nuc ish(MLLx2)(5´MLL sep 3´MLLx1)[169/200]. **Conclusion:** Germline MLL locus 11q23; MLL gene is rearranged most often in de novo infant leukemia, which results from t(4;11)(q21;q23) associated with a dismal prognosis, therapy refractoriness and central nervous system (CNS) infiltration. The simultaneous occurrence of 2 different kinds of neoplasms in a child is infrequent, just one case are reported in the literature by D'angelo P. et. al. Common mechanism may be involved in this two early on-set neoplasias. .

Mutation detection in circulating tumor DNA in early stage cancer samples. *A. Chen, M. Anselmo, J. Jaboni, S. Li, G. Braunstein, A. Kammesheidt.* Pathway Genomics, San Diego, CA.

Background: Circulating Tumor DNA (ctDNA), a subset of cell-free DNA (cfDNA), are small DNA fragments in the blood stream released by tumor cells, that reveal somatic mutations from existing tumors. Pathway Genomics CancerIntercept™ is a CLIA validated, laboratory-developed blood test that can be used by physicians as a screening tool for the detection of biomarkers associated with specific cancer types in patients without a cancer diagnosis but at high risk for developing a cancer or as a test to monitor patients who have been diagnosed with cancer. The assay detects the presence of 96 mutations in nine genes (*BRAF, CTNNB1, EGFR, FOXL2, GNAS, KRAS, NRAS, PIK3CA,* and *TP53*). In this study, we sought to determine the frequency of ctDNA detected in stage I and II cancer patients. Methods: To date this study series has analyzed 85 plasma samples from individuals with stage I (n=81) and stage II cancers (n=4). Cancer types included breast, colorectal, gastric, lung, ovarian, pancreatic, thyroid, head and neck, and prostate cancer. Clinical information such as grade, TNM, tumor size, lymph node status was available for most samples. For each sample, cfDNA was isolated from 1-2 ml of frozen plasma, and analyzed using the CancerIntercept™ assay. Results: In this series, all the breast, ovarian, prostate, and head and neck cancer samples were screened negative. A total of 15 of the 85 stage I and II specimens (17.6%) had at least one positive mutation. The positive samples included 5/24 gastric, 3/7 pancreatic, 3/9 colon, 2/10 lung, and 2/11 thyroid cancer specimen. Three cancer samples (one each from pancreatic, lung and colon) had two mutations. The 18 mutations detected in the stage I and II cancers included 15 unique mutations across *BRAF, EGFR, GNAS, KRAS, PIK3CA,* and *TP53*. Conclusion: In this series across multiple cancer types, the combined ctDNA mutation rate in the stage I and II cancers detected was 17.6%. Three of the 15 positive samples had more than one detectable mutation in this screening assay.

731T

Recurrent mutations of *BRCA1* **in Algerian triple-negative breast cancer patients: Implications for genetic screening criteria selection and counseling.** *F. Cherbal[1], H. Gaceb[1], C. Mehemmai[1], K. Yatta[1], M. Belkacemi[1], A. Aguentil[1], R. Bakour[1], K. Boualga[2].* 1) Unit of Genetics, LMCB, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Radiation Therapy Services, Anticancer Center of Blida, Blida, Algeria.

Background Breast cancer is currently the leading cause of cancer deaths among Algerian women. Triple-negative breast cancer (TNBC) shows substantial overlap with basal-type and BRCA1-related breast cancers. In the present study, we screened for *BRCA1* germline mutations in 141 women with TNBC including all exons where a mutation was previously found in Algerian population (exons 2, 3, 5, 11, 18, 20). **Materials and Methods** 141 TNBC patients and their families were referred through several public hospitals and private medical clinics which provide oncology services throughout Algeria. *BRCA1* gene was screened by PCR-direct sequencing in 56 TNBC patients with family history of breast cancer and 85 sporadic TNBC patients including all exons where a mutation was previously found in Algerian population (exons 2, 3, 5, 11, 18, 20). *In silico* analyses have been performed using different bioinformatics programs to individualize genetics variations that can disrupt the *BRCA1* function. **Results** The analysis of DNA samples of 141 women with TNBC revealed that 10 patients carried pathogenic germline mutations in *BRCA1* gene and unclassified variants (UVs) (7%), respectively. Most of TNBC patients with mutations had family history of breast and were diagnosed at age ≤ 45 years. 4 distinct pathogenic mutations: c.83_84delTG, c.181T>G, c.798_799delTT and c.2125_2126insA and two unclassified variants p.His-41Arg and p.Arg1753Gly, respectively, were identified in this study. The recurrent *BRCA1* mutation c.83_84delTG has been identified in 3 patients with a frequency of 2.1%. The c.181T>G/p.Cys61Gly mutation has been detected here in one patient. To date, C61G mutation has been detected already in two Algerian families. The *BRCA1* mutation c.798_799delTT has been identified in a young TNBC patient diagnosed at age 34 years. Interestingly, the *BRCA1* c.2125_2126insA deleterious mutation was detected for the first time in 3 patients (and in some first relatives of two patients) with a family history of breast cancer and/or prostate cancer.The two *BRCA1* UVs H41R and R1753G were found to be low and high probability pathogenicity by AGVGD (C25 and C65), deleterious and disease causing by SIFT and Mutation Taster, respectively. **Conclusions** Recurrent mutations of *BRCA1* have been detected in TNBC patients diagnosed at earlier age.TNBC immunophenotype should be considered as an additional criterion for genetic screening in Algerian women with early onset breast cancer.

732F

Prognostic value of syntenin in colorectal adenocarcinoma. *Y. Cui[1], J.H. Shin[2], E.S. Jung[3], S.T. Oh[4], J.G. Kim[4], S.Y. Kim[1], S.H. Lee[3].* 1) Department of Pathology, College of Medicine, The Catholic University of Korea,, Seoul, Seoul, South Korea; 2) Department of Hospital Pathology, St. Paul's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea; 3) Department of Hospital Pathology, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea; 4) Department of Surgery, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea.

Background: Syntenin is reported to modulate migration and invasion in several tumors. To date, the expression has not been clearly elucidated. In this study, we compared syntenin expression with various clinicopathological parameters and molecular markers to evaluate its clinical significance in colorectal adenocarcinoma. **Method:** We evaluated the immunoreactivity of syntenin using tissue microarray in 202 surgical specimens of primary colorectal adenocarcinoma from patients consecutively treated between 2008 and 2011 at Seoul St. Mary's Hospital, The Catholic University of Korea. The relationship between syntenin expression and various clinicopathological parameters and molecular markers was analyzed. **Results:** Of the 202 cases, 28 cases show cytoplasmic syntenin positivity in tumor cells. Syntenin expression is significantly associated with increased lymphatic invasion (p=0.038), perineural invasion (p=0.005) and higher nodal stage (p=0.013). In addition, syntenin expression has weak positive correlation with syndecan expression (γ=0.167, p=0.019). However, syntenin expression is not significantly correlated with tumor stage, metastasis, vascular invasion, tumor differentiation, K-ras mutation and/or EGFR expression status. **Conclusions:** The expression of syntenin may be of clinical value in colorectal adenocarcinoma and may help in identifying aggressive forms of colorectal adenocarcinoma.

733W

Identification of prostate cancer driver mutations and transcriptomic profiling from cultured circulating tumor cells. *B.R. Downie[1], B. Adams[1], C. Ryan[2], J. Lim[1].* 1) Xcell Biosciences, San Francisco, CA; 2) UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA 94115.

Biopsies are labor-intensive, invasive procedures that capture tumor tissue for downstream processing. While liquid biopsy technologies relying on amplification of cell-free DNA particles has promised to assist clinical decisions, no technology to date has enabled the direct capture and expansion of living cancer cells due to the extremely low fraction of circulating tumor cells (CTCs) in blood. We present here a cell culturing workflow for the isolation and expansion of CTCs followed by next-generation sequencing and analysis. As proof of principle, we successfully cultured 4-22 blood-derived colonies of cells per prostate cancer patient under tumor-relevant culturing conditions. RNA from selected colonies was extracted, sequenced, and profiled for prostate cancer relevant signaling pathways. Disruptive driver mutations with established pathogenicity in ClinVar could be identified in the DNA repair genes BRCA1, BRCA2, and PARP1. Additionally, androgen receptor (AR) downstream target genes co-express together with constitutively active AR splice isoforms. These data, together with expression of neuroendocrine differentiation marker genes are used to generate a composite score which could be used to better inform clinical decisions. Together, these results demonstrate that colonies of tumor-derived cells can be expanded and interrogated using a range of integrative next-generation technologies.

734T

Identification of somatic mutations and copy number variations in multiple myeloma using next generation sequencing. *H. Fukushima[1,2], Y. Sasaki[2], M. Tamura[2], H. Ikeda[3], K. Ishiguro[4], T. Tokino[2], A. Sakurai[1].* 1) Department of Medical Genetics, Sapporo Medical University, Sapporo, Hokkaido, Japan; 2) Department of Medical Genome Sciences, Research Institute for Frontier Medicine, Sapporo Medical University, Sapporo, Hokkaido, Japan; 3) Department of Hematology, Sapporo Medical University, Sapporo, Hokkaido, Japan; 4) Department of Gastroenterology, Sapporo Medical University, Sapporo, Hokkaido, Japan.

    Introduction of novel agents such as bortezomib, thalidomide, and lenalidomide have remarkably improved the overall survival in multiple myeloma (MM [MIM 254500]), but the prognosis of patients with relapse and refractory MM remains poor. The comprehensive analysis of genetic alterations in tumor by next generation sequencing can allow for the prediction of drug resistance and facilitate improvements in the treatment of MM.We tried to define genetic changes specific for each myeloma sample using targeted semiconductor sequencing technology. DNA was extracted from magnetic bead-enriched bone marrow CD138-positive malignant plasma cells from 11 cases of MM, and CD138-negative cells were used as matched non-tumor cells. Forty nanograms of DNA were used for multiplex PCR amplification with an Ion Ampliseq Comprehensive Cancer Panel that offers targeted coverage of all exons in 409 tumor suppressor genes and oncogenes frequently cited and frequently mutated in human cancers. (covered regions: 95.4% of total). We sequenced 15,992 regions which obtained more than 1.5 megabases of target sequence. Each sample underwent on average 8.3 million sequencing reads after quality filtering. The mean read depths were 539x, and >95% of targeted bases were represented by at least 20 reads. The average number of non-synonymous mutations detected per patient was 6.1 (range 3-11). The copy number variations in which segments of the genome can be duplicated or deleted from sequencing data were also detected. Somatic mutations were found in known MM-associated genes, including *TP53* and *NRAS*. We also identified novel recurrent alterations (single nucleotide variants, indels and copy number variants). Pathway assessment has shown that somatic aberrations within MM genomes are mainly involved in several important pathways, including cell cycle regulation, RTK–MAPK-PI3K and NF-kB. We performed targeted next-generation sequencing for rapid (2 days), standardized, and cost-effective gene analysis of malignant plasma cells from patients with MM. This targeted next generation sequencing may allow clinically oriented variant screening in MM.

735F

Clonal hematopoiesis of indeterminate potential (CHIP) and pathobiology of myelodysplastic syndromes (MDS). *B.B. Ganguly.* MGM New Bombay Hospital, Navi Mumbai, Maharashtra, India.

    After the detection of *BCL2* and *BCR-ABL* rearrangements in non-malignant individuals in 1995, copy number variations were reported in 5q/11q/17p/20q in hematopoietic stem cells (HSCs) in 2012 followed by identification of point-mutations in genes involved in epigenetic mechanism in non-pathogenic apparently healthy elderly individuals in 2014-2015. The advent of genome/exome sequencing techniques has heralded the detection of landscapes of mutations in RNA-splicing/DNA-methylation/epigenetic mechanism/chromatin modification/transcription factors/cohesin complex, etc. most of which are passengers/initiating lesion. Age-related increase of such clonal mutations, mostly included *DNMT3A, TET2* and *ASXL1* with a significant prevalence of *DNMT3A*, has led to speculate that accumulation of these clonal mutations might be the cause of high morbidity and mortality in elderly with higher risk of hematologic neoplasia. These dormant mutations or clonal hematopoiesis in idiopathic nonpathogenic cytopenic patients (idiopathic cytopenia of undetermined significance, ICUS) has hypothesized the clinical entity of clonal hematopoiesis of indeterminate potential (CHIP). The presence of ≥2 mutations with significant variant allele frequencies has resulted in neoplastic transformation in ~1%/year of 10% of elderly of >70 years age detected with clonal mutations, who are also at risk for cardiovascular and psychopathic disorders. The cooperation/interaction of MDS-specific driver mutations and/or subsequent acquisition of non-random mutations through clonal expansion results in self-renewal of hematopoietic stem cells and perturbation of cellular differentiation/maturation. The knowledge gained on clinical significance of CHIP has posted an urge on monitoring elderly people visiting clinicians for ICUS with a view to lowering/preventing the onset of overt malignancy.

736W

Molecular diagnosis of lung cancers. *K. Iravathy Goud[1], M. Kavitha[1], M. Adi Maha Lakhsmi[1], V. Ravi[1], D. Sagarika[1], P. Madhuri[1], P. Vijayananad Reddy[2], G. Swarnalatha[3], P. Michelle[3], S. Meenakshi[3], M. Tejal[3], A.V.S.N. Anuradha[3].* 1) Molecular Biology & Cytogenetics Laboratory, Apollo Hospitals, Hyderabad, India, India; 2) Oncology Department, Apollo Hospitals, Hyderabad, India; 3) Histopathology Department Apollo Hospitals, Hyderabad, India.

Abstract Lung cancer is the leading cause of cancer-related deaths in the in the world. Initially molecular tools which were used as research tools are now been applied to the clinical use. These molecular tests help in identifying those patients who respond to targeted therapy; and reduce side effects of ineffective treatments. Current study focuses on the significant approach of detection of epidermal growth factor receptor (EGFR) mutations in exon 18-21 and anaplastic lymphoma kinase gene (ALK) rearrangement analysis using molecular methods such as pyrosequencing and florescence in-situ hybridization (FISH) on formalin fixed paraffin embedded (FFPE) of 267 lung cancer patients. **Methods** In this study, paraffin-embedded tissue blocks of confirmed NSCLC by two pathologists which had at least 50% of neoplastic cells per sample were collected from 267 consecutive patients (185 males and 82 females; with mean age 56 years (25-84)) during December 2009 – March 2015 and referred to the Department of Molecular Biology and Cytogenetics, Apollo Health City, Hyderabad, India, for EGFR mutation testing by pyrosequencing & ALK-1 gene rearrangement by FISH analysis. Informed consent was obtained from all the patients. Fixed samples were processed routinely and stained with hematoxylin and eosin (HE) for microscopic diagnosis. If necessary, additional IHC was performed to verify the microscopic diagnosis. Paraffin block sections of 3 μm thick were taken for FISH on frosted slides and 6 μm of 6 sections were deposited in 1.5ul eppendorff tubes for sequencing analysis and 3 **Results** Among the 267 patients 11 were positive for ALK-1 gene rearrangement. *EGFR* mutations were detected in 55 patients. The most common mutations found were exon 19 (56.36%), exon 21 (27.27%), exon 20 (3.63%) and exon 18 (9.09%). The influence of gender, non-smoking, and histological type on the *EGFR* mutations showed increase in female group. **Conclusions** Molecular techniques have been invariably used in many hematological and solid tumor diagnosis and treatment. Among such cancers, lung carcinoma is one such disease where molecular techniques are used to detect molecular alterations. The use of molecular techniques would enable in effective identification of lung cancer patients who would benefit from targeted anti-ALK therapies. Mutation testing is mandatory in lung carcinomas for the management of NSCLC. **Key words:** EGFR mutations, ALK FISH.

737T

A novel *BRCA2* mutation identified in a family with male and female breast cancer patients. *M. Islam, A. Bisgin.* Department of Medical Genetics, Balcali Clinics and Hospital, Cukurova University Faculty of Medicine, Adana, Turkey.

Introduction: Certain predisposition factors such as *BRCA1* and *BRCA2* mutations play a pivotal role in developing familial breast cancer both in males and females. More than 1,800 mutations in *BRCA2* gene have been identified till date. Many of them are directly associated with an increased risk in developing not only breast cancer but also ovarian and prostate cancers. Although all carriers do not show the symptoms for cancer, it exhibits a potential risk while transferring the mutation among generations. Genetic diagnosis to identify the mutations affecting the populations help in risk assessment of patients and individuals that undergo genetic screening. In this study, a novel disease-causing *BRCA2* mutation was reported in a Turkish family linked to breast cancer in both women and man. **Methods:** A 41-year-old Turkish female diagnosed with breast cancer was referred to our Medical Genetics Department. Genetic testing for *BRCA1* and *BRCA2* was performed by using next-generation sequencing (Illumina MiSeq). Then the variant in the sequence was characterized by in-silico analysis (Mutation Taster, SIFT, and PolyPhen-2). **Results:** The clinical history of the patient lead us to consider the possibility of inherited *BRCA1* and *BRCA2* mutations among two sisters, father, mother, two aunts and a cousin diagnosed with breast cancer. All the breast cancer patients in the family presented a novel heterozygous *BRCA2*.p.P26L(c.77C>T) mutation. **Conclusion:** To the best of our knowledge, this mutation has not been previously reported in Breast Cancer Information Core (BIC) database. It is, therefore, critical to identify and report this family with male and female breast cancer patients to offer appropriate clinical assessment and to analyze the mutation-associated risks.

Germline mutations in 94 cancer predisposition genes among large epithelial ovarian cancer cohort. *R. Janavicius[1,2], V. Rudaitis[1,2], N. Archipova[1], O. Mickeviciute[1], L. Griskevicius[1].* 1) Vilnius University Hospital Santariški%1; Clinics, Vilnius, Lithuania; 2) State Research Institute, Innovative Medicine Center, Vilnius, Lithuania.

   INTRODUCTION. Recent advances in massive parallel DNA sequencing led to the generation and application of various cancer predisposition genes (CPG) panels, improving the stratification of genetic cancer subtypes for better management and targeted therapy. To determine the utility of multigene testing approach we assessed the frequency of pathogenic variants in 94 pan-CPGs in a large epithelial ovarian cancer (EOC) cohort from a homogenous population of Lithuania. METHODS. Patients with EOC (n=574) w/wo family history (FH) were recruited through single hospital center (VUHSK HOTC) and germline DNA was sequenced and analysed using Illumina Miseq multigene panels of 94 CPGs, including *BRCA1* and *BRCA2*. RESULTS. *BRCA1/2* mutations were identified in 158 patients (47%) - *BRCA1* – 141, *BRCA2* – 17 – and were present in 38,2% EOC cases w FH and 22,4% wo FH. Additional deleterious mutations were identified in 9 clinically actionable genes [*MLH1, PMS2, TP53, CHEK2, ATM, RAD51C, BRIP1, MUTYH, NBN*] (n=12; 6,6%). PT mutations were identified in 4 genes with no clear clinical actionability and association with EOC [*WRN, FANCC, FANCF, FANC*] (n=4; 2,8%). In patients w/o FH pathogenic BRCA1/2 mutations were found in 18,3% and 4,2% harboured mutations in other genes. CONCLUSION. The heritable component of EOC due to mutations in other genes than *BRCA1/2* genes is less prevalent and not affected by FH. Clinical utility for newer genes remains to be established. This work was suported by Lithuanian Research Council grant SEN18/2015.

Assessment of the real-time PCR method for detection of *EGFR* mutation by using malignant pleural effusion samples from non-small-cell lung cancer patients. *J. Kim[1], S. Shin[2], Y. Kim[1], G. Yoo[1], K. Lee[3].* 1) Lab Med, Yonsei University Wonju College of Medicine, Wonju, Wonju, South Korea; 2) Lab Med, Hallym University Kangnam Sacred Heart Hospital, Seoul, Korea; 3) Lab Med, Yonsei University College of Medicine, Seoul Korea.

   Background: *EGFR* mutation is emerging biomarker for treatment selection in non-small-cell lung cancer (NSCLC) patients. However, optimal mutation detection is hindered by complications associated with the biopsy procedure, tumor heterogeneity, and limited sensitivity of the test methodology. In this study, we evaluated the diagnostic utility of real-time PCR, using malignant pleural effusion samples. **Methods:** A total of 77 pleural fluid samples from 77 NSCLC patients were tested using cobas *EGFR* mutation test (Roche Molecular Systems). The pleural fluid was centrifuged, and the separated cell pellets and supernatants were tested in parallel. The results were compared with Sanger sequencing and/or peptide nucleic acid (PNA)-mediated PCR clamping of matched tumor tissue or pleural fluid samples. **Results:** All samples showed valid real-time PCR results in one or more DNA samples extracted from the cell pellets and supernatants. Compared with other molecular methods, the sensitivity of the real-time PCR method was 100%. Concordance rate of real-time PCR and Sanger sequencing plus PNA-mediated PCR clamping was 98.7% **Conclusions:** We confirmed that real-time PCR using pleural fluid had a high concordance rate with the conventional methods, with no failed samples. The *EGFR* real-time PCR method was fast, sensitive, and robust that it can be applied to routine diagnostics in the clinical laboratory.

740T

Cooperative mutation study in Korean patients with *MLL*-rearranged acute myeloid leukemia using targeted next generation sequencing. *S. Kim[1], J. Yang[2], T. Park[2], Y. Cho[3], S. Jang[3], C. Park[3].* 1) LabGenomics Clinical Laboratory, Seongnam, Korea; 2) Department of Laboratory Medicine, School of Medicine, Kyung Hee University, Seoul, Korea; 3) Department of Laboratory Medicine, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Background: Recent advancements of technologies including next generation sequencing (NGS) have led to discovery of molecular pathogenesis of malignant diseases including hematologic malignancies, and these discoveries are now enabling the beginning of molecular targeted therapy. The *MLL*-rearranged fusion gene is among the main leukemogenic mutation which is found in both acute myeloid leukemia (AML) and acute lymphoblastic leukemia with a frequency of about 5-10%, and is associated with a poor clinical prognosis. Cooperative mutation study among *MLL*-rearranged leukemia based on NGS technology has mainly been conducted in Caucasian or western population, and has yet been carried out in Asian ethnicity including Korean population. **Methods:** This study includes total of 24 *MLL*-rearranged AML patients who visited two separate tertiary care hospitals between the period of January 2009 and May 2014. The number of each *MLL* fusion genes are as follows; *MLL/MLLT3* n=12; *MLL/MLLT4* n=6; *MLL/ELL* n=2; other *MLL* fusion genes n=4. Mutation profile study for 19 candidate genes for cooperative mutation (*TET2, DNMT3A, IDH1, IDH2, NPM1, FLT3, CEBPA, ASXL1, BRAF, CBL, KIT, KRAS, NRAS, PTPN11, RUNX1, TP53, WT1, SETD2, JAK2*) was carried out using Miseq sequencing equipment (Illumina, San Diego, CA). **Results:** Among the twenty-four *MLL*-rearranged patients, 7 patients (29.2%) had positive results for more than 1 gene mutations which were analyzed for. Positive gene mutations found were in the order of frequency; *ASXL1* (n=4), *FLT3* (n=2), *CEBPA* (n=2), *KRAS* (n=1), *NRAS* (n=1) and *PTPN11* (n=1). Interestingly, 4 out of 6 patients harboring *MLL/MLLT4* were found to have additional gene mutations. Two patients had multiple gene mutations while one patient had four gene mutations concurrently detected. **Conclusion:** This is the first cooperative mutation study on *MLL*-rearranged AML patients of Asian ethnicity using targeted NGS technology. Despite small number of cases, a higher incidence of gene mutation among *MLL/MLLT4* patient group (4/6) and relatively higher incidence of *ASXL1* mutation (4/24) being found could be carefully suspected as an ethnical difference in the disease of AML. Further study requires a larger number of *MLL*-rearranged *MLL* patients and additional mutation profile study with ethnical comparison.

741F

Taming concerns regarding the accuracy of laboratory clinical data: A detailed comparative analysis. *H. LaDuca, R. McFarland, S. Gutierrez, A. Yussuf, N. Ho, P. Reineke, T. Cain, K. Blanco, J.S. Dolinsky.* Department of Clinical Diagnostics, Ambry Genetics, Aliso Viejo, CA.

Purpose: Genetic testing laboratories accumulate large amounts of clinical data from clinicians via test requisition forms (TRFs) and other clinical documents such as pedigrees and/or detailed clinic notes ('clinicals'). When curated, phenotype data can be used in variant assessment, genetic disease characterization, and clinical research; however, the completeness and accuracy of phenotype data from laboratory-based cohorts is often questioned. The purpose of this study is to evaluate the completeness and accuracy of TRF data for patients undergoing hereditary cancer multigene panel testing (MGPT). **Methods:** Ten percent of MGPT cases were randomly selected and reviewed from a cohort tested between January and June 2015 at a single clinical laboratory. For cases where clinicals were submitted *after* the test order date, TRF-reported cancer types and ages at diagnosis (dx) for probands and relatives were evaluated for accuracy and completeness using clinicals as the comparison standard. **Results:** Of 2,893 MGPT cases reviewed, 43.7% (n=1,263) submitted a pedigree and/or clinic note. For 31.3% (n=395) of cases, clinicals were submitted *after* the test order date and thus further evaluated. Cancer type and age at dx (+/- 2 years) were accurately reported for 99.4% and 97.8% of proband cancers, respectively. Proband cancer type was incomplete for 5.1% of cases and age at dx was incomplete for 7.4% of cases. Compared to probands, cancer type and age at dx for relatives were also highly accurate (type: 98.9%, p=0.553; age at dx: 95.8%, p=0.130) but significantly more likely to be incomplete (type: 29.7%; p=3E-28; age at dx: 26.4%; p=3E-16). When compared to 1st and 2nd degree relatives, incomplete data was more frequently observed among 3rd degree relatives and beyond (p=6E-8 and p=3E-5 for cancer types and ages, respectively). No significant differences were observed between maternal and paternal family history data. **Conclusions:** In this laboratory cohort, cancer type and age provided on the TRF is highly accurate for probands and relatives. Proband cancer histories exhibited a high level of completeness; however, this diminishes somewhat among relatives, particularly as relationship to the proband becomes more distant. It is imperative for clinicians to provide complete data not only on probands but also on relatives to aid in accurate molecular results interpretation, disease characterization and interpreting the overall health implications of genomic data.

742W

Multiplex TaqMan assays for rare mutation analysis using digital PCR. *M. Laig, B. Moy, F. Chan, L. Lac, T. Straub, K. Varma, D. Keys.* Genetic Analysis, Thermo Fisher Scientific, South San Francisco, CA.

   Introduction Detection of rare mutations for research purposes in tumor tissue and cell free DNA (cfDNA) allows for monitoring of tumor progression and regression. cfDNA isolated from plasma combined with a sensitive detection method like digital PCR is non-invasive and enables earlier detection compared to conventional imaging techniques. Building on the TaqMan based Rare Mutation assay set for detection of rare mutations using digital PCR on the QuantStudio 3D Digital PCR System, we are now developing multiplex assays for simultaneous detection of several mutations. We selected relevant mutations in the EGFR and KRAS genes for our initial multiplex application: EGFR G719, EGFR exon 19 deletions, and KRAS G12/G13. These mutations may have implications for potential future targeted therapy.   Methods Primers and probes of singleplex Rare Mutation Assays were reformulated to generate multiplex assays detecting the EGFR and KRAS mutations. All multiplex assays were tested on template composed of wild-type genomic DNA background mixed with mutant plasmid reflecting each of the mutations detected by the multiplex assays.   Summary Initial experimental results were successful and showed excellent signal intensity and clear cluster separation when analyzed with the QuantStudio 3D AnalysisSuite™ Cloud Software. The EGFR G719 mutations (COSM6239, COSM6253, COSM6252) were detected using a 3plex assay, EGFR exon 19 deletions (COSM12383, COSM12422, COSM12678, COSM6223, COSM6254, COSM6255) were detected using a 6plex assay, and KRAS G12/G13 mutations are underway.   Conclusion Multiplexing assays for three relevant mutation loci proved feasible and presents an efficient way to assess the presence and the percentage of mutations.

743T

Association of plasma *AR* copy number with response to pre-chemotherapy abiraterone acetate in metastatic castrate resistant prostate cancer. *J. Li[1,2], M.J. Du[1], D. Hillman[3], L.G. Wang[3], L.W. Wang[3], H.J. Zhang[1,4], P. Zhang[1], L. Wang[1], M. Kohli[3].* 1) Medical College of Wisconsin, Milwaukee, WI; 2) People's Hospital of Zhengzhou University, Zhengzhou, China; 3) Mayo Clinic, Rochester, MN; 4) Zhengzhou 7th People's Hospital, Zhengzhou, China.

   Background. We determined *AR* genomic changes in plasma cell-free DNA (cfDNA) and evaluated their associations with response to abiraterone acetate/prednisone (AA/P) and overall survival in a prospective clinical trial conducted in the pre chemotherapy metastatic castrate resistant prostate cancer stage. Copy number variation (CNV) analysis in *AR* using digital PCR technology was analyzed for determining association of *AR* CNVs with clinical outcomes. **Materials and Methods.** Metastatic sites of CRPC stage patients initiating pre-chemo AA/P were biopsied prior to (pre-AA/P) and after 12 weeks of treatment (post) and plasma was collected at the same time point on this prospective trial (NCT# 01953640). Composite response to AA/P at 12 weeks (primary endpoint) was evaluated with PSA, RECIST, bone scan and symptoms (per PCWG2). Plasma based biomarker analyses presented here are part of the correlatives included in the study protocol. CNVs were tested using Taqman CN assays in QuantStudio3D digital PCR system (dPCR). Statistical analyses were performed to test association of *AR* amplification with clinical outcomes (progression-free survival or PFS and overall survival or OS). **Results.** Between 6/2013 and 8/2015, 92 patients were enrolled of which 70 patients had plasma samples at both time points (58 patients with bone metastases; 27 with nodal metastases; 38/70 had high volume and 32/70 had low volume metastatic disease at the time of trial enrollment). At 12 weeks, 31/70 patients showed the composite progression; 21 patients had died at the time of this analysis (median/range follow up: 15.73/7.9-25.9 months). CNV analysis by dPCR showed 34/70 patients with AR amplification and 26/70 without amplification in pre-AA/P plasma. When AR CNV differences between pre- and post-treatment samples (log 2 ratio of pre- vs. post-treatment CNVs) were evaluated, the copy number increase after treatment was associated with 3-month progression (p=0.0013). A significant association of increased AR copy number with both PFS (HR= 1.23 and p=0.0019, Cox-regression) and OS (p<0.05, Kaplan-Meier analysis) was observed. **Conclusions.** *AR* amplification status in cfDNA was associated with disease progression and clinical outcomes in metastatic CRPC patients treated with AA/P in this study. Additional validation in prospective patient cohorts are needed to further test its clinical utility.

744F

An unusual translocation t(5;7) in a case with T-ALL with a complex karyotype. *L. Mendoza-Maldonado[1,2], L. Bobadilla-Morales[1,3], G. Serafín-Saucedo[3], E. Velazquez-Rivera[3], A. Vázquez-Reyes[1,2], F. Sanchez-Zubieta[5], J. Corona-Rivera[4], A. Corona-Rivera[1,3].* 1) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo, Instituto de Genética Humana "Dr. Enrique Corona Rivera", CUCS, Universidad de Guadalajara; 2) Doctorado en Ciencias en Biología Molecular en Medicina, CUCS, Universidad de Guadalajara; 3) Unidad de Citogenética, Servicio de Hemato-Oncología Pediátrica, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca"; 4) Servicio de Genética, División de Pediatría, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca"; 5) Servicio de Hemato-Oncología Pediátrica, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca".

   T-cell acute lymphoblastic leukemia (T-ALL) is an aggressive neoplasm of the bone marrow (Litzow and Ferrando, 2015). The acquisition of genetic abnormalities results in the proliferation of malignant lymphoid hematopoietic progenitors and could contribute to a poor prognosis (Mrózek *et al.*, 2009). Actually, only exist one report where found the presence of t(5;7)(q32;q22) which was related to cancer (Maubach *et al.*, 1985). We present a case with T-ALL with a complex karyotype including t(5;7)(q32;q22). Case report. Eight years old male with persistent low back pain and petechiae. He presented hyperleukocytosis, bicytopenia, tumor lysis syndrome, mediastinal mass, acute kidney injury, occipital lobe mass with midline shift and compression of the right lateral ventricle. On Juanuary 7, 2016, bone marrow aspirate was performed. The morphology analysis showed 82% cerebriform, large blasts. The immunophenotype result was CD2+, CD3+, CD7+, CD19+, CD22+, CD4+, CD24+, CD34+, CD38+, CD45+, HLA DR+. The patient was diagnosed with T-ALL with aberrant markers and primary CNS infiltration. Chemotherapy was initiated with doxorubicin, vincristine, L-asparaginase on January 12, 2017. He dies on 31 January, 2016. The diagnosis of defunsion was pulmonary hemorrhage, disseminated intravascular coagulation, septic shock and T-ALL. The result of karyotype was 48,XY,del(3)(q23),t(5;7)(q32;q22),+7,+8[12]/48,idem,add()14(q32)[2]/46,XY[1]. The pacient showed genetic abnormalities implicated in development of T-ALL in karyotype. Raimondi (2007) described the 14q32 region contains *TCL1, IGH, BCL11B* genes which are activated in T-cell neoplasms. Independently, trisomy 7 and 8 are common abnormalities as part of hyperdiploid karyotype in ALL and AML. However, there is only a case report by Maubach *et al.* (1985) of an adult with AML where both trisomies are presented like ours. The t(5;7)(q32;q22) is a chromosomal abnormality has been reported once in a case of recurrent glioma by Pruchon *et al.* (1994). Hoffman (2013) described *PDGFRB* gene it's found at 5q32 region and it has been identified with 22 different fusion partners in chronic myeloproliferative neoplasms although they are indeed very rare. This case report provides knowledge about a new chromosomal translocation in T-ALL which in combination with other genetic abnormalities provides a poor prognosis for the patient.

745W

A sensitive method for circulating DNA library preparation. *J.D. Murdoch[1], K. Krishnan[1], L. Apone[1], P. Liu[1], C.E. Massie[2], C.G. Smith[2], V. Panchapakesa[1], K. Duggan[1], D. Rodriguez[1], E. Dimalanta[1], T. Davis[1].* 1) New England Biolabs, Ipswich, MA 01938; 2) Cancer Research UK, University of Cambridge, Cambridge, UK CB2 ORE.

   Next-generation sequencing has enabled large-scale studies of cancer genomes to identify mutations. These tumor-specific somatic changes offer great potential as biomarkers to inform clinical practice, including detection, personalized medicine and disease monitoring. The ability to detect the mutational landscape of tumor cells using non-invasive approaches could enable rapid, personalized variant screening and efficient monitoring of therapy. Unfortunately, limitations of current standard technologies include lack of sensitivity and the scalability for a rapid analysis, especially in the case of small amounts of DNA from blood plasma samples. We have developed a DNA library preparation workflow for next-generation sequencing, which allows multiplexing and produces high quality, reproducible data using small amounts of healthy circulating plasma DNA. With as little as 500 pg of DNA we were able to generate sequencing libraries for whole genome (WGS) and whole exome (WES) with good GC coverage. We also achieved sufficient library complexity for high-confidence copy number detection and variant recovery, and we accurately determined the ratio of sex chromosomes in a mixed sample down to 5% of Y chromosome input. Exome target enrichment allowed recovery of known variants (>80%), showed good correlation with expected allele frequencies, and detection was consistent and reproducible across different starting concentrations of DNA. The simple and rapid workflow of this new kit allows a quick and sensitive approach to detect genomic variations. This method could facilitate biomarker identification to supplement diagnostic, prognostic and therapeutic applications.

746T

Amplicon panels for the detection of germline and somatic *BRCA1* **and** *BRCA2* **mutations.** *D. Obermoeller, R. Hrdlickova, J. Nehyba, C. Firmani, J. Kinman, D. Fox, A. Lewis, M. Toloue.* Bioo Scientific, Austin, TX.

The *BRCA1* and *BRCA2* tumor suppressor genes are associated with a high risk of breast, ovarian, and other types of cancer. Any germline, heterozygous, loss-of-function mutations in these DNA repair proteins lead to a strong predisposition to malignant disease. Moreover, the role of somatic mutations in these genes during the development of various cancers was recently described. Next generation sequencing allows a rapid and sensitive detection of mutations in these two genes. However, the available library preparation assays for their detection does not cover all of the needs of various applications of the analysis of *BRCA1* and *BRCA2* mutations. Bioo Scientific developed four panels for rapid detection of these mutations. For users seeking to identify germline mutations from fresh and frozen tissues, panels with 130 amplicons in two pools that can use as little as 20 ng of input DNA are available. The performance of these panels has been validated by positive identification of five described germline mutations in 20 ng DNA samples from Corriel Institute. With 100% uniformity these panels allow a large number of libraries to be multiplexed during sequencing. For 100x coverage of every targeted base, over 300 libraries could be sequenced on one Illumina MiSeq instrument making it the most economical assay on the market. For identification of somatic mutations from partially degraded DNA, panels of 260 smaller amplicons with a higher redundancy are available in four pools. These assays were fully validated with several FFPE samples reaching 99% uniformity at 20% coverage and 100% uniformity at 10% coverage. Only 40 ng of DNA extracted from the FFPE samples is necessary for the preparation of one library. These panels for the detection of somatic mutations in partially degraded DNA are available for both the Illumina and Ion Torrent platform. All of the *BRCA1* and *BRCA2* panels cover 20.4 kb pairs comprising 48 coding *BRCA1* and *BRCA2* exons and limited flanking intron regions (4.3 kb). These panels offer a versatile and economical tool for diagnostic and further research of the role of these tumor suppressor genes in human cancer filling in the current gap in the market. .

747F

Quantitative measurement of burden of Calreticulin using pyrosequencing in patients with myeloproliferative neoplasm. *Y. Oh[1], Y. Park[1], H. Kim[1], J. Lim[1], Q. Choi[2], G. Kwon[1], S. Koo[1], S. Kim[1,3].* 1) Department of Laboratory Medicine, Chungnam National University Hospital, Daejeon, South Korea; 2) Department of Laboratory Medicine, Dankook University Hospital,Cheonan, South Korea; 3) Cancer Research Institute, Chungnam National University School of Medicine, Daejeon, Republic of Korea.

Frame-shift mutations in the calreticulin (*CALR*) gene were recently identified as key pathogenic mutations of myeloproliferative neoplasms (MPNs). We developed novel method to quantitate *CALR* mutations burden using pyrosequencing technique. We validated the performance of this technique in synthesized DNA bearing type 1 and type 2 mutations, and evaluated the clinical usefulness in the MPN patients. To determine analytical performance of the *CALR* quantitation, we cloned plasmid vector bearing mutant DNA fragment bearing type 1 and type 2 *CALR* mutations. Triplets' tests for 6 serial equal-volume dilutions were performed to detect the sensitivity of the assay. Genomic DNA of bone marrow and peripheral blood samples from 14 patients diagnosed as MPN without *Jak2* or *MPL* mutation were collected. Each primer sets were designed to detect type 1 and type 2 *CALR* mutations and DNA fragment including *CALR* was amplified by polymerase chain reaction followed by Pyrosequencing (Qiagen, Hilden, Germany). Pyrograms were generated, which is then converted to peak height. The data was processed manually to quantitate the mutation burden. All the mutations were reassessed by Sanger sequencing. The assay showed high precision, linearity and reproducibility. From the sensitivity and specificity study, mutation detection level was detected as about 1%. Among the 14 patients; there were 3 type 1 mutations, 1 deletion mutation, 2 insertion mutations (GTGTC and TTTGTC). All 14 samples showed 100% concordance compared to Sanger sequencing. In conclusion, pyrosequencing can accurately measure the burden of type 1 and type 2 *CALR* mutations and can also detect other types of *CALR* indels. Therefore, pyrosequencing is considered as a rapid, convenient and reliable method for detecting type 1 and type 2 *CALR* mutations.

748W

Consensus molecular classification of colorectal cancer and association with the colonic microbiome. *R. Purcell[1], J. Pearson[2], S. Schmeier[3], F. Frizelle[1].* 1) Department of Surgery, University of Otago, New Zealand, Christchurch, Canterbury, New Zealand; 2) Department of Biostatistics and Computational Biology Unit, University of Otago, New Zealand, Christchurch, Canterbury, New Zealand; 3) Institute of Natural and Mathematical Sciences, Massey University, Private Bag 102-904, North Shore City, New Zealand.

   Colorectal cancer (CRC) is the second most common cancer worldwide, and shows heterogeneous response to treatment and outcomes. Most CRCs are sporadic, and follow a pattern one would expect from a yet unidentified environmental source. This study brings together two key emerging research avenues, namely the new clinical frontier of applying information on the gut microbiome to treatment and management of CRC, and the use of advanced molecular classification systems to better investigate the development of CRC. Recent studies have classified CRC based on *BRAF* and *KRAS* mutation status, microsatellite instability, CpG island methylator phenotype, and activation of various molecular pathway, but discrepancies exist between these classification systems. In 2015, a large international consortium published a classification system based on gene expression data. These published classifiers stratify CRC into four consensus molecular subtypes (CMS): CMS1 (MSI immune), CMS2 (canonical), CMS3 (metabolic), and CMS4 (mesenchymal). We have stratified 34 tumors from our CRC cohort into CMS subtypes using RNA-Seq data. Extensive clinical and follow-up data available on our cohort allowed us to investigate the associations of the molecular subtypes with clinical and histological features, and with response to therapy. The human colon plays host to a vast and complex microbial community of $< 10^{12}$ microorganisms, and gut dysbiosis is believed to play a role in the development of CRC. Given the high number of different bacterial species found in the gut ($< 10^3$), and the wide interpersonal variation in CRC microbiomes, redundancy of function is quite likely. Therefore, examining changes in meta-communities, clusters of orthologous groups, and putative virulence factors, represents a more promising means for deciphering the contribution of microbial dysbiosis to the genesis of CRC. We have used metagenomic analysis to map the CRC microbiomes of our cohort, and will examine the association between differeing microbiome patterns and CMS subtypes of our tumour cohort. We anticipate that this will reveal particular species of bacteria or bacterial virulence factors involved the development of a particular CRC subtype. This would represent an important step in understanding the interplay between microbial diversity in the gut and the molecular mechanisms involved in the development of CRC.

749T

Variants of uncertain significance in *BRCA*, a challenge yet to be solved by clinical geneticists. *V.E. Radoi[1,2], R.I. Ursu[1,2], G. Chelu[2], C. Arsene[2], R.E Bohiltea[1], L.C. Bohiltea[1].* 1) "Carol Davila" University of Medicine and Pharmacy, Faculty of General Medicine, Bucharest, Romania; 2) SYNEVO Romania, Central Laboratory, Department of Medical Genetics, Buchatrest, Romania.

   Background: BRCA1 and BRCA2 gene mutations account for 20-25% of hereditary breast cancer and about 5-10% of all breast cancers. In addition, mutations in these genes account for about 15% of all ovarian cancers. The BRCA 1 and BRCA2 have been the most studied and reported genes in human genome over the past decades. **Purpose**: The using of cuttingedge genetic analysis technologies imposes the existance of large comprehensive genomic databases for an accurate clinical interpretation. At the same time, these modern diagnostic techniques lead to the identification of novel variants with unknown or controversial clinical significance which raise great challenges for the clinicians in the analysis. **Material. Methods.** A review of the main BRCA databases (1000 Genomes,ClinVar,NCBI,SNPedia,PharmGK-B,OMIM,COSMIC,UCSC Genome Browser, BioGPS, etc.) and professional workgroups` guidelines and recommendations has been performed for a comprehensive outline of the current knowledge on BRCA variants associated with hereditary breast and ovarian cancer. Different classification categories proposed by leading national and international professional societies have been taken into consideration. **Results.** By analyzing the abovementioned databases and variant classes we observed slight differences between the variant clinical correlation classification criteria, number of classes and especially terminology used to define these classes. These discrepancies tend to produce confusion when in terms of analysis and clinical interpretation, some variants with uncertain significance being extremely difficult to categorize, with consequences in managing the patients. **Conclusions:** In conclusion, establishing an unified BRCA database would be of great value in the assessment of the multitude of data provided by modern genetic technology. The existance of a large database containing all the current BRCA knowledge would not only help physicians in accurately interpreting the implications of these variants in cancer etiopathogeny, but would also lead to the correct identification of novel pathogenic variants.

Detection of monoclonal *IGH* rearrangements in circulating cells from general population from Western Mexico. *S. Rodríguez[1,2], M.T. Magaña-Torres[2], A.R. Jaloma-Cruz[2], P. Barros-Núñez[2].* 1) CENTRO UNIVERSITARIO DE CIENCIAS DE LA SALUD, UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, JALISCO, MEXICO; 2) CENTRO DE INVESTIGACIÓN BIOMÉDICA DE OCIDENTE, CMNO, IMSS, GUADALAJARA, JALISCO, MEXICO.

The monoclonal B-cell lymphocytosis (MBL) is a condition characterized by the presence of small populations of monoclonal lymphocytes B circulating in peripheral blood ($<5\times10^9$/L), in the absence of chronic lymphocytic leukemia (CLL) or other B-cell lymphoproliferative disorder, infections or autoimmune diseases. MBL frequency in the general population (asymptomatic individuals, unrelated, without neoplastic history) is significantly different in diverse studied groups, ranging from 0.6% in the USA population to 12% in the Spanish population. Approximately 1-5% of individuals carrying MBL evolve annually to CLL, while virtually all the CLL cases are preceded by MBL. In this study, we estimated the frequency of monoclonal B-cell lymphocytosis in the general population from the western of Mexico. DNA extracted from a sample of peripheral blood by CTAB/DTAB method was used to amplify the rearrangements of the immunoglobulin heavy chains by multiplex PCR, using 20 specific primers for the complete rearrangements (VDJH), and seven primers for the incomplete rearrangements (DJH) of the *IGH* gene. After, the products were separated by capillary electrophoresis and statistical analysis was performed. We studied the *IGH* rearrangements in 188 individuals of the general population from Western of Mexico. In 24 (12.8%) of them, monoclonality was detected in at least one of the regions amplified by PCR. The MBL frequency increases with the age and all individuals showing monoclonality were over 40 years. A higher frequency of MBL was observed in men, with a higher frequency of monoclonal incomplete rearrangements. In conclusion, the MBL incidence in the general population of the Western of México is significantly major to those previously described for other populations but similar to those reported in the Spanish population. Detection of monoclonal rearrangement in individuals may help to identify cases requiring continuous clinical monitoring in order to anticipate disease progression.

751W

Next-generation sequencing of the *BRCA1* and *BRCA2* genes in 700 patients for the genetic diagnostics of hereditary breast and/or ovarian cancer. *D. Trujillano[1], B. Jori[1], K. Kumar Kandaswamy[1], M. Weiss[1], S. Lehnert[1], A. Marais[1], R. Schröder[1], C. Voight[1], J. Köster[1], N. Nahavandi[1], O. Brandau[1], R. Abou Jamra[1,2], P. Bauer[1], A. Rolfs[1,3].* 1) Centogene AG, Rostock, Germany; 2) Institute of Human Genetics, University of Leipzig Hospitals and Clinics, Leipzig, Germany; 3) Albrecht-Kossel-Institute for Neuroregeneration, Medical University Rostock, 18147 Rostock, Germany.

Genetic testing for hereditary breast and/or ovarian cancer (HBOC) mostly relies on laborious molecular tools that use Sanger sequencing to scan for mutations in the *BRCA1* and *BRCA2* genes. We introduced a more efficient strategy based on next-generation sequencing in 700 (HBOC) patients. We first validated this approach in a cohort of 115 samples with previously known *BRCA1* and *BRCA2* pathogenic variants and polymorphisms. The entire coding region of *BRCA1* and *BRCA2* including 10bp of intronic flanking sequences was amplified and sequenced on the IonTorrent PGM sequencer (Life Technologies) in the genomic DNA. The combination of robust bioinformatics tools allowed us to detect all previously known pathogenic variants and polymorphisms in the 115 samples, without detecting spurious pathogenic calls. The assay achieved a sensitivity of 100% (95% CI: 99.71% to 100%), with a specificity of detecting non-variant sites from the reference sequence of 99.99% (95% CI: 99.99% to 100%), a positive predictive value of 91.17% (95% CI: 89.72% to 92.62%), and a negative predictive value of 100% (95% CI: 100% to 100%). The same assay has been used in a discovery cohort of 585 uncharacterized HBOC patients for *BRCA1* and *BRCA2*. In addition, we describe the allelic frequencies across 700 HBOC patients of 97 unique definitely and likely pathogenic and 92 uncertain *BRCA1* and *BRCA2* variants, some of them not previously annotated in the public databases. Targeted NGS is ready to substitute classical molecular methods to perform genetic testing on the *BRCA1* and *BRCA2* genes, and provides a greater opportunity for more comprehensive testing for at-risk patients.

752T

Clonal hematopoiesis confounding genetic epidemiology research in a prospective cohort of individuals undergoing genetic cancer risk assessment. *J.N. Weitzel[1,2], S.R. Sand[1,2], D. Castillo[2], R. Mejia[1], J. Herzog[2], S.L. Neuhausen[1,2], T.P. Slavin[1,2], Clinical Cancer Genomics Community Research Network.* 1) City of Hope Comprehensive Cancer Center, Duarte, CA; 2) Beckman Research Institute of City of Hope, Duarte, CA.

We previously demonstrated apparent somatic interference in germline multigene panel test (MGPT) results from blood and sputum samples, wherein pathogenic *TP53* variants with mean allele fractions (MAF) < 30% were detected in patients without phenotypic manifestations of Li-Fraumeni syndrome. Absence of the pathogenic variants in alternate sources of constitutional or at-risk tissue suggested that clonal hematopoiesis, with or without incipient hematologic abnormalities, was likely the source of the variant in the majority of cases. The recently described entity of clonal hematopoiesis of indeterminate potential (CHIP) is defined as somatic myeloid pathogenic gene variants involving ≥2% of an individual's blood, without that individual meeting other diagnostic criteria for hematologic malignancy. For this study, we evaluated CHIP using an exon capture panel containing *ATM, CHEK2, KIT, NF1, NRAS, RUNX1, SETBP1, SF3B1, TP53,* and *PPMD1*. We conducted next generation sequencing (NGS) on an Illumina 2500HT on germline (blood) DNA from 251 women and 30 men, with uninformative commercial genetic test results, from the City of Hope Clinical Cancer Genomics Community Research Network registry. The mean age at blood sample collection was 51.7 years (range 17-90 years); prior cancer history included 183 breast or ovarian cancers, 84 colorectal cancers and other cancer diagnoses among 263 affected participants; 18 participants were unaffected. Four individuals (1.4%) had potential CHIP pathogenic gene variants: *TP53*:c.736A>G, *PPM1D*:c.1448delC, and *ATM*: c.1236-2A>G and c.1236-2A>T. Read depths ranged from 29 to 157 and allele fractions ranged from 18.5-38.3%. All 4 individuals had prior chemotherapy for breast cancer and/or were > 50 years old at the time of enrollment and sample collection (both features seen in other populations with clonal hematopoiesis), and none had any evidence of hematologic neoplasia. It is possible that more cases with CHIP would have been identified with inclusion of other genes more frequently associated with CHIP, such as DNMT3A. Thus, CHIP is detectable with conventional NGS methods and may confound cancer genetic epidemiology studies and MGPT. The clinical implications of CHIP with regard to prospective development of hematologic malignancies deserve further study.

753F

Targeted resequencing of *BRCA1* and *BRCA2* in familial breast cancer. *M. Wong-Brown[1], R. Scott[1,2].* 1) University of Newcastle, Newcastle, New Lambton Heights, Australia; 2) Pathology North, Newcastle, Australia.

Inherited loss-of-function mutations in *BRCA1* and *BRCA2* predispose to high risk of breast cancer. Since the discovery of breast cancer susceptibility genes *BRCA1* and *BRCA2* two decades ago, there have not been any other genes identified that play a significant role in predisposition to inherited breast cancer. A large proportion of individuals with inherited breast cancer are negative for *BRCA* mutations and despite numerous research efforts, further breast cancer susceptibility genes still remain elusive. We hypothesize that potentially deleterious mutations may reside in the less-researched non-coding sequences. This study aims were to identify genetic anomalies in *BRCA1* and *BRCA2* by completely re-sequencing 200 kilobases surrounding *BRCA1* and *BRCA2* using next-generation sequencing. For this study, DNA was used from 10 individuals referred for genetic testing after meeting the criteria for inherited breast cancer, and had been screened for *BRCA1* and *BRCA2* mutations by the Hunter Area Pathology Service (Newcastle, NSW, Australia). All individuals used for this study did not harbour causative genetic changes in the coding regions of *BRCA1* or *BRCA2*. Targeted sequencing of the entire *BRCA1* and *BRCA2* genes was performed. Common SNPs were removed from further analyses. Single nucleotide variants (SNVs) and insertions/deletions (indels) were identified in most individuals tested in regions that had previously remained unexplored, such as the non-coding regions of BRCA1 and BRCA2, 5'-UTR, 3'-UTR and promoter sites. One patient in particular displayed a large number of BRCA1 3'-UTR variants. The PITA miRNA target prediction algorithm showed that target miRNAs and their alignment scores were altered due to variants in this region. An overview of the alignment scores show changes of binding strengths in several miRNAs, including those that have been shown to target BRCA1. Multiple BRCA1 3'-UTR variants could potentially change miRNA target prediction profile. The relative expression of BRCA1 mRNA in this patient's cell lines was also shown to be significantly lower compared to several control cell lines, suggesting that miRNAs may be regulating BRCA1 gene expression The aim of this study is the increase in current knowledge of the genetic variations that results in the development and/or progression of inherited breast cancer, and aid in the management of individuals with breast cancers by providing a more specific diagnosis of disease risk.

754W

Comparison of genetic heterogeneity between tumor tissues and circulating cell-free DNA in hepatocellular carcinoma. *X. Zhao[1], A. Huang[2], F. Li[1], X. Yang[2], K. Wu[1], J. Fan[2], J. Zhou[2], Y. Hou[1].* 1) BGI-Shenzhen, Shenzhen 518083, China; 2) Liver Surgery Department, Liver Cancer Institute, Zhongshan Hospital, Fudan University, China.

Intratumor heterogeneity presents a major challenge for precise evaluation of hepatocellular carcinoma (HCC). Recent evidence suggests that circulating cell-free DNA (cfDNA) could reveal the profiles of mutational landscape in solid tumors. However, it remains unknown whether the intratumor heterogeneity in HCC could be reflected in cfDNA and to what extent the information obtained from cfDNA could reveal the genetic intratumor heterogeneity for clinical utility in HCC. Here we characterized the genomic architectures and clonal evolution in fifty-two tumor tissues and ten cfDNAs from five HCC patients prior to and one week after surgical removals of tumors by whole exome sequencing and targeted deep sequencing. The whole exome sequencing identified intratumor heterogeneity in tumor tissues of all cases. By targeted deep sequencing preoperative cfDNA (Pre-cfDNA), we detected approximately 82.7% (72%~96%) of somatic mutations that were found in multiregional tumor tissues. The mutation level in pre-cfDNA have showed the diversity on clonal hierarchy. And the tumor spatial heterogeneity might be the critical factor which affected the detection rates and proportion of clonal hierarchy of tumor-derived somatic mutations in pre-cfDNA. We also found the percentage of tumor-derived somatic mutations which be detected in postoperative cfDNA (Post-cfDNA) were reduced in eighty percent of HCC patients. The detection rate of ubiquitous mutations, which were detected in all the tumor regions of each patient, in post-cfDNA of high heterogeneity patients could be used as a prognostic indicator for recurrence after surgical treatment in HCC. Our findings could provide a different insight into the utility of cfDNA as liquid biopsy in clinical application of HCC for diagnosing and monitoring.

755T

Somatic driver mutations enhance survival prediction in familial chronic lymphoid leukemia. *W. Zhou[1,2], L. Goldin[2], M. Wang[1,2], M. McMaster[2], S. Chanock[2], M. Dean[2], M. Yeager[1,2], N. Caporaso[2].* 1) Cancer Genomics Research Laboratory, Leidos Biomedical Research/NCI, Bethesda, MD 20892; 2) Division of Cancer Epidemiology and Genetics (DCEG), NCI, 9609 Medical Center Drive MSC 9776 Bethesda, MD 20892.

Chronic lymphoid leukemia (CLL) is the most common type of leukemia in adults. Traditionally, four common chromosomal aberrations (deletion of 11q, 13q, 17p, duplication of 12) as well as the mutational status of the immunoglobulin heavy chain variable (IGHV) gene have been shown to stratify CLL patients into distinct prognostic groups. In the last few years, several tumor sequencing studies have revealed a number of recurrent mutations, some of which also contribute to prognosis. In this study, we performed whole exome-sequencing of whole blood samples from 98 CLL patients (and 95 subjects with SNP microarray data) from 40 CLL families. Log R ratio (LRR) and B allele frequency (BAF) were used to assess copy number alterations as well as to calculate the proportion of cancer cells. Overall, 142 detectable somatic copy number alterations (SCNAs) from 54 subjects were detected (57%), including the four most common CLL-associated cytogenetic aberrations: losses of chromosome 13q (28.9%), 11q (5.6%), and 17p (2.1%); gain of chromosome 12 (4.2%). We found many chromosomal alterations were observed only in a portion of the cells (mosaicism). We used a somatic pipeline caller to detect somatic mutations and used other filtering methods to eliminate likely germline mutations. We focused on a panel of 52 genes that previously reported as putative driver alterations in mature B-cell non-Hodgkin lymphomas. Overall, 72 non-synonymous somatic mutations in 34 of these genes were detected among 47 subjects (48%). The most frequently mutated gene was *TP53* (7.1%). We found that patients having both a point mutation in a CLL driver gene and SCNA have worse survival (HR=3.98, 95%CI=1.25-12.64; P=0.02, ref = single 13q deletion) than patients having either a point mutation (HR = 2.19 and P = 0.02, ref = no point mutation) or SCNAs (HR = 3.13 and P = 0.05 in SCNA, ref = single 13q deletion). *TP53* mutations were associated with the poorest overall survival (HR=6.01, 95%CI=1.68-21.49; P=0.006). Subjects having a somatic mutation in *CHD2*, *MYD88*, and *KLHL6* had similar survival times to those without these mutations. Additionally, we confirmed that *TP53* mutation status has independent prognostic value and that males with CLL have poorer survival than female CLL patients. Our study demonstrates that combining somatic CNAs and mutational data can add to predicting the pathway from an initial diagnosis to outcome in CLL.

756F

Isochromosome i(7q) in two patients with acute lymphoblastic leukemia.
A. Corona-Rivera[1,2], L. Mendoza-Maldonado[1], P. Chávez-Panduro[2], G. Serafín-Saucedo[2], L. Bobadilla-Morales[1,2]. 1) Dept BMG, Inst GH, Univ Guadalajara, CUCS, Guadalajara, Jalisco, Mexico; 2) Lab. De Citogenética, Genotox. y Biomonit., CUCS, UdeG. Serv. de Hemato-Oncol. Ped., HCG "Dr. Juan I. Menchaca". Guadalajara, Jalisco, México.

INTRODUCTION The i(7q) is a rare chromosomal aberration in ALL, it may present isodicentric abnormality and breakpoints in proximal 7p. Although the association between malignancy and the presence of i(7q) suggests it plays an important role in disease progression has not been possible to elucidate its consequences in patients with ALL. OBJECTIVE To present two patients with pre-B ALL and i(7q) in karyotype. CASE REPORTS Patient 1. Male, 15 years old, refers vomiting, headache, backache and presents cervical lymphadenopathy, leukocytosis. It is performed bone marrow aspirate and karyotype. He is diagnosed with pre-B ALL in December, 2011. Chemotherapy starts and achieves remission at 14 days, radiation is added for primary CNS infiltration with CSF positive in July, 2012. He is in surveillance since November, 2014. The result of the initial karyotype was 46,XY,idic(7)(p11)[13]/46,XX[7][cp20]. Patient 2. Female, 17 years old with obesity, anemia and leukocytosis. It is performed bone marrow aspirate and cytogenetic analysis. She is diagnosed with pre-B ALL in August, 2011. Chemotherapy starts and achieves remission at 14 days. She is in surveillance since August, 2014. The result of the initial karyotype was 46,XX,idic(7)(p11)[3]/46,XX[3].ish.idic(7)(p11;p11)(D7Z1++,CUTL1++,D7S2419-D7S2624++) CONCLUSION The evolution of patients in this study does not show i(7q) as the only chromosomal aberration, confers a poor prognosis, this is according to Pui et al., 1992 where 10/83 isochromosomes cases with no additional chromosomal abnormality were considered, but its mechanism of action is unclear what this is still open to discussion.

757W

Chromosomal aberration pattern predicts uveal melanoma mutation status and prognosis. *A. de Klein[1], S. Yavuzyigitoglu[1,2], W. Drabarek[1,2], A. Obulkasim[2], T. Brands[1,2], B. Eussen[1], E. Kilic[2].* 1) Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Ophthalmology,Erasmus MC, Rotterdam, Netherlands.

Rationale: In uveal melanoma (UM) non-random chromosomal aberrations occur and correspond to patients' prognosis. Mutations in UM specific genes, such as *BAP1*, *SF3B1* and *EIF1AX* are also used to predict survival. Aim of this study is to identify whether these mutations correspond to a specific chromosomal signature in UM. Methods: For 277 UM patients SNP array data (n = 214) and/or conventional karyotyping (n = 119) of the tumor was available. The mutational status was determined in 189 patients. Independent of the mutational status, SNP array and conventional karyotyping data was analyzed for recurring copy number variations (CNVs) and structural variants (SVs). Hierarchal clustering of the SNP array data was performed to construct clusters. These clusters were correlated to the mutational status. Results: *BAP1*, *SF3B1* and *EIF1AX*-mutated UMs display specific chromosomal patters with recurring CNVs. Both *BAP1*-mutated and *SF3B1*-mutated UMs are characterized by specific chromosome changes. *BAP1*-mutated tumors showed predominantly numerical changes of chromosome 3 and 8 whereas *SF3B1* mutated tumors are characterized by multiple (>3) structural chromosomal anomalies. *EIF1AX*-mutated UM are characterized by only chromosome 6p gain without any additional CNVs. Hierarchal clustering of the SNP array data revealed five clusters of which two clusters predicted *BAP1* mutations: these UM patients have a high risk of developing early (<5 y) metastatic disease. Tumors with *SF3B1* mutations also cluster together and these patients have an intermediate risk of developing, often late (7-10y), metastasis. The remaining cluster are a mix of *EIF1AX*-mutated tumors or UM without detectable mutations; these patients have in general a low risk of developing metastasis. Conclusion: UMs with either *BAP1*, *SF3B1* or *EIF1AX* mutations display a mutation-specific chromosomal pattern. Based on the chromosomal patterns a genetic mutation in one of the UM cancer genes can be predicted. .

758T

The impact of LPL and CRY1 expression as prognostic genetic markers in B-Cell Chronic Lymphocytic Leukemia of Egyptian patients. *A.E. Ibrahim[1], M. Shehab[1], A. Elgerzawy[1], K. Mohammed[2], S. Abd-Elbaset[3], M. Ahmed[3], T. Abd-Elhamid[4].* 1) Human Cytogenetics Department, National Research Centre, Cairo, Egypt; 2) Molecular Genetic Department, National Research Centre, Cairo, Egypt; 3) Faculty of Science, Al-Azhar University (Girls Branch), Cairo, Egypt; 4) Medical Oncology and Hematology, National Cancers Institute, Cairo, Egypt.

  Introduction: Chronic lymphocytic leukemia (CLL) is the most common leukemia in adults.CLL is a heterogeneous disease, some patients die within a few months of diagnosis and others live for many years**.** So, it is needed to investigate reliable prognostic factors for predicting stable or progressive forms of CLL that facilitate risk-adapted treatment strategies. Cytogenetic abnormalities and molecular prognostic markers such as lipoprotein lipase (*LPL*) and cryptochrome-1 (*CRY1*) have been evaluated. **Materials and Methods:** This study included 42 patients with CLL (25 males and 17 females) and 10 controls. Patients newly diagnosed on the basis of clinical criteria and laboratory features. Thay are subdivided to 2 groups according to their response of treatment; patients with favorable outcome and patients with unfavorable outcome. Fluorescence In Situ Hybridization (FISH) technique was done for the detection of del(13q14) and del(17p13). Quantitative real-time PCR (qRT-PCR) technique was done for the detection of gene expression of target genes *CRY1*, *LPL* and Housekeeping gene Beta-Glucuronidase (*GUS*) in patients and controls. **Results:** Patients' age fell in the range (26-76) year with a median of 61 years. Deletion 17p13 combined with del(13q14) were the most common abnormality (64.3%), followed by del(17p13) 19% and del(13q14) 14.3%. Other chromosomal abnormalities were found among CLL patients; more than one copy (polyploidy) of gene locus DLEU in chromosome 13q14 and gene locus p53 in chromosome 17p13 were found in 45.2% of cases. Polyploidy is rare in CLL and not commonly found, so this study were the first study of CLL Egyptian patients had polyploidy with this percentage. High expression of *CRY1* gene was detected in 64.3% and high expression of *LPL* gene was detected in 75.6%. Significant inversely correlation of *CRY1* and *LPL* genes expression was found between patients and controls. Significant correlation was found between *CRY1* gene expression, *LPL* gene expression, patients' outcome and deletion 17p13. **Conclusion:** Patients in early stage of CLL with high *CRY1* or *LPL* genes expression must be early treated even in the presence of favorable prognostic parameters. *CRY1* and *LPL* genes expression had a higher detection rate of prognosis than cytogenetic markers. The combination of them provided more information about the prognosis than *CRY1* gene or *LPL* gene alone. .

Malignant glioma with primitive neuroectodermal tumor-like component (MG-PNET): Novel microarray findings in a pediatric patient. *J. Liu[1], M.P. Keisling[1], A. Samkari[2,3], G. Halligan[2,3], J.M. Pascasio[1,2], C.D. Katsetos[1,2,4].* 1) Department of Pathology and Laboratory Medicine, Drexel University College of Medicine, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania, USA; 2) Department of Pediatrics, Drexel University College of Medicine; 3) Sections of Oncology, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania, USA; 4) Sections of Neurology, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania, USA.

  Central nervous system (CNS) tumors exhibiting dual features of malignant glioma (MG) and primitive neuroectodermal tumor (PNET) are rare and diagnostically challenging. Previous studies have shown that MG-PNET carry *MYCN* or *MYC* gene amplifications within the PNET component concomitant with glioma-associated alterations, most commonly 10q loss, in both components (Perry et al., Brain Pathol. 2009;*19*:81-90). Here we confirm and extend the profile of molecular genetic findings in a MG-PNET involving the left frontal lobe of a 12-year-old male. Histologically, the PNET component showed features akin to anaplastic medulloblastoma highlighted by widespread immunoreactivity for βIII-tubulin (TUBB3) and non-phosphorylated neurofilament protein, and to a lesser degree, Neu-N, synaptophysin, and CD99, whereas the gliomatous component was demarcated by GFAP labeling. Interphase fluorescent in situ hybridization (FISH) study on touch preparations from frozen tumor showed amplification of *MYC*. Single nucleotide polymorphism (SNP) microarray analysis revealed that the tumor carried gains of multiple chromosomes and chromosome arms, losses of multiple chromosomes and chromosome arms, gains of multiple chromosomal segments (not limited to amplification of chromosomal segments 4q12 including *PDGFRA,* and 8q24.21 including *MYC*), and chromothripsis on chromosome 8. The molecular genetic findings support the presence of a CNS-PNET as an integral part of the tumor coupled with overlapping genetic alterations found in both adult and pediatric high-grade gliomas/glioblastoma. Collectively, microarray data point to complex underpinning genetic alterations associated with the MG-PNET tumor phenotype. .

760W

Frequency of additional cytogenetics abnormalities in chronic myeloid leukemia patients at time of diagnosis and during follow-up: A single centre experience. *S. Shan[1], M. Nadeem[2], S. Sheeba[3], A. Nida[4], S. Tahir[5].* 1) Cytogenetics, National Institute of Blood Diseases & BMT, Karachi, Sindh, Pakistan; 2) HOD, National Institute Of Blood Disease & BMT, Karachi, Sindh, Pakistan; 3) Ex Employee, Cytogenetics, National Institute of Blood Diseases & BMT, Karachi, Sindh, Pakistan; 4) Consultant, National Institute Of Blood Disease & BMT, Karachi, Sindh, Pakistan; 5) MD, National Institute Of Blood Disease & BMT, Karachi, Sindh, Pakistan.

INTRODUCTION:At the time of presentation, 90-95% cases of Chronic Myeloid Leukemia (CML) have characteristic t(9;22)(q34;q11.2) reciprocal translocation that results in Ph Chromosome. The remaining cases either have variant translocations that involve a third or even a fourth chromosome in addition to chromosomes 9 and 22 or have cryptic translocation of 9q34 and 22q11.2 that cannot be identified by routine cytogenetic analysis. The additional cytogenetic abnormalities, at times, have been associated with adverse prognostic outcome and resistance to treatment.OBJECTIVE:To study the frequency of cytogenetic abnormalities in addition to Ph Chromosome in patients of CML at the time of diagnosis.MATERIAL AND METHODS:A cross sectional study was carried out in the department of cytogenetics NIBD Karachi from May 2010 to April 2016. Cytogenetic analysis was performed on newly diagnosed patients & patient on followup of CML using un-stimulated 24 hrs and stimulated 72 hrs cultures employing trypsin giemsa banding technique.RESULTS:Bone Marrow samples of 220 Ph positive CML patients were analyzed for cytogenetic abnormalities. There were 142 (64.5%) male and 78 (36%) female patients with median age of 38 years (range 14-73 years). Out of total, 19 (07%) patients had additional cytogenetic abnormalities including Trisomy 8 (01 patients), Complex Karyotype (05 patients), -Y (1 patient), t(1;17) (1 patient), double Ph Chromosome (02 patients), Hyperploidy (03 patient), inv (9) (01 patient), Trisomy 21 (01 patient), t(7;9;22) a novel translocation (01 patient),t(4;9;22) (01 patient), del(7q) (02).CONCLUSION:Additional cytogenetic abnormalities are not infrequent in patients of CML. High degree of suspicion and thorough examination of metaphases should be performed to detect these aberrations. Presence of additional chromosomal aberrations at diagnosis or during the course of disease, at times signifies impending conversion to advance phase and/or resistance to therapy.**KEYWORDS:**Chronic Myeloid Leukemia, Ph Chromosome, Additional Cytogenetic Abnormalities.

Mapping complex genomic translocations in tumor cells using Strand-Seq. *M.W. Yuen[1,2], M. Hills[2], A.D. Sanders[2], E. Falconer[2], D. Spierings[3], P. Lansdorp[2,3].* 1) University of British Columbia, Vancouver, Canada; 2) Terry Fox Laboratory, BC Cancer Research Centre, Vancouver, Canada; 3) European Research Institute for the Biology of Aging (ERIBA), University of Groningen, The Netherlands.

Structural variations (SV) such as translocations are often difficult to study. Traditional methods lack the effective resolution to determine breakpoints or require *a priori* knowledge of the type and location of rearrangements. Next generation sequencing has improved our ability to map novel SV, but often requires deep sequencing to identify reads that can be used to detect the breakpoints. Here we explored the use Strand-seq, a single cell sequencing technique that preferentially sequences inherited parental DNA template strands, to map SV. Strand-seq differentiates Watson and Crick strands, and the changes in strand-state can be used to mark regions of chromosome rearrangements. To validate the use of Strand-seq in a global, unbiased interrogation of SV, we used an Acute Lymphocytic Leukemia cell line that was characterized by cytogenetics and found to harbour a complex 4-way translocation with 1 known fusion gene. Sequencing with just a single MiSeq lane, we identified each of the 4 translocations and were capable of resolving the breakpoint at each translocation within a ~20kb region. This is orders of magnitude better than commonly used cytogenetics approaches. We are exploring automation of the analysis pipeline to allow rapid, high-resolution breakpoint identification and the ability to resolve translocation partners for each breakpoint. Taken together, the Strand-seq single cell sequencing approach presents a new vista in cancer genomics, with potential for accurate, high throughput calling of genomic rearrangements present in a plurality of cells as well as in smaller sub-populations.

Clinical application of next generation sequencing in Omani patients with gastrointestinal tumors. *A. Alsaegh[1], M. AlMondhari[2].* 1) Genetics and Developmental Medicine Clinic, Sultan Qaboos University, Muscat, Oman; 2) Sultan Qaboos University, Muscat, Oman.

    Cancer genetics service was officially established in Sultanate of Oman in August 1st 2012 at the Genetics and Developmental Medicine Clinic in Sultan Qaboos University Hospital. Individuals with diagnosed gastrointestinal tumors (GI) were referred mainly from the oncology department from Sultan Qaboos University Hospital and other tertiary hospitals in the country. From 2012 to 2016, a total of 45 patients with GI tumors underwent Next Generation Sequencing (NGS) <u>as a first line investigation</u> . 28/45 (62%) patients were found to have pathogenic mutations associated with familial cancer syndromes , out of which 18 mutations associated with lynch syndrome, 9 with familial adenomatous polyposis and 1 with PTEN mutation. This study emphasizes on the clinical applications of NGS and the high diagnostic yield in identifying individuals with high risk familial cancer syndromes associated with GI Tumors.

763W

Diagnostic detection, characterization & classification of partial single exon deletions in hereditary cancer genes. *P. Fernandes, B. Morris, K. Brown, D. Mancini-DiNardo, K.R. Bowles.* Myriad Genetics Laboratories, Inc., Salt Lake City, UT.

    Background: Hereditary cancer syndromes are caused by pathogenic genetic variants, including sequence variations and large rearrangements (LRs). Methodologies such as Chromosomal Microarray Analysis, exon-based targeted Microarray-CGH, Next Generation Sequencing (NGS) and Multiplex Ligation Probe Amplification are often used to detect large deletions and duplications. However, LRs involving partial exons require additional follow-up in order to determine the exact breakpoints for accurate characterization. Here, we describe our testing strategy for confirming LRs involving partial exons and providing appropriate clinical classifications. **Methods:** Our laboratory uses exon-based targeted Microarray-CGH and/or NGS dosage analysis to identify LRs as part of a 25-gene hereditary cancer panel. In addition, Long Range PCR (LR PCR) and subsequent Sanger sequencing analyses are utilized for breakpoint determination of large deletions and duplications involving partial exons. **Results:** To date, we have identified 43 unique LRs (41 deletions and 2 duplications) involving partial exon deletions/duplications in individuals referred to our laboratory for hereditary cancer testing. 38/43 of these LRs were classified as 'pathogenic' or 'likely pathogenic' based on disruption or loss of critical gene regions or removal of consensus splice junctions, most likely resulting in abnormal RNA splicing. The remaining 5 LRs were classified as 'uncertain' based on specific criteria. These include, but are not limited to, LRs with a deletion of in-frame non-critical gene region(s), the deletion of a region located after the last known deleterious mutation, or terminal duplications of unknown location or orientation. LR PCR was performed in 15/43 cases, as breakpoint determination could significantly impact classification. One such case was the analysis of a *BRCA2* LR ("partial del exon 11") where we confirmed the presence of an in-frame deletion of 711 base pairs within a non-critical region, leading to an 'uncertain' classification. **Conclusions:** Using a combination of exon-based targeted Microarray-CGH and/or NGS dosage analysis along with LR PCR and Sanger sequencing, we are able to resolve the precise endpoints of a subset of LR deletions and duplications involving partial single exons. This leads to appropriate classifications of these rearrangements and provides healthcare providers with accurate information to appropriately guide patient management.

764T

High-throughput characterization of *BRCA1* **and** *BRCA2* **splicing defects.** *R. Karam, S. Farber-Katz, V. Hsuan, S. Wu, H. Vuong, H.M. Lu, R. Huether, S. Lam, J. Hoo, A. Elliott. Ambry Genetics, Aliso Viejo, CA.*

Statement of purpose: Advances in DNA Next Generation Sequencing (NGS) techniques resulted in the detection of many thousands of germline unclassified variants with unknown functional impact. Variants of unknown significance (VUS), especially in clinically actionable genes such as the hereditary breast and ovarian cancer susceptibility genes *BRCA1* and *BRCA2* (OMIM 113705 and 600185 respectively), pose significant challenges to the medical community and patients. Among the variants that are frequently classified as VUS are those with unclear effects on splicing. Currently, there are no cost effective and high-throughput assays to quantify and characterize germline splicing defects in a time-frame necessary for clinical testing. Here we discuss the validation and implementation of a novel high-throughput RNA-NGS assay designed to perform *quantitative* and *qualitative* characterization of splicing VUS. Methods: We compared the gold-standard mRNA splicing assays recommended by members of the ENIGMA (Evidence-based Network for the Interpretation of Germline Mutant Alleles) consortium, including Capillary Electrophoresis and Sanger sequencing of subcloned transcripts, to high-throughput RNA-NGS assays. Following the ENIGMA protocol we performed cDNA analysis of lymphoblastoid cell lines (LCLs) generated by the kConFab consortium from carriers of *BRCA1* or *BRCA2* variants known to be associated with splicing defects, and of control LCLs, blood samples, and breast tissue. In parallel, we performed RNA-NGS assays and compared the results derived from these analyses to evaluate sensitivity and specificity of our assays. Summary of Results: Using these techniques described above, we were able to detect and characterize the splicing aberrations described in the literature by the ENIGMA consortium. Differences in protocols allowed us to determine whether RNA-NGS assays are a reliable alternative for clinical characterization of *BRCA1* and *BRCA2* splicing alterations. RNA-NGS provides a cost effective and high-throughput alternative to the gold-standard with a reduced turnaround time, thereby improving the interpretation of splicing variants detected on clinical genomic tests.

765F

Implementation of a multi-gene panel testing for hereditary cancer (qCanceRISK) in a hereditary cancer and genetic counselling unit. *M. Palacios[1], A. Abulí[1], B. Rodríguez-Santiago[2], L. Armengol[2], R. Fábregas[3], M. Cusidó[4], X. Estivill[1,5,6]. 1) Unit of Medical Genomics, Department of Obstetrics, Gynaecology and Reproduction. Introduction Advances in next-generation sequencing (NGS) technology have allowed testing multiple genes at a reasonable price and time. Several multi-gene panels have been introduced in hereditary cancer. However, their clinical utility has not been fully established. Nevertheless, multi-gene cancer panels can help to identify causative mutations in high-risk patients with clinical implications in their management and in genetic testing for at-risk relatives. **Material and Methods** Patients who underwent a multi-gene NGS panel (qCanceRISK) at Dexeus Women's Health were included in the study. Patients with personal or family history of cancer had an oncology risk assessment visit and were offered genetic testing based on risk assessment. Patients received pre and post-test genetic counselling. The panel consists of 100 genes associated with risk for breast and other types of cancer. **Results** A total of 89 individuals were included in the study. Approximately 81% (72/89) of patients had personal and 19% (17/89) had family history of cancer. Clinical criteria for hereditary breast and ovarian cancer (HBOC) were met by 61% (54/89) of families and 20% (19/89) had moderate risk. Only one patient met clinical criteria for hereditary non-polyposis colon cancer (HNPCC). We found a pathogenic mutation in 12% (11/89) and a likely pathogenic mutations in 2.2% (2/89) of cases with breast cancer and one pathogenic mutation in *MLH1* in the patient who met HNPCC criteria. Pathogenic and likely pathogenic mutations were found in *BRCA1*, *BRCA2*, *PALB2*, *PMS2* and *NBN* genes. A heterozygous pathogenic mutation was also found in *MUTYH*. Variants of unknown significance (VUS) were found in 37% (33/89) of cases. The global detection rate of qCanceRISK panel was 15% (13/89) and for high-risk patients 20% (11/55). **Conclusions** Our study identified mutations in other genes that would have been missed if classic testing of *BRCA1* and *BRCA2* would had been performed; however, we also found VUS in an important percentage of patients. Multi-gene panel testing should be performed in the context of an adequate pre and post-genetic counselling sessions, in which transmitting to the patient information regarding incidental findings and the higher detection rate of VUS are the main challenge.

766W

The *PTEN* promoter: To be or not to be included on multigene panel tests? *R. Pilarski[1], S. Li[2], R. McFarland[2], H. LaDuca[2], B. Smith[2], T. Pesaran[2].* 1) Division of Human Genetics, Comprehensive Cancer Center, Ohio State Univ, Columbus, OH; 2) Ambry Genetics Corp, Aliso Viejo, CA.

Background Pathogenic *PTEN* alterations have been associated with an increased risk of developing cancers of the breast, thyroid, endometrium, and others as part of *PTEN* hamartoma tumor syndrome. Although several alterations in the *PTEN* promoter region have been described as mutations, data are insufficient to support a classification of pathogenicity and they are currently characterized as variants of unknown significance (VUS) by clinical labs. We sought to assess the association of *PTEN* promoter variants with breast and other cancers in a cohort of 61,552 patients undergoing *PTEN* testing. Methods Clinical histories of patients who underwent comprehensive *PTEN* analysis from January 1, 2014 to March 31, 2016 as part of a multigene panel testing (MGPT) were retrospectively reviewed. Personal and family cancer histories of *PTEN* promoter variant carriers (PV; N=704) were compared against *PTEN* mutation-positive patients (MP; N=57) and also matched mutation-negative individuals (WT; N= 2,194). The frequency of MP, PV and WT were compared between patients with and without selected cancer phenotypes using the Fisher's exact test and multivariate logistic regression analysis, controlling for age at testing, MGPT ordered, ethnicity and gender. Age differences were tested using Welch t-test or Wilcoxon rank test based on the data distribution. Results *PTEN* promoter variants were observed with a frequency of 1.1% (704/61,552). PV individuals were significantly less likely than MP individuals to have a personal history of female breast cancer (p=0.003), bilateral breast cancer (p=0.014), uterine cancer (p=0.001), or kidney cancer (p=0.002). No differences were observed when comparing personal history of colon cancer or thyroid cancer, or family history of female breast cancer among first degree relatives between these two groups. No significant differences were observed when comparing PV individuals to WT individuals. MP individuals had a younger diagnosis age of female breast cancer (p=0.022; p=0.021), endometrial cancer (p=0.027; p=0.015) and thyroid cancers (p=0.042; p=0.032) compared to WT and PV individuals, respectively. Conclusions In this cohort, *PTEN* promoter variants were not associated with an increased risk of *PTEN*-related cancers. These results do not support the inclusion *PTEN* promotor sequencing on cancer panels, as the identification of these alterations contributes to increased VUS burden without increasing diagnostic yield.

767T

A broader genotype-phenotype spectrum in hereditary colorectal cancer syndromes. *A.M.H. Rohlin[1], E. Rambech[2], A. Kvist[2], T. Törngren[2], F. Eiengård[1], U. Lundstam[3], T. Zagoras[1], S. Gebre-Medhin[4,5], A. Borg[2], T. Olausson[1], J. Björk[6], M. Nilbert[2,7], M. Nordling[1].* 1) Department of Molecular and Clinical Genetics, Institute of Biomedicine, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; 2) Division of Oncology and Pathology, Department of Clinical Sciences Lund, Lund University, Medicon Village, SE 22381 Lund, Sweden; 3) Department of Surgery, Sahlgrenska Academy at University of Gothenburg, Sahlgrenska University Hospital/Östra, SE 416 85 Gothenburg, Sweden; 4) Division of Clinical Genetics, Department of Laboratory Medicine, Lund University, Lund, Sweden; 5) Department of Clinical Genetics, Office for Medical Services, Division of Laboratory Medicine, Lund, Sweden; 6) The Swedish Polyposis Registry, Department of Medicine, Karolinska Institute, Stockholm, Sweden; 7) The HNPCC-register, Hvidovre University Hospital, Copenhagen University, Hvidovre, Denmark.

Hereditary colorectal cancer (CRC) can be divided into syndromes. High penetrant mutations in known CRC genes explain 5-6% of the cases. Clinical testing is usually preformed based on phenotype of the different syndromes. However, overlapping phenotypes between CRC syndromes, including both polyposis and non-polyposis, present diagnostic difficulties in the clinic. It is crucial that the patient get a correct molecular diagnosis that allows for adequate follow-up since the majority of the syndromes include predisposition for tumors also in other organs.   To address this concern we constructed a panel consisting of 19 CRC susceptibility whole gene regions including introns. Analysis of SNPs, indels and CNVs were performed on approximately 100 individuals divided into clinical subtypes based on phenotype.   After filtration by a comprehensive clinical pipeline we detected several pathogenic mutations. In patients diagnosed with classical FAP, attenuated FAP, atypical FAP and none-polyposis subgroups, we identified mutations in *BMPR1A* and *SMAD4*. These two genes are mutated in juvenile polyposis. We also detected novel CNVs in upstream regions of *SMAD4*, *MSH3*, *CTNNB1* and one deletion in an intronic region of *CDH1*   By using this gene panel we obtained increased mutation detection frequency for CRC syndromes which enable appropriate follow of patients based on the clinical feature of each syndrome. We have also found misdiagnoses for especially juvenile polyposis, which also broadens the genotype-phenotype spectrum for these genes. By using this gene panel more extensive possibilities to detect deletions and other structural rearrangements can be achieved. This lies beyond the potential of the commonly used techniques eg MLPA, and also includes a reduction in costs and work load.   .

768F

Clinical NGS Pipeline outperforms a combined approach using Sanger sequencing and MLPA in targeted gene panel analysis. *L. Schenkel[1], J. Kerkhof[2], A. Stuart[2], J. Reilly[2], C. Howlett[1,2], P. Ainsworth[1,2], B. Sadikovic[1,2].* 1) Department of Pathology and Laboratory Medicine; Western University; London, ON, Canada; 2) Molecular Genetics Laboratory; Molecular Diagnostics Division, London Health Sciences Centre, London, ON, Canada.

Recent advances in next-generation sequencing (NGS) have enabled parallel analysis of multiple genes allowing the implementation of more cost-effective, rapid and high-throughput methodologies for the molecular diagnosis of multiple genetic conditions. Clinical-grade NGS analysis must meet high standards of sensitivity and specificity for both sequence mutations and structural rearrangements including copy number alterations. The objective of this study was to develop a single NGS-based pipeline to replace clinical Sanger sequencing and MLPA copy number analysis, first for hereditary breast and ovarian cancer testing, and then to expand to other clinical gene panel tests. We analyzed by NGS 402 retrospective patients, with previous Sanger and MLPA confirmation of HBOC, and 240 clinical prospective patients. Custom sequence capture probes were designed using the SeqCap EZ Choice Library system and included enrichment for 46 exons, including *BRCA1* exons 2, 3, 5-24 and *BRCA2* exons 2-27, with 20 nucleotides of intronic regions both 5' and 3' of each exon. The DNA sequencing was conducted using an Illumina MiSeq platform with 24 different patient samples multiplexed per run. Sequence analysis for variant identification, alignment and coverage distribution was performed with NextGene software v2.4.1, and copy number variant analysis was performed using single nucleotide resolution depth of coverage and a quantile normalization algorithm. Within those patients, 183 unique variants, including sequence and copy number variants were detected in the retrospective (95) and prospective (88) cohorts. This standardized NGS pipeline demonstrated 100% sensitivity and 100% specificity, in addition to uniformity and high depth nucleotide coverage per sample (approximately 7000 reads per nucleotide). Using the same approach, this NGS pipeline was applied to the analysis of larger gene panels, including Charcot Marie Tooth, hereditary cancer syndromes, mitochondrial genome, epilepsy syndromes, lysosomal and urea cycle disorders, all of which have shown similar uniformity, sample to sample reproducibility in coverage distribution, and sensitivity and specificity for detection of sequence and copy number variants. In conclusion, we have validated a clinical-grade NGS pipeline which outperforms the "gold standard" Sanger sequencing and MLPA for sensitive and specific detection of sequence and copy number alterations in a single test.

769W

Standardized multiplex genetic testing in a population-based hereditary cancer clinic. *K.A. Schrader[1,2], T.R. Docking[1], I. Bosdet[1], S. Young[1], T. Tucker[1], S. van den Berg[2], M. He[1], Z. Lohn[1], J. Nuk[1], C. Cremin[1], J. Scott[1], A. Mindlin[1], C. Portigal-Todd[1], K. Turner[1], J. Thompson[1], A. Bedard[1], L. Armstrong[2], B. McGillivray[2], G. Aubertin[1], S. Sun[1], G. Mitchell[1], HCP Cclinical Team[1], R. Moore[1], A. Mungall[1], L. Swanson[1], L.P. Yang[1], J. Slind[1], M. Balasundaram[1], J. Schein[1], A. Karsan[1,2].* 1) BC Cancer Agency, Vancouver, British Columbia, Canada; 2) Univ British Columbia, Vancouver, British Columbia, Canada.

The BC Cancer Agency's Hereditary Cancer Program (HCP) is the sole provider of cancer genetics services to the population of British Columbia and the Yukon. Publically funded testing is currently conducted at the Centre for Clinical Genetics (CCG) using a 14-gene panel for affected individuals ages 19 and over meeting testing criteria for at least one syndrome on the panel. The HCP has utilized this panel which tests for Hereditary Breast and Ovarian Cancer (*BRCA1, BRCA2*), Li Fraumeni (*TP53*), Cowden (*PTEN*), Hereditary Diffuse Gastric Cancer (*CDH1*), Peutz Jeghers (*STK11*), Lynch Syndrome (*MLH1, MSH2, MSH6, PMS2*), MYH-Associated Polyposis (*MUTYH*), Familial Adenomatous Polyposis (*APC*), and Juvenile Polyposis (*SMAD4, BMPR1A*) since October 2014. The uptake of multiplex genetic testing in the hereditary cancer clinic has altered the way in which patients and families are counseled regarding genetic testing, with increased attention given to the risk for identification of variants of uncertain significance and unexpected diagnoses. Interim analysis of 411 cases revealed variants of uncertain significance in 42% of individuals tested. Examination of the subpopulation of cases meeting criteria for Hereditary Breast and Ovarian Cancer revealed the rate of positive findings in genes other than *BRCA1* and *BRCA2* to be 10% (4/38). We will present aggregate results from our consecutive experience to date of over 1000 individuals who have been tested through the HCP using the 14-gene panel approach. We will present mutation detection rates for both expected and unexpected presumed pathogenic germline variants, variants of uncertain significance, and the frequency of findings per individual. Results from this population-based ascertainment with extensive phenotypic data will help provide important insights into potential germline findings using panel approaches and may provide guidance in settings that analyze panels of genes in affected individuals, such as secondary analysis of cancer genes in tumor-normal sequencing. These data demonstrate that even within relatively small testing panels, phenotypic heterogeneity is seen within well-defined syndromes, likely due to previous biases in ascertainment and testing criteria.

770T

A randomized controlled trial of exome sequencing vs. usual care in patients with colorectal cancer/polyposis syndromes: Preliminary results. *D.L. Veenstra[1], L.M. Amendola[2], P. Heagerty[3], B. Comstock[3], M. Horse-Pyne[2], F. Hisama[2], M. Li[1], A. Burt[2], R.L. Bennett[2], M.O. Dorschner[4], P. Tarczy-Hornoch[5], S.M. Fullerton[6], S.B. Trinidad[6], D.A. Regier[7], D.L. Patrick[8], D.A. Nickerson[9], W. Burke[6], G.P. Jarvik[2].* 1) Pharmaceutical Outcomes Research and Policy Program, University of Washington, Seattle, WA; 2) Medical Genetics, University of Washington, Seattle, WA; 3) Biostatistics, University of Washington, Seattle, WA; 4) Pathology, University of Washington, Seattle, WA; 5) Biomedical Informatics and Medical Education, University of Washington, Seattle, WA; 6) Bioethics and Humanities, University of Washington, Seattle, WA; 7) Canadian Centre for Applied Research in Cancer Control, BC Cancer Agency, Vancouver, BC; 8) Health Services, University of Washington, Seattle, WA; 9) Genome Sciences, University of Washington, Seattle, WA.

   Background. Next generation DNA sequencing is a potentially transformative technology in clinical care, but little evidence exists as to whether this approach improves patient outcomes or provides good economic value. This knowledge gap can be addressed by comparative effectiveness and patient-centered outcomes research. **Methods.** Patients seeking genetic testing to evaluate hereditary colorectal cancer and polyposis syndromes (CRCP) were randomized to usual care (UC) vs. UC + whole exome sequencing (WXS). Patients received findings associated with colorectal cancer and additional findings in separate visits. The primary outcome was whether the patient had any detection of pathogenic variants associated with CRCP; secondary outcomes included psychosocial impact and healthcare resource utilization. Additional findings returned were determined by a formal return of results committee, and initially consisted of incidental findings from 112 medically actionable gene-disease pairs, and have been expanded to include a limited set of pharmacogenomics variants and carrier status genes. UC was dependent on the provider, but in general evolved from smaller to larger CRCP gene panels during the course of the study. **Results.** A total of 65 patients were randomized to usual care (UC), and 68 were randomized to UC+WXS. The proportion of patients with a CRCP variant that was pathogenic, likely pathogenic, or of unknown significance was 24.6% (16/65) in the UC group vs. 32.4% (22/68) in the UC+WXS group, (p=0.3); the proportion with a pathogenic variant was 6.2% vs. 7.4%, respectively. Additional findings in the 52 patients in the WXS+UC arm who had been sequenced included a disease finding (strong genetic risk) in 5.8% of patients and a pharmacogenomic finding in 73.1% of patients. Patient-reported anxiety, depression, and test result-specific psychosocial impact did not differ between groups. Healthcare resource utilization was similar between groups, although a higher proportion of patients in the WXS+UC group thought about making life insurance changes. **Conclusions.** Our preliminary results indicate exome sequencing led to a 1.3 fold increased genetic diagnosis for CRCP cases that was not statistically significant, return of clinically important additional findings, and no differences in average patient quality of life or healthcare costs. Larger studies are needed to achieve power to confirm these findings.

771F

To panel or not to panel: Do genetic professionals differ in NGS testing preferences? *G.L. Wiesner[1,2], S. Lewis[1], K. Taylor[1], K. McReynolds[1], S.K. Rao[1].* 1) Vanderbilt-Ingram Cancer Center, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Vanderbilt University, Nashville, TN.

   Introduction: The advent of NGS testing has ushered in a new era in genomics where genetic testing has become easily accessible and yet more complicated to interpret. Literature is lacking about current genetic panel test ordering preferences amongst genetics professionals. The Hereditary Cancer Genetics Clinic at Vanderbilt University Medical Center is uniquely placed in having credentialed genetics providers of various backgrounds; 3 genetic counselors (GC), 1 genetics advance practice nurse (NP) and 2 geneticists (MD); that see patients at high risk for Hereditary Breast/ Ovarian Cancer (HBOC) syndrome. We report on our own experiences in cancer genetic testing. **Methods:** A retrospective analysis was done of the Hereditary Cancer Registry of patients seen during a 30 month period between July 2012- Dec 2014. Study data were collected and managed using RedCap electronic data capture tools hosted at Vanderbilt University (Harris et al; *J Biomed Inform* 2009). Parameters analyzed were test type (panel vs. single gene; single site excluded), and provider type (GCs vs MD/NPs) stratified by breast/ovarian cancer affected and unaffected probands, over first and second half of time period described. Summary statistics and chi square analyses were done. **Results:** For breast/ovarian patients (n=535); 48.6% (260/535) tests were ordered by MD/NPs and 51.4% (275/535) by GCs. Of these, 69% (179/260) of MD/NP orders were panel tests versus 55% (151/275) by GCs (p= 0.0004). For unaffected probands with a family history of breast/ovarian cancer (n=188); MD/NPs (80.7%) and GC (72.5%) patterns were similar (p= 0.1786). An analysis comparing the first and second 15 month periods showed that NGS panel orders rose overall from 34.6% to 82.3% (GCs 17% to 76.5%; MD/NPs 48.8% to 88.8%;p= 0.0001). **Conclusion:** This data indicates a significant difference in test ordering profiles between genetic professionals. Genetic counselors appear to be more conservative in NGS panel testing compared to MD/NPs geneticists. The time progression analysis shows an increased uptake overall with the clinician providers adopting panel testing earlier and the counselor group making a more gradual transition. Some parameters not analyzed in this study were patient's insurance coverage, or surgical decision constraints which might affect NGS panel test ordering decisions. Nonetheless, these data will provide a foundation for further studies into the uptake of new technologies into clinical care.

772W

Low cost liquid biopsy by selective sequencing of mutant DNA. *M.J. Wiggin[1], L. Mai[1], S. Walsh[1], D. Broemeling[1], A. Marziali[1,2]. 1) Boreal Genomics, Vancouver, BC, Canada; 2) University of British Columbia Dept. of Physics & Astronomy, Vancouver BC, Canada.*

Clinical circulating tumor DNA (ctDNA) assays (liquid biopsy) require high sensitivity and specificity, multiplexing over multiple mutations, and importantly, low cost. Achieving all of these requirements simultaneously is very challenging, and the most common approaches to liquid biopsy assays are limited by either very low multiplexing (droplet digital PCR, ddPCR), or very high cost (barcoded sequencing), making many clinical applications impractical. In sequencing-based liquid biopsy assays, majority of reads are wasted re-sequencing wild-type cell free DNA (cfDNA) fragments that deliver no useful information about the patient. Therefore, a powerful solution to the problems of cost, sensitivity, and specificity is to separate mutant cfDNA from wild-type cfDNA so that only tumor molecules are sequenced. Given that in many clinical cases the ctDNA represents only 0.1% - 0.01% of the total cfDNA, this approach has the potential to reduce the required sequencing by 1,000 – 10,000 fold, dramatically reducing sequencing cost. By narrowing the sample to contain primarily mutant ctDNA, both the sequencing cost and false positive sequencing errors are greatly reduced. We have developed such a technology, which can selectively enrich for hundreds of different mutations simultaneously from a single sample, which we call the OnTarget assay. We present the technical details of the OnTarget assay, including the underlying method used to enrich samples for mutations, and results from an analytical validation study using controlled reference samples. These results demonstrate limit of detection measurements on each mutation in the assay, demonstrating that OnTarget performance is similar or better than ddPCR on individual mutations, while testing many more mutations in parallel, at a fraction of the cost of barcoded sequencing assays. We also present data from clinical samples in studies that include both cancer patients and healthy individuals, as a precursor to larger clinical studies for population-wide screening and early cancer detection. In summary, the addition of wild-type DNA depletion to NGS assays enables lower cost, high sensitivity, and high specificity liquid biopsy tests, enabling commercialization of this powerful diagnostic in applications with limited reimbursement, potentially including early cancer detection.

773T

What do public databases really tell us about classification of variants in *BRCA1* and *BRCA2*? *R. Nussbaum[1], S. Lincoln[1], S. Yang[1], M. Cline[2], C. Zhang[2], Y. Kobayashi[1], S. Topper[1], D. Haussler[2], B. Paten[2]. 1) Invitae, San Francisco, CA; 2) University of California, Santa Cruz, CA.*

The ClinVar database has collected over 170,000 de-identified records from commercial and academic clinical laboratories. However, certain laboratories not only decline to submit data, but they also prominently highlight disagreements in various public databases, suggesting that these differences "preclude their wider use in clinical practice". While disagreements are real, this proposition is inconsistent with our experience. For example, in a published study of 975 patients, we observed 99.8% concordance of reports in BRCA1 and BRCA2, comparing actionable vs. not-actionable classifications (a) based on publicly available data, the literature, and recent guidelines, with (b) classifications from another lab who also used a large proprietary database. This result is intuitive because experienced and responsible lab directors never simply copy variant classifications from any public database. Instead, they critically evaluate underlying evidence and report classifications following established guidelines. In this study we sought additional data to address this question. We gathered ClinVar submissions from established clinical laboratories, most from the last 5 years, including Myriad Genetics' classifications submitted to ClinVar by the Sharing Clinical Reports Project (SCRP). For variants in BRCA1/2, concordance between pairs of labs is high (98.5%) in a data set that represents test results from roughly 20,000 patients. Importantly, all of the discordant interpretations were seen in rare variants that, by definition, are present in very few patients. Moreover most rare variants (98.4%) have fully concordant classifications. We used prevalence data and population allele frequencies to estimate that 99.8% of patients would be expected to receive concordant reports from two labs for BRCA1/2, a similar finding to our previous study's results. While substantial disagreements in BRCA1 and BRCA2 are infrequent, they are of course important to patients and their clinicians. It is essential that we as a community work to resolve these differences collaboratively in order to deliver the best patient care, as is done in other areas of medicine. It is also essential that we establish standards for how concordance is measured and reported in order to avoid misleading clinicians.

774F

Targeted next-generation sequencing for the identification of genomic BCR-ABL1 fusion junctions to quantify residual disease in CML patients in CMR. *M. Alikian[1,2], P. Ellery[2], M. Forbes[1], D. Kasperaviciute[3], A. Sozinski[3], L. Foroni[1], J. Apperley[1].* 1) Centre for Haematology, Imperial College London, London, United Kingdom; 2) Imperial College London NHS trust, London, United Kingdom; 3) Clinical Sciences Centre and bioinformatics facility, Imperial College London, London, UK.

Recent studies indicate that 40% of CML patients who achieve complete molecular remission (CMR) on imatinib remain disease-free after drug discontinuation, raising the possibility of an "operational cure". However, the safe introduction of a TKI withdrawal policy would require a reliable and cost effective method of identifying patients with the lowest likelihood of relapse, which is likely to be related to presence residual disease. Preliminary data suggest that PCR of genomic DNA might be more sensitive for the detection of residual disease than one that relies on cDNA and may therefore help to predict outcome post-withdrawal. However, the former method is arduous since it requires a customised patient-specific assay. Here we describe a method based on targeted-next-generation sequencing allowing identification of BCR-ABL1 breakpoints from enriched genomic BCR and ABL1 DNA followed by rapid generation of DNA-based qPCR assays. The location of the BCR-ABL1 fusion junction was mapped in disease samples from 36 CML patients using Illumina's MiSeq platform. A custom TruSeq DNA target enrichment kit (Illumina) was used to enrich for the BCR and ABL1 genes. Subsequent mapping of t(9;22) translocation junctions was performed via a custom designed bioinformatics algorithm. All breakpoints were successfully mapped. DNA qPCR assays were designed and validated for 18 patients. In clinical samples from patients in complete molecular remission, the RT-qPCR assays detected residual disease in 6 out of 18 patients (33.3%), demonstrating that DNA-qPCR can detect residual disease in patient samples in which CML cells persist below the detection threshold of RT-qPCR. Furthermore, we investigated disease status in 48 CMR samples coming from 6 CML patients (3 positive and 3 negative by DNA-qPCR) using digital PCR (dPCR)(Fludigm BioMark HD platform) which allows single DNA molecule detection. We found that all 6 patients had detectable disease signals and that the level of positivity was reducing over time despite being negative by DNA-qPCR. In Conclusion, NGS-facilitated DNA-dPCR may therefore prove valuable for the stratification of patients with low levels of residual disease and, therefore, in the identification of patients for whom TKI therapy could be safely reduced or stopped.

775W

Accurate detection of copy-number changes in the highly conserved regions of *PMS2* using NGS. *V. Ramey, M. Kennemer, D. Kvitek, K. Ouyang, R. Harte, S. Lincoln, S. McCalmon, N. Patil, S. Aradhya.* Invitae, San Francisco, CA.

Background: Lynch syndrome is caused by inherited mutations in PMS2 in 4-11% of cases. However, testing for PMS2 is hampered by the presence of a pseudogene, PMS2CL, which is nearly identical to PMS2 in both intronic and exonic regions of exons 12–15. Ordinary NGS reads cannot be unambiguously aligned to PMS2 or PMS2CL, and gene conversion between PMS2 and PMS2CL further complicates this issue.   Methods: We developed a unique process to test PMS2 for copy number variants (CNVs). The first step is a bioinformatics screen in which NGS reads are analyzed for potential CNVs using a modified, PMS2CL masked reference sequence. We then use multiplex ligation-dependent probe amplification (MLPA) [2] to confirm CNV calls made by the screen. Finally we use long-range PCR (LR-PCR) and sequencing of the MLPA targeted paralogous sequence variant (PSV) or an alternative NGS-detected variant to disambiguate the CNV location.   Results: A sensitivity of 100% and specificity of 100% for this method has been demonstrated using specimens tested using traditional methods. Clinical cases will be shown where our NGS methods detect variants that the MLPA based approach would still find ambiguous.   Conclusions: Detecting CNVs by NGS in general can be challenging, although methods are available that achieve high clinical performance standards [2]. Regions with high homology however remain challenging. Our approach addresses this issue and can help reduce the cost while improving accuracy of comprehensive genetic tests. Development of highly multiplexed reference materials for inherited cancer testing. *R. Santhanam[1], C. Huang[2], J. Dickens[2], D. Yuzuki[2], R. Garlick[1], B. Anekella[2].* 1) SeraCare Life Sciences, Milford, MA; 2) SeraCare Life Sciences, Gaithersburg, MD.

   Introduction: Next Generation Sequencing (NGS) has improved the diagnostic yield of genetic testing, but has presented new challenges for test development, validation, and quality control management. Genetic tests for increased cancer risk are challenging due to variability of NGS workflow and difficulty in mapping large or complex variants. Reference materials are fundamental for monitoring NGS assays and evaluating both wet-lab procedures and software analysis pipelines. We sought to develop a reference material that assesses detection of variants that are challenging to detect including large indels (>10 bp), insertion of Alu elements, tandem duplications and combined deletion/insertion elements.   **Methods:** Human genomic DNA was extracted from the well-characterized GM24385 cell line and blended with biosynthetic constructs bearing human heritable mutations. Blending was performed to achieve 50% allele frequency and allele specific digital PCR (dPCR) verified mixing accuracy. A pilot study used a biosynthetic construct with nine (9) SNVs and one (1) large (25 bp) deletion. Testing on two different capture-based NGS assays in different laboratories suggested that a reference material that focused on the more challenging variants, with a few simple SNVs that represented common pathogenic variants would be most useful. **Results:** Preliminary testing of biosynthetics showed SNVs were detected with the expected allele balance at 50%. Testing of the 25 bp deletion was detected at ~30% frequency by both NGS assays, even though the variant frequency in the reference material was verified at 50% by dPCR; the difference was attributable to challenges mapping variants of this size. The results from the pilot study were used to design a new reference material containing portions of seven (7) human genes including MSH2, MSH6, MLH1, PMS2, CDKN2A, BRCA1 and BRCA2. Each gene segment contains one or more variants of clinical significance such that there are eleven (11) large/complex variants and six (6) common pathogenic SNVs and small indels.   **Conclusions**: Seraseq™ Inherited Cancer Reference Material is a comprehensive reference material designed to challenge NGS based genetic tests for inherited cancer susceptibility and fulfill unmet needs for accurate, multiplexed quality controls. These materials challenge variant detection pipelines, aid in assay optimization, and provide assurance in the ability to detect complex mutations on an ongoing basis.

777F

Single-cell genetic analysis reveals insights into clonal development of cervical cancer and confirms gain of *TERC* **as an early and dominant aberration.** *K. Heselmeyer-Haddad[1], A. Bradley[1], L. Hernandez[1], I. Torres[1], S. Andersson[2], T. Gaiser[3], D. Hirsch[3], P. Ströbel[4], S.A. Chowdhury[5], E.M. Gertz[6], R. Schwartz[7], A.A. Schäffer[6], T. Ried[1].* 1) Genetics Branch, CCR, NCI, Bethesda, MD; 2) Karolinska University Hospital Solna, Department of Women and Children's Health, Karolinska Institutet, Stockholm Sweden; 3) Institute of Pathology, University Medical Center Mannheim, Germany; 4) Institute of Pathology, University Medical Center Göttingen, Germany; 5) Simons Center for Data Analysis, Simons Foundation, New York, NY and Lewis Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ; 6) Computational Biology Branch, National Center for Biotechnology Information, NIH, MD; 7) Computational Biology Department, Carnegie Mellon University, Pittsburgh, PA.

   We developed a Multiplex Fluorescence in situ Hybridization (FISH) approach allowing enumeration of 20 different gene loci within individual nuclei from archival histological patient samples to assess tumor heterogeneity and clonal evolution. We have previously shown that this assay allowed us to gain new insights into breast tumor evolution analyzing synchronous DCIS and invasive breast cancer.   Our current project aims to shed light on cervical tumor evolution. The assay targets candidate genes in locations that are frequently gained in cervical cancer, including *COX2* (1q), *TERC* (3q, most commonly gained), *TERT* (5p), *MYC* (8q), *ZNF217* (20q) or lost, including *ING5* (2q), *FHIT* (3p) and *CHEK1* (11q).   Lesions representative of cervical intraepithelial neoplasia 3 (CIN3) and invasive cervical carcinoma (ICC) were macrodissected from 50 μm sections of FFPE tissue blocks. A subset of these lesions were synchronous CIN3 and ICC. Sequential hybridizations of multicolor FISH cocktails were analyzed with a custom-made automated spot counting software. Data were analyzed with algorithms developed to deduce phylogenetic trees.   Nineteen out of 20 lesions (11/11 CIN3, 8/9 ICC) showed a major clonal population with a gain of *TERC* confirming the dominant role of this aberration. Nine out of the 20 lesions showed a concomitant loss of *FHIT*, suggesting an isochromosome 3q formation. Most lesions were dominated by a major clone comprising around 30-40% of all cells analyzed. Major clones could be either explained by a single event, like an isochromosome 3q formation, or were more complex involving aberrations for several or most of the genes analyzed. The only lesion without a *TERC* gain was defined by a *MYC* gain in 90% of the cells. Interestingly, gains of *MYC* were more prevalent in ICC compared to CIN3 (78% vs. 27%), indicating that *MYC* might play a role in progression. Of note, the synchronous CIN3 and ICC analyzed did not show similar major clones, indicating independent evolution (multifocal disease). However, their only commonality was a *TERC* gain, confirming the importance of this aberration in cervical carcinogenesis. While overall levels of heterogeneity were indistinguishable between CIN3 and ICC, phylogenetic models of single tumors suggested greater average numbers of aberrations per cell in ICC versus CIN3. Our study will improve the understanding of clonal development during cervical carcinogenesis and genome dynamics at early stages of carcinogenesis.

Functional analysis of variants of uncertain clinical significance in components of the TORC1 and RAS signaling pathways. *M. Nellist, M. Hoogeveen-Westerveld, M. Kroos-de Haan, P. Elfferich, J. Boonman, G. Mancini, Y. van Bever, R. van Minkelen, F. Verheijen.* Functional Unit, Department of Clinical Genetics, Erasmus MC, Wytemaweg 80, 3015CN, Rotterdam, The Netherlands.

   One of the major problems in clinical genetic diagnostic is the interpretation of variants of uncertain clinical significance (VUS) and novel approaches to implement effective functional screening of genomic variants are required. We will present two examples that have been validated for use in our diagnostic laboratory.   1. The mechanistic target of rapamycin (mTOR) complex 1 (TORC1) is an essential protein kinase complex that controls cell growth and metabolism. Mutations in different components of the TORC1 signaling pathway are associated with a broad spectrum of inherited and somatic diseases, including cancer. We have developed simple cell-based assays to investigate the effects of VUS identified in genes encoding components of the TORC1 signaling pathway on TORC1 activity. To date we have analysed >300 variants in *AKT3*, *DEPDC5*, TBC1D7, *TSC1* and *TSC2*.   2. *NF1* encodes neurofibromin, a GTPase activating protein (GAP) for RAS and inactivating mutations in *NF1* result in increased levels of active RAS-GTP, increased RAS signaling and cause neurofibromatosis type 1 (NF1). We have performed RAS-GTP pull-down assays to assess the RAS-GAP activity of *NF1* VUS identified in our NF1 patient population.   Our work has provided insight into the likely pathogenicity of VUS in *AKT3*, *DEPDC5*, *TBC1D7*, *TSC1* and *TSC2*, the genetic risks in the families segregating the tested variants, genotype-phenotype correlations and structure-function relationships. Investigating the effects of VUS on TORC1 and RAS signaling is a useful adjunct to standard genetic testing and can provide essential information for appropriate clinical management.

Variants of hereditary breast and ovarian cancer associated genes in Czech patients: The first experience with targeted NGS sequencing. *M. Koudová[1], V. Krutílková[1], F. Lhota[1], L. Černá[1], M. Bittóová[1], B. Honysová[1], F. Zembol[1], J. Libich[1], Z. Kleibl[2], D. Stejskal[1].* 1) GENNET s.r.o., Prague, Czech Republic; 2) Inst. of Biochemistry and Exp. Oncology, First Faculty of Medicine, Charles University, Prague, Czech Republic.

   Introduction: Next-generation sequencing (NGS) allows to concurrently analyze germline variants of multiple genes associated with hereditary breast and ovarian cancer (HBOC). **Methods:** 283 DNA samples of patients (148) and healthy relatives (135) fulfilling HBOC criteria according to Czech guidelines (similar as the National Comprehensive Cancer Network guidelines) were analyzed using NGS panel CZECANCA (**CZE**ch **CA**ncer pa**N**el for **C**linical **A**pplication) designed at Inst. of Biochemistry and Exp. Oncology, First Faculty of Medicine, Charles University in Prague. This panel targets 212 cancer susceptibility and candidate genes based on the genetic variability of Czech cancer patients. We focused on analysis of 13 HBOC predisposing genes (*BRCA1, BRCA2, TP53, CDH1, PTEN, STK11, CHEK2, PALB2, BRIP1, ATM, RAD51C, RAD51D, NBN)*. NGS was complemented by the MLPA screening for large genomic rearrangements of *BRCA1, BRCA2 PALB2, RAD51C, RAD51D* and deletion of exons 9-10 of *CHEK2* gene. Positive results were validated by direct sequencing. We have developed a bioinformatic pipeline using local installation of Ensembl genomic database for annotation and SQL server variant database for data handling and clinical reporting. **Results:** In total 48/283 samples (17%) a deleterious variant was detected- in 31/148 patient samples (20,9%) and in 17/135 healthy relatives samples (12,6%). Out of these, 3/283 samples (1,1%) digenic heterozygous variants were found. Variants of *BRCA1/2* genes constituted 47,1% of findings, *CHEK2* gene variants 31,3% and other gene variants 21,6% of findings. **Conclusion:** These results are consistent with the published findings that *BRCA1/2* gene mutations are responsible for up to half of the heritable mutations in HBOC and highlight the importance of extending the examination to other susceptibility genes and testing of all first degree relatives at risk if affected family member is not available.

780F

ERASE-seq: Implementation of super-accurate mutation detection at low allelic frequency and liquid biopsy applications. *N. Kamps-Hughes, C. Ionescu-Zanetti.* Research and Development, Fluxion Biosciences, South San Francisco, CA.

Purpose: Cancer genotyping experiments are increasingly utilizing blood samples to non-invasively track the mutational profile over time, requiring variant detection with increased sensitivity and specificity. We present validation of ERASE-Seq, a method for accurate detection of low frequency DNA variants that yields significant performance improvements with respect to molecular barcoding methods. Our approach differs from previous methods by using a custom replicate amplification step coupled to calling variants based on statistically significant differences in allele counts between replicate sample amplification reactions and a previously determined locus specific noise model, thereby eliminating false positives resulting from both jackpot mutations and error-prone loci. **Methods:** Analytical samples were created by spiking DNA from a number of different cell lines into human reference DNA samples down to expected variant allele frequencies of 0.1%. The ERASE-Seq assay was applied to these samples in order to determine analytical sensitivity and specificity. The clinical utility of ERASE-Seq was demonstrated on a set of circulating tumor cell samples from colorectal and pancreatic cancer patients. **Results:** ERASE-Seq low frequency variant detection in spiked DNA mixtures demonstrates perfect sensitivity and specificity down to 0.3% allele frequency across multiple pan-cancer amplicon panels. At 0.1%, the specificity remains perfect and the sensitivity remains above 70%. WGA pre-amplified samples maintain perfect specificity down to 0.3% allele frequency with ERASE-Seq but show a small number of false positives when calling variants to 0.1% (specificity = 0.9999). For clinical samples, we obtained an average of 3 high confidence calls per sample (>0.3% allele frequency), including alterations commonly found in solid tumor tissue for the relevant indications. In biological replicates from two CRC patients we have found a correlation of 80% between the draws. **Conclusions:** We present validation of ERASE-Seq, a highly sensitive solution for the detection of somatic variants from a blood draw using standard amplicon technology. The method's performance has been validated to the 0.1% allele frequency range where robust sensitivity and specificity have been demonstrated across DNA sample types. The clinical applicability of this performance was then demonstrated with robust and reproducible detection of somatic mutations in patient liquid biopsies.

Characterization of *TP53* sequencing variants initially detected in peripheral blood using next generation sequencing analysis. *D. Mancini-DiNardo, B. Coffee, H.C. Cox, K. Brown, S. Manley, K.R. Bowles, B.B. Roa.* Myriad Genetics Laboratories, Inc, Salt Lake City, UT.

Background: Individuals with germline pathogenic variants (PVs) in *TP53* have Li-Fraumeni Syndrome (LFS), which is associated with a high cancer risk and early age of diagnosis. Approximately 40% of *TP53* PVs were detected at Next-Generation Sequencing (NGS) allele frequencies between 10-30% and are suspected to be somatic mosaic variants. However, internal evidence demonstrates that NGS read frequencies for somatic PVs can increase over time to overlap with those observed for true germline heterozygotes (30%-70%). Given the severe clinical implications of germline PVs in *TP53* and the relatively recent recognition of the prevalence of somatic *TP53* PVs, it has now become critical that apparent germline PVs be confirmed to enable appropriate medical management. Here, we present findings from a commercial testing laboratory program that offers confirmatory analysis to all individuals with an apparent germline *TP53* PV. **Methods:** Individuals tested with a 25-gene hereditary cancer panel from September 2013-present who were found to have an apparent germline *TP53* PV (n>100) were assessed and offered confirmatory testing via genetic testing of a family member, testing of fibroblast cells, or repeat testing on a blood sample from the proband. **Results:** At this time, 24 individuals with *TP53* PVs have participated in additional testing (13 fibroblast testing, 9 family testing, 2 repeat blood testing). These studies have provided additional evidence regarding the PV origin (germline or somatic) for 19 (79.2%) individuals thus far. Somatic *TP53* PVs were confirmed for 4 (16.7%) individuals. Germline transmission was confirmed in 2 (8.3%) cases where a relative was found to carry the same *TP53* PV. Evidence that was consistent with, though not conclusive for, germline origin was found in 13 (54.2%) individuals. Negative genetic test results in relatives were uninformative for the remaining 5 individuals (20.8%). **Discussion:** In this ongoing study, we have demonstrated that *TP53* PVs detected with NGS read frequencies consistent with an inherited PV can be either germline or somatic in origin. The confirmation of germline *TP53* PVs in patients with a clinical presentation inconsistent with LFS may have a significant impact on medical management decisions, while confirmation of a somatic PV may prevent inappropriate patient care. Overall, this demonstrates the value of confirmatory testing in individuals with apparent germline *TP53* PVs.

Validation of a droplet PCR-based targeted gene panel for the detection of sequence variants in myeloid neoplasms. *A. Sahota[1], L. Liang[1], N. Sanapareddy[1], F. Patel[1], Q. Tan[1], W. Hussain[1], H. Gaspard[1], L. Goodell[2], S. Bhagavathi[2], G. Riedlinger[2], J. Rosenfeld[3], D. Foran[3], L. Rodriguez[3], R.M. Rattray[4], S.M. Gandhi[5], D. Qin[5], G.J. Tsongalis[6], S.A. Turner[6], F.B. de Abreu[6], H.B. Steinmetz[6], A. Brooks[1], J.A. Tischfield[1].* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept Path Lab Med, Rutgers Robert Wood Johnson Med Sch, New Brunswick, NJ; 3) Cancer Inst New Jersey, New Brunswick, NJ; 4) Molec Genomics Lab, Providence Health and Services, Portland, OR; 5) Molec Diagnostics Lab, Moffitt Cancer Ctr, Tampa, FL; 6) Dept Path Lab Med, Dartmouth Hitchcock Med Ctr, Lebanon, NH.

   Introduction: Next generation sequencing of cancer tissue is becoming a mainstream technique in clinical laboratories because of its potential to contribute to the selection of patient-specific therapies. Here, we describe the validation of the ThunderBolts (TB) Myeloid Panel from RainDance Technologies for the detection of sequence variants in DNA isolated from bone marrow or peripheral blood samples from patients with a variety of myeloid neoplasms. **Methods:** We received 72 previously tested DNA samples from three CLIA-certified and CAP-accredited laboratories (located in OR, FL, NH). All three labs used the TruSight Myeloid Panel and the MiSeq instrument from Illumina for variant analysis. We used 40 ng DNA for the TB panel and pooled PCR libraries from up to 12 samples and sequenced them on the MiSeq. DNA from three well-characterized human cell lines was also used to validate the TB panel. Sequence data were analyzed using the NextGENe software from SoftGenetics. **Results:** We observed an average of 4,886 reads per amplicon and over 98.3% of the amplicons had a read depth of ≥500X. The analytical sensitivity and specificity of the assay, tested using DNA from three cell lines, was 98.1%. The reproducibility of the assay, determined by analyzing two patient samples in three runs was 92.8%. We determined the lower limit of detection for sequence variants by mixing cell line DNAs in different proportions. We were able to detect sequence variants at the 2% level in these mixtures. Sequence data were available for 46 samples from the three external labs. These labs did not report any pathogenic variants or variants of unknown significance in 12 of these samples and variants in 5 samples could only be detected by the TruSight panel. The corresponding genes were not part of the TB panel. The external labs reported 50 sequence variants in the remaining 29 samples. The TB panel detected 48 of these variants, giving a concordance of 96%. Our software did not detect 2 variants, but one variant was in the region of a gene (CEBPA) where the coverage depth was low (281X). When we examined this region in more detail, we were able to detect this variant. This gave an overall concordance of 98%, suggesting excellent agreement between the TB and the TruSight panels. **Conclusions:** We have validated the TB myeloid panel for the detection of sequence variants in myeloid neoplasms. The assay has high accuracy and it can readily detect minor allele frequencies below the 5%.

783F

Multi-center assessment of a next-generation sequencing assay for detection of germline and somatic *BRCA1* and *BRCA2* gene variants from formalin fixed paraffin embedded samples. *C. Scafe[1], R. Qi[1], G. Nistala[3], G. Bee[3], N. Garg[5], M. Manivannan[5], A. Broomer[6], V. Mittal[7], P. Williams[7], D. Brinza[1], F. Hyland[1], J. Bishop[6], S. Sadis[7], B. Passkiewicz[4], J. Sherlock[2].* 1) Sequencing Applications, Thermo Fisher Scientific, South San Francisco, CA; 2) Life Sciences Solutions, Thermo Fisher Scientific, Paisley, Scotland, UK; 3) Clinical Sequencing Division, Thermo Fisher Scientific, Carlsbad, CA; 4) Life Sciences Solutions, Thermo Fisher Scientific, Pleasanton, CA; 5) Clinical Sequencing Division, Thermo Fisher Scientific, South San Francisco, CA; 6) Life Sciences Solutions, Thermo Fisher Scientific, Carlsbad, CA; 7) Life Sciences Solutions, Thermo Fisher Scientific, Ann Arbor, MI.

   We designed a new highly multiplexed amplification-based assay which allows detection of *BRCA1* and *BRCA2* gene variants (SNVs, in/dels and exon/gene deletions) in somatic and germline samples through semiconductor-based DNA sequencing. This study comprises the findings of over 20 research centers in 12 countries that were given early access to the new assay to evaluate its performance on a variety of sample types, including formalin fixed paraffin embedded (FFPE) tissues, under realistic conditions. *BRCA1* and *BRCA2* gene target regions, including all coding exons, were enriched via highly multiplexed amplification reactions. Libraries were constructed using manual and automated preparation methods, followed by semiconductor-based sequencing on multiple instrument platforms. Single nucleotide and insertion or deletion variants were identified using commercially available software solutions. Participants reported the concordance between the variants detected by the new assay and expected variants, identified by orthologous techniques. A novel software application for detection of exon-level and whole gene deletions in *BRCA1* and *BRCA2* was developed by analyzing known deletion samples. This coverage-based method implements an algorithm which first identifies large gene-level deletion candidates and then executes a fine-grained detection of exon-level variants. Automated and graphical data quality evaluation that was developed has been shown to be particularly useful for FFPE samples with mixtures of normal and tumor tissue. A high degree of coverage uniformity, 98%, was achieved on both germline and somatic samples. Sensitivity of detection of SNV and short insertion or deletion variants was 97.8%, with positive predictive value of 94.3%. Exon deletion detection on simulated variants in germline cell-line samples showed high call rates and sensitivity, with low rates of false positive calls. The single exon, multiple-exon and whole-gene deletions in the multi-center early access study data were also called with high sensitivity, high call rates, and minimal false positive call rates. Performance of the new *BRCA1* and *BRCA2* sequencing assay in this collaborative early access study indicates the new research use only panel, planned for official release in late 2016, will enable *BRCA1* and *BRCA2* gene researchers to interrogate a broader spectrum of variant types in both blood and FFPE samples.

784W

Chromosomal abnormalities in meningiomas. *B. Ouled Amar Bencheikh, C. Mirarchi, P.A Dion, G.A Rouleau.* Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada.

Background: Meningioma are deemed to be benign tumors of the central nervous system. However, a subset of these tumours are actually malignant and present an aggressive behavior that is refractory to treatments combining surgery and radiotherapy. Loss of a chromosome 22q region (containing the *NF2* gene) is the most frequently observed alteration for these tumors (>70% of meningioma); additional chromosomal abnormalities were also reported (e.g. 1p, 1p, 6q, 7, 9q, 9q, 10q, 14q, 15q 17q, 18q, 19q, 20q). We are now using data from a high density SNP chip microarray to further complete a profile of chromosomal abnormalities in sporadic meningioma and hopefully identify novel genetic drivers that will be specific to these particular tumors.   **METHODS:** A cytogenetics microarray (Cytoscan® HD, Affymetrix, Santa Clara, CA, USA) was used to examine 112 sporadic meningioma samples obtained from unrelated individuals. Previous studies conducted based on microsatellite markers excluded chromosome 22q abnormalities across these 112 samples. **RESULTS:** Chromosomal abnormalities were detected in 73 meningioma (65%). The remaining tumors appeared to be normal using the Cytoscan HD array. The nature of the abnormalities observed included loss of heterozygosity and/or complete deletion or duplication. Interestingly, we identified a loss of chromosome 22q in 45 (40%) meningioma with abnormalities. This last observation warrants for the increased sensitivity of the array used here as 22q abnormalities went unnoticed from the earlier microsatellites genotyping efforts conducted in previous years. Additional chromosomal alterations were identified with or without loss of 22q, these alterations were both new and known abnormalities (LOH, deletion and duplication) in all autosomal and X chromosomes.   **CONCLUSION:** Our findings confirm and extend previous observations in regard to the high frequency of 22q loss in meningioma. Our observation of previously unreported abnormalities across chromosomes also support the notion that there is a great extent of genetic heterogeneity across these tumours (with or without 22q loss). A better understanding of meningioma subtypes may help to better define the more aggressive tumors and in conjunction with additional clinical information help to deploy more personalized treatments for those affected.

785T

Significant effect of polymorphisms in *CYP2D6* **on response to Tamoxifen therapy for breast cancer: A prospective multicenter study.** *H. Zembutsu[1], S. Nakamura[2], S. Akashi-Tanaka[2], T. Kuwayama[2], C. Watanabe[2], T. Takamaru[2], H. Takei[3], T. Ishikawa[4], K. Miyahara[4], H. Matsumoto[5], Y. Hasegawa[6], G. Kutomi[7], H. Shima[7], F. Satomi[7], M. Okazaki[8], H. Zaha[9], M. Onomura[9], A. Matsukata[10], Y. Sagara[10], S. Baba[10], A. Yamada[11], K. Shimada[11], D. Shimizu[12], K. Tsugawa[13], A. Shimo[13], T. Yu[14], M. Hartman[15], C. Wan[15], S. Lee[16], Y. Nakamura[17].* 1) Research Institute, National Cancer Center, Tokyo, Tokyo, Japan; 2) Showa University, Tokyo, Japan; 3) Nippon Medical School, Tokyo , Japan; 4) Tokyo Medical University, Tokyo , Japan; 5) Saitama Cancer Center, Saitama , Japan; 6) Hirosaki Municipal Hospital, , Japan; 7) Sapporo Medical University, Sapporo , Japan; 8) Sapporo Breast Surgical Clinic, Sapporo , Japan; 9) Nakagami Hospital, Okinawa , Japan; 10) Sagara Hospital, Kagoshima , Japan; 11) Yokohama City University Medical Center, Yokohama , Japan; 12) Yokohama Minato Red Cross Hospital, Yokohama , Japan; 13) St. Marianna University School of Medicine Hospital, Kawasaki , Japan; 14) Tan Tock Seng Hospital, Singapore; 15) Yong Loo Lin School of Medicine, National University of Singapore and National University Health System, Singapore; 16) National University Cancer Institute, National University Health System, Singapore; 17) Department of Medicine, The University of Chicago, Chicago, USA.

Purpose CYP2D6 is the key enzyme responsible for the generation of the potent active metabolite of tamoxifen, "endoxifen". We previously reported that reduced- or null-function alleles of *CYP2D6* were significantly associated with poor clinical outcome of breast cancer patients treated with tamoxifen. However, there are still controversial reports questioning the association between *CYP2D6* genotypes and tamoxifen efficacy. Hence, we carried out a prospective multicenter study to evaluate the clinical effect of *CYP2D6* genotype on tamoxifen therapy. **Patients and Methods** We enrolled patients with hormone receptor–positive and human epidermal growth factor receptor 2-negative, invasive breast cancer receiving pre-operative tamoxifen monotherapy for 14 - 28 days. Ki-67 response in breast cancer tissues after tamoxifen therapy was used as a surrogate marker for response to tamoxifen. We prospectively investigated the effects of allelic variants of *CYP2D6* on Ki-67 response, pathological response and hot flushes. **Results** Ki-67 labeling index in breast cancer tissues significantly decreased after preoperative tamoxifen monotherapy (P = .0000000000000013). Moreover, proportion and Allred scores of estrogen receptor positive cells in breast cancer tissues were significantly associated with Ki-67 response. Although *CYP2D6* variants were not associated with pathological response nor hot flushes, they showed significant association with Ki-67 response after pre-operative tamoxifen therapy. **Conclusion** This is the first prospective study evaluating the relationship between *CYP2D6* variants and Ki-67 response after tamoxifen therapy. Our results suggest that genetic variation in *CYP2D6* is a key predictor for the response to tamoxifen in patients with breast cancer.

Development of a cloud-based comprehensive cancer transcriptome profiling pipeline for clinical diagnostics. *H.A. Costa, C. Kunder, J.L. Zehnder, C.D. Bustamante.* Stanford University School of Medicine, Stanford, CA, USA.

The application of DNA sequencing in clinical cancer genomics has proven to be an invaluable tool to characterize acquired tumor mutational load, inform therapeutic routes and to predict treatment response in oncology patients. Despite these powerful benefits, this approach lacks the ability to quantitatively characterize downstream gene expression levels or capture non-genomic transcript variation—two important avenues currently under characterized in next generation sequencing based clinical diagnostics. RNA sequencing (RNAseq) addresses these issues by quantitatively capturing the entirely of the expressed transcripts in a tissue, while additionally detecting all of the expressed genomic alterations as seen in DNA sequencing. One of the barriers to its implementation in a clinical setting is the availability of computational pipelines and bioinformatics tools to comprehensively characterize the broad range of variation present in transcriptome data. To this end, we have developed a cloud-based RNAseq computational workflow to detect expressed variation including SNVs, INDELs, structural variants, gene fusions, differential gene expression, allele specific expression, and novel alternative allele isoforms in a single pipeline. We apply our method to characterize the transcriptomes of pediatric sarcoma and lung adenocarcinoma to identify novel variation. Further, we demonstrate that our approach compares favorably to DNA based sequencing methods when performing variant calling on somatic patient samples.

Genetic testing of 248 Chinese aortopathy patients using a panel assay. *Y. Ma[1], H. Yang[1], M. Luo[2], Y. Fu[1], Y. Cao[3], K. Yin[1], C. Meng[1], K. Zhao[1], J. Zhang[2], Y. Fan[4], C. Shu[2], Q. Chang[2], Z. Zhou[1].* 1) State Key Laboratory of Cardiovascular Disease, Beijing Key Laboratory for Molecular Diagnostics of Cardiovascular Diseases, Diagnostic Laboratory Service, Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences an; 2) State Key Laboratory of Cardiovascular Disease, Center of Vascular Surgery, Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; 3) Analyses Technologies, Beijing, China; 4) John Welsh Cardiovascular Diagnostic Laboratory, Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA.

Inherited aortopathy, which is characterized by a high risk of fatal aortic aneurysms/dissections, can occur secondarily to several syndromes. To identify genetic mutations and help make a precise diagnosis, we designed a gene panel containing 15 genes responsible for inherited aortopathy and tested 248 probands with aortic disease or Marfan syndrome. The results showed that 92 individuals (37.1%) tested positive for a (likely) pathogenic mutation, 70 (28.2%) had a variant of uncertain significance (VUS). Most of the (likely) pathogenic mutations were located in the *FBN1* gene. Also, We found that patients with a *FBN1* truncating or splicing mutation were more prone to have a severe aortic disease or valvular disease. Among patients with a *FBN1* truncating or splicing mutation, 15 suffered a life-threatening aortic dissection, 5 had a severe valvular disease, while 9 had an aortic aneurysm and therefore were performed a prophylactic surgery. Additionally, in the aneurysm group, patients with a *FBN1* truncating or splicing mutation took a prophylactic surgery at a younger age (25.6y vs. 33.4y) than those with a missense mutation. To date, this is the largest reported cohort of Chinese patients with aortic disease who have undergone genetic testing. As such, it can serve as a considerable dataset of next generation sequencing data analysis of the Chinese population with inherited aortopathy. Moreover, in our study, we developed an optimized pipeline named iAorta that can realize automatic analysis. Additionally, according to the accumulated data, we optimized the analysis pipeline by adding quality control steps to assess the sequencing quality and to indicate possible false-negative variants, remove frequent false-positive mutations based our existing data and drop the low confidence indel variants to reduce the false-positive rate. In summary, our data further expands the *FBN1* mutation spectrum and offer evidence for the genotype-phenotype correlation between *FBN1* mutation type and aortic events. The aortopathy panel assay undoubtedly presents a highly valuable clinical tool and lays the foundation for further study. We are dedicated to constructing the largest Chinese aortopathy genetic database and continually improving our testing quality.

Uncovering copy number variants (CNVs) in degraded post-mortem samples of carries of congenital heart disease (CHD). *F.A.R. Madia[1], A.T. Dias[1], M. Rocha[2], E.A. Zanardo[1], T.V.M.M. Costa[1], J.G. Damasceno[1], C. Milani[1,3], A.F. Amorim[1], A.M. Nascimento[1,3], G.M. Novo-Filho[1,3], M.M. Montenegro[1,3], Y.G. Oliveira[1,3], F.T. Gonçalves[4], C. Fridman[4], C.A. Kim[3], R. Schultz[5], L.D. Kulikowski[1,2,3].* 1) Laboratório de Citogenômica, LIM 03, Departamento de Patologia, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 2) Centro de Reprodução e Genética, Departamento de Saúde Coletiva, Faculdade de Medicina do ABC, Santo André-SP, Brazil; 3) Unidade de Genética do Instituto da Criança, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 4) Departamento de Medicina Legal, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 5) Serviço de Anatomia Patológica , Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil.

Congenital heart disease (CHD) is the most prevalent group of congenital malformations affecting approximately 8-1,000 live births and is a significant cause of childhood morbidity and mortality. Recently, the literature demonstrated the increased frequency of pathogenic copy number variants (CNVs) in congenital heart disease. However, there are few post-mortem genomic studies in congenital heart disease cases. Several technical issues can make post-mortem genetic testing challenging. Thus, the aim of the study was identify the CNVs in post-mortem degraded samples of CHD. We investigate samples from skin and heart tissues of 15 cases of stillbirth and new-born from Serviço de Verificação de Óbitos, HC-FMUSP. The molecular analysis was performed by genotyping of seven autosomal STR loci (D13S317, D7S820, D2S1338, D21S11, D16S539, D18S51, CSF1PO and FGA), and the results allowed us to disclose different CNVs. Thus, the results showed pathogenic CNVs associated with syndromes in 20 % (3/15) of stillbirth and new-born cases, including Edwards Syndrome, Down Syndrome and one case of Turner Syndrome with Y chromosome mosaicism. The genomic analysis showed efficiency for identifying pathogenic CNVs in post-mortem degraded samples of CHD and also help to provide the adequate genetic counseling to families. Financial support: FAPESP: 09/53105-9 and FINEP-CT INFRA 0160/12 SP.

Next-generation sequencing diagnostics of inherited arrhythmogenic cardiac disorders. *C. Marschall, K. Wittkowski, H.G. Klein.* Center for Human Genetics, 82152 Martinsried, Germany.

A custom NGS 72 gene panel approach was performed on a collective of 100 unrelated patients referred for genetic testing for hereditary arrhythmogenic cardiac disorders such as long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome (BrS), hypertrophic cardiomyopathy (HCM), dilatative cardiomyopathy (DCM) and arrhythmogenic right ventricular cardiomyopathy (ARVC). All these diseases are associated with significant morbidity and mortality and are a known risk factor for sudden cardiac death. The presymptomatic diagnosis is essential as for most of the cases a therapy is available. Mutation detection in the index cases followed by cascade screening of the family members could be life saving. As some cardiomyopathies may present with only little structural symptoms, differential diagnosis of arrhythmogenic disorders may be difficult. Moreover, some arrhythmogenic disorders are clinically and genetically extremely heterogeneous. An Agilent SureSelect Target Enrichment assay was designed for the capture of coding regions including splice sites of 72 genes known to be associated with arrhythmogenic disorders. Target enrichment followed by re-sequencing on the Illumina NextSeq platform was used for mutation detection. Data analysis was performed with the CLC Genomics Workbench and custom developed Perl scripts. Potentially disease causing variants and regions with an insufficient coverage were re-analyzed with Sanger sequencing. Pathogenic or potentially pathogenic variants were detected 20-50% of cases. Diagnostic sensitivity was compared with results from Sanger sequencing of more than 5,000 patients. The diagnostic yield was higher with NGS in CPVT, BrS, ARVC and DCM. Additional 5-50% of cases showed variants of unclassified significance.

790W

Diagnostic yield of three years next generation sequencing in clinical genetic diagnostics of cardiomyopathies. *R.C. Niessen, P.A. van der Zwaag, L.G. Boven, Y.M. Hoedemaekers, R.J. Sinke, J.D.H. Jongbloed.* Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, Netherlands.

The strength of next generation sequencing (NGS) in both research and diagnostics is becoming increasingly evident. NGS is successfully applied to find causal mutations and thus confirm the clinical diagnosis in patients suspected of genetic cardiomyopathies. In 2012 NGS analysis was introduced in the diagnostic clinical genetic laboratory in the University Medical Center Groningen. Since then, we analyzed DNA of 1153 patients with several types of cardiomyopathies using an enrichment kit targeting 55 genes associated with hereditary cardiomyopathies. Two classification trees were used to classify variants, taking in account population frequencies, in silico predictions, type and location of mutation, conservation scores, clinical data and information from the literature. Additional haplotype and cosegregation analyses were performed to further support pathogenicity of novel potentially causal mutations that had been identified multiple times. Our approach results in a significant increase in diagnostic yield: in 14% (157/1153), of patients a pathogenic mutation was identified, explaining the clinical phenotype. In 10% (114/1153), one or more likely pathogenic mutations were identified. In 593 patients (51%) 885 variants of unknown clinical significance were found, including the patients who also carried a (likely) pathogenic mutation. Taken together, in 23% of patients the clinical phenotype was (likely) explained by either a pathogenic or a likely pathogenic mutation. Analysis of the different cardiomyopathy subtypes is ongoing and these results will be presented. The contribution of the variants of unknown significance remains to be elucidated. In the near future, we hope to further characterize these variants by sharing our data with other laboratories in the Netherlands and abroad, by performing segregation studies and functional studies. In conclusion, the results from this large cohort show that NGS provides a genetic diagnosis in a large proportion of cardiomyopathy cases and that datasharing is essential to further classify the many variants with unknown significance.

791T

Glycine missense variants in the *COL3A1* **triple helix domain: How to assess functional domain data during clinical variant interpretation.** *D. Beltran, J. Thusberg, M. Anderson, Y. Kobayashi, J. Garcia, T. Winder, S. Topper, K. Nykamp.* Invitae, San Francisco, CA, U.S.A.

Clinical variant classification should incorporate gene-specific knowledge about critical residues or essential protein domains. Missense variants that affect these residues or regions are more likely to be deleterious and pathogenic than variants that affect other residues or domains. However, clear guidelines for identifying a residue or region as essential do not exist. Without such guidelines, variant classification becomes subjective and capricious. To address this shortcoming, we developed a statistical approach for the identification of critical residues that takes into account background variation, the distribution of rare, clinically observed variants, and knowledge of the three-dimensional structure of proteins. We selected *COL3A1* as the paradigm for protein domain evaluation. *COL3A1* is a well-characterized gene associated with vascular Ehlers-Danlos syndrome (vEDS). Most of the protein is made of a triple-helix (TH) domain encoded by 343 Gly-X-Y (GXY) repetitions. Gly residues therein are essential for protein structure, and missense variants affecting TH Gly residues are over-represented in vEDS patients (97%) but under-represented in ExAC (5%). ExAC contains five TH G*XY missense variants, each of which is present three or fewer times. As a general rule, structural residues in TH domains can be considered essential, as there is a substantial statistical difference between the variation seen in patients and that in a control data set such as ExAC. Applying this analysis to other collagen genes, we can easily distinguish between those for which this logic is warranted (*COL3A1*) and those such as *COL5A1* and *COL5A2* for which it is not because the number of TH G*XY missense variants described in patients is low or the frequency of some of the missense variants at these residues in ExAC exceeds that expected for pathogenic variants. Detailed analysis also suggests a correlation between the exactness of the GXY repetition in TH and the severity of the associated phenotype. A similar approach is applied to cysteine missense variants in EGF-like domains in genes such as *FBN1*, *FBN2*, and *LDLR*.

792F

Use of exome sequencing in cases of sudden cardiac death. *E. Smith[1,2], S.B. Seidelmann[1,2,3], A. Mani[1,2,3,4].* 1) Yale University School of Medicine, New Haven, CT; 2) Yale Program for Cardiovascular Genetics, Yale School of Medicine, New Haven, CT; 3) Division of Cardiovascular Medicine and Department of Radiology, Division of Cardiac Imaging, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Genetics, Yale School of Medicine, New Haven, CT.

Sudden cardiac death (SCD) caused by ventricular arrhythmia in subjects with or without normal structural heart disease can be caused by single gene mutations. This condition incorporates a spectrum of inherited disorders from Long QT (MIM 192500) and Brugada syndromes (MIM 601144), to hypertrophic (MIM 192600) and dilated cardiomyopathies (MIM 115200). Clinical information obtained in these cases, including automatic external defibrillator rhythm recordings, post-resuscitation electrocardiograms or echocardiograms, and cardiac MRI often does not provide a definitive clinical diagnosis. In such circumstances, genetic testing may be greatly useful for diagnosis, risk stratification and management of the patients and their close relatives. With the advent of exome sequencing, one may be able to obtain a genetic diagnosis in cases in which the clinical data has remained inconclusive. Twenty-eight adult patients with a presenting diagnosis of SCD underwent proband-only exome sequencing as a first line test. These individuals are part of larger cohort of adults with inherited cardiovascular diseases who underwent exome sequencing at our center. All genetic diagnostic reports were made based on American College of Medical Genetics, as well as College of American Pathology and CLIA guidelines. When possible, segregation analysis was carried out to further elucidate the potential underlying genetic causes. Variants were called pathogenic or likely pathogenic for 9 patients (32%). Another 9 patients had variants of uncertain significance in related genes. There were seven subjects in whom more than one variant was reported. In this group of 28, a total of 64% of SCD cases received either definitive or presumptive genetic diagnosis. Identified variants were all in genes involved either in excitation or contraction of cardiomyocytes or both. Most common variants identified were radical *TTN* mutations. In conclusion, exome sequencing was effective in determining the potential genetic etiology of SCD in two-third of cases where clinical presentation was inconclusive.

793W

Prenatal genetic testing following abnormal fetal ultrasound reveals 6% of cases with pathogenic variants implicated in Noonan spectrum disorders. *N. Cody, G. Cai, J. Liao, G. Mendiratta-Vij, S. Sperber, L. Edelmann, R. Kornreich.* Genetics and Genomics Sciences, Icahn School of Medicine at Mount Sinai, New York City, NY.

Noonan spectrum disorders (NSD) are an autosomal dominant, multi-systemic group of disorders caused by mutations in the RAS-MAPK pathway and have an estimated prevalence of 1 in 1000 to 1 in 2500 live births. Abnormal ultrasound findings that may be indicative of NSD in fetuses include increased nuchal translucency or nuchal fold, cystic hygroma, hydrops, pleural effusion and cardiac or renal anomalies. We conducted a retrospective study of 195 prenatal cases with indication for NSD testing. Molecular tests were performed on either direct or cultured chorionic villi or amniocytes. We reviewed the indication for testing along with the number of pathogenic variants detected using a next generation sequencing (NGS) panel. The panel currently tests 14 well-established genes implicated in NSD: *PTPN11, SOS1, RAF1, KRAS, NRAS, BRAF, MAP2K1, MAP2K2, CBL, HRAS, NF1, SHOC2, RIT1,* and *SPRED1.* Increased nuchal translucency or nuchal fold (126 of 195), followed by cystic hygroma (57 of 195), were the most common fetal ultrasound findings leading to NSD testing. In addition, seven fetuses had cardiac defects on ultrasound, two had hydrops fetalis and four had a previous family history of Noonan syndrome. Following genetic testing, 13 of 195 patients (6%) were determined to carry a pathogenic or likely pathogenic variant. The most frequently mutated genes were *PTPN11* (5/13) and *RIT1* (4/13). *KRAS, BRAF, SOS1,* and *RAF1* were each found to be causative in one fetus. Of the seven cases in which parental testing could be performed, 4 carried de novo variants, two were maternally inherited and one was paternally inherited. While increased nuchal translucency was the most common indication for testing, it had a very low positive predictive value with 1 of 126 (0.8%) fetuses testing positive for NSD. The presence of a cystic hygroma on ultrasound resulted in a positive rate of 16% (9/57) and is perhaps the most predictive indicator for prenatal testing for NSD. These findings are consistent with other studies and support the use of a multi-gene panel for genetic testing for NSD.

794T

Exploiting whole genome sequencing for finding new genetic causes of familial dilated cardiomyopathy. *A.E. Minoche[1], C. Horvat[2], M.E. Dinger[1], D. Fatkin[2], M.J. Cowley[1].* 1) Garvan Institute of Medical Research, 384 Victoria Street, Darlinghurst NSW 2010 Australia; 2) Victor Chang Cardiac Research Institute, 405 Liverpool St, Darlinghurst NSW 2010 Australia.

   The genetic cause of familial dilated cardiomyopathy (DCM) is often unknown. The genetically heterogeneous nature of the disease and ongoing research requires testing for genetic variation in constantly growing lists of genes. Whereas gene panel sequencing struggles to keep up with this challenge, whole genome sequencing overcomes it and has the potential to advance the discovery of new variant disease associations.   We show that WGS not only covers more genes, it even covers disease genes captured by targeted sequencing more comprehensively. For a set of 67 DCM genes targeted by panel sequencing, WGS covered 7.8% to 21.1% more gene positions >=15x (depending on the selected isoforms). On median WGS covered 99% of exon bases with this read depth.   All causative SNVs detected in 21 of 42 patients using panel sequencing were also found in WGS. Beyond that WGS enabled the detection of 10 additional predicted high and medium impact variants per patient within the same set of target genes, structural variation including copy number variation and variants in regulatory regions. Further through WGS we identified damaging variants in additional genes not targeted by the panel, including 15 recently identified DCM genes, 274 genes specifically expressed or over expressed in heart and 47 genes recommended for reporting incidental findings (ACMG genes).   Of these additional variants one was found causative (Nkx2.5). In the remaining patients, we have identified additional 12 candidate variants that are rare in healthy individuals, and predicted to be damaging, which are currently tested for co-segregation. Seven of these are in known DCM genes and missed by targeted sequencing; two are in newly discovered DCM genes (GATA4, DSC2), two in genes expressed in the heart (TRIM63 and PDE4DIP), and two caused by structural variants (DSC2 and BAG3). In only seven patients we didn't find any new candidates. With WGS the genetic cause was found for 52% of the patient cohort, which is already slightly higher than with panel sequencing. Overall it is expected that the yield for WGS will further increase, thanks to candidate variants in 33% of undiagnosed patients.

795F

Targeted sequencing for genetic diagnosis of cardiovascular disorders. *S. Mikaeeli[1], N. Mahdieh[2], B. Rabbani[2], S. Mikaeeli[3].* 1) Islamic Azad University of Medical Branches, Tehran, Iran; 2) Genetic Research Center, Rajaie Cardiovascular Medical and Research Center, Iran University of Medical Sciences, Tehran, Iran; 3) Islamic Azad University of North Tehran Branches, Tehran, Iran.

   During last few years next generation sequencing (NGS) technique has provided the vast majority of applications both in basic and clinical research. This technique is applied, in order to identify rare variants in genetic disorders more especially in heterogeneous diseases such as cardiomyopathies. Hence, targeted sequencing technique could be affordable and rapid technique to overwhelm diagnostic problems. Here, we present families whom their children suffer from Marfan Syndrome (MFS [MIM 154700]) and Dilated cardiomyopathy (DCM[MIM 115200]), candidate genes were selected using targeted sequencing technique for genetic testing followed by Sanger sequencing test for confirming recognized variants. In one family, 24 different variants were obtained out of 14 candidate genes which Sanger test has revealed that only one mutation at c.7783G>A (Gly259Ser) position which is located at *FBN* gene has pathogenic effect. In another family 65 variants out of 23 applicant genes were discovered and one pathogenic mutation identified at c.3373G>A (Val1125Met) position in *MYBPC3* gene. Of course in silico analysis predicted the pathogenicity of the mutations. This investigation could demonstrate the pivotal role of targeted sequencing in diagnostic genetic testing.

796W

Next generation sequencing (NGS) evaluation of *CYP11B1* and *CYP11B2* single nucleotide variants (SNP) for a correlation in hypertension and Cushing Syndrome. *W. Shi, C. Chin, A. Beams, J. Lameh, R. Pollner.* Bio-Pharma, Genoptix Medical Laboratory, A Novartis company, Carlsbad, CA.

   Introduction: Members of the CYP11B subfamily participate in the biosynthesis of important steroid hormones. Among them, CYP11B1 and CYP11B2 control the synthesis of cortisol and aldosterone, respectively. Cortisol is a steroidal hormone essential for homeostasis by regulating changes in the body in response to stress. Prolonged exposure to excess cortisol leads to Cushing syndrome. Aldosterone has been implicated in the pathogenesis of hypertension, heart failure, and renal disease. A new potential method to treat Cushing syndrome or hypertension is controlling plasma cortisol and aldosterone levels by CYP11B1 and CYP11B2 inhibition. We developed a NGS amplicon-based assay for sequencing *CYP11B2* and *CYP11B1* gene regions, and are evaluating the correlation of SNPs with clinical presentations among different populations. **Methods**: We designed custom primers to cover all *CYP11B1* introns and exons as well as 500 bp upstream and 500 bp downstream. Further upstream *CYP11B1* promoter was excluded due to the presence of repetitive sequences. Primers for *CYP11B2* were designed to cover all exons and introns, a 2 kb promoter region, and 500 bp downstream of the strop codon. A total of 78 amplicons, ranging in sizes from 125 to 375 bp, were generated in three pools to enable maximum coverage of both genes and to minimize gaps. DNA from whole blood was isolated. Library preparations using Hi-Q Library reagents followed the Ion AmpliSeq 2.0™ procedure. Subsequent sequencing was performed using Thermo Fisher's Hi-Q sequencing reagents with 318 v2 chips on the Ion Chef™ and Personal Genome Machine™ (PGM) was all performed. Germline SNPs and indels were identified using Thermo Fisher's Ion Reporter™ Software version. **Results**: The NGS amplicon assay developed for evaluation of *CYP11B1* and *CYP11B2* SNPs based on the Thermo Fisher PGM™ platform shows sufficient coverage among all 78 custom-designed amplicons. We found that the assay performance was accurate by evaluating the Illumina Platinum Genome, NA12878. Multiple-sequenced NA12878 showed high concordance with each other and to the reference Illumina Platinum Genome for the regions of interest. Clinically relevant SNPs were identified in a subset of subjects and tested for an association with hypertension or Cushing syndrome. **Conclusions**: Reliable SNPs reported for amplicons covering both *CYP11B1* and *CYP11B2* genes can potentially provide valuable information for developing novel therapeutics and guiding treatment decisions.

797T

***CTNS* molecular genetics profile in a Persian nephropathic cystinosis population.** *B. Behnam[1,2,3], F. Ghazi[1], R. Hosseini[2], H. Otukesh[2], M. Ackouchakian[1], S. Teimourian[1], Z. Ataee[1], F. Vali[1], W. Gahl[3].* 1) National Human Genome Research Institute, National Institute of Health, Bethesda, MD, USA; 2) Department of Medical Genetics and Molecular Biology, Faculty of Medicine, Iran University of Medical Sciences (IUMS), Tehran, Iran; 3) Department of Pediatrcics, Faculty of Medicine, Ali Asghar Children Hospital, Iran University of Medical Sciences (IUMS), Tehran, Iran.

   Purpose: In this report, we document the *CTNS* gene mutations of 28 Iranian patients with nephropathic cystinosis age 1-17 years. All presented initially with severe failure to thrive, polyuria, and polydipsia. **Methods:** Cystinosis was primarily diagnosed by a pediatric nephrologist and then referred to the Iran University of Medical Sciences genetics clinic for consultation and molecular analysis, which involved polymerase chain reaction (PCR) amplification to determine the presence or absence of the 57-kb founder deletion in *CTNS*, followed by direct sequencing of the coding exons of *CTNS*. **Results:** The common 57-kb deletion was not observed in any of the 28 Iranian patients. In fourteen of 28 patients (50%), mutations were observed in exons 6 and 7. No mutation was detected in exon 5, and only one (3.6%) patient with cystinosis showed a previously reported 4-bp deletion in exon 3 of *CTNS*. Four patients (14.3%) had a previously reported mutation (c.969C>A; p.N323K) in exon 11, and five (18%) had novel homozygous deletions in exon 6 leading to premature truncation of the protein. These deletions included c.323delA; p.Q108RfsX10) in three individuals and c.257-258delCT; p.S86FfsX37 in two cases. Other frame-shift mutations were all novel homozygous single base pair deletion/ insertions including one in *CTNS* exon 9 (c.661insT; p.V221CfsX6), and four (14.3%) in exon 4, i.e., c.92insG; p.V31GfsX28 in two and c.120delC; p.T40TfsX10 in two. In total, we identified eight previously reported mutations and eight novel mutations in our patients. The only detected splice site mutation (IVS3-2A>C) was associated with the insertion mutation in the exon 9. **Conclusion:** This study, the first molecular genetic analysis of non-ethnic-specific Iranian nephropathic cystinosis patients, may provide guidance for molecular diagnostics of cystinosis in Iran.

798F

Mutation spectrum of *ABCD1* in 17 Vietnamese patients with X-linked adrenoleukodystrophy. *K.N. Nguyen[1], D.C. Vu[1], H.T. Nguyen[1], T.P. Bui[1], N.B.T. Can[1], H.T. Le[1], N. Shimozawa[2].* 1) Medical Genetics and Metabolism, Vietnam Children's Hospital, Hanoi, Viet Nam; 2) Division of Genomics Research, Life Science Research Center, Gifu University, Department of Pediatrics, Gifu University School of Medicine, Gifu, Japan.

   Background: X-linked adrenoleukodystrophy (X-ALD) is caused by a defect in the gene *ABCD1*, which maps to Xq28 and codes for a peroxisomal membrane protein that is a member of the ATP-binding cassette transporter superfamily. This disease characterized by progressive neurologic dysfunction, occasionally associated with adrenal insufficiency. **Objective:** to identify mutations of gene *ABCD1* in Vietnamese patients with X-ALD. **Method:** Genomic DNA from 17 Vietnamese patients from 15 unrelated families was extracted using standard procedures from the peripheral blood leukocytes. Mutation analysis of *ABCD1* was performed using Polymerase chain reaction (PCR) and DNA direct sequencing. **Results:** We identified 14 different mutations of *ABCD1* in 17 patients including missense mutations (9/14), deletion (4/14) and splice site mutation (1/14). Of which, six novel mutations including c.1202G>T (p.Arg401Trp); c.1208T>A (p.Met403Lys); IVS8+28-551bp del; c.1668G>C (p.Q556H); c.292_296delTCGGC (p.S98RfsX95); and the extent of deletion included between IVS1+505 and IVS2+1501, containing whole the exon 2 (4243bp), plus insertion of 79bp from BAP31 and 8bp from unknown origin in this deleted region were identified in six unrelated patients. Eight reported mutations including c.796G>A (p.Gly266Arg); c.1628C>T (p.Pro543Leu); c.1553G>A (p.Arg518Gln); c.1552 C>T (p.Arg518Trp); c.854G>C (p.R285P); c.1825G>A (p.E609K); c.1415_1416delAG (p.Q472RfsX83) and c.46-53del insG were identified in 10 patients from 8 families. **Conclusion:** Mutation analysis of *ABCD1* helped confirmation of diagnosis of X-ALD, genetic counselling and prenatal diagnosis.

799W

The Personalized Diabetes Medicine Program identifies multiple individuals with treatment-altering diagnoses of monogenic diabetes. *J.W. Kleinberger[1], K.A. Maloney[1], L.J.B. Jeng[1], E.A. Streeten[1], S.A. Stein[2], Y. Mohtasebi[1], Y. Guan[1], C.L. Overby[3], T.J. Mathias[1], N. Ambulos[1], D. Sewell[1], K. Tanner[1], C.M. Damcott[1], M.J. Nicholson[1], K. Palmer[1], T.D. O'Connor[1], R.B. Horenstein[1], K.D. Silver[1], A.R. Shuldiner[1], T.I. Pollin[1].* 1) University of Maryland School of Medicine, Baltimore, MD; 2) DC Endocrine, Washington, DC; 3) The Johns Hopkins University School of Medicine, Baltimore, MD.

   Monogenic diabetes accounts for approximately 1-2% of all diabetes mellitus and is often misdiagnosed due to factors such as lack of awareness, clinical similarity to common forms of diabetes, limited availability/high cost of genetic testing and complexity of result interpretation. A diagnosis of certain forms of monogenic diabetes can lead to replacement of insulin with oral medications or even no treatment at all while maintaining or improving glycemic control and allowing diagnosis of family members. The Personalized Diabetes Medicine Program (PDMP) is a project in the NIH supported Implementing Genomics in Practice (IGNITE) Network to implement and evaluate a sustainable approach to detection, diagnosis and individualized treatment for patients with monogenic diabetes. Patients being treated for diabetes in endocrinology clinics in an urban academic medical center, a Veterans Affairs medical center, an integrated healthcare system and a suburban private practice are screened using a simple questionnaire and review of standard bloodwork and/or referral by clinicians noting unusual phenotypes. Those suspected to have monogenic diabetes are enrolled, and the patient's medical and family history is collected upon consent. Genetic testing, when indicated, is performed using a next generation sequencing custom gene panel covering coding and flanking splice regions of 40 monogenic diabetes genes. Rare protein-altering variants are manually reviewed and classified according to ACMG/AMP guidelines for interpretation of sequence variants. Pathogenic or likely pathogenic variants are confirmed in a CLIA/CAP accredited laboratory and results are communicated to the patient by a genetic counselor and endocrinologist/clinical geneticist, placed in the electronic health record, and routed to the patient's diabetes care provider. To date, 4 patients with pathogenic variants and 2 with likely pathogenic variants were found in 65 individuals tested. These variants in *HNF1A*, *GCK*, and *INS* genes generated specific treatment recommendations. Our discovery rate of 9% indicates that our screening approach is enriching the test sample for mutation-positive individuals. Additionally, 54 variants of uncertain significance (VUS) were discovered in 34 patients, including multiple suspicious variants in the most common monogenic diabetes genes. We are currently evaluating the feasibility of incorporating *in vitro* and animal model studies to aid the variant interpretation process.

800T

The first Iranian case of mucopolysaccharidosis IIIC: Use of homozygosity mapping in a consanguineous pedigree. *N. Hosseini[1], A. Eslahi[1], F. Ashrafzadeh[2], K. Hasanpour[3], M. Mojarrad[1,4].* 1) Department of Medical Genetics, School of Medicine, Mashhad University of Medical Sciences, Mashhad, IRAN; 2) 2Department of Pediatric Neurology, Ghaem Medical Center, Mashhad University of Medical Sciences, Mashhad, Iran; 3) Departmentof Clinical Sciences, Sabzevar University of Medical Sciences, Sabzevar, Iran; 4) Medical Genetics Research Center, School of Medicine, Mashhad University of Medical.

Mucopolysaccharidosis type IIIC (MPSIIIC) is a rare subtype of mucopolysaccharidosis disorder family caused by mutations in *HGSNAT* gene. Mucopolysaccharidosis type IIIC consist of four subtype which have overlapping features and are indistinguishable in clinical level. In population with high consanguineous marriage rate like Iran homozygosity mapping can be a good choice to finding of disease locus.Herein we report a female patient with a novel mutation in *HGSNAT* gene. Homozygosity mapping was performed using SNP-array technology to detect candidate locus in this patient. All coding exons of *HGSNAT* gene were scanned by direct DNA sequencing. We found a novel ins/del mutation as c.1357TA>C in *HGSNAT* gene. This mutation is a frameshift mutation which eventually leads to premature protein truncation. To the Best of our knowledge this is the first case report of sanfilippo type C in Iranian population. This result supports applicability of homozygosity mapping to diagnosis of sanfilippo subtypes.

801F

QuantStudio carrier screening panel for Ashkenazi Jewish diseases. *M. Procter[1], R. Mao[1,2].* 1) ARUP Institute for Clinical & Experimental Pathology, Salt Lake City, UT; 2) Dept. of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Background In an effort to expand our current Ashkenazi Jewish (AJ) mutation panel, we investigated the QuantStudio platform, capable of targeting up to 64 variants simultaneously. The QuantStudio platform is able to handle varying assay complexities, from small multiplex panels, to the Ashkenazi Jewish mutation panel of 53 targets, to larger panels in varying formats. We evaluated the feasibility of using a multi-sample array wherein loci are amplified and analyzed independent of each other, eliminating PCR competition. **Materials and Methods** Fifty-three loci on 17 genes on the Ashkenazi Jewish panel were amplified in micro assay wells called "through-holes" using TaqMan chemistry on a QuantStudio™ 12K Flex OpenArray®. Each array chip contains 48 subarrays, each of which is capable of amplifying 64 loci in separate through-holes. Thus, a single OpenArray chip can test 48 patients simultaneously. We chose to test patient samples in duplicate, therefore 24 patient samples and controls are tested on a single chip. Four OpenArray chips can be amplified in a single run, the entire work flow from set up to results takes approximately 4-5 hours to complete. Forty-five previously genotyped, positive, de-identified DNA specimens were tested on the OpenArray chips to define assay performance and turn-around time. Additionally, six plasmid pools and three individual plasmid stocks including all loci detected in this assay were used to test the specificity of primers and probes. **Results** Accuracy of both the AJ assay was found to be greater than 99%. The failure rate of total targets is relatively low at less than 5%. However these sporadically failed targets occur over multiple samples, making the percentage of patient repeats higher than 5%. Plasmid targets verified oligo specificity and complemented the positive sample pool for variants for which we did not have positive genomic DNA. **Discussion** Sporadic call ambiguity and amplification failure of single loci necessitates running AJ samples in duplicate. Multi-sample array provides rapid turn-around time for our expected AJ sample volumes and is considerably more cost effective than alternative methodologies such as NGS. The QuantStudio format is a high quality, low cost method for carrier screening.

802W

The application of targeted next-generation DNA sequencing to newborn screening for inherited metabolic diseases. *R. Gao[1], J.L. Ren[1], C. Liu[1], W.X. Zhen[1], Z.H.W. Huang[1], J. Zhu[2,3], H. Zhang[4].* 1) FirStories science and technology Co., LTD; 2) The National Office for Maternal and Child Health Surveillance of China; 3) West China Second University Hospital, Sichuan University; 4) PrecisionMDX Co., LTD.

Purpose: In Mainland China, LC-MS/MS newborn screening (NBS), have succeeded in reducing morbidity and mortality for approximately 13 years. However, several issue of LC-MS/MS method, such as relative low recall rate, instability of metabolite and complex cutoff value setting, have limited its application in NBS program. DNA sequencing, on the other hand, won't be influenced by those issues. Furthermore, using trace-level DNA as start-up material, genetic testing could be performed by applying only one dried blood spot. This kind of genetic testing could be introduced as a second-tier method in conventional LC-MS/MS NBS program, and facilitate the confirmation process. Methods: A total of 63,024 dried blood samples (DBSs) of newborns have been screened for 48 IMDs by using LC-MS/MS from Jan 2014 to Dec 2015. Two hundred and sixty subjects have an abnormal result from the initial test and 178 (68.5%) were recalled successful for further confirmation. The other 82 subjects failed to be recalled and nobody knows whether they have diseases or not at the moment. We had access to collect 50 samples from the 82 subjects and analyzed them on TNGS (target-capturing next generation sequencing) of 48 inherited metabolic diseases (IMDs). The metabolites' concentration of all the 50 samples was far out of the cutoff threshold in first-time LC-MS/MS screening. The TNGS test was performed on the residual DBS after the first-time screening. Result: From the conventional NBS confirmation process, 15 of the 178 recalled subjects were finally diagnosed with certain diseases. It is noticeable that miss detection of 82 failed recall subjects could inevitably contribute to false negative in the conventional NBS program. For the 50 subjects conducted with genetic testing, 9 new subjects were detected with disease-causing mutations in the candidate gene. Taken the abnormal LC-MS/MS result into consideration, we infer these 9 samples are with high-risk of the correspondence diseases. Nevertheless, all of them were ignored by the conventional NBS program due to failed recall for further diagnosis. This could be the main source of false negative in the conventional NBS program. We thereby believe that the application of TNGS to LC-MS/MS NBS programs for all the positive subjects after first-time screening is beneficial. Especially, the process doesn't need repeat sample collection and all the subjects could benefit from the early, presymptomatic diagnosis.

803T

Defining *KIR* and *HLA class I* genotypes at highest resolution using high-throughput sequencing. *P.J. Norman[1], N. Nemat-Gorgani[1], W.M. Marin[2], S.J. Norberg[3], M. Ronaghi[3], J.A. Hollenbach[2], P. Parham[1].* 1) Structural Biology, Stanford, Stanford, CA; 2) Neurology, University of California San Francisco School of Medicine, San Francisco, CA; 3) 3.Illumina Inc., 5200 Illumina Way, San Diego, CA.

The physiological functions of natural killer (NK) cells in human immunity and reproduction depend upon diverse interactions between killer cell immunoglobulin-like receptors (KIR) and their HLA class I ligands: HLA-A, -B and -C. Extensive allelic and structural variation of *KIR* genes directly affects NK cell activity by diversifying the expression, signaling capacity or HLA binding properties of KIR allotypes. The genomic regions containing the *KIR* and *HLA class I* genes are unlinked, structurally complex, highly polymorphic, and co-evolving. They are also strongly associated with a wide spectrum of disease, including infections, autoimmunities, cancers, and pregnancy disorders, as well as the efficacy of transplantation and other immunotherapies. To facilitate study of these extraordinary genes, we developed a method that captures, sequences and analyzes the 13 *KIR* genes (MIM: 604936-7, 604945-7, 604952-6, 605305, 610095, 610604) and the *HLA-A*, -B and -C genes (MIM: 142800, 142830 and 142840) from genomic DNA. We also devised a bioinformatics pipeline to call high-resolution genotypes for each of the *KIR* genes. PING (Pushing Immunogenetics to the Next Generation) uses a novel combination of virtual sequence probes and filtering to attribute sequencing reads to specific *KIR* genes and determine their alleles and copy number. The complete method was validated using DNA from well-characterized cell lines by comparison with established methods of *HLA* and *KIR* genotyping. We also determined *KIR* genotypes from the 1000 Genomes Project sequence data using PING. This identified 116 novel *KIR* alleles, which were all demonstrated authentic by sequencing them from source DNA using standard methods. Analysis of just two *KIR*, showed that 22% of the 1000 Genomes individuals have a novel allele or a structural variant. In analyzing over 1000 Europeans with the complete method we identified one in ten individuals to harbor a previously undiscovered *KIR* variant. These findings indicate heterozygosity at the *KIR* locus likely rivals that of the *HLA class I* genes, which have more than 10,000 alleles identified following sequencing millions of potential bone marrow donors worldwide. The method we describe is suited to the large-scale analyses that are needed for characterizing human populations and defining the precise *HLA* and *KIR* factors associated with disease. The methods are applicable to other highly polymorphic genes. PING is an open-source R program available on Github.

804F

Well-groomed participants: Eyebrow plucks as surrogates for biomarker samples and a viable source of constitutional DNA. *D. Castillo[1], J. Herzog[1], S. Sand[1], T. O'Connor[2], C. Clark[2], J.N. Weitzel[1,2].* 1) Division of Clinical Cancer Genetics, City of Hope National Medical Center, Duarte, CA; 2) Beckman Research Institure, City of Hope, Duarte, CA.

Purpose: The human hair follicle is a potential source of proliferating epithelial cells and can be used in multiple clinical applications. This study tested the feasibility of using plucked eyebrow hairs as biomarker samples in pharmacodynamics (PD) studies and as quality surrogates for DNA sources. Previous reports of eyebrow plucks as DNA damage indicators following drug treatment have suggested that they would be useful as PD markers for poly(ADP-ribose) polymerase (PARP) inhibitor and other drug-related DNA damage. **Methods**: For PD studies on NCT01149083, a PARP inhibitor trial, plucked follicles were stored in saline and processed within 24 hours; control samples were treated with H_2O_2 and fluorescent antibodies, using confocal microscopy to reveal YH2AX foci as an indicator of double strand breaks. After creating a standard operating procedure (SOP) for collecting and processing eyebrow plucks to extract DNA, samples with 10-15 plucks were obtained from subjects with suspected somatic mosaic *TP53* mutations or hematologic malignancies who enrolled in an IRB-approved registry. **Results**: For the PD study YH2AX foci were detected in the control samples, but not in patient samples following veliparib and carboplatin treatment . Eyebrow pluck uniformity was limited due to variability inherent in the fact that hair follicles have 5 stages of maturation. Eyebrow plucks were obtained from 11 patients for the alternate source of DNA study; 5 to establish whether a previously found *TP53* mutation was mosaic or constitutional, and 6 taken from allogeneic transplant patients seen for genetic testing. Of the 11 samples, 9 were clinical quality (>1 μg yield with 260/280 OD=1.8-2.0), and 3 of these were successfully used in commercial *TP53* testing to establish clonal hematopoiesis in mosaic *TP53* mutations found in the blood that were not present in the eyebrow DNA. The 2 samples not meeting standards had fewer quality hair follicle bulbs and had longer times from pluck isolation to DNA extraction. **Conclusions**: While DNA yield is limiting, collection of eyebrow hair follicles is less invasive and faster than skin biopsy. We obtained quality DNA as long as the sample was handled in a timely manner and in accordance with our SOP. Thus, applications may include assessment of DNA for patients with bone marrow transplant or hematological disorders. The variability of follicle maturation must also be considered when designing PD studies for this biospecimen.

805W

Evaluation of the gene *FANCA* DEL/DUP through MLPA in a cohort of Fanconi anemia patients. *L. Bobadilla-Morales[1,2], A. Vázquez Reyes[1], E. Zapata-Aldana[2], E. Torres-Anguiano[1], H.J. Pimentel-Gutiérrez[2], C. Ortega-de-la-Torre[2], M. Ortíz[2], R. Silva-Cruz[1], L. Corona-Bobadilla[1,2], F. Sánchez-Zubieta[2], J.R. Corona-Rivera[1,2], A. Corona-Rivera[1,2].* 1) Laboratorio de Citogenética, Genotoxicidad y Biomonitoreo, Instituto de Genética Humana, CUCS, Universidad de Guadalajara; 2) Servicios de Genética, 2Unidad de Citogenética y 3Hematoncología, División de Pediatría, Hospital Civil de Guadalajara Dr. Juan I. Menchaca.

Introduction: The Fanconi anemia (FA) is an inherited disorder from the DNA reparation system characterized with progressive pancytopenia and impaired bone marrow function, various congenital malformations and predisposition to develop solid or hematologic tumors (OMIM: 227650). Herein are characteristic, growth delay, short stature and hematologic, musculo-sceletal, renal, cardiovascular, endocrinologic, dermatologic and central nervous system disorders. The FA has an incidence rate of 1 in 350,000. It has been established 15 genetic subtypes, but 60% of the patients present the gen FANCA (16q24.3) mutation. The MLPA technique is an effective method to detect an abnormal number of copies through multiple PCR. In the present study we evaluated a cohort of patients with FA as studied in the Hospital Civil de Guadalajara "Dr. Juan I. Menchaca" (HCGJIM) aiming to detect the presence of DEL/DUP of the gene FANCA applying the MLPA technique. **Methods.** Descriptive study accomplished during the period January 2009 to May 2016 in a cohort of patients attended by the Pediatric and Genetic Hemato-Oncology services in the HCGJIM with clinical diagnosis of FA. All the patients included in such study had cytogenetical corroboration of the choromosomal instability evaluated by means of mitomycin C as inductor. Prior informed consent it was obtained DNA from peripheral blood. For the MLPA assay it was deployed the MLPA kit® SALSA p031/p032 *FANCA* (MCR-Holland, Amsterdam, The Nehterlands). Data analysis of the data was performed by the software Coffalyser®. **Results.** We evaluated 14 patients presenting positive choromosomal instability before time of exposure to mitomycin C. Morover, one of the 14 patients presented homozygotic deletion of the exon 11 to 18, whose parents presented heterozygotic state; furthermore, another patient and his mother showed gains of the 42 exon. **Conclusions.** Our results show a frequency of deletions lower to the reported, prospectively due to the fact that we are a reference center, thus we do not represent the general population, all of our patients therefore show hematologic disorders; on the other hand, the gain of the 42 exon in a heterozygotic way should be established as a Fanconi Anemia coincidence. Before anemia development, the MLPA method could be applied as an initial screening in order to detect deletions of the gene FANCA, and as an aid to search for the gene carriers.

Fanconi anemia: Five years experience for patients referred to the Human Cytogenetics Department National Research Center - Egypt.
M.M. Eid[1], G.Y. El Kamah[2]. 1) Human Cytogenetic , National Research Center, Cairo, Egypt, Cairo, Dokki, Egypt; 2) Clinical Genetics , National Research Center, Cairo, Egypt, Cairo, Dokki, Egypt.

Fanconi anemia (FA) is one of a well described chromosomal instability disorder. It is inherited usually as autosomal recessive disorder except complementation subtype B inherited as X -linked disorder. To date 19 complementation subtype have been reported in the literature. Bone marrow failure leading to aplastic anemia is usually the presenting symptoms, unless the patient has an apparent congenital malformation such as thumb or radial rays anomaly. About 10% of the patients the presenting symptom is the myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML). The diagnosis of FA depends on the clinical assessment and induction of chromosomal breakage by diepoxy butane (DEB).   In this work we report on the patients referred to our department in the last 5 years for DEB test and various studies carried out for them. A total of 238 patients were referred to perform DEB test for, the common presenting feature is pancytopenia. The other causes for the referral is either being a sib for patient with Fanconi anemia, or having one of common features of FA such as radial anomaly with or without thumb affection and/or skin pigmentation abnormalities and microcephaly. Out of the 238 patients, FA was diagnosed in 70 patients, 32 were normal sibs for the FA patients they were referred either to exclude FA or the possibility to be a proper bone marrow donor for their affected sib and 136 were diagnosed as having acquired aplastic anemia. The male to female ratio of the FA patients was 1.25:1. Six families show 2 affected sibs. Usually the second sib diagnosed accidentally through the family investigation. MDS and acute myeloid leukemia was the presenting symptoms in 3 patients. The sensitivity for the DEB is variable between the patients. 8 patients show mosaicism in their response to DEB. These group of patients have normal cell line in 40% up to 90% of their studied metaphases. The patient that has 90% normal cell line she has near normal blood picture and her age was 18yrs.   Immunoglobulin evaluation shows low level of all immunoglobulin groups in one FA patient. Anti oxidant and pro oxidant status studies were done for FA patients which revealed a significant response to various antioxidant.   Although our research for FA have covered different aspects still we did not achieve much as regard molecular aspects. However mutation screening using MLPA is currently under study and we expect to reach valuable results from it.

807F

HLA-DQ1 alpha and beta genotypes associated with non-celiac gluten sensitivity. *M. Maki, D. Caporale.* Biology, University of Wisconsin Stevens Point, Stevens Point, WI.

Non-Celiac Gluten Sensitivity (NCGS) is a gastrointestinal disease occurring in 3-6% of the population, while celiac disease (CD) and wheat allergy (WA) are only found in 2-4%. This indicates that 17 million Americans may have NCGS. Only by eliminating a diagnosis of CD and WA through medical testing and the elimination of foods from their diet can a patient be diagnosed with NCGS. Some reports have shown that proteins embedded in the membranes of leukocytes known as human leukocyte antigens (HLAs) are linked to comparable gastric diseases like CD and WA. It is possible that certain HLA genotypes may also be associated with NCGS. To test this hypothesis, we screened a cohort of 50 NCGS and 50 non-NCGS participants for their HLA DQ alpha and beta genotypes, using AllSet+ Gold DQ alpha 1 and beta 1 high resolution allele-specific PCR kits. DNA fingerprints were generated by electrophoresing the PCR products on large 3% agarose gels and photodocumented for allele identification. Since the HLADQ surface protein consists of one alpha polypeptide and one beta polypeptide and both subunits are in association with the antigen molecule, it seemed most appropriate to combine the alpha and beta genotypes for each individual and observe allele combinations within and between each cohort. For simplicity, alpha and beta allele types were numbered α1 through 5 and β1 through 6, respectively. So far, the most common genotype combinations within the gluten-sensitive cohort were A1-3/B2-6 and A1-5/B2-6. The most common genotype combinations for the control group were A1-3/B3-5 and A1-3/B3-6; both were also unique to the control group. The genotype combination A1-3/B2-6 was only found within the gluten-sensitive cohort. Interestingly, allele A5 (DQA1:05) and allele B2 (DQB1:02) are both higher in frequency within the gluten-sensitive group than within the control group. Previous studies have shown high association between these two allele types and Celiac disease. We are continuing to screen more participants within each cohort, to test the statistical significance of our findings. If the A5 and B2 allele frequencies continue to be significantly higher in the gluten-sensitive cohort, then screening for these alleles may be used as a more efficient diagnosis tool in the future.

808W

Spectrum of alpha and beta thalassemia mutations in Singapore. *K. Tan[1], P.T. Huan[1], L. Chiu[1], S.S. Chong[1,2], E.S.C. Koay[1,3].* 1) Laboratory Medicine, National University Hospital, Singapore, Singapore; 2) Department of Paediatrics, Yong Loo Lin School of Medicine, National University Singapore, Singapore; 3) Department of Pathology, Yong Loo Lin School of Medicine, National University Singapore, Singapore.

Background Thalassemia is a common inherited gene disorder and is prevalent in South East Asia. Molecular testing of the alpha and beta globin genes plays an important role in the diagnosis of thalassemia. Methods The Molecular Diagnosis Centre in the National University Hospital in Singapore performs molecular analysis for thalassemia which includes DNA extraction and mutation analysis for both alpha and beta globin genes. The alpha globin gene cluster is examined for seven deletional mutations (SEA, -3.7, -4.2, FIL, THAI, -20.5 and MED) by gap-PCR, and six point mutations within the alpha2-globin (*HBA2*) gene (codon 30 / Hb G, codon 59 / Hb Adana, Hb Quong Sze, Hb Constant Spring, Hb Pakse and polyA signal), known to be common to individuals in this region, by PCR and sequencing. The beta globin gene was examined by PCR followed by sequencing of all three exons. Results Over a period of 10 years from 2006 to 2016, peripheral blood from 970 individuals were analyzed. There were no mutations found in 363 patients. The most common alpha globin deletion mutations were the -3.7 and SEA deletions, which were each present in 20% of the individuals tested. Forty eight individuals were homozygous for the -3.7 deletion, and 13 had both the -3.7 and the SEA deletion together, while only 2 were homozygous for the SEA deletion. The -4.2 deletion was present in 17 cases, while the FIL and THAI deletions were present in 6 and 2 cases respectively. The -20.5 and MED deletions were not detected. Among the beta globin mutations, the HbE mutation was the most common, and was present in 6% of all cases. The next most common beta globin mutations were the codons 41/42 (-TCTT) mutation (26 cases), the IVS1 nt5 mutation (22 cases) and the IVS2 nt654 mutation (21 cases). Five percent of all cases (49 individuals) had both alpha globin mutations and beta globin mutations together. Conclusion Molecular analysis is valuable in clarifying the diagnosis of thalassemia and both the alpha and beta globin genes should be examined. .

809T

Whole exome sequencing for identification of genetic alteration of light chain amyloidosis. *S.Y. Kim[1,3], Y. Park[1], H. Kim[1], Y. Oh[1], J. Lim[1], Q. Choi[2], G.C. Kwon[1], S.H. Koo[1].* 1) Department of Laboratory Medicine, Chungnam National University School of Medicine, Daejeon, South Korea; 2) Department of Laboratory Medicine, Dankook University Hospital, Cheonan, Republic of Korea; 3) Cancer Research Institute, Chungnam National University School of Medicine, Daejeon, Republic of Korea.

Light chain (AL) amyloidosis is a plasma cell disorder characterized by a clonal population of plasma cells that produce monoclonal immunoglobulin chains that are deposited in tissues, resulting in associated symptoms. In AL amyloidosis patients, immunoglobulin is deposited in tissues before a large tumor burden develops; therefore, AL amyloidosis patients typically do not present with overt multiple myeloma (MM) at the time of diagnosis. Because of rarity of disease and lower burden of clonal plasma cells, few data on genomic alterations of clonal plasma cells in AL amyloidosis have been reported. In this study, we performed whole exome sequencing (WES) of in bone marrow (BM) and peripheral blood (PB) cells collected from 5 AL amyloidosis patients and 2 MM patients. Four AL amyloidosis patients presented monoclonal gammopathy related to light chain lambda type, and one AL amyloidosis patient presented kappa light chain deposition. The median plasma cell burden in BM aspirate samples of AL amyloidosis patients was 10% (range, 2%-41%). After extraction of DNA from total nucleated cells of BM and PB samples, WES was performed using Illumina HiSeq 2000. Putative mutations in BM samples of each patient were analyzed in comparison to PB samples. No previously reported hotspot mutations in hematologic malignancies were found in 5 AL amyloidosis patients. We intensely investigated for the presence of 95 variants of AL amyloidosis that was recently reported by Paiva et al. (2016), however, none of these mutations were found. In our patients, non-recurrent variants were found in each case in genes including *GBP4*, *SH2D4A*, and *AR*. In addition, variants in the intergenic region including SLC25A46-TSLP were also found. Our results was concordant with previous studies of WES of AL amyloidosis in that unifying mutation by WES is absent in AL amyloidosis. To elucidate pathogenesis of AL amyloidosis, deeper and broader genetic investigations beyond exome may be needed.

810F

The frequency *F8* gene intron 22 inversion in patients with hemophilia A from Russian Federation. *T. Beskorovainaya, T. Milovidova, A. Polyakov.* Federal State Budgetary Institution "Research Centre for Medical Genetics", Moscow, Russian Federation.

Introduction: Hemophilia A (HA) is a frequent X-linked recessive bleeding disorder resulted from deficiency or dysfunction of coagulation factor VIII (FVIII). It affects 1 of 5000 males. HA is caused by mutations in *F8* gene located on chromosome Xq28 and consisted of 26 exons. More than 3000 mutations were described in the gene. The most common mutation is the intron 22 inversion (Inv22). It was found in 40-45% patients with severe HA (coagulation activity of FVIII <1%). Materials and Methods: In this study we searched Inv22 in unrelated probands with HA (38 patients) and relatives of probands whose material was not available (33 persons) from 71 Russian families using inverse-PCR method (Rossetti L.C. et al., 2005). Results: Inv22 was found in 32.4% cases. Mothers of probands with detected Inv22 were carriers of this mutation in all cases. Four probands with clinical diagnosis "hemophilia B" (HB) were also analyzed for Inv22 which was found in one case. Moreover, in two families large rearrangements of the *F8* gene not due to inversion intron 22 were identified by the presence of abnormal length fragment on the electrophoresis. Further these fragments were analyzed by direct sequencing. Conclusions: Results of this study are consistent with literature data. It was suggested that coagulation test allowing to distinguish HA and HB wasn't made for all patients. This technology has wider diagnostic capabilities than expected and can detect some genetic rearrangements besides the *F8* gene inversion intron 22 (long deletions or insertions up to exon 21).

811W

Comparative analysis of whole exome sequencing and targeted next-generation sequencing in patients with primary immunodeficiencies. *J. Chou, W. Bainter, B. Cangemi, M. Massaad, R. Geha.* Division of Immunology, Boston Children's Hospital and Harvard Medical School, Boston, MA.

Primary immunodeficiencies (PIDs) are typically monogenic disorders characterized by recurrent infections, autoimmunity, and/or malignancy. Identifying the genetic etiology of PIDs is challenging due to genetic diversity and phenotypic heterogeneity. Targeted next-generation sequencing (NGS) panels and whole exome sequencing (WES) have been used to identify genetic causes of PIDs, but there are no published studies comparing these two approaches. A total of 148 individuals with clinical and/or laboratory data indicative of a PID were sequenced. WES was performed on the first 101 study subjects using the Illumina HiSeq 2000 system with an average coverage of 150x. Downstream processing and variant calling were performed using SAMtools, Picard Tools, and the Genome Analysis Toolkit. The average analysis time for each exome was two hours. Targeted NGS was performed on the next 47 study subjects enrolled, using the Ion S5™ to sequence 264 genes associated with immune function. Average coverage was 406x. Variant calling and annotation were performed with IonReporter™. The average analysis time for each subject's targeted NGS panel was 25 minutes. WES identified causative variants in 56 of 101 individuals (55%), of which 43 had a pathogenic variant in a gene known to cause PID. Nine of the 56 individuals had a deleterious variant in a gene not previously associated with human disease, resulting in a disease-causing effect confirmed by functional studies. Four individuals had causative mutations in genes unrelated to immune function, resulting in a clinical phenotype resembling a PID. Nineteen (19%) of the 101 individuals had candidate variants that remain under investigation, and 26 (26%) had no identified genetic etiology. Targeted NGS sequencing identified causative genetic variants in 38 of 47 individuals (81%). Three of the 47 individuals (6%) had candidate variants that require additional investigation; no causative variant was found in the remaining 6 individuals (13%). Targeted NGS had a shorter analysis time than WES and identified a causative variant in a higher percentage of individuals. This difference may be due to the higher depth of coverage and greater ease of identifying large exonic deletions. These findings support the use of targeted NGS for initial genetic screening of patients with PIDs, with WES reserved as a second-tier approach for identifying novel causes of human disease.

812T

TACI, *ICOS* **and** *BAFFR* **mutation analysis in 449 Common Variable Immunodeficiency (CVID) patients.** *E. Pariltay[1], A. Aykut[1], A. Durmaz[1], F. Hazan[2], N. Gulez[3], N. Karaca[4], H. Onay[1], O. Ardeniz[5], G. Aksu[4], F. Genel[3], N. Kutukculer[4], F. Ozkinay[1].* 1) Ege University, Faculty of Medicine, Department of Medical Genetics Izmir, Turkey; 2) Dr. Behcet Uz Children's Hospital Department of Medical Genetics Izmir, Turkey; 3) Dr. Behcet Uz Children's Hospital Department of Pediatric Immunology Izmir, Turkey; 4) Ege University, Faculty of Medicine, Department of Pediatric Immunology Izmir, Turkey; 5) Ege University, Faculty of Medicine, Department of Immunology Izmir, Turkey.

Common Variable Immunodeficiency (CVID) is an immune system disorder resulting recurrent infections of respiratory and gastrointestinal tract. CVID is the most common clinically manifested primary immunodeficiency. Bacterial infections are significand and also CVID patients may develop autoimmune and lymphoproliferative complications. Human immune system is very complicated and mandatory for defensing against viral and bacterial infestations. Molecular mechanism is not well understood yet. In CVID patients at least two isotypes of immunoglobulin defect lead hypogammaglobulinemia. Primary defect is not clear but CVID is related with some gene defects such as "Transmembrane activator and CALM interactor (TACI or TNFRSF13B)", "Inducible co-stimulator (ICOS)" and "B-cell-activating factor receptor (BAFFR or TNFRSF13C)". Tumor necrosis factor receptor superfamily (TNFRSF) member TACI is most frequent gene defect that almost %10 of the CVID patients have at least one mutation, but unaffected heterozygous mutation carriers also reported that suggests unknown regulatory elements are needed for clinical manifestation. Here we present mutation analysis of 449 individuals who are clinically diagnosed as CVID. TACI gene is sequenced in all of the cases and in 36 of the patients we found at least one mutation. p.C104R (n=8), p.C172Y (n=5) and R202H (n=4) were the most common mutations. We found two novel mutations with unknown clinical significance. At 7 of the cases ICOS gene is sequenced and at the 64 of the cases both ICOS and BAFFR genes are sequenced. All sequenced ICOS genes (73) were normal. We found c.475 C>T (p. H159Y) / c.62 C>G (p.P21R) mutation at BAFFR gene in two unrelated cases. Parental controls suggested these mutations to be cis position. These changes are known as polymorphism but also reported to be disease causing at cis position. Beyond these tree genes CVID molecular mechanism is still need to be investigated. Wide definition of clinical diagnosis and un-clarified molecular regulatory mechanisms complicate genetic diagnosis. We found mutation in almost 9% of the patients which is consistent with literature.

813F

Complete androgen insensitivity syndrome due to the silent p.S510S mutation causing a premature stop codon in androgen receptor gene. *A.D.S. Rodrigues, R.L. Batista, M.Y. Nishi, E.M.F. Costa, S. Domenice, B.B. Mendonca.* Unidade do Desenvolvimento, Laboratorio de Hormonios e Genetica Molecular, Hospital da Clinicas-Faculdade de Medicina da Universidade de Sao Paulo, Sao Paulo, Brazil.

Background: Androgen insensitivity syndrome (AIS) is the most common cause of 46,XY disorder of sex development (DSD). The clinical spectrum of this disorder ranges from partial to complete form (CAIS). Most CAIS patients have defects in androgen receptor (*AR*) gene. The existence of a shortened *AR*-transcript variant in addition to the full-length *AR*- messenger RNA (mRNA) has been reported in and this seems to be the result of a variable splicing event. The association between this type of mutation with complete form of AIS has not been reported. **Objective**: To describe a silent mutation altering the splicing site in *AR* in two families with CAIS. **Patients:** three 46,XY affected members from one family and a single 46,XY patient from another family, all of them with normal female external genitalia, with a history of primary amenorrhea, inguinal hernia and spontaneous breast development. **Method**: The whole coding region of the *AR* gene, including exon/intron boundaries, were PCR-amplified and submitted to direct automated sequencing in ABI PRISM 3130XL. *AR* cDNA was obtained from reverse transcription of mRNA extracted from testicular tissue of one affected patient (family 1) and amplified by PCR. The size of the fragment amplified was compared with a commercial pool of testes mRNA. **Results:** Sanger sequencing identified the silent mutation c.1530C>T (p.S510S) in exon 1. Mutation taster and Human Splicing Finder sites predicted the variant as deleterious due to splicing site changing. Sequencing of partial cDNA, flanking the mutation region, showed that the patient's *AR* mRNA lost around 90 bp at the end of exon 1 leading to a premature stop codon. **Conclusion**: We identified a novel mutation in the *AR* gene associated an abnormal splicing resulting in a truncate protein. This is the first description of a silent mutation associated to CAIS. Our results further expand the spectrum of mutations associated with the AIS and may contribute to the understanding of the molecular mechanisms involved in splicing defects.

814W

A novel mutation of *NR5A1* gene in 46,XYDSD with gender dysphoria. *H. Yagi[1], M. Takagi[1], A. Ohtake[2], Y. Hasegawa[1].* 1) Tokyo Metrpolitan Children's Medical Center, Tokyo, Japan; 2) Saitama Medical University, Saitama, Japan.

   Androgen exposure to the fetal brain is well known to be associated with male-typical behavior. Genetic cause, hormonal effects and psychosocial factors also influence pshycosexual development. Pshychosexual development of 46,XY disorder of sex development (DSD) is not well known, and the actual prevalence of the gender identity in DSD patients is reported variously. Here we report on a 31-year-old social female with 46,XY DSD. She was clinically diagnosed as 46,XY DSD, through the examination of inguinal hernia. When she became teenager, she felt herself as a male without knowing her karyotpye. At 31 years old, she referred to our hospital for further infromation about her disorder. Through counseling, she selected neither of the sex orientation for herself. We checked all the coding exons and flanking introns of *NR5A1* by PCR and direct sequencing, and found a novel heterozygous mutation of c.227-229delTGG (p.Val76Glyfs*15). Functional analyses revealed that this novel mutation lost transcriptional activity as a result of loosing DNA binding affinity. This is the first report to describe gender dysphoria in individuals with *NR5A1* gene mutation. Early accurate diagnosis and reccurent explanation depending on their age and long-term psychosocial suppots are necessry for DSD patients.

815T

47,XXY Klinefelter syndrome associated with partial androgen insensitivity phenotype conferred by a complete inactivating mutation in the androgen receptor gene. *R.L. Batista, A. Feitosa, A.D.S. Rodrigues, E.M.F. Costa, S. Domenice, B.B. Mendonca, M.Y. Nishi.* Laboratorio de Hormonios e Genetica Molecular LIM42, Hospital das Clinicas da FMUSP, Sao Paulo, Brazil.

   Background: Klinefelter syndrome (KS) and androgen insensitivity syndrome (AIS) are among the most common disorders of sex development and rarely, both syndromes affect the same individual. **Clinical case**: A 19 years old healthy woman sought medical attention due to primary amenorrhea and severe pain in both inguinal regions. At physical examination she was a proportional tall overweighed young female (height=173.3 cm (SD +1.85); weight: 89.4 Kg (SD +4.2), BMI: 30; Breast development was Tanner V and pubic hair was normal at Tanner IV stage. External genitalia examination disclosed an enlarged clitoris (3.5x1.5 cm), two perineal opening and bilateral inguinal gonads. Her karyotype was 47,XXY. Ultrasonography of the inguinal region disclosed a 3.6 -4.9 mL male gonads. Hormonal investigation revealed elevated basal LH (20 U/L - nv: 0.4 to 5.7) and FSH (35 U/L -nv: 1.1 to13.5) levels and testosterone levels at normal male levels (325 ng/dL- nv: 260 to 990). She has undergone bilateral orchiectomy at 20 years old and anatomopathological result was consistent with seminiferous tubules atrophy. The analysis of the androgen receptor (*AR*) gene using genomic DNA revealed a heterozygous mutation c.3070_3071insA at exon 7, which results in a frameshift, leading to a premature stop codon (p.Asn849Lysfs*32). This mutation has been described in several patients with CAIS. Microsatellite analysis using 14 X-STS markers identified the same haplotype in Xp (8 markers) and different haplotype in Xq (6 markers), indicating a uniparental dissomy of X-chromosome. KS is rarely associated with ambiguous genitalia, mainly with almost female external genitalia. This fact associated with high LH levels, normal male testosterone levels and normal breast development suggested complete androgen insensitivity syndrome. The heterozygous state of *AR* mutation and microsatellite analysis point to a maternal (Xm1Xm2Y) nondisjunction event in meiosis I, plus a recombination between maternal short arms of X chromosome. The PAIS phenotype of our patient suggests that normal *AR* is partially expressed. Probably, because of random X-inactivation in tissues our patient had a complete breast and pubic hair development. **Conclusion**: We report a female patient with KS and PAIS phenotype due to a nonsense *AR* mutation that should generate a CAIS phenotype. We emphasize the importance of considering this association in KS patients with ambiguous genitalia.

816F

Cytogenetic findings in children with ambiguous genitalia. *I.I. Qazi.* microbiology and molecular genetics, University of the Punjab, lahore, punjab, Pakistan.

Qazi I.I. Department of Microbiology and Molecular Genetics, University of the Punjab Lahore, Pakistan. In affiliation with Department of Cytogenetics, Children's Hospital and Institute of Child health, Lahore, Pakistan. **Abstract:** Sexual ambiguity is a complex and often confusing medical problem in new born. Determination of the under lying cause of ambiguity is an urgent matter especially in congenital adrenal hyperplasia (CAH). This study was aimed to identify the chromosome compliment of children presenting with ambiguous genitalia in order to describe the underlying cause of their condition and consequently to reassign gender to these patients. A total of 25 patients with ambiguous genitalia, aged between 0-18years were studied over the period of one year. Peripheral blood samples were cultured in RPMI-1640 media and harvested through a routine as well as synchronized procedure. Chromosomes at metaphase were karyotyped for chromosome compliment in addition to the identification of any gross abnormality. Hormonal profile and abdominal ultrasound were also conducted to supplement the diagnosis. In this study, before cytogenetic analysis, 60% (15/25) of the patients were assigned a male status, while female sex was assigned to 40% (10/25) due to the appearance of their external genetalia at the time of birth. After karyotyping 44% (11/25) turned out to be with 46, XY complement and 52% (13/25) had 46, XX compliment. Klinefelter's syndrome accounted for 4% (1/25). Furthermore, pseudohermaphroditism and more specifically congenital adrenal hyperplasia in majority of these patients was found to be due to 21- hydroxylase deficiency. Additionally, Male pseudohermaphrodites accounted for 40% (10/25) of the cases. True hermaphrodites, Klinefelter's syndrome accounted for 4% (1/25) cases. The current study has helped in reassigning the sex in patients with misassigned or unidentified sex at an early stage so that the social trauma be reduced. It aims further to help in diagnosis of salt losing state of 21-hydroxylase deficiency which is a life threatening condition. Hormonal profile of these patients has also helped in planning the required hormone therapy for these patients. **Key words:** Ambiguous genitalia; Congenital adrenal hyperplasia (CAH); Chromosome compliment; External genitalia; Karyotype; Klinefelter's syndrome; Pseudohermaphrodite; Peripheral blood; True hermaphrodite.

817W

Comprehensive genetic testing for alpha-1 antitrypsin deficiency in COPD patients. *M. Lamontagne[1], N. Gaudreault[1], F. Maltais[1], W. Tan[2], J. Bourbeau[3], Y. Bossé[1,4] for the Canadian Respiratory Research Network, for the CanCOLD study group.* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Québec, Québec, Canada; 2) University of British-Columbia, Vancouver, British-Columbia, Canada; 3) McGill University, Montréal, Québec, Canada; 4) Department of Molecular Medicine, Laval University, Québec, Canada.

Background: Alpha-1 antitrypsin deficiency (AATD) is one of the most common hereditary disorders. AATD is caused by genetic mutations in the *SERPINA1* gene and is associated with increased risk of lung and liver diseases. Only a minority of AATD patients is identified and the current multi-step diagnosis algorithms are not helping to enhance recognition of this condition. **Methods**: DNA sequencing of the coding regions of *SERPINA1* was performed as a single diagnostic test to detect AATD. The frequencies of deficient alleles were evaluated in 400 Canadian patients with chronic obstructive respiratory disease (COPD). **Results**: Nineteen genetic variants were identified including 15 missense mutations. These includes three mutations known to generate normal protease inhibitor (Pi) M1 to M4 alleles; five causing deficient Pi alleles Z, S, P$_{Lowell}$, F, and I; and seven with unknown significance. Overall, at least 9.4% of alleles in this Canadian COPD cohort were deficient. Three patients were identified as AATD including two homozygotes ZZ and one compound heterozygote SZ. Seventy-one out of 400 patients (18%) were carriers of at least one deficient allele. DNA sequencing can be easily implemented, with a turnaround of less than 48 hours, and a price that is lower than the multi-step algorithms currently used to diagnose AATD. **Conclusions**: DNA sequencing of *SERPINA1* is effective as a single test strategy to detect AATD. Simplifying and improving diagnostic strategy will ultimately expedite the clinical decision-making process recommended by many national and international lung societies about targeted testing and augmentation therapy.

818T

Mutational hotspot in the *ACTG2* gene and mutation frequency in Chronic Intestinal Pseudo-Obstruction. *A. Milunsky[1,2], C. Baldwin[1], X. Zhang[1], D. Primack[1], A. Curnow[3,4], J. Milunsky[1,2].* 1) Center for Human Genetics, 840 Memorial Drive Suite 101, Cambridge, MA; 2) Department of Obstetrics and Gynecology, Tufts University School of Medicine, 860 Washington Street, Boston, MA; 3) St. Luke's Regional Medical Center, 190E Bannock Street, Boise, ID; 4) University of Washington Center for Mendelian Genomics, Seattle, WA.

Chronic Intestinal Pseudo-Obstruction [CIPO] or hollow visceral myopathy, mostly with megacystis, is a progressive mostly autosomal dominant disease due to a failure of enteric smooth muscle. This study aimed to determine the mutational spectrum in the ACTG2 gene in CIPO and the frequency of a mutation in this monogenic disorder. Sequelae include a high mortality rate, vomiting, abdominal pain and distension, and a massive non-functional bladder, frequently evident at birth, and prenatally by ultrasound. Life-long total parenteral nutrition and bladder catherization is the rule, compounded by catheter sepsis, urinary tract infection, and liver compromise. Diagnosis has depended on clinical features, manometry and imaging, and often unnecessary intestinal biopsy. Initial Whole Exome Sequencing of 4 families revealed only one with an ACTG2 mutation. Subsequent Sanger sequencing of 24 additional probands detected another 3 with mutations. Detailed clinical data of the 4 affected probands and their siblings or parents (7 in all) include the following: all 7 had CIPO and megacystis, 3 died in childhood, and 3 had a late-term prenatal diagnosis. Other features of the 7 were colectomy (3), ileostomy (3), G-tube (3), GERD (4), and lifetime TPN (4). At 38 years, after 29 years of TPN, one had total visceral transplantation with removal of intestine, stomach, liver, pancreas and spleen. We combined our 28 probands with published probands who had ACTG2 sequencing and found that 45/106 (42.5%) harbored a pathogenic variant. Moreover, a mutational hotspot in the ACTG2 gene was recognized. Genetic heterogeneity was also evident. New pathogenic variants in the ACTG2 gene are common, the rate being unknown at present. Early precise diagnosis by ACTG2 sequencing is important, helps avoid unnecessary invasive and other tests, and enables future avoidance/prevention by prenatal or pre-implantation genetic diagnosis. Clinical and genetic heterogeneity is recognized while another gene or genes are still to be determined.

819F

Molecular characteristics of 100 Vietnamese patients with congenital hyperinsulinism. *D.C. Vu[1], D.A. Dang[1], N.B.T. Can[1], K.N. Nguyen[1], T.P. Bui[1], H.T. Le[1], D.P. Nguyen[1], D.M. Tran[1], S. Flanagan[2], S. Ellard[2].* 1) Medical Genetics and Metabolism, Vietnam Children's Hospital, Hanoi, Viet Nam; 2) University of Exeter Medical School. Royal Devon & Exeter Hospital. South West NHS Genomic Medicine Centre. UK.

Background: Hyperinsulinemic hypoglycemia (HH) is a consequence of unregulated insulin secretion by pancreatic β-cells. Congenital HH is caused by mutations in genes involved in regulation of insulin secretion (*ABCC8, KCNJ11, GLUD1, CGK, HADH, SLC16A1, HNF4A* and *UCP2*). Severe forms of congenital HH are caused by inactivating mutations in *ABCC8* and *KCNJ11,* which encode the two components of the pancreatic β-cell ATP-sensitive potassium channel. **Objective and hypotheses:** Our aim is to identify mutations in the *ABCC8* and *KCNJ11, HNF4A* and *GLUD* genes, and to describe genotype and phenotype correlations of Vietnamese children with congenital hyperinsulinism. **Method:** A prospective study was conducted on 100 cases with congenital hyperinsulinism diagnosed and treated at Vietnam Children's Hospital from January 2007 to March 2016. Patients were selected by using inclusion criteria of Hussain K (2008). All exons of *ABCC8; KCNJ11, HNF4A* and *GLUD1* were amplified from genomic DNA and directly sequenced. **Results:** Mutations were identified in 51 cases (51.0%) including mutations of *ABCC8* gene (45 cases; 45.0%), Among these cases 26 with homozygous/compound heterozygous of *ABCC8* and 19 cases with one paternal/maternal mutation of *ABCC8* gene); *KCNJ11* (5 cases; 5.0%), *HNF4A* (1 case; 1.0%). 100% of cases with homozygous/compound heterozygous recessive mutations or one paternal dominant mutation of *ABCC8* gene did not respond to diazoxide treatment and required 95% pancreatectomy or octreotide injection. Other cases without identified mutations responded to diazoxide and/or glucose infusion. **Conclusion:** children with congenital hyperinsulinism should be performed mutation analysis which helps in making diagnosis and treatment decision. Families of children with congenital hyperinsulinism should be given genetic counseling. Prenatal diagnosis should be performed as well as follow - up and treatment should be given to children with congenital hyperinsulinism immediately after birth.

820W

Update of *CFTR* **recurrent mutation spectrum in Russia.** *T. Adyan, A. Stepanova, S. Krasovsky, A. Polyakov.* Research Centre for Medical Genetics, Moscow, Russian Federation.

   Cystic fibrosis (CF) is a common and generally severe autosomal recessive disorder caused by mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR). Over 1500 putative mutations have been described in *CFTR*, which can be divided into classes according to the molecular mechanism of the genetic defect. The CFTR mutation detection rate varies by test method and ethnic background. A total of 386 CF patients from different regions of the Russian Federation were investigated. DNA of the probands was analyzed for the presence of 38 common mutations in CFTR gene by multiplex AFLP-analysis (CFTRdele2,3 (Del21kb), F508del, I507del, 1677del-TA, 2143delT, 2184insA, 394delTT, 3821delT, L138ins, 3944delGT, 604insA, 4015delA, 4022insT) and by MLPA-method (E92K, G542X, R334W, S1196X, 621+1g>t, W1282X, N1303K, 3849+10kbC>T, 3272-26A>G, W1282R, 2789+5G>A, 3272-16T>A, S466X, 1898+1G>A, 3120+1G>A, R347P, S945L, G85E, S1159P, W1310X, R553X, 3849G>A, 712-1G>T, S1159P, G551D, dup7-11). As a result of the analysis in 309 probands CFTR mutations were identified on both chromosomes and in 77 probands on a single chromosome. The most frequent mutation was F508del with allelic frequency 53,6%; the following by frequency of occurrence were CFTRdele2,3 (Del21kb) (6,5%) and E92K (5,3%) mutations. Another 10 mutations met with frequencies ranging from 1% to 3%, 17 mutations met with a frequency of less than 1%, 8 mutations did not meet at all. Total allelic frequency of 38 studied mutations in the sample of patients accounted 90%, probability of finding two mutations in proband - 81% and probability of finding at least one mutation - 99%.

821T

Assessment of genetic pathogenicity for combined pituitary hormone deficiency. *Q. Fang, A.S. George, P. Gergics, M.L. Brinkmeier, A.H. Mortensen, L.Y.M. Cheung, M.I.P. Millan, A. Daly, A. Ajmal, S.A. Camper.* Department of Human Genetics, University of Michigan, Ann Arbor, MI.

   Combined Pituitary Hormone Deficiency (CPHD), or panhypopituitarism, is defined as the deficiency of growth hormone and at least one other pituitary hormone. CPHD affects 1 in 8,000 individuals. Both genetic and environmental factors contribute to the incidence of CPHD. Since *POU1F1* was reported as the first causative gene in 1992, more than 30 genes and about 2,500 genetic variants have been identified in CPHD patients. Additional CPHD genes will be discovered by increased clinical resequencing of patient genomes. There has not been a systematic analysis to review the pathogenicity of the reported genes and variants using the criteria set in 2015 by the American College of Medical Genetics and Genomics (ACMGG) and the Association for Molecular Pathology (AMP). We searched for genetic causes of CPHD by keywords in PubMed, OMIM and HGMD databases and evaluated them at the gene-level using 4 criteria: 1) Were mutations in the gene found in different affected families? 2) Is the gene expressed in the developing head, pituitary and/or hypothalamus? 3) Is the gene involved in known biological pathways for pituitary development and physiology? 4) Is there a convincing functional study to support the role of the gene in hypothalamus or pituitary gland? Only 22 genes passed the gene-level evaluation by meeting at least 2 out of 4 criteria. Using the 2015 guidelines, we classified the pathogenicity of each individual variant in those 22 genes by the inheritance and segregation pattern, the allele frequency in the population, the computational and predictive annotations, and *in vitro* and *in vivo* functional data. The recessive variants, such as those in *PROP1* and *POU1F1*, meet the criteria for authentic pathogenicity consistently. Dominant variants with incomplete penetrance, such as those in *GLI2* and *OTX2*, are difficult to classify without strong evidences from functional studies, and some of these cases may involve digenic or oligogenic diseases. In an international collaboration, we sequenced the exomes of 64 CPHD patients and unaffected relatives from 26 different families. We found mutations in several known genes and identified several candidate genes for functional studies. The high degree of genetic heterogeneity for CPHD makes it difficult to achieve all four criteria for causality amongst novel candidate genes. Our systematic analysis of CPHD genetics provides a framework for clinical geneticists and endocrinologists to evaluate future cases. .

822F

A case of hypopituitarism with 9q34.3 subtelomeric deletion syndrome. *S. Higuchi, M. Takagi, Y. Hasegawa.* Endocrinology and metabolism, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

   Introduction; While reports of short stature, micropenis or cryptorchidism with 9q34.3 subtelomeric deletion syndrome have been reported, hypopituitarism with the syndrome has not been reported. We here present a 6-year-old Japanese male with hypopituitarism developed in 9q34.3 deletion. **Case report;** He was born uneventfully by spontaneous cephalic delivery. At the age of 1 year, he was referred to our department for genital anomalies. He had developmental delay, hypotonia, atrial septal defect, micropenis and cryptorchidism without hypoglycemia and polyuria. Microarray was performed in the inspection of the multiple malformations. 9q34.3 deletion was detected. The parents did not have the deletion. Height velocity began to decrease around the age of 2 years. At the age of 3 years, we diagnosed him as having hypothyroidism by thyroid function test. We started l-thyroxine. At the age of 4 years, height was 88.0 cm (-3.3 SD). Endocrinological tests at this time showed GH deficiency. The pituitary was hypoplasia on MRI and posterior pituitary bright spot was orthotopically noted. Cortisol peak to CRH showed adrenocortical insufficiency at the age of 5 years, when hydrocortisone therapy was started. 9q34.3 deletion does not include the genes, which reportedly cause congenital hypopituitarism. We will analyze the mutations for congenital hypopituitarism. **Conclusion;** ;This is the first report of hypopituitarism with 9q34.3 subtelomeric deletion syndrome. We should check endocrinological tests when following up patients with 9q34.3 deletion who have retarded growth, genital abnormalities or hypothyroidism.

823W

Prevalence of an *Alu* insertion mutation in the *CASR* gene. *B.Y.L. Wong[1], G.N. Hendy[2], D.E.C. Cole[3].* 1) Molec Gen Lab, Sunnybrook Hlth Sci Ctr, Toronto, ON, Canada; 2) Experimental Therapeutics and Metabolism, McGill University Health Centre-Research Institute, and Departments of Medicine, Physiology and Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Dept of Clinical Pathology, Sunnybrook Health Sciences Centre; Depts of Lab Medicine & Pathobiology, Pediatrics, and Medicine, University of Toronto, Toronto, Ontario, Canada.

   Inactivating mutations in the *CASR* gene cause Type 1 familial hypocalciuric hypercalcemia (FHH) if heterozygous, and neonatal severe hyperparathyroidism if homozygous. Most *CASR* mutations involve a single nucleotide mutation or small insertion/deletion (indel). Copy number variations due to large rearrangements are reportedly quite rare. The only large insertion reported within the *CASR* gene is a founder *Alu*-insertion (~300bp) mutation described in 3 large inter-related kindreds from south west Nova Scotia in 1995. It has not been seen since. Recently, however, we identified the very same *Alu*-insertion mutation c.[2631_2643dup{ins{T(88);oS77605.1}}] in 4 geographically distant and apparently unrelated FHH individuals. Two of the cases were identified when the genomic samples were screened for *CASR* mutations by Sanger sequencing. Normally, the *Alu* insertion would not be detected by routine PCR based methods because of failure to amplify due to the long polyT tail in the *Alu* element. However, the possibility that an insertion might be present arose when allelic dropout of the nearby p.A986S SNP signal was noted in one of two overlapping primer sets. Using an *Alu* specific primer set, the two individuals were confirmed by sequencing to carry the *Alu*-insertion identical to that reported for the Nova Scotian deme. The other 2 cases were found when 49 putative FHH samples, previously screened negative for *CASR* mutation by denaturing HPLC and either heterozygous or homozygous for the p.986S minor allele, were analyzed with the *Alu* specific primer set. Among the 4 new cases we found, one came from the west coast of Canada (Greater Vancouver Area), two from central Canada (Toronto) and one from western Canada (Calgary). Given the prevalence in our case series, we have elected to add a screening step for all of our p.986S positive subjects putatively identified as FHH but with an otherwise negative *CASR* mutation screening result. The origin and full geographic dispersal of this mutation is not known. Surveys at other test centres would be of interest and of practical importance in the molecular diagnostic workup of FHH and related conditions.

824T

Identification of pathogenic variants in Osteogenesis Imperfecta by massively parallel sequencing. *T. Felix[1,2], L. Todeschini de Souza[1,2], E. Brizola[2], B. Pinheiro[2], M. Zambrano[2], A.P. Vanz[2].* 1) Servico Genetica Medica, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Reference Center for Osteogenesis Imperfecta, Porto Alegre, RS, Brazil.

Osteogenesis imperfecta (OI) is a heritable bone fragility disorder associated with dominant inheritance in 85-95% of cases due to mutations in type I collagen genes.. Genes associated with recessive forms (10-15% of cases) are involved in type I collagen post-synthetic modifications or trafficking. **Objective:** The aim of this study was to identify pathogenic variants in 18 genes associated with type I collagen pathway in patients with clinical diagnosis of OI by Massively Parallel Sequencing. **Methods:** The study comprised 28 individuals with a clinical diagnosis of OI type III and IV without previous molecular analysis and a case with type V OI with known *IFTIM5* c.-14C>T mutation as a control. The panel was costumized by Ion AmpliSeq Designer (www.ampliseq.com/ Life Technologies) and cover 99.6% of the coding region of *COL1A1, COL1A2, CRTAP, LEPRE1, PPIB, WNT1, TMEM38B, SERPINH1, BMP1, SP7, SERPINF1, FKBP10, SMPD3, CREB3L1, PLOD2, P4HB, PLS3, IFITM5* and 5`UTR region of *IFITM5.*The sequencing was performed by the Ion Torrent Personal Genome Machine (Ion-PGM) platform. Data from the sequencing run were processed using Torrent Suite software (version 5.0; Life Technologies) for base calls, read alignments, and variant calling using the reference genomic sequence (hg19) of target genes. Called variants were annotated using Ion Reporter (version 5.0; Life Technologies). The variants were classified according to ClinVar-NCBI and LOVD 2.0 databases. In silico prediction tools were used for analysis of variants of uncertain significance and included SIFT , Polyphen-2, PredictSNP and Mutation taster **Results:** Of the 28 cases, 404 variants were identified. Of these, 266 missense and small indel mutations were located in intronic regions, 101 in exonic regions and 37 in splice sites, 3' or 5' UTR regions. Several mutations were previously reported as pathogenic variants according to the databases. Mutations in 4 genes were identified: *COL1A1*(10 mutations), *COL1A2* (6 mutations), *LEPRE1*(1 mutation) and *SERPINF1*(1 mutation). Ten variants predicted to be pathogenic were identified in *COL1A1*, *COL1A2* , *LEPRE1* , *SERPINF1, PLOD2*, *BMP1,, CREB3L1and P4HB*. **Conclusion:** At least, one pathogenic mutation (reported or predicted) was found in each individual. This study confirms that this panel with 18 genes using based semiconductor sequencing may identify missense and small indel mutations in disorders with genetic heterogeneity as OI. .

From phenotype to genotype and back again: Whole exome sequencing in the diagnosis of patients with skeletal dysplasia. *A. Beleza-Meireles[1], M. Jansson[2], P. Louro[1,3], S. Lillis[2], J. Hoyle[2], J.W. Ahn[2], K.J.P. Ryan[2], A. Calder[4], C. Hall[4], A. Offiah[5], M. Simpson[6], S. Yau[2], S. Mohammed[1], M. Melita[1].* 1) Clinical Genetics Department, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; 2) Viapath Analytics LLP, London, United Kingdom; 3) Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; 4) Radiology Department, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; 5) Academic Unit of Child Health, Sheffield Children's NHS Foundation Trust, Sheffield, United Kingdom; 6) Division of Genetics and Molecular Medicine, King's College London School of Medicine, London, United Kingdom.

Background: Skeletal dysplasia (SD) is a genetically heterogeneous group of over 350 distinct disorders. An experienced clinician may be able to identify the clinical diagnosis of a specific SD condition with the aid of a skeletal survey. Multidisciplinary work, involving geneticists, radiologists, orthopaedic surgeons and growth specialists is often necessary in the diagnostic work-up of these patients. Nonetheless, it is frequently challenging to reach a clinical diagnosis, and genetic analysis using a single gene testing strategy is often unhelpful owing to difficult as a result of significant genetic heterogeneity. Increasingly, however, the use of whole exome sequencing (WES) is overcoming diagnostic uncertainty and providing new opportunities for accurate, rapid characterisation of skeletal dysplasia conditions. Our purpose is to highlight the clinical utility of WES analysis as a diagnostic tool for SD, discuss new challenges it can present, and emphasise the continued importance of clinical phenotyping in the interpretation of WES data.   Methods: Twenty-three patients with presumed SD were selected from the specialist multidisciplinary clinic. WES was performed using Agilent SureSelectXT Human All Exon V5 followed by sequencing on an Illumina HiSeq 2500. Raw sequence data was aligned using Novoalign, and variants called with Samtools. Qiagen Ingenuity Variant Analysis was used to aid assessment of variant pathogenicity after applying a virtual panel of 220 SD genes in combination with multidisciplinary clinical interpretation.   Results: Pathogenic variants were detected in ten patients; while in five other patients we found variants of uncertain pathogenicity, which require additional work such as inheritance studies. Of the remaining eight cases, no pathogenic variants were detected in the SD gene panel. Post-WES clinical reassessment suggested that three of these eight cases are unlikely to have a SD.   Conclusions: WES has confirmed, or provided a diagnosis, in 43% (10/23) of our patients, and identified possible candidates in another 22% (5/23). These results demonstrate that WES analysis using targeted bioinformatic analysis is a cost-effective diagnostic tool for SD. The importance of thorough clinical evaluation and the close liaison with clinical scientists has proven essential in providing an optimal and efficient service. Detailed phenotyping of patients with presumed SD remains of paramount importance in the diagnostic pathway.

826W

RIPPLY2: **Believe it or not.** *N. Vena[1], L. Rochford[2], R.J. Hopkin[2], C. Rajakuruna[2], T.A. Burrow[2], S.A. Hosseini[1].* 1) Claritas Genomics, Cambridge, MA; 2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

We present on a 9 mo. old male with multiple vertebral anomalies associated with compound heterozygous *RIPPLY2* variants. The proband was born to non-consanguineous parents via vaginal delivery. Cervical spine instability due to complete absence of the C2 vertebra, hypoplasia of the other cervical vertebrae, craniocervical junction stenosis and spinal cord compression lead to spinal cord injury during labor and delivery resulting in respiratory failure, hypotonia and decreased mobility. He subsequently became hypertonic with spasticity and muscle spasms and continues to be trach-dependent. Absence of cervical vertebrae is extremely rare and no genetic causes have been identified. Exome testing identified two variants in *RIPPLY2* in the compound heterozygous state. *RIPPLY2* encodes a nuclear protein belonging to a family of proteins required for vertebrate somitogenesis and functions in the *NOTCH* signaling pathway; several other genes involved in this pathway are associated with segmentation defects of the vertebrae (SVD). Null mutant mice show axial skeleton segmentation defects due to defective somitogenesis. In humans, limited case reports of individuals with SDV and Klippel-Feil syndrome associated with *RIPPLY2* variants have been reported. The c.240-4T>G variant in *RIPPLY2* was previously reported in two siblings with multiple regional segmentation defects of the vertebrae. Functional studies have not been performed, but this variant is predicted to affect the splice acceptor consensus sequence. The c.286G>A variant in *RIPPLY2* is unreported in the literature or control datasets. It occurs at a highly conserved nucleotide and amino acid, and is predicted to be deleterious by *in silico* prediction models. The two variants were observed on opposite strands in the NGS data, suggesting a *trans* configuration. Due the limited information available regarding these variants, they were classified as uncertain. However, due to the clinical diagnosis in the proband, the *trans* configuration, and the role of *RIPPLY2* in somitogenesis, they likely represent the molecular diagnosis for the proband's phenotype. This case highlights the role of *RIPPLY2* in vertebral development and provides further evidence that *RIPPLY2* is a gene responsible for autosomal recessive malformation of the cervical vertebrae. Functional studies are necessary to determine the pathogenicity of the identified variants and to fully evaluate the phenotypic spectrum of disease associated with this gene.

Next generation sequencing as a confirmatory diagnostic tool in a Brazilian Skeletal Dysplasia Tertiary Center. *W.A.R. Baratela[1], G.L. Yamamoto[1,2], L.C. Testai[2], R. Honjo[1], L.A.N. Oliveira[7], M.J.R. Doriqui[4], R. Rosa[8], J.G.C. Meira[3], J.M. Pina-Neto[6], D.P. Cavalcanti[5], C.A. Kim[1], M.R. Passos-Bueno[2], D.R. Bertola[1,2].* 1) Unidade de Genética, Instituto da Criança - Hospital das Clínicas - Universidade de Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Centro de Pesquisas sobre o Genoma Humano e Células-tronco, Instituto Biociências – Universidade de São Paulo, SP, Brazil; 3) Serviço de Genética - Hospital Universitário Professor Edgard Santos/ Universidade Federal da Bahia, Salvador, Bahia, Brazil; 4) Hospital Infantil Dr Juvêncio Mattos Rua Sao Pantaleao, s/n centro, Sao Luis, Maranhão, Brazil; 5) Department of Medical Genetic, University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; 6) Departamento de Genética - Faculdade de Medicina de Ribeirão Preto - Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil; 7) Departamento de Radiologia - Hospital das Clínicas - Universidade de São Paulo, São Paulo, Brazil; 8) Universidade Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil.

Skeletal dysplasias (SD), a heterogeneous group of genetic conditions impairing normal bone growth and development, currently encompass 436 disorders classified in 42 groups based on molecular, biochemical and/or radiographic criteria. Our group (Hospital das Clínicas/University of São Paulo) started a SD clinic in 2012, aiming not only to provide accurate diagnosis, but also to address clinical aspects of these conditions. Approximately 400 individuals have been included in the SD cohort after clinical and radiographic analysis. An algorithm was established to test patients by Sanger sequencing with the current available gene analysis (*FGFR3*, *TRPV4*, *LIFR*, *SOST*, *CHST3*, *CANT1*, or *WNT7A*) or the new implemented next generation sequencing (NGS): a targeted panel for 120 genes related to SD or exome sequencing. The latter for cases in which the disease associated gene was not included in the panel or the etiology unknown. Approximately 113 cases were tested by Sanger sequencing (84 for *FGFR3*), 94, by the NGS panel, and 9 families by exome sequencing. A molecular diagnosis was achieved in 83/113 (73%) by Sanger, in 60/94 patients (64%) by panel, and 3/9 by exome. Applying the current classification of SD to the cohort of NGS panel, the positivity in groups was: I (3/4), II (7/11), III (2/4), IV (8/10), VII (4/5), VIII (3/4), IX (2/5), X (3/3), XI (1/1), XIII (4/4), XV (1/2), XVI (1/2), XVIII(1/1), XVIII (1/1), XX (1/1), XXI(0/1), XXII (0/1), XXIV (1/2), XXV(10/13), XXVI (2/2), XXVII (1/1), XXXV (4/15), XLII (0/1), while in exome: II (0/1), V (*HSPG2* 1/1), IX (0/1), XII (*PCYT1A* 1/1), XVI (0/1), XXI (*PEX7* 1/2), XXXVI (0/1), XXXVIII (0/1). The two most prevalent groups in SD (I and XXV) were under-represented in NGS due to Sanger testing for *FGFR3* and selection of only the severe or consanguineous cases of OI for testing. The lowest sensitivity in XXXV probably occurred due to a less strict clinical criteria for the disorder. Of interest, a case presenting brachyolmia and mutations in both copies of *PAPSS2* showed skeletal abnormalities similar to *TRPV4* spectrum, influencing genetic counseling. Furthermore, through exome, we found mutations in *HSPG2* in a case of Rolland-Desbuquois. Although analysis of this sample of patients is ongoing, initial findings show that NGS sequencing has been concordant to the clinical/radiographic diagnosis in around 64% of patients. Due to heterogeneous nature of SD, 33% have their molecular basis yet to be discovered. FAPESP.

Mutation screening of the γ-secretase genes in sporadic and familial Hidradenitis Suppurativa (acne inversa) and acne conglobata. *D.D Jhala[1], U. Ratnamala[2,3], N.K. Jain[2], N.M. Saiyed[4], B.C. Gorijala[5], P.V.S. Prasad[6], U. Radhakrishna[7].* 1) Department of Zoology, School of Sciences, Gujarat University, Ahmedabad, Gujarat, India; 2) Department of Life Sciences, School of Sciences, Gujarat University, Gujarat University, Ahmedabad, India; 3) Department of Pharmacology, Creighton University, Omaha, NE, USA; 4) Biotechnology, Nirma Institute of Science, Nirma University, Ahmedabad, India; 5) Oncology Department, Krishna Institute of Medical Sciences, Secunderabad, India; 6) Department of Dermatology, Annamalai University, Chidambaram, India; 7) Department of Obstetrics and Gynecology, Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA.

   Hidradenitis Suppurativa (acne inversa) is a chronic, inflammatory and recurrent, debilitating skin disease that usually affect**s** people between puberty and middle age. It is a progressive disease where single boil-like, pus-filled abscesses become hard lumps, followed by painful, deep-seated, often inflamed clusters of lesions with chronic seepage. It most commonly affects areas bearing apocrine glands. The γ-secretase genes have been identified as the cause for a subset of familial HS. Twenty-five γ-secretase gene mutations have been published, including two from our research group, accounting for almost 88.5% of Asian and European familial HS. Remarkably, the genetic variants have been described mostly in families with a history of the disease, including acne conglobata; however, only a very small proportion of sporadic patients have reported mutations. Direct sequencing of DNA samples from 2 large families and 95 sporadic cases with HS and acne conglobata screened in the entire coding sequence and splice junctions of the γ-secretase complex genes *NCSTN*, *PSENEN,* and *PSEN1* showed only one pathogenic variant in a family with acne inversa and acne conglobata and excluded one family and 95 sporadic cases. A nonsense mutation, 1876C > T in exon 16, which would result in a substitution of Arg at codon 626 (p. Arg626X) and premature stop codon was observed in one family. The 95 sporadic cases and a large HS family with multiple affected members did not reveal pathogenic variants in either coding or noncoding regions including splice sites. This report will be valuable to delineate possible genotype-phenotype associations in HS. The present study provides evidence that HS is a heterogeneous disease as γ-secretase genes are involved only in the pathogenesis of some familial and/or sporadic HS cases. Epigenome-wide studies also should be considered in HS individuals excluded with γ-secretase complex gene mutations. .

Acrodermatitis enteropathica-like forms of atopic dermatitis revealed by whole-exome sequencing. *S. Küry[1], T. Besnard[1], X. Latypova[1], D. Quinquis[1], S. Schmitt[1], I. Ricordeau[1], M. Sedghi[2], J. Nasiri[2], M. Salehi[2], S.P. Paul[3], D. Candy[3], E. Blouin[4], S. Bezieau[1].* 1) CHU de Nantes, Nantes, France; 2) Isfahan University of Medical Sciences, Isfahan, Iran; 3) St Richard's Hospital, Chichester, UK; 4) Laboratoire LABCATAL, Montrouge, France.

   Background: Acrodermatitis enteropathica (AE; MIM #201100) is a rare and severe autosomal recessive zinc deficiency disorder molecularly diagnosed by the identification of a biallelic anomaly of zinc transporter gene *SLC39A4*. Its pathognomonic symptom is an acral and periorificial dermatitis occurring in early life that responds in a spectacular fashion to zinc therapy. Yet, our experience in the molecular diagnosis of AE showed that more than a half of the cases of suspected AE were not due to a primary zinc dyshomeostasis that would be associated by alterations of *SLC39A4*. **Purpose:** Our goal was to determine the genetic cause of genodermatoses very suggestive of an AE, albeit with no *SLC39A4* mutation. Method: We sequenced the whole-exome of a series of simplex and multiplex families with a AE-like dermatitis. **Results:** Beside the identification of a few exceedingly rare syndromes mimicking AE, the most striking result was the presence of dominant mutations in filaggrin and in laminins, some of them were already known to be associated with an increased susceptibility to atopic dermatitis (AD). **Conclusions:** Our work highlighted atopic dermatitis as the main clinical diagnosis of AE. This suggests that a sub-group of the common disease represented by AD could be diagnosed by genetic testing. Further studies are needed to determine whether these severe cases of AD are exceptional or if the efficiency of zinc therapy can be extended to the treatment of all AD patients with similar anomalies.

Delineation of genetic alterations in patients with pigmentary mosaicism.
C. Salas-Labadia[1], V. Ulloa-Aviles[1], M.P. Navarrete-Meneses[1], A. Reyes-Leon[1], D. Martinez-Anaya[1], R. Criz-Alcivar[1], O. Castro-Ayala[1], S. Gomez-Carmona[1], C. Duran-McKinster[1], E. Yokoyama-Rebollar[1], E. Lieberman-Hernandez[1], A. Gonzalez-Del Angel[1], V. Del Castillo-Ruiz[1], P. Perez-Vera[1], D. Cervantes-Barragan[2], A. Ruiz-Herrera[3]. 1) Instituto Nacional de Pediatria, Mexico City; 2) Hospital Central sur de Alta Especialidad, Pemex, Mexico City; 3) Hospital de Especialidades Pediatricode Leon, Leon, Guanajuato, Mexico.

Patients with pigmentary mosaicism (PM) are a heterogeneous phenotypic group, characterized by specific skin lesions (Blaschko lines pattern), but in association with a great variety of central nervous, musculoskeletal and ocular alterations. Miscellaneous chromosomal aberrations have been observed in 30-60% of PM cases, and also other types of genetic alterations have been reported like microdeletions and mutations. The aim of this study was: a) To establish a complete cytogenetic and molecular characterization of patients with PM and b) To determine whether our strategy analysis contributes to the establishment of a better characterization of this entity. We included 63 patients with PM and other systemic anomalies. The GTG-bands from lymphocytes, light and dark skin samples were analyzed, reviewing 50 metaphases per tissue. Molecular analysis with SNP array and/or FISH were performed to finely characterize chromosomal abnormalities (CA), and also in some patients with normal karyotype but strong clinical suspicion of chromosomal alterations below the detection level of cytogenetics. A total of 60 cases have been completely analyzed by cytogenetics and the results could be classified as follows: **1)** Normal karyotype n=39; **2)** Mosaics with 2 or more different cell lines with structural alterations n=12: **a)** mos del(18)(q21)/normal (nl) (2 patients); **b)** mos +i(12)(p10)/nl; **c)** mos r(22)(p11.2q13.3)/dup r(22)(p11.2q13.3)/nl (2 patients); **d)** *mos r(7)(p22q36.3)/dup r(7)(p22q36.3)/-7; **e)** t(1;8)(p?36;q?22)/nl; **f)***mos +mar/+14/nl; **g)** *mos +mar/45,X/nl; **h)** *mos +mar/nl (3 patients); **3)** Balanced translocations X;autosomes n=2: **a)** t(X;16)(p11.2;p13.3); **b)** t(X;22)(p11.2;q13.3); **4)** Polyploidy (mosaic) n=1; **5)** *Others n=6. In *6 patients with abnormal karyotype, the molecular analysis delineated the structural alteration, identified other structural alteration (<5Mb) and characterized the different cell lines proportions. In 1/5 patients with normal karyotype was identified a 603Kb deletion in 16p11.2. Our analysis strategy could contribute to a better characterization of patients with PM. It was possible to demonstrate that cytogenetics is a very important first filter for identification of CA. Molecular analysis allowed the delineation of the abnormalities and identified CA not detected previously by GTG-bands. The combination of both methodologies allowed us to perform better associations with the phenotype. CONACyT 1882277, Recursos Federales 2016, Genetadi.

831F

Linked-reads accurately map variants to *NEMO* and its pseudogene (*IKBKGP*). *F.A. Mafra, C. Kao, R. Pellegrino, J. Garifallou, C. Kaminski, A. Cederquist, E. Ryan, T. Wang, L. Tian, H. Hakonarson.* Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Anhidrotic Ectodermal Dysplasia with ImmunoDeficiency (EDA-ID) and Incontinentia Pigmenti (IP) are two rare diseases arising from mutations in *IKBKG/NEMO*. Located in Xq28, this gene encodes the regulatory subunit of the IKK complex that activates NF-kB, which is involved in a variety of physiological and cellular processes, such as immunity, inflammation, cell proliferation, and survival. *NEMO* hypomorphic mutations, have been identified in EDA-ID and IP patients, while null mutations seem to be exclusively associated with IP. The structural architecture around *NEMO* imparts genomic instability that can lead to pathogenic alterations. On the 5' side, *NEMO* partially overlaps with the *G6PD* gene, which is a recombination hotspot containing multiple *Alu* sequences; on the 3'-side *NEMO* is part of a low-copy-repeat (LCR1) with an inverted duplicated copy (LCR2) located ~75kb away that contains a highly conserved pseudogene (*IKBKGP*) with >99% sequence identity to *NEMO* between exons 3-10. The LCRs are prone to inversion/gene-conversion events causing the repositioning/copying of mutations from pseudogene to gene. Current whole exome and targeted NGS-based sequencing represents a challenge. Short reads arising from regions such as *NEMO* may not be mapped accurately since it would be difficult to know if they are coming from the gene or the pseudogene. Clinical testing for variants in *NEMO* traditionally requires customized methods such as long-range PCR, which can be laborious and slow. We illustrate an NGS-based method here to resolve reads and variants in *NEMO* and its pseudogene, using linked reads generated by 10x Genomics Chromium technology in combination with whole exome sequencing using Agilent SureSelect baits. We used linked read WES on a number of "truth" samples with established variants in *NEMO* and/or *IKBKGP*. One candidate immunodeficiency family in particular is highlighted, where a candidate variant was identified in the putative splice junction site of exon 9. The linked read WES results was in accordance with the long-range PCR and Sanger sequencing, demonstrating that this is a non-pathogenic SNP present in both *NEMO* and *IKBKG*. We also used linked read WES to accurately map and confirm variants in samples from known female carriers of *NEMO* mutations.

832W

Hereditary neuralgic amyotrophy and intellectual disability in a patient with 3.85 MB 17q25.1-q25.3 duplication involving *SEPT9.* C. Esmer[1], M. Villegas[2], C. Gómez-Elias[2], S. Avila[3], J.L. Castrillo[3], A. Bravo-Oro[2]. 1) Genetics, Hospital Central "Dr. Ignacio Morones Prieto", San Luis Potosi, Mexico; 2) Child neurology, Hospital Central "Dr. Ignacio Morones Prieto", San Luis Potosi, Mexico; 3) Genetadi, Biotech, Bilbao, España.

Several unbalanced rearrangements of terminal 17q have been described associated with monosomy or trisomy of other chromosomes; pure 17q25 duplications are infrequent and remain inadequately delineated. Partial duplications in septin 9 (*SEPT9*) was shown to be causal for hereditary neuralgic amyotrophy, an episodic peripheral neuropathy with autosomal dominant inheritance but duplication of the entire gene have been reported only once. We report an individual with pure non-recurrent 17q25.1-q25.3 duplication. The case was evaluated for the first time at 8 years of age referred to genetic consultation due to developmental delay, poor scholar performance, attention deficit disorder and craniofacial dysmorphism. At physical examination showed short forehead, hypotelorism, short palpebral fissures, high nasal bridge, small mouth with protruding lips, retromicrognatia. Physical examination at the age of 18 months showed relative macrocephaly, a large anterior fontanel, triangular facies, a prominent forehead, hypertelorism, down-slanting palpebral, low-set ears and abnormal posterior hairline. The mother reveals a history of episodic pain and impaired movement of the left shoulder and arm. The muscles in the affected area showed mild atrophy and weakness, mild scapular winging was also present. The array CGH revealed a gain in 17q25.1-q25.3 spanning approximately 3.85 Mb (72,695,356-76,548,866) and contains at least 86 genes. The 17q23-qter portion is the region most commonly duplicated in almost all the dup 17q cases reported in literature. Duplication 17q has been associated with a wide range of clinical findings, including psychomotor/mental retardation, growth retardation, and dysmorphic features that were also present in our case. This region includes genes involved in several diseases, such as retinitis pigmentosa, ciliary dyskenesia, microcephaly, bradyopsia, etc. This is the first time that a patient with a large chromosomal 17q duplication shows clinical evidence of hereditary neuralgic amyotrophy.

833T

A 30 gene clinical panel for dementia: The first 100 cases. S.A. Bucks[1], C.J. Hale[2,3], D.S. Hanna[2,3], M.B. Dauer[2,3], L. Mathew[2,3], D. Sarroza[2,3], S. LaDuke[2,3], M.A. Weaver[2,3], M. Rumbaugh[1], D. Tsuang[1,4], S. Jayadev[1], T.D. Bird[1,4,6], M.O. Dorschner[2,3,5]. 1) Department of Neurology, University of Washington, Seattle, WA; 2) Department of Pathology, University of Washington, Seattle, WA; 3) Center for Precision Diagnostics, University of Washington, Seattle, WA; 4) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 5) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 6) Geriatric Research, Education, and Clinical Center, VA Puget Sound Health Care System, Seattle, WA.

Dementia, or cognitive impairment, affected an estimated 35.6 million people worldwide in 2010. As the elderly population continues to grow, the number of dementia cases and the associated socio-economic burdens will swell in concert. Several neurological syndromes cause or associate with dementia, including Alzheimer disease (AD), Parkinson disease (PD), frontotemporal dementia (FTD), and vascular dementia. Identifying specific genetic changes associated with dementia in individual patients contributes to accurate diagnosis, inclusion into appropriate clinical trials, and potential discovery of novel gene targets that could be pursued for therapeutic development. Additionally, if a known genetic cause is discovered, unaffected family members may opt for genetic testing to help determine their risk status and assist with life planning. We have developed a clinical exome-based panel for over 30 genes known to have common causative, rare causative, and risk variants for dementia. The clinical panel was developed by a group of experts actively engaged in neurodegeneration research and clinical practice at the University of Washington, and it includes genes from a variety of diseases associated with a dementing phenotype, including AD, PD, FTD, and amyotrophic lateral sclerosis. We used an IDT Exome v1.0 capture system for library enrichment followed by Illumina sequencing. More than 100 individuals with early onset dementia have been subjected to testing with this panel to evaluate its performance. We have identified potential disease-associated variants in >16 genes known to cause familial AD or related disorders. Further analysis of these variants is ongoing and includes the use of disease-specific and exome-derived variant databases, literature searches, and *in silico* predictive algorithms for altered mRNA and/or protein structure and function. Results are returned to patients and their families using a multidisciplinary team including neurologists and genetic counselors to help convey the appropriate utility and caveats of test results. Overall, our clinical dementia panel is comprehensive and can identify disease-causing variants in patients.

834F

Evaluating the strength of evidence for gene/condition relationships: Impact on multi-gene panel testing design. *C. Tan, D. Riethmaier, M. Hogue, N. Patil, K. McDonald Gibson, T. Winder, J. Westbrook, S. Topper.* Invitae Corp., San Francisco, CA.

    Background: As multi-gene panels have become routine in evaluating patients for genetically heterogeneous conditions, growing inter-laboratory variability has occurred in the number of genes offered in a given panel for many disorders. Although some of this variability can be attributed to the relationship between the timing of assay design and the rapid discovery of new gene–condition relationships, it is becoming increasingly important to understand the clinical validity of the diverse offerings of multi-gene panels in today's molecular diagnostic setting. Establishing the clinical validity of a multi-gene panel depends on an accurate and detailed understanding of the validity of each included gene. We proposed a method for establishing the clinical validity of genes and evaluated that method with a set of pediatric and neuro-muscular gene–condition relationships. Method: A robust variant classification method based on ACMG guidelines was used to evaluate the pathogenicity of published, clinically observed variants. Gene–condition relationships were categorized as strong (convincing evidence that an observed variant meets criteria for pathogenicity) or suggested (preliminary evidence). A third category, emerging, was used to describe an additional condition purportedly caused by a gene already determined to have a strong relationship with a different condition. Our method was applied to 187 genes implicated in a range of pediatric-onset and neuromuscular conditions. Results: We categorized 175 genes as having a strong association with at least one condition, of which 18 also had an additional suggested or emerging association with another condition. Twelve genes were categorized as having only a suggested association with a condition. Conclusion: We created a framework for categorizing gene–condition relationships, thereby establishing a method to distinguish between genes proven to cause a condition and genes for which only preliminary evidence suggests an association. Although there can be legitimate benefits to testing a gene before its clinical validity is conclusively established, understanding the rationale for its inclusion on a panel is critical for clinicians. The clinical utility of the findings in any gene ultimately depends on the strength of the evidence linking that gene to disease.

835W

The many faces of *SCN1A***.** *E. Weltmer, A. Bergner, A. Yussuf, Z. Powis, N. Ghahramani, J. Wang.* Ambry Genetics, Aliso Viejo, CA.

    Clinical presentations of *SCN1A*-related disorders can be highly variable, which can prove challenging for diagnostic test selection. We describe several different testing pathways to an *SCN1A* diagnosis and highlight the benefit of having multiple phenotypic-based approaches available. A total of 105 cases from next generation (panel-based) sequencing and 180 cases from exome sequencing with a referral indication of epilepsy, intellectual disability, and/or autism spectrum disorder were reported by our laboratory from October 2015-May 2016. Five cases were positive for an *SCN1A* mutation. We reviewed the clinical phenotypes and testing strategies employed for these five cases. Among the five *SCN1A*-positive cases, four different testing pathways were represented. Case 1 is a toddler with febrile seizures and intractable epilepsy. A nonsense mutation was identified on a targeted 13-gene febrile seizures panel. Case 2 is a toddler with febrile seizures and suspected Dravet syndrome, and case 3 is an adult with intractable epilepsy and intellectual disability. A comprehensive 100-gene epilepsy panel was ordered for both, revealing a nonsense mutation and a missense mutation, respectively. Case 4 is an adult with unspecified seizures and an autism spectrum disorder. A missense mutation was revealed on a broad 196-gene neurodevelopment panel. Whole exome sequencing (~20,000 genes targeted) identified a *de novo* nonsense mutation in case 5, an adult with unspecified seizure disorder, intellectual disability, dysmorphic features, and positive family history. Four different testing pathways were employed, all resulting in a diagnosis of an *SCN1A*-related disorder. Cases 1 and 2 presented as toddlers with febrile seizures, but clinicians opted for different test strategies. Case 2 may have benefitted from a targeted fever panel, resulting in more timely and cost-effective diagnosis. Cases 3 and 4 both presented as adults with somewhat non-specific phenotypes; however, individual features (intractable epilepsy vs. unspecified seizures plus autism) warranted testing via different broad panels. Case 5 presented with the most complex phenotype involving multiple organ systems, and utilized the broadest testing option. Although variability in clinical presentation may be challenging for diagnosis, the availability of a variety of phenotypic-based testing options allows clinicians the opportunity to tailor testing to each patient while not missing an important diagnosis.

836T

A robust, PCR-based assay for detecting *SMN1* copy number variation and performance using three commercial instruments. *M. Cai, L. Jiang, Z. Kabir, S. Paquerault, H. Huuskonen, I. Knight.* Canon U.S. Life Sciences, Inc., Rockville, MD.

Introduction: Spinal muscular atrophy (SMA) is an autosomal recessive neurodegenerative disorder caused by a mutation in the *SMN1* gene on chromosome 5. About 95% of SMA is due to a *SMN1* deletion, resulting in *SMN1* copy number variations (CNV) of 2 copies, 1 copy, or no copies per genome. Rapid detection of *SMN1* CNV is critical for the diagnosis of SMA. We developed a fast and easy analysis approach for *SMN1* CNV detection using a duplex PCR assay with high-resolution melting (HRM) analysis. **Methods**: Three different duplex PCR assays were designed and then evaluated using genomic DNA samples with 2, 1, or no *SMN1* copies per genome. Each duplex assay contained a pair of primers for the *SMN1* sequence and another for the ultra-conserved element (UCE) sequence that contains 2 identical copies per genome. The UCE serves as an internal control to normalize the PCR reactions, which is essential for melting curve analysis. Using deoxynucleotides (dNTP) as the limiting reagent of the PCR reaction, the duplex PCR and HRM analysis were performed on three commercial HRM-enabled thermocyclers. Analysis was performed using each instrument's corresponding software package. During data analysis the melting temperature range was selected to include both the *SMN1* and UCE melting domains. The melt curves were normalized, and the software automatically clustered the results. A difference plot was used to determine the *SMN1* copy number for each sample, and the one copy *SMN1* curve was manually selected as the baseline for the difference curve. Accordingly, the two-copy *SMN1* curves were those above the baseline, and the zero-copy *SMN1* curves were those below the baseline. **Results**: The *SMN1* copy number was accurately determined, with respect to the documented copy number, for the genomic samples isolated from Coriell cell lines. The CNV results were replicated using all three instruments. Analysis of the melting curves using difference plots clustered the results in three distinct groups according to their 2, 1, or no *SMN1* copy number. **Conclusion**: We accurately detected *SMN1* CNV by developing a robust, single-tube, duplex PCR assay combined with HRM analysis. The assay performed consistently using three different commercial instruments. Our study demonstrates that using the difference plot available on each commercial software package is a simple solution to detect *SMN1* CNV.

Association of *ELAVL2* and *PTPRD* genes with epilepsy in purebred Chinese Crested dogs. *B.C. Ballif[1], A.L. Siniard[2], I.S. Piras[2], M. Krug[1], V. Zismann[3], J. Trent[3], M.J. Huentelman[2], L.G. Shaffer[1,4].* 1) Paw Print Genetics, Genetic Veterinary Sciences Inc, Spokane, WA; 2) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 3) Integrated Cancer Genomics Division, Translational Genomics Research Institute, Phoenix, AZ; 4) School of Molecular Biosciences, College of Veterinary Medicine, Washington State University, Pullman, WA.

We performed a genome-wide case-control study in a sample of epileptic Chinese Crested dogs and matched controls to investigate the contribution of genetic variants to the high epilepsy risk in the breed. The genotyping was performed using the Canine HD Whole-Genome Genotyping BeadChip (Illumina). After quality controls, we obtained a dataset of 27 cases and 38 controls (Call Rate > 80%) for a total of 106,392 informative autosomal SNPs. Association analysis at the SNP level was conducted using PLINK running a logistic regression including age, gender and correcting for population stratification. None of the SNPs analyzed reached genome-wide significance (P = 4.7E-07). However, at nominal significance levels we observed 7, 15 and 2 SNPs with P < 0.001 in the additive, dominant and recessive models, respectively. Among the top genes observed were *KHRDBS3*, *ELAVL2*, *TCF25*, *DEF8*, *PTPRD*, *RNF25*, *GALNT10*, *DPYD*, *ATAD2* and *WDYHV1*. The association test was rerun for the SNPs located in the most potentially biologically relevant genes for epilepsy (*KHRDBS3*, *ELAVL2* and *PTPRD*) with additional samples not included in the GWAS due to call rate, for a total of 4 or up to 9 additional samples depending on the SNP. The results confirmed the significance for the SNPs located in *PTPRD* and *ELAVL2* (P = 9.9E-05 and P = 9.9E-05, respectively). The results for the variant located in *KHRDBS3* were not considered due to the low quality of the additional samples for that particular SNP. Our preliminary results suggest the involvement of variants located in *ELAVL2* and *PTPRD* with epilepsy in the Chinese Crested dog. *ELAVL2* is highly expressed in hippocampal CA3 pyramidal neurons and hilar interneurons. It has also been reported in animal models that ELAVL2 protein level in the hippocampus is acutely down regulated after a kainic acid induced seizure. *PTPRD* has been identified by GWAS of 889 newly treated patients to be significantly associated with remission of seizures after starting treatment. We also observed 2 SNPs located in *ADAM23* (P = 0.0012), a gene previously associated with idiopathic epilepsy in 4 different dog breeds. Due to our limited sample size, the results are not significant at the genome-wide level after correction for multiple testing. However, the biological significance of some of these genes justifies a potential role in epilepsy in the Chinese Crested dog. A larger sample size is being used to help to confirm the results.

838W

Motor neuron disease associated genes: Next generation target resequencing in sporadic and familial ALS cases. *C. Gellera[1], V. Pensato[1,2], B. Castellotti[1], S. Magri[1], F. Taroni[1], C. Mariotti[1], E. Dalla Bella[2,3], G. Lauria[2,3].* 1) Unit of Genetics of Neurodegenerative and Metabolic Diseases, Fondazione IRCCS - Istituto Neurologico Carlo Besta, Milan, Italy; 2) Motor Neuron Diseases Centre, Fondazione IRCCS Istituto Neurologico 'Carlo Besta', Milan, Italy; 3) Unit of Neurology III, Fondazione IRCCS Istituto Neurologico 'Carlo Besta', Milan, Italy.

ALS is an adult-onset, progressive, neurodegenerative disease caused by the selective loss of motor neurons with a large prevalence of sporadic cases (SALS). The pathogenesis is not completely known, but genetic factors play a major role in the disease. Although mutations in several genes have been described, with a major genetic cause in the repeat expansions in the C9orf72 gene, the underlying cause is still unknown in about 30% of familial ALS (FALS) and in the large majority of SALS (80%). In order to better define the genetic contribution in SALS and to fill the genetic gap in FALS, we set up a NGS approach, using the Illumina technology and the MiSeq apparatus, for a customized analysis for the screening of 78 ALS and ALS-like syndromes causative genes. We selected 213 consecutive ALS cases (37 FALS and 176 SALS), recently referred to our Institute for clinical and genetic definition of the disease. Diagnosis of ALS was made according to the El Escorial revised criteria (Brooks et al. 2000). They were negative for *SOD1*, *FUS*, *TARDBP* and *C9orf72* gene mutations at the preliminary molecular screening. Data analysis showed that 139 patients were negative for variants (filtered for MAF > 1%). The remaining cases (n=74) presented at least one variants, in heterozygous form. In particular, we have identified 7 patients carrying pathogenetic mutations in *VCP* (p.Arg155Cys; p.Arg93Cys), *OPTN* (p.Leu304Phe; p.Gln314Leu; p.Ala481Val) and *TRPV4* (p.Arg269His; p.Asn833Ser). We also report the identification of 56 novel variants of possible pathogenic significance and 16 extremely rare variant (MAF< 0.05%), whose pathogenetic significance should be assessed, and currently classified as VUS. Moreover, we have identified a number of variants in heterozygous form in genes associated with a recessive trasmission of the trait and thus considered as non causative. This study allowed the identification of causative mutations in three genes in 7 patients, and the identification of extremely rare variants or novel possibly causative variants in a significative number of patients (n=67; 31%).

839T

Clinical exome sequencing for identification of undiagnosed genetic disorders. *Y. Ko[1], H. Lee[1], H.D. Kim[2], J.S. Lee[2], C. Lee[1], J.S. Lee[1].* 1) Department of Clinical Genetics, Department of Pediatrics, Yonsei University College of Medicine, Ph.D; 2) Department of Pediatrics, Division of Pediatric Neurology, Yonsei University College of Medicine.

Recent advances in next-generation sequencing (NGS) technologies make it possible to comprehensively explore and identify disease-associated variants and genetic variants that could be associated with disease susceptibility. Here, we investigated the utility of NGS for the diagnosis of 196 patients with unknown genetic origin and molecular characterization. Intractable epilepsy or seizure like phenotype (60% of patients) is the most prevalent type in our cohort. Our pipeline for the analysis of disease-associated variants, could successfully identified the definite genetic causes as well as likely pathogenic variants. In this study, we utilized the TruSight One sequencing panel providing comprehensive coverage of < 4,800 clinically known disease-associated genes. Sequencing was performed using the Illumina MiSeq. The sequenced reads were mapped to the human reference (UCSC hg19) with Burrows-Wheeler Aligner (BWA), and variants were identified with the Genome Analysis toolkit (GATK). Molecular diagnoses could be made for 110 patients (56.1%), which reveals higher diagnostic yield than other study. All mutations have been confirmed by conventional Sanger sequencing and validated by parent testing. Especially, significantly higher diagnostic yield (59.3%) for seizure patients was observed. 50% of confirmed variants are predicted as functionally damaging or deleterious. Many pathogenic variants including known SCN8A (p.Glu710Lys) and SCN2A (p.Thr435Pro) genes are identified as genetic origin for the epilepsy. However, novel pathogenic variants associated with GRIN2A, STXBP1, and CDKL5 were also identified. In this study, we showed that targeted NGS has been successfully applied as a diagnostic tool for patients with undiagnosed genetic disorders. We conclude that NGS are likely to be a very useful in a diagnostic setting.

840F

SMN **copy number analysis: A comparison of three different methodologies.** *P.S. Lai[1], O.S. Yim[1,2], S. Marrs[3], J. Regan[3], P.S. Low[1].* 1) Dept Pediatrics, National Univ Singapore, Singapore, S128044; 2) Dept Psychology, National Univ Singapore, Singapore, S117570; 3) Digital Biology Center, Bio-Rad Laboratories 5731 West Las Positas Blvd, Pleasanton, CA 94588, USA.

Spinal muscular atrophy (SMA) is a neuromuscular disorder characterized by loss of motor neurons in the anterior horn of the spinal cord. The survival motor neuron (*SMN*) genes that influence SMA status are present on 5q13 as two homologous copies, a telomeric *SMN1* gene and a centromeric *SMN2* gene. Homozygous deletion of *SMN1* is responsible for more than 95% of all SMA cases. *SMN2* gene copy number can influence disease severity although it cannot compensate for *SMN1* loss. Thus, determining the *SMN* copy number is important for clinical diagnosis and prognosis, and the most commonly used molecular methods for this screening are multiplex ligation probe amplification (MLPA) and real-time PCR (qPCR). In this study, we set out to compare a new technology, droplet digital PCR (ddPCR), with MLPA and qPCR for *SMN* copy number determination. To do so, we tested 44 subjects for *SMN1* and *SMN2* copy number using a commercial assay for MLPA, previously validated home-brew qPCR assays, and newly commercialized assays for ddPCR. ddPCR and MLPA were found to be concordant in 43 out of 44 samples, and qPCR analyses were discordant with both MLPA and ddPCR in 8 and 10 samples for *SMN1* and *SMN2*, respectively. Two samples initially gave conflicting ddPCR results for *SMN2* copy number and upon reanalysis, only one of them remained discordant which was with the qPCR results. There was also one unique sample for each gene in which ddPCR showed discordant results with both MLPA and qPCR. ddPCR displayed tight coefficient of variation (CV), as only 9% of *SMN1* samples and 16% of *SMN2* samples had CVs higher than 5%, with the maximum CVs being 15.2% and 10.1%, respectively. In conclusion, we found ddPCR to accurately measure 0 – 4 copies of both genes. The methodology is easy to perform and the analysis is straightforward. Furthermore, its high-throughput nature makes it amendable for not only diagnosis and disease characterization, but also for carrier screening.

841W

A NGS strategy for molecular diagnosis of Duchenne/Becker muscular dystrophy in patients without gross DMD gene rearrangements. *O.P. Ryzhkova, N.V. Komarova, A. Loginova, A.V. Polyakov.* Research Centre for Medical Genetics, Moscow, Russian Federation.

Duchenne and Becker muscular dystrophies (DMD/BMD) are the most common inherited neuromuscular disease. The genetic diagnosis is not easily made because of the large size of the dystrophin gene, complex mutational spectrum and high number of tests patients undergo for diagnosis. Multiplex ligation-dependent probe amplification (MLPA) has been used as the initial diagnostic test of choice. Although MLPA can diagnose 70% of DMD/BMD patients having deletions/duplications, the remaining 30% of patients with small mutations require further analysis, such as Sanger sequencing. We worked out a new system to analyze of "point" DMD mutations. This method based on AmpliSeq technology with the addition of fragmentary analysis step between multiplex PCR and sequencing. For this purpose we used specially designed primers including the fragment complementary to fluorescently labelled universal primer. The fragmentary analysis made possible to achieve the necessary level of quality and quantity of each amplicon. This added stage helped us to equalize coverage between some regions. We use the system described above by analysis of 97 patients with DMD/BMD without gross DMD gene rearrangements. Forty-two patients (43%) had LOF-mutations in DMD gene. Previously described missense-mutation was found in one case. A total of 43 variants were Sanger sequenced and all were confirmed to be real (100%). Of these mutations 41% were nonsense-mutation, 23% small insertion, 20% small deletion, 14% splice-site mutation and only one (2%) was confirmed disease-causing missense-mutation. The most of them were not previously reported.

842T

Two novel panels for detection of genetic determinants of epileptic diseases. *C. Clear, R. Hrdlickova, J. Nehyba, C. Firmani, D. Fox, A. Lewis, M. Toloue.* Bioo Scientific, Austin, TX.

   Epilepsy is the most common neurological disease, affecting over 50 million people worldwide. It is characteristized by recurrent seizures due to abnormal neuronal firing in the brain. It is estimated that over 70% of these conditions have genetic background and are associated with inherited mutations in one of several genes encoding proteins involved in neural signalization. Next generation sequencing is a powerful tool for the precise identification of mutations which are associated with specific diseases. Targeted sequencing further economizes the diagnosis by focusing on genes known to be associated with an observed phenotype. Bioo Scientific developed two sequential panels for the detection of epilepsy. The first panel detects the sequences of two neuronal voltage-gated sodium channel genes, *SCN1A and SCN1B*, and the ligand gated gamma aminobutyric acid (GABA) receptor gene, *GABRG2*. The mutations found in these genes are the most frequent cause of early epileptic encephalopathies and have been associated with a spectrum of phenotypes including Dravet Syndrome, Generalized Epilepsy with Febrile seizure (GEFS+), Borderline Severe Myoclonic Epilepsy and other epileptic disorders. The second panel identifies the sequences of another two genes which encode the subunits of voltage-gated sodium channels *SCN2A* and *SCN9A*. The mutations in *SCN2A* are associated with benign neonatal and infantile seizures (BFNIS), but also with other syndromes such as autism, intellectual disability, and schizophrenia. The mutations in *SCN9A* were identified in *SCN1A* negative Dravet Syndrome patients. These amplicon panels cover 100% of the coding regions of *SCN1A, SCN1B, GABRG2, SCN2A,* and *SCN9A* genes and are compatible with Illumina (including compatibility with the MiniSeq) and Ion Torrent sequencing. These panels have been validated with a unique library preparation protocol which only takes 3 hours. Both panels are 100% uniform, which allows for the economical multiplexing of hundreds of libraries in one run by using the accompanying set of 384 barcodes. The development of these two economical, flexible, and well-designed panels for sequential detection of mutations associated with common neurological diseases will serve as a powerful tool to further research the genetic determination of these disorders.

Diagnostic targeted next generation sequencing in patients with epilepsy. *Y.J. Vos[1], P. Rump[1], D.R.M. Vlaskamp[1,2], P.M.C. Callenbach[2], C.M.A. van Ravenswaaij[1], R.J. Sinke[1], O.F. Brouwer[2].* 1) University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, the Netherlands; 2) University of Groningen, University Medical Center Groningen, Department of Neurology, Groningen, the Netherlands.

   Introduction: Epilepsy has a heterogeneous aetiology with a substantial genetic component. We used a targeted next generation sequencing (NGS) gene panel for clinical genetic testing in a heterogeneous cohort of 125 patients with epilepsy. **Materials and Methods:** A gene panel, based on Agilent Sure Select Target Enrichment®, including 144 genes and validated for diagnostic purposes, was used. Within this panel nine partly overlapping subpanels were designed based on different epilepsy phenotypes, namely: benign familial neonatal/infantile epilepsy (5 genes), epileptic encephalopathy (39 genes), focal epilepsy (12 genes), fever related epilepsy (12 genes), progressive myoclonic epilepsy (19 genes), metabolic disorders with epilepsy (43 genes), generalized epilepsies (14 genes), epilepsy in combination with paroxysmal disorders (11 genes), and syndromes with epilepsy and intellectual disability (63 genes). Based on the phenotype of the patient one or more of these subpanels were analysed. **Results:** A (likely) pathogenic variant was identified in 12% of the patients. All confirmed by Sanger sequencing. The yield was highest in patients with benign familial neonatal/infantile epilepsy (23%) followed by fever related epilepsy (17%). The genes involved were: *CACNA1A, CDKL5, GRIN2A, KCNQ2, KCNQ3, KCNT1, MECP2, NHLRC1, PCDH19* (n=3)*, PRRT2, RANBP2* (n=2)*,* and *SYNGAP1.* Using this approach we were also able to detect a mosaic pathogenic variant in the *PCDH19* gene in a male patient. A variant of unknown significance was reported in 12.8% of the patients. In most instances clinical relevance could be excluded. **Conclusion:** Our results demonstrate that targeted next generation sequencing offers a quick, comprehensive and efficient molecular screening in patients with epilepsy.

844W

Early infantile epileptic encephalopathy (EIEE) in females due to an X-linked *ALG13* variant: 4 new cases and a review of the literature. *S.A. Wong, S.L. Klemm, J.L. Schuette, D.J. Cardeiro, C.M. Stanley, N.M. Le. Courtagen Life Sciences, Woburn, MA.*

The *ALG13* gene, along with *ALG14*, encodes a subunit of UDP-GlcNAc transferase, which catalyzes a key step in endoplasmic reticulum N-linked glycosylation. This gene has been previously associated with a severe seizure phenotype in a male patient associated with an N-linked congenital disorder of glycosylation, CDG type1s (Timal et al., 2012) and intellectual disability in four brothers from a single family (Bissar-Tadmouri et al., 2014). The *ALG13* c.320A>G (p.N107S) variant has been reported in only female patients in the literature, with five cases to date discovered through exome sequencing and all of which were *de novo* mutations (Smith-Packard et al., 2015, Dimassi et al., 2016). One of these patients had biochemical testing, which showed a normal glycosylation pattern. We ascertained four additional female patients with this variant via a 471-gene NextGeneration sequencing panel, epiSEEK*ℝ*. The patients ranged in age from 16 months to 13 years. We observed the frequency of this variant to be approximately 0.34% of our tested population (4/1166). The variant met ACMG-based criteria for being pathogenic. Targeted parental testing was performed for two of the four cases, and both variants were *de novo,* consistent with the previous reports. Some patients had additional variants of uncertain significance (*RAI1, PRICKLE1, PRICKLE2, KMT2D, SETBP1, PTCH1* and *NOTCH3*). Of the three cases with detailed clinical information, all had early onset infantile spasms, epileptic encephalopathy, and developmental delay. The 13-year-old patient's spasms had progressed to generalized seizures; she also had dysmorphic features and microcephaly. As this variant was not identified in any male patients, it is possible that it is sex-limited, or as previously suggested in other papers, exhibits a dominant-negative effect. Isoelectric focusing results were not available to us, so it is unclear if these patients exhibited an abnormal profile. *ALG13* is present in several commercially available CDG gene panels and in select epilepsy gene panels. In females with severe early onset infantile spasms and global delay, testing of *ALG13* should be considered via gene panels, or if identified by whole exome sequencing, considered causative/pathogenic, as this variant may be more common in these patients than previously expected.

845T

Clinical detection of pathogenic copy number variation in epilepsy-related disorders. *H. Yang, M.B. Stosser, A. Lindy, O. Cano, D. McKnight. GeneDx, Inc., 207 Perry Parkway Gaithersburg, MD 20877.*

Copy number variants (CNVs) have been reported to play an important role in epilepsy; studies have demonstrated that CNVs account for 5-9% of pathogenic variants in epilepsy-related disorders. We conducted a retrospective study to assess the frequency and type of pathogenic CNVs detected in patients with epilepsy-related disorders who had undergone targeted multi-gene testing. Exon-level array CGH and next generation sequencing of up to 70 genes associated with epilepsy-related disorders was performed on 9314 samples. In 1442 positive cases, pathogenic CNVs were identified in 9% (n=136/1442). Of the cases found to have a single pathogenic CNV in a recessive gene, 4% (5/136) were also found to have a sequencing variant in the same gene. Additionally we reported single pathogenic CNVs in recessive genes that may or may not contribute to the phenotype (n=31). The amount of exomic sequence included in each CNV ranged from one or two exons (30%, 51/167) or 3 or more exons (27%, 45/167) to whole gene (18%, 31/167) or multiple genes (24%, 41/167). CNVs in positive cases were most frequently reported in the following genes: *CDKL5* (10%, 13/136), *SCN1A* (7%, 9/136), *KCNQ2* (6%, 8/136) *TSC2* (8%, 11/136), *PRRT2* (7%, 9/136), *STXBP1* (4%, 6/136), *GRIN2A* (4%, 5/136), *CLN3* (3%, 4/136), *MEF2C* (3%, 4/136), *PCDH19* (2%, 3/136), and *TSC1* (2%, 3/136). Multiple gene CNVs were also reported in positive cases, and often involved genes known to be part of microdeletion or duplication syndromes such as *UBE3A* (15%, 20/136), *KCNQ2/CHRNA4* (5% each, 7/136), *CHRNA7* (5%, 7/136), *SCN1A/2A* (4% each, 4/136). These microdeletion/duplication syndromes were in previously reported, recurrent CNV hotspots such as the 15q11.2 hotspot for Prader-Willi/Angelman syndromes (*UBE3A*), 16p11.2 region that contains *PRRT2* and *CLN3*, and the 15q13.3 region that contains *CHRNA7*. Additionally, the majority of positive findings reported for the *UBE3A* (60%, 20/33), *CHRNA7* (100%, 7/7), and *MEF2C* (57%, 4/7) genes were CNVs and not sequence based changes. Some CNVs were identified in genes not previously reported to have exon-level deletions/duplications (*GABRG2, MFSD8, PNKP,* and *TPP1,* n=5/136). Partial gene CNVs, which made up 57% (96/167) of the CNVs detected in this cohort, may not be detected by whole genome microarrays and could be missed by that technology. These data demonstrate the utility of exon level array technology as part of a comprehensive genetic analysis for patients with epilepsy-related disorders.

846F

NF1 gene deletion in neurofibromatosis type I patients from Egypt. *O. Eid[1], M. Eid[1], A. Kamel[1], G. El-Kamah[2], G. Abdel-Salam[2].* 1) Human Cytogenetic Department, National research centre - Egypt, Giza, Egypt; 2) Clinical Genetics Department, National research centre - Egypt, Giza, Egypt.

   Neurofibromatosis type I (NF1) is the most common hereditary neurocutaneous disorder. Its incidence is 1 in 3,000 to 4,000 births. It is an autosomal dominant disorder characterized by café au lait spots, neurofibromas, Lisch nodules, freckling of the axillary and inguinal regions, optic nerve gliomas and bone dysplasia. It is associated with an elevated risk for malignant tumors of tissues derived from neural crest cells. NF1 is diagnosed on the basis of clinical criteria, while identifying the genetic background of the disease is important mainly for genetic counseling and malignant predisposition. NF1 is caused by defects in the *NF1* gene, a tumor suppressor gene, located at 17q11.2. Point mutations in the *NF1* gene found in 90-95% of NF1 patients, while deletion/duplication found in 5-10% of the patients. Whole *NF1* deletions tend to cause a more severe phenotype. Here, we report the clinical and molecular cytogenetic findings of 28 patients, 16 unrelated patients and 12 patients from five families with NF1 from Egypt. Using FISH technique, *NF1* gene deletion were found in 17.9% of the patients. We also evaluated the frequency of *NF1* gene deletion, emphasizing the importance of deletion analysis in NF1 patients. A more sensitive genetic test such as MLPA, is necessary in order to detect partial *NF1* gene deletion that couldn't be detected by FISH.

847W

Diagnosis of spinal muscular atrophy: A simple method for quantifying the relative amount of *SMN* using Sanger DNA sequencing. *Y. Cao, W. Zhang, Y. Qu, J. Bai, Y. Jin, H. Wang, F. Song.* Medical Genetics, Capital Institute of Pediatrics, Beijing, China.

   Background: Spinal muscular atrophy (SMA), a common genetic disease in childhood, is caused by deletion or mutations in the survival motor neuron 1 gene (*SMN1*). Therefore, *SMN1* genotyping is very important for SMA diagnosis. **Aims:** We developed a novel method to simultaneously screen for *SMN1* homozygous deletion and *SMN1* point mutations. **Methods:** This relative quantifying method is based on PCR and Sanger DNA sequencing. *SMN1* and *SMN2* were simultaneously amplified by the same pair of primers, serving as an internal reference for each other to indicate the relative amount, as observed from the base peaks on the Sanger sequencing chromatogram at differential sites between genes. The accuracy, effectiveness and reproducibility of our method were evaluated using recombinant plasmids with various ratios of *SMN1* to *SMN2*, SMA patients' samples with known *SMN* genotype, respectively. Moreover, 223 SMA patients and 216 healthy controls were screened in parallel, using our method in comparison with multiplex ligation-dependent probe amplification (MLPA). **Results:** Our method showed experimental sensitivity and specificity of 98.6% compared with MLPA. And ROC curve analysis indicated high consistency between the results of two methods ($P < 0.001$). In addition, among 10 patients with diagnostic *SMN1* heterozygous deletion, nine *SMN1* point mutations were identified. **Conclusions:** Under certain conditions such as *SMN1* and *SMN2*, Sanger DNA sequencing can be used in relative quantification analysis. Based on this peculiarity, we developed a relative quantifying method not only for *SMN1* homozygous deletion but also for *SMN1* point mutations.

848T

Detection of copy number and structural variation in the clinical lab using massively parallel sequencing. *J.M. Devaney, B.W. Meltzer, M.B. Seprish, S.L. Everhart, J.M. Campos, K.P. Cusmano-Ozog, S.E. Hofherr.* Laboratory Medicine, Children's National Health System, Washington, DC.

   Statement of Purpose: Massively parallel sequencing (MPS) is offered as a clinical tool to discover genetic variation including single nucleotide variants and small insertions or deletions. Recently, the significance and frequency of pathogenic intragenic deletions or duplications (copy number variation) and large structural variants have become increasingly evident. We sought to validate the use of the Clinical Exome (4,813 genes) combined with bioinformatics tools to discover CNVs and SVs. **Methods:** The genomic DNA was prepared for targeted sequencing using the TruSight One (TSO) panel that contains the amplification, amplicon enrichment, and indexing for samples. The samples were analyzed on a NextSeq 500 system (Illumina, USA) using a High Output Kit v2 (300 cycles). Using BaseSpace Sequence Hub, we performed alignment to the hg19 reference genome with Burrows-Wheeler Aligner (version 0.7.7) with the Genome Analysis Toolkit (GATK v1.6) to generate BAM files. The BAM files were analyzed with the NextGENe software v2.4.0.1 (SoftGenetics, USA) for exon level copy number variation (CNV) detection. CNVs are detected by comparing the coverage (Reads Per Kilobase per Million mapped reads) of specified regions in a "sample" project and a "control" project to provide a coverage ratio. A beta-binomial model is fit to the coverage ratio in order to model the amount of dispersion (noise). Likelihood values are calculated based on the dispersion measurements and coverage ratios. Using a Hidden Markov Model, the probabilities are used to CNV classifications for each region as Normal, Duplication, or Deletion. We examined samples that were previously analyzed on the Affymetrix CyctoScan DX system (35 samples) and samples from Coriell Institute for Medical Research that contain CNVs (15 samples). In addition, we confirmed two samples with CNVs called from MPS data on the Affymetrix system. **Results and Conclusions:** We were able to use the NexGENe software to call single exonic deletions, exonic duplications, partial gene deletions and duplications, gene deletions, gene duplications, and two different trisomy conditions. The sensitivity was 100% with detection of all known deletions and duplications. The analysis requires multiple samples of the same sex as controls for one sample and all samples must be part of the same run. Overall, this tool was successful for the calling of CNVs and we are in the process of making it part of our clinical pipeline for MPS.

849F

Expanding the genomic search for etiology of the congenital microcephaly in Brazil. *E.A. Zanardo[1], J.G. Damasceno[1], A.M. Nascimento[2], M.M. Montenegro[1], G.M. Novo-Filho[1], R.L. Dutra[1], F.A.R. Madia[2], Y.G. Oliveira[1], T.M.M. Costa[1], A.T. Dias[1], C. Milani[2], F.B. Piazzon[1], M.I. Melaragno[3], C.A. Kim[4], L.D. Kulikowski[1,2,5].* 1) Laboratório de Citogenômica, Departamento de Patologia, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; 2) Laboratório de Citogenômica, Departamento de Pediatria, Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; 3) Departamento de Morfologia e Genética, Universidade Federal de São Paulo, São Paulo, Brazil; 4) Unidade de Genética, Departamento de Pediatria, Instituto da Criança do HC/FMUSP, São Paulo, Brazil; 5) Centro de Reprodução Humana e Genética, Departamento de Saúde Coletiva, Faculdade de Medicina do ABC, Santo André, Brazil.

   Congenital Microcephaly (CM) is a birth defect associated with small head circumferences that result in severe neurological consequences. CM seems to arise from a combination of various genetic and environmental factors that can alter the developing brain, resulting in structural and functional abnormalities, however most cases of clinically diagnosed microcephaly remain unexplained. Recent Brazil is facing a disturbing increase in cases of CM which coincided with Zika virus (ZIKV) infections in mothers during pregnancy. Zika is a neurotropic virus that can lead to microcephaly still in the placental environment and is suggestive of a possible relationship of birth defect rise in Brazil. Although Infections are a known cause of microcephaly, most of the reports are based on circumstantial evidences. Systematic investigations in congenital brain malformations using array analysis have implicated copy number variations (CNVs) in their etiology. In the past years, about several different genomic syndromes were described linking congenital microcephaly with pathogenic CNVs suggesting that other factors than ZIKV could be responsible for CM. Thus in this study, we evaluated 109 patients with multiple congenital abnormalities and developmental delay without genetic conclusive diagnostic using different genomic array platforms. One-third (29,4%) of patients studied (32/109) presented congenital microcephaly, among them about 46,9% (15/32) showed pathogenic CNVs that were not found in patients without microcephaly phenotype. The genotype-phenotype relationship between CM and specific pathogenic CNVs is still unclear in the literature and insufficient notified in Brazil. Also the array analysis in these patients may possibly identify other risk factors to the clusters of microcephaly and neurological disorders and help us better understand the relationship between ZIKV and the rise of detected cases of congenital malformations in this moment. Grants: FAPESP: 14/02565-8 and FINEP-CT INFRA 0160/12 SP8.

Molecular combing reveals structural variations in the Spinal Muscular Atrophy locus in African-American population. *M. Pierret, S. Berthoumieux, A. Thomas, C. Chypre, S. Barradeau, A. Bensimon.* Genomic Vision, Bagneux, France.

The Spinal Muscular Atrophy (SMA) is an autosomal recessive motor neuron disease, which is the most common genetic cause of infant death, due to deletions/mutations in the *SMN1* gene. Improvement of the detection of SMA carriers is important in genetic counseling, especially in African-American population in which undetectable carriers are particularly frequent. The *SMN1* gene, and its homologous *SMN2* gene are localized on chromosome 5q13.2 in a complex region characterized by an inverted duplication of around 500 kb sequence. However, the precise mapping of this locus is extremely difficult with the current technologies, such as sequencing or DNA microarray, due to high density of segmental duplications and other structural variations. Molecular Combing allows direct visualization of single DNA molecule, combining constant and uniform stretching of DNA molecules with a unique detection strategy, the Genomic Morse Code (GMC). The GMC, fluorescently provides a specific color-coded pattern for the direct and high resolution visualization of loci of interest. In order to precisely characterize the *SMA locus*, we developed a specific GMC that cover the entire *SMA locus* over 2 Mb. This GMC was hybridized on combed genomic DNA extracted from amnyocyte-derived cell cultures from African-American individuals. The image acquisition of fluorescent array signals is performed using an automated epifluorescence microscope, FiberVision®. After acquisition, SMA fluorescent array signals are pinpointed by the dedicated FiberStudio® software. The alignment of the different fluorescent array signals to the theoretical GMC deduced from the human genome reference sequence (GRCh38/hg38) reveals major discrepancies. First, it appears that the two *SMN* genes are not in a head to-tail orientation as annotated but are in a head-to-head orientation. Moreover, a color pattern from the theoretical GMC was not observed in African-American samples indicating the absence of the corresponding sequence. Finally, we also identified a repeat sequence with a variable number of repeated units located at the telomeric and/or centromeric regions indicating the presence of an unknown copy number variation sequence. In conclusion, Molecular Combing is a powerful technology that allows us to precisely and accurately map the *SMA locus* in the African-American population. This corrected map gives information that would be helpful to develop relevant SMA screening test for this population.

851T

Novel *UBE3A* variant detected in a family with familial Angelman syndrome and osteogenesis imperfecta type I. *E.A. Leeth[1,2], E.M. McGinnis[1], D.A. Kirschmann[1], C. McCabe[1], E. Caparelli[1], V.R. Sanders[1], J. Charrow[1,3], K.M. Leuer[1,2], L.J. Jennings[1,2].* 1) Ann and Robert H Lurie Children's Hospital, Chicago, IL; 2) Pathology and Laboratory Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) Pediatrics-Genetics, Feinberg School of Medicine, Northwestern University, Chicago, IL.

Approximately 10% of individuals with Angelman syndrome (AS) possess causative loss of function variants in the maternally derived E6-AP ubiquitin-protein ligase (UBE3A) gene. UBE3A consists of 16 exons where the last two nucleotides of exon 7 and exons 8-16 make up the coding regions of the gene. To date, over 200 pathogenic variants have been reported, spanning across the entire region. We describe a patient who initially presented to our institution for an evaluation due to a maternal family history of osteogenesis imperfecta (OI) type I. Analysis of the COL1A1 gene identified the familial mutation in the proband. Subsequently, developmental delay and seizures prompted a neurological evaluation. Analysis of the SNRPN region showed normal methylation. A comprehensive epilepsy panel revealed a novel UBE3A missense variant in the proband, his mother and affected maternal half-sibling. The c.1763G>T (NM_000462.3) variant is located in exon 9 and codes for an amino acid in the C-terminal HECT domain, which plays an essential role in transferring the ubiquitin to proteins targeted for degradation. Although two nearby splicing pathogenic variants have been published, to our knowledge, no missense variants at this location have been reported. Additionally, this variant is absent from population databases and several prediction algorithms suggest a deleterious or possibly damaging effect. Based on family segregation analysis, we currently interpret the c.1763G>T variant as likely pathogenic. This case example describes a novel likely pathogenic UBE3A variant as well as adds to the literature indicating the importance of screening UBE3A for causative variants in patients with suspected AS. Sadikovic et al. (2014) suggests that approximately 29% of causative variants identified in UBE3A are inherited, which poses a significant risk of recurrence for families and highlights the need for genetic counseling. Genetic counselors can help educate providers on the various genetic etiologies of AS as well as the importance of screening UBE3A. They can also encourage patients and their families to participate in additional family studies when a novel UBE3A variant is identified. Additionally, the finding of two familial genetic disorders, OI type I and AS, also emphasizes the importance of continued genetic evaluations and testing even in light of an established genetic diagnosis.

Neuronal ceroid lipofuscinoses (NCLs), a heterogeneous group of lysosomal storage disorders, include the rare autosomal recessive neurodegenerative disorder CLN2 disease (CLN2). CLN2 is due to mutations in *TPP1/CLN2* gene causing tripeptidyl-peptidase-1 (TPP1) enzyme deficiency. Classic late-infantile CLN2 has pediatric onset with initial symptoms of seizures and language delay followed by progressive dementia, motor and visual deterioration and early death. Variant phenotypes occur more rarely. CLN2 diagnosis is based on laboratory testing following clinical suspicion. Early diagnosis is key to optimizing clinical care and future therapies outcomes, yet delays in diagnosis are common due to low disease awareness, non-specific initial symptoms and limited diagnostic testing access in some regions. In May 2015, international experts met to recommend best laboratory practices for early CLN2 diagnosis. When clinical signs suggest NCLs, TPP1 activity should be the first test performed (along with palmitoyl-protein-thioesterase-1 to exclude CLN1). However, since reaching initial suspicion of CLN2 and NCLs is challenging, where available, use of epilepsy gene panels to investigate unexplained seizures in childhood is endorsed. These panels should include *TPP1/CLN2* besides genes for other NCLs lacking biochemical tests. Diagnostic TPP1 enzyme test in leukocytes is well established and robust and in DBS is considered diagnostic if followed by molecular testing. Future methods to measure TPP1 activity via MS/MS may improve DBS-based TPP1 testing sensitivity allowing also future newborn screening.   To confirm clinical suspicion of CLN2, the recommended gold standard for laboratory diagnosis is demonstrating deficient TPP1 activity and detecting causative mutations in each allele of *TPP1/CLN2* gene..

Genetic testing strategies for children and adults with peripheral neuropathy. *T. Brandt, H. Zghal Elloumi, F. Millan Zamora, A. Bamford, K. Retterer.* GeneDx, Inc., Gaithersburg, MD.

Inherited peripheral neuropathies are a genetically heterogeneous group of disorders with considerable phenotypic overlap, making it challenging to choose the most appropriate genetic test. This retrospective study examines the positive cases resulting from two different testing options for patients with peripheral neuropathy in our clinical laboratory: a 50-gene custom capture-based NGS panel (including genes most commonly associated with neuropathy) and whole exome sequencing (WES). Data include results from 311 neuropathy panel tests and 262 WES tests for patients with an indication of peripheral neuropathy. Results are defined as positive if pathogenic or likely pathogenic variants related to the neuropathy phenotype were identified. There was no significant difference in the positive rates for neuropathy cases between the targeted panel testing (70/311, 23%) and WES (46/262, 18%). However, the positive rate of WES was significantly higher for pediatric neuropathy patients (100 patients <18 y.o., 28% positive) compared to adult neuropathy patients (162 patients ≥18 y.o., 11% positive) defined by age at testing (p<0.01). This finding was independent of the WES testing approach, and applied to concurrent parental testing (trio) with 30% (pediatric) versus 13% (adult), as well as to cases where both parental samples were not available, with 19% (pediatric) versus 11% (adult). In contrast, age at testing did not influence the diagnostic rate for panel testing. Half of the WES positive findings in children with neuropathy involved genes not on the neuropathy panel, representing 14% of all pediatric WES neuropathy cases (14/100). Those genes are associated with syndromic disorders with a broad phenotypic spectrum that includes neuropathy. For example, multiple pediatric cases were found to have diagnostic findings for Brown-Vialetto-Van Laere syndrome (*SLC52A2* gene) by WES. In contrast, only 4% (7/162) of adult WES patients with neuropathy had positive findings in genes not on the panel, and each of these seven cases had findings in a different gene. Therefore, the 50-gene panel is well-suited for adult patients with neuropathy, with WES testing offering limited additional gains. On the contrary, as half of the diagnostic findings in children with neuropathy were identified in genes associated with syndromic disorders not typically included on neuropathy panels, WES provides a significant benefit in the molecular diagnosis of childhood neuropathy.

854T

A comprehensive NGS gene panel for the challenging genetic diagnosis of spinocerebellar ataxias and spastic paraplegias. *S. Magri, D. Di Bella, E. Sarto, L. Nanetti, C. Gellera, C. Mariotti, F. Taroni.* Unit of Genetics of Neurodegenerative and Metabolic Disease, IRCCS Istituto Neurologico Carlo Besta, Milan, Italy.

Spinocerebellar ataxias and hereditary spastic paraplegias are genetically highly heterogeneous groups of neurological disorders. Although >50 genes have been identified for each group, >50% of the patients remain undiagnosed. Molecular diagnosis is made difficult also by the clinical overlap with continuity of the phenotypic spectrum (spastic ataxia). Aim of the study was to analyze all the patients referred to our laboratory with two subsequent NGS approaches: 1) Two different TruSeqCustomAmplicon (TSCA, Illumina) panels including 76 genes for both dominant (SCA) and recessive (SCAR) spinocerebellar ataxias, and 50 spastic paraplegia genes; 2) One single probe-based panel (Nextera Rapid Capture, Illumina) containing >200 genes associated with spastic paraplegia (112) or ataxia (139) phenotypes. Coverage analysis revealed a higher sensitivity and uniformity of the probe-based *vs* the amplicon-based strategy (99% *vs* 78% of target region with ≥20X coverage). We analyzed 243 index cases (70-80% sporadic), 120 with spastic paraplegia and 123 with ataxia previously screened for the most frequent forms as appropriate. Overall, pathogenic mutations were identified in 53/243 patients (21.8%), 25/123 ataxic and 28/120 HSP patients. In particular, we identified mutations in challenging genes such as *SYNE1* (5 index cases), *SACS* (2), *SETX* (1), *SPG11* (10) and *PNPLA6* (2) which are difficult to be studied by conventional sequencing because of their length. Moreover, we identified mutations in rare genes such as *SPG8*, *SPG21*, *SPG47*, *SPG48*, *PNKP* (AOA4), *GBA2* (SPG46), *KIF1A* (dominant SPG30), *SPTBN2* (SCA5), and *PRKCG* (SCA14). CNV analysis based on depth-of-coverage comparison allowed us to identify a single exon deletion in *ANO10* (SCAR10) gene and a large deletion (exon 1-43) of *ITPR1* (SCA15). This comprehensive approach allowed also to identify mutations in genes unexpected based on the clinical diagnosis: *ATP13A2* (PARK9), *CYP27A1* (cerebrotendinous xanthomatosis), *EXOSC3* (PCH1B) and *PLP1* (a mutation in a female patient with an SPG-TCC phenotype). These results prompted reevaluation of clinical phenotypes and diagnostic reclassification. The usefulness of this combined ataxia-HSP multiplexed gene panel approach is further demonstrated by the identification of *FA2H* (SPG35) and *AP4B1* (SPG47) mutations in 2 predominantly ataxic patients, and *SYNE1* mutations in a patient with a complex spastic paraplegia phenotype. (E-Rare EUROSCAR and Italian MoH RF-2011-02351165 grants to FT).

855F

HMSN type Lom (*CMT4D*) in a non-Roma Czech boy caused by an isodisomy of the whole chromosome 8. *D. Safka Brozkova[1], M. Krutova[1], M. Trkova[2], R. Valkovicova[1], J. Haberlova[1], P. Seeman[1].* 1) DNA laboratory, Charles University 2nd Medical School and University Hospital Motol, Prague, Czech Republic; 2) Centre for Medical Genetics and Reproductive Medicine GENNET, Prague, Czech Republic.

Inherited peripheral neuropathies (IPN) are a heterogeneous group of disorders characterized by distal weakness and atrophies on lower limbs and also the sensory loss. IPN are genetically extremely diverse with more than 90 genes implicated with the IPN. Therefore the classical methods as Sanger sequencing is useful for the four most frequent causes and massively parallel sequencing (MPS) with panel of all the known IPN genes is suitable for the very many rare causes. Five years old patient with walking problems from two years of age was referred to our clinic from the local pediatrician. The nerve conduction study showed very low nerve conduction velocities (20 m/s), in a range of demyelinating neuropathy. CMT1A/HNPP , *MPZ* and *GJB1* gene were initially tested and not confirmed. MPS revealed two candidate mutations as disease causing – homozygous p.Arg148X in *NDRG1* gene and heterozygous p.Arg113X in *REEP1* gene. The patient is not Roma. Interestingly the *NDRG1* mutation p.Arg148X, in homozygous state responsible for HMSN type Lom in patients of Roma origin, was detected only in father, not in mother. Additional haplotype analysis with use of dinucleotide markers for chromosome 8 and 17 revealed homozygous haplotype inherited only from father, with missing information from mother for chromosome 8 and one haplotype from each parent for chromosome 17. Whole genome genotyping on Illumina Human Cyto SNP chip revealed complete isodisomy of chromosome 8, probably resulting from monosomy rescue. The segregation analysis in family revealed the *REEP1* mutation also in clinically healthy father and grandfather; therefore it was excluded as disease causing. HMSNL in our patient is caused by p.Arg148X mutation occuring in heterozygous state in healthy father. Due to an isodisomy of whole chromosome 8 with the mutated *NDRG1*, the p.Arg148X occurs in a homozygous state in patient. The family is not aware of Roma ancestors, but due to a presence of this mutation the very distant ancestor of Roma origin is probable. Support- AZV 15-31899A.

856W

Exon analysis of 74 genes potentially involved in hereditary spastic paraplegias through targeted next generation sequencing in a large cohort. *G. Stevanin[1,2,3], L. Raymond[1,2], M. Mairey[1,2], S. Morais[1,2,4], L. Parodi[1,2,5], R. Valter[1,2], C-S. Davoine[1], G. Banneau[3], E. Leguern[3], F. Barreca[1,2,5], L. Elsayed[1,2,6], G. Vazza[5], I. Alonso[4], A. Brice[1], A. Durr[1,3].* 1) Institut du Cerveau et de la Moelle, NEB, INSERM 1127, Paris, France; 2) Ecole Pratique des Hautes Etudes, PSL research University, Paris, France; 3) APHP, Department of Genetics, Pitie-Salpetriere Hospital, Paris, France; 4) UnIGENe, IBMC, Porto, Portugal; 5) University of Padova, Department of Biology, Padova, Italy; 6) University of Khartoum, Khartoum, Sudan.

Hereditary spastic paraplegias (HSP) are neurological diseases. They are genetically heterogeneous (59 spastic paraplegia genes, SPG) and are inherited through all known inheritance patterns accounting for a prevalence of 1-5:100 000 in most populations. HSPs are characterized by spastic gait, hyperreflexia, extensor plantar responses and proximal weakness, frequently associated to other neurological and extra-neurological signs. This heterogeneity makes classical molecular tests time-consuming and difficult to interprete, and this prompted us to develop a kit that couples a targeted capture and next generation sequencing to analyse 74 genes potentially involved in HSPs and related diseases. The kit has been used to sequence and analyse 324 index patients (153 French, 98 Portuguese, 32 Italian and 41 patients from Sudan). DNAs libraries were prepared through KAPA library preparation kit (KAPA Biosystems). The panel included the target region probes (1042 regions) corresponding to all coding exons belonging to 74 HSP genes and was designed by Roche-NimbleGen (SeqCap EZ). The DNA sequencing was realized using the MiSeq or NextSeq sequencers (Illumina). Alignment and variants detection were done through the Genomics Workbench software (CLC bio, Qiagen). Variants were filtered and prioritized, then verified through Sanger sequencing on patients and other family members, in order to establish the segregation patterns. A mutation responsible for the disease phenotype was identified in 1/3 of the patients overall analysed. For 1/3 of the patients, no pathogenic variant could be detected. One or more variants with unknown significance was identified among the remaining 1/3 of the cohort; in these cases the actual knowledge regarding the gene involved didn't allow to draw a conclusion regarding a possible pathogenic effect, and therefore its role in HSP onset. In addition, we identified a series of 8 patients carrying heterozygous variants in the motor domain of KIF1A inherited in a dominant pattern or de novo which contrast with the classical recessive transmission mode of this gene in SPG30. Through the coupling of targeted capture and NGS it was possible to increase the molecular diagnostic rate if compared to more classical strategies based on decision trees. Our results therefore show the importance of testing the same set of genes in patients with different transmission patterns, allowing the detection of multiple and unexpected transmission pathways.

Genetic epidemiology of inherited peripheral neuropathy in 481 Japanese pedigrees. *A. Yoshimura, M. Ando, Y. Hiramatsu, J. Yuan, Y. Higuchi, A. Hashiguchi, Y. Okamoto, H. Takashima.* Department of Neurology and Geriatrics, Kagoshima University, Kagoshima, Japan.

Background and Objective Inherited peripheral neuropathies (IPNs) are a group of related diseases primarily affecting the peripheral motor and sensory neurons and have been linked to over hundred genes or loci. These diseases are clinically heterogeneous and mainly comprise of Charcot-Marie-Tooth disease (CMT), hereditary sensory and autonomic neuropathy (HSAN), hereditary neuropathy with liability to pressure palsy (HNPP), and hereditary motor neuropathy (HMN). In this study, we aim to describe the clinical and genetic spectrum of patients with IPNs in Japanese population. **Methods** In the period from October 2014 to March 2016, we collected 481 index cases with IPNs who were referred by neurological and neuropediatric departments throughout Japan. All of these cases had been proved negative of *PMP22* duplication/deletion mutation; cases with HSAN were excluded from this study. We designed an Ion AmpliSeq gene panel encompassing 72 IPN-related genes. All target genes were amplified and subsequently sequenced using Ion Proton system (Life Technologies). Candidate variants were validated by Sanger sequencing, and if available, segregation analysis was performed. **Results** Among 481 cases with IPNs, mutations were detected in 159 cases (33.1%), consisting of 118 pathogenic mutations and 41 likely pathogenic mutations. Of all patients identified with pathogenic mutations, *GJB1* gene mutation was the most common cause in our cohort (29 cases, 24.6%), followed by *MPZ* (22 cases, 18.6%), *MFN2* (21 cases, 17.8%), *BSCL2* (6 cases, 5.1%), *MME* (5 cases, 4.2%), *PMP22* (5 cases, 4.2%). Besides, less than five cases were found harboring mutations in the other eighteen disease-causing or candidate genes, respectively. The mutation detection rate was 17.0% in cases suspected with autosomal recessive (AR) CMT (8/47), 37.9% in autosomal dominant (AD) CMT (44/116), and 21.3% in sporadic CMT (61/287). Mutations in recently described *MME* gene was found to be the primary cause for genetically confirmed axonal AR-CMT (5/9). **Conclusion** Targetted resequencing confirmed the diagnostic yield of the most frequent genetic defects besides *PMP22* duplication/deletion mutation, *GJB1*, *MPZ* and *MFN2*, total of which account for 61.02% of all mutation-positive cases. *MME* is the most frequent cause of AR-CMT2 in our cohort. The mutation detection rate of suspected AR-CMT was relatively lower than AD or sporadic CMT, suggesting more genetic diversity and require further study.

858F

Clinical diversity caused by novel *IGHMBP2* mutations. *J. Yuan[1], A. Hashiguchi[1], Y. Higuchi[1], A. Yoshimura[1], H. Yaguchi[2], K. Tsuzaki[3], A. Ikeda[4], K. Wada[5], M. Ando[1], Y. Hiramatsu[1], Y. Okamoto[1], H. Takashima[1].* 1) Department of Neurology and Geriatrics, Kagoshima University, Kagoshima, Japan; 2) Kashiwa hospital, Jikei University School of Medicine, Chiba, Japan; 3) Department of Neurology, Kansai Electric Power Hospital, Osaka, Japan; 4) Kanagawa Children's Medical Center, Yokohama, Japan; 5) Department of Neurology, Tottori University Faculty of Medicine, Yonago, Japan.

Background and Objective Charcot-Marie-Tooth disease (CMT), as the representative disease of inherited peripheral neuropathies (IPNs), is typically characterized by progressive motor and sensory polyneuropathy. However, a certain CMT disease-causing gene might also produce distinguish phenotypes and therefore clinically diagnosed as other inherited neuropathies. Like *IGHMBP2*, which was linked to both autosomal recessive axonal CMT and spinal muscular atrophy with respiratory distress type 1 (SMARD1). The aim of this study is to identify the genetic spectrum of patients with IPNs in Japan and demonstrate their phenotypic features. **Methods** From June 2014 to December 2015, we collected 408 cases diagnosed with IPNs on the basis of clinical findings and electrophysiological study. We conducted mutation screening by applying an Ion AmpliSeq gene panel, which comprises of 72 disease-causing or candidate genes of IPNs. **Results** We identified novel compound heterozygous or homozygous mutations of *IGHMBP2* in four cases, consisting of p.Ala345Glu and p.Arg595Trp in patient 1, p.Thr115Met and p.Gly399Ser or c.1060+5G>C in patient 2, p.Gln276* and p.Gln568* in patient 3, and homozygous p.Tyr920Cys in patient 4. Segregation study was carried out in pedigrees of patient 1 and 3, confirming that a single mutated allele was inherited from each parent. Parental consanguinity was only recorded in patient 4. Three patients (1, 2, and 4) were diagnosed with CMT, manifesting childhood-onset axonal polyneuropathy. Patient 3 was characterized by low birth weight, weak cry, reduced spontaneous movement, respiratory distress from four months after birth, and thus comparable to SMARD1. **Conclusion** We present the original report of patients with axonal CMT caused by recessive *IGHMBP2* mutations in Japan. In our cohort, the *IGHMBP2* mutation was detected in less than 1% of IPNs. We report four novel mutation genotypes of *IGHMBP2* leading to significant clinical diversity, whereas the interaction between genotype and phenotype remains controversial and requires further research.

859W

Mutational analysis of sequence variants in *GCDH*: Frequency of variants in NBS-positive versus symptomatic patients. *B.D. Apple, H.-C. Yu, N. Meeks, K. Kronquist, M. Woontner, S. Goodman, E. Spector.* Department of Pediatrics, University of Colorado School of Medicine and Children's Hospital Colorado, Aurora, CO.

Glutaric acidemia type 1 (GA1, OMIM 231670) is an autosomal recessive disorder caused by sequence variants in *GCDH*, encoding the protein glutaryl-CoA dehydrogenase (GCDH). GA1 is one of the 31 metabolic disorders included in all newborn screening (NBS) panels. We present 12 years of data from clinical Sanger sequencing in our laboratory. Overall, 1331 probands were analyzed. The ACMG Guidelines for Interpretation of Sequence Variants was used to interpret the pathogenicity of all sequence variants not reported in the literature. In a subset of 341 cases where a reason for testing was provided, the indications included: abnormal NBS (245 or 72%), clinical suspicion of GA1 (64 or 19%) and abnormal biochemical testing in an older patient (32 or 9%). Of the 245 cases in the NBS positive group, 26 possessed *GCDH* variants; 16 were carriers and 5 were homozygotes or compound heterozygotes for a pathogenic variant. This data indicates a yield of 5/245 or 2.0% for a molecular diagnosis of GA1 among NBS positive patients. This detection rate is in line with the high false positive rate of the NBS. Of the patients with a clinical phenotype suspicious of GA1, 4/64 cases were either homozygous or compound heterozygotes giving a 6.2% diagnostic yield. Of the group of older patents with abnormal biochemical testing, 9/32 samples were either homozygous or compound heterozygous, giving a 28.1% diagnostic yield. Among all of the 1331 probands tested we identified three variants known to be associated with a low-excretor phenotype. The variants were: Val400Met (6.6%), Arg227Pro (5.2%) and Met405Val (1.9%). Interestingly, only two individuals possessing one of these low-excretor alleles were detected in the NBS positive group. One hundred and thirty-four variants were identified: 64 were pathogenic, 28 likely pathogenic, 38 VUS, 1 likely benign and 1 benign. Of these 134 variants 48 have not been previously reported. The majority of variants were missense variants (107). In addition to the missense variants, 6 nonsense, 5 splice-site, 10 indels causing a frame shift and 3 in-frame indels were found. No deletions or duplications at the exonic level were identified in 54 patient samples tested by aCGH. Of all the variants (known and novel), almost 70% of them were either pathogenic or likely pathogenic. Our data confirm that *GCDH* is a highly conserved gene and that the majority of new sequence variants identified are either pathogenic or likely pathogenic.

860T

Diagnostic yield for chromosome microarray analysis in patients with autistic features. *A. Bandholz, V. Mehta, Z. Powis, E. Spiteri, M. Rossi.* Ambry Genetics, Aliso Viejo, CA.

Autism Spectrum Disorders (ASDs) are clinically heterogeneous, highly heritable neurodevelopmental disorders seen in 1-2% of children. Chromosomal microarray (CMA) is a first-tier test in the evaluation of individuals with ASDs with the diagnostic yield varying based on population examined, ranging from 5-25% in recent literature. Subjects in the majority of published studies are formally evaluated for ASD prior to inclusion; however, in the clinical setting formal autism evaluations may not occur prior to genetic testing. Herein we calculate the diagnostic rates for copy number variations (CNV) by CMA in a cohort of patients with ASD, pervasive developmental disorder not otherwise specified (PDD-NOS), or autistic features (AF) with or without formal evaluation submitted for clinical testing. The most recent 614 unselected cases referred for postnatal microarray to Ambry Genetics (Aliso Viejo, CA) with indication for testing provided were reviewed. Patients with clinical indications including ASD, PDD-NOS and AF were included in the cohort. Of the 614 cases, 128 (21%) were reported to have ASD/PDD-NOS/AF with or without additional features excluding two patients with prior abnormal diagnostic lab results. For cases with more than one CNV identified, the CNV of highest pathogenicity determined the overall case classification. Of the 128 ASD/PDD-NOS/AF cases, 7 (5.5%) were pathogenic, 2 (1.6%) variant likely pathogenic (VLP), 37 (28.9%) variant of uncertain significance (VUS), 10 (7.8%) variant likely benign (VLB), and 72 (56.3%) normal. Overall, 9/128 (7.0%) patients had a pathogenic or VLP CNV; 6/9 (66.7%) with microdeletions, 1/9 (11.1%) with a microduplication, and 2/9 (22.2%) with sex chromosome aneuploidy. Recurrent CNVs demonstrating reduced penetrance and variable expressivity were frequent amongst the pathogenic and VLP cases including single patients with 15q11.2 BP1-BP2 microdeletion, 16p11.2 microdeletion, 15q13.3 microdeletion, distal 1q21.1q21.2 microduplication, and intragenic *NRXN1* deletion. Among VUS CNVs, two autism candidate genes were noted, *CHRNA7* and *CNTN6*. The majority of the pathogenic/VLP results (67%) were identified in patients with additional physical findings suggesting a higher detection rate for the more complex cases. The rate of pathogenic and likely pathogenic findings is comparable to the conservative published estimates of diagnostic yield for CMA in patients with ASD.

861F

Array comparative genomic hybridization findings in autism spectrum disorders. *A. Battaglia, G. Scarselli, R. Tancredi, A. Cosenza, R. Igliozzi, F. Apicella.* Dev Neurosciences, Stella Maris nst/Univ Pisa, Pisa, Italy.

Early presumptions opined that autism spectrum disorder (ASD) was related to the rearing of children by emotionally-distant mothers. Advances in the 1960s and 1970s clearly demonstrated the biologic basis of autism with a high heritability. To date, specific etiologic factors in ASDs can be identified in 30%–40% of patients. The development and refinement of array comparative genomic hybridization (a-CGH) has led to expanded applications as a diagnostic tool. Recent reports suggest a high diagnostic yield for a-CGH in ASDs. The objective of this study was to determine the diagnostic yield in a-CGH for ASDs at the Stella Maris Clinical Research Institute for Child and Adolescent Neuropsychiatry. We report the diagnostic yield of a-CGH in 200 samples with a primary indication of autism. All propositi were personally assessed with a detailed dysmorphologic, neurological, and neuropsychological evaluation. ASD diagnosis was based on criteria from the DSM-IV-R, and DSM5 since 2013, which was confirmed by ADOS and ADI-R assessments. 20% of the patients had abnormal findings on a-CGH. This study further supports a-CGH in the etiologic evaluation of ASDs, and elevation of array to a first tier diagnostic test. In the current era of emerging efforts in "personalized medicine", identifying an etiology will be critical in identifying endo-phenotypic groups and individual variations that will allow for tailored treatment for individuals with ASD.

862W

Identification of structural variants in neurodevelopmental disorders from sequence data in a New Zealand cohort. *W. Whitford[1], I. Hawkins[1], E. Glamuzina[2], D.R. Love[3], J. Taylor[4], R. Hill[5], K. Lehnert[1], R.G. Snell[1,6], J.C. Jacobsen[1,6].* 1) School of Biological Sciences, The University of Auckland, Auckland 1142, New Zealand; 2) Adult and Paediatric National Metabolic Service, Auckland City Hospital, New Zealand; 3) Diagnostic Genetics LabPLUS, Auckland City Hospital, Auckland, New Zealand; 4) Genetic Health Service New Zealand, Auckland City Hospital, New Zealand; 5) Department of Neurology, Auckland City Hospital, New Zealand; 6) Centre for Brain Research, The University of Auckland, New Zealand.

There is a significant overrepresentation of genetic structural variants (SV) in individuals with Neurodevelopmental Disorders. New Zealand has a unique and diverse population for studying genetic diseases, however current standard diagnostic practices do not include next generation sequencing (NGS). SVs including copy number variants (CNV) and balanced chromosomal rearrangements are currently identified using low resolution techniques such as karyotyping and array comparative genomic hybridisation (aCGH). To overcome the inherent limitations of these techniques we have employed NGS by means of whole genome sequencing (WGS) data in a New Zealand cohort of ASD and other related neurodevelopmental disorders, and we present the results from one of the cases here. The family consists of two affected siblings, who presented with recurrent episodes of neurological deterioration, bilateral basal ganglia strokes, and in one sibling, autism spectrum disorder. aCGH revealed two shared CNVs that could not be linked to the disease phenotype. We subsequently employed WGS which revealed an inherited heterozygous missense mutation in exon 2 (c.68C>V) of the solute carrier family 19 (thiamine transporter), member 3 (*SLC19A3* [MIM 606152]) gene. This p.Gly23Val missense mutation affects a conserved amino acid in the transmembrane domain of the carrier protein. No other putative SNP was identified in this gene, however subsequent analysis of the WGS revealed the presence of a 4808 base pair deletion in the 5' untranslated region of *SLC19A3* (Chr2:228,582,251–228,587,059). Mutations in this gene have previously been found to cause Thiamine metabolism dysfunction syndrome 2 (THMD2 [MIM 607483]) which aligns with the clinical manifestation in these children. The syndrome is known to be biotin and thiamine responsive, with an alternate name of thiamine-biotin responsive basal ganglia disease. Subsequent treatment with biotin and thiamine has resulted in significant clinical improvements. Thus, WGS was able to identify a compound heterozygous mutation that was not detected by current diagnostic assays, and has resulted in a successful targeted treatment.

863T

Novel mutations and further phenotypic expansion for early onset epileptic encephalopathy genes. *E. Bettella[1], R. Polli[1], E. Leonardi[1], F. Cesca[1], M. Vecchi[1], I. Toldo[1], C. Boniver[1], S. Sartori[1], A. Murgia[1,2].* 1) Department of Women's and Children's Health, University of Padua, Padua Italy; 2) Department of Neuroscience, University of Padua, Padua Italy.

Early Onset Epileptic Encephalopathies (EOEEs) are a common and a heterogeneous group of neurological disorders of early infancy, characterized by premature and often drug-resistant seizures mainly resulting in motor and cognitive deficits. Indeed EOEEs represent a final common pathway for a broad spectrum of genetically heterogeneous conditions. As single gene testing is no longer a practical approach, the use of Next Generation Sequencing (NGS) should be applied as a routine molecular diagnostic strategy in patients with EOEE. With the use of a custom targeted multigene panel and data analysis pipeline, we have identified and characterized 7 disease-causing variants that seem to further expand the phenotypic range of five early onset epilepsy genes. We have detected four novel *de novo* mutations: *SCN1A* c.5732A>G(p.K1911R) (MIM#182389; NM_001165963), *SCN2A* c.4993C>T(p.L1665F)(MIM#182390;NM_021007), *KCNQ2* c.845A>T(p.D282V) (MIM#602235;NM_172107) and *FOXG1* c.1135C>T(p.L379F) (MIM#164874;NM_005249); one novel maternally inherited variant in *SCN1A* c.3572G>A(p.C1191Y) and one *de novo* known variant in *SCN2A* c.3631G>A(p.E121K). Furthermore, we have identified a novel homozygous mutation of the *ALDH7A1* gene c.1256C>T(p.S419L) (MIM#107323;NM_001202404) in the newborn child of consanguineous Pakistani parents. The phenotypes of all the patients carrying these mutations were peculiar both from the clinical and electroclinical standpoints and can further expand the genotypic and clinical spectrum of these disorders. Our findings contribute to highlighting the extreme variability of phenotypes associated with mutations in known early onset epilepsy genes and show that the more insights we get into the molecular bases of genetic disorders which definition is based uniquely on clinical grounds, the more we have to accept that the relationship between the genotype and phenotype may be anything but straightforward. Finally, a careful, refined and comprehensive description of the patients' clinical features is the key factor to expand the phenotypic spectrum associated with single nucleotide variants, depending on their nature and location .

864F

Splice site mutation of *TCF4* gene in a patient with suspected Pitt-Hopkins syndrome. *S. Chahrokh-Zadeh, A. Munzig, M. Ziegler, S. Doelken, I. Rost.* Center for Human Genetics and Laboratory Medicine, Martinsried, Germany.

Pitt-Hopkins syndrome (PHS) is a rare neurodevelopmental genetic disorder, remaining underdiagnosed due to similarities with other known genetic syndromes like Angelman or Rett Syndrome. It is mainly characterized by extensive developmental delay, severe intellectual disability (ID), and a typical facial gestalt. Other features include episodic hyperventilation, seizures, eye abnormalities and constipation. Mutations of the *TCF4* gene were identified as disease-causing and haploinsufficiency of TCF-4 has been reported to cause classical PHS.   We report on a 20-year old girl, born as a second child to healthy, non-consanguineous parents, presenting with severe developmental delay, severe speech delay, facial dysmorphism and movement disorder. Initial genetic investigations at age 4 including molecular genetic diagnostics of Angelman-Syndrome (Methylation assay, Deletion-/UPD-testing, sequencing of *UBE3A*-gene) and Fragile X syndrome (Southern Blot analysis), classical karyotyping and array-based comparative genomic hybridization (array-CGH) revealed negative results.   We performed molecular genetic diagnostics of *TCF4* gene consisting of Sanger sequencing followed by MLPA (multiplex ligation-dependent probe amplification) analysis. By sequence analysis we were able to identify the splice donor variant c.1486+3A>C of the *TCF4* gene (NM_001083962.1; chr18:52901776(hg19)). This substitution is localized at position +3 of intron 16 (IVS16+3 A>C) and was not reported in relevant databases (ExAC Browser (Exome Aggregation Consortium); dbSNP; EVS) or the literature to date. By the result of parental analysis the variant had occurred de novo in the patient. Bioinformatic algorithms (MaxEntScan, Human Splicing Finder a.o.) predicted not to significantly alter the splice site activity.   In order to determine the in vivo effect of this substitution on the splice donor site of intron 16 in RNA extracted from the patients' platelets and leukocytes we performed functional RNA studies to elucidate the true effect of the variation detected in this individual. We were able to show, that this variant results in the production of a critical amount of aberrantly spliced transcripts, ultimately leading to haploinsufficiency of tcf4 protein. Aberrant transcripts contain translational stop codons leading to productions of variant proteins, that most likely will be completely degraded.

865W

Use of chromosomal microarray in Hong Kong patients with autism spectrum disorder: Implications of a copy number variation involving *DPP10*. *H. Chung[1,2,4], S.L. Mak[3], T.G.A. Chiu[1,4], K.C. Leung[1], C.Y. Mak[1], W.Y. Chu[1], T.K. Mok[1], Y.K. Chan[2], S.Y.A. Kan[2], H.Y.M. Tang[2], T.K. Lau[2], C.W. Fung[1,4], S.L. Lee[1,4].* 1) Pediatrics and Adolescent Medicine, Queen Mary Hospital, HKU, Hong Kong; 2) Obstetrics and Gynaecology, Queen Mary Hospital, HKU, Hong Kong; 3) Obstetrics and Gynaecology, Queen Elizabeth Hospital. , Hong Kong; 4) Pediatrics and Adolescent Medicine, Duchess of Kent Children's Hospital, HKU, Hong Kong.

Background Array Comparative Genomic Hybridization (aCGH) is now the recommended first-tier genetic test for children with autism spectrum disorder (ASD). However, its interpretation can be challenging. Genetic counselling can be further complicated by the fact that contribution of CNVs in non-European ASD patients has not been well studied. We report the CNV findings in a clinical cohort of Chinese children with ASD in Hong Kong.   **Methods** DNA samples were obtained from 288 ASD patients recruited from a child assessment centre in Hong Kong between January 2011 and August 2014. aCGH was performed using the NimbleGen CGX-135k oligonucleotide array or Agilent CGX 60k oligonucleotide array in a clinical laboratory. Results were classified based on existing guidelines with reference to medical literature and CNV databases.   **Results** Of the 288 patients, 5 had pathogenic and 4 had likely pathogenic CNV. The diagnostic yield was ~3%. A small duplication overlapping the *DPP10* gene (hg[19]chr2:116,534,689-116,672,358), which was previously implicated in the pathogenesis of ASD, was identified once in the ASD cohort (0.35%). The same variant was observed at a frequency of 0.96% in our internal controls, and 1.2% amongst the parental samples (all of typical development) sent for prenatal diagnosis respectively. Multiple individuals of typical development carrying a similar DPP10 duplication were also identified in regional CNV databases with predominantly Chinese population.   **Conclusions** Our findings suggest that the *DPP10* duplication is likely a benign copy number polymorphism frequently seen in southern Chinese. This highlights the importance of (a) using ancestry-matched controls in clinical interpretation of aCGH findings and (b) recruiting cases and controls of well-mixed ethnicity backgrounds in genomic studies.

866T

Maternal derived 15q11.2-q13.1 duplication in a patient with autism and seizure. Case report. *M. Perez Sanchez[1,2], M. Martinez[1,2], S. Garcia[1,2], A. Mora[1,2], A.R. Gonzalez[2,3].* 1) Genetics, Complejo Hospitalario de Granada., Granada, Granada, Spain; 2) Instituto Biosanitario de Granada, Spain; 3) FIBAO, Complejo Hospitalario de Granada, Spain.

   Autism is a neurodevelopmental disorder charazterized by impaired social interaction and comunication and a restricted range of interests and activities, with onset during thethe first 3 years of life. Duplications of the 15q11-q13 region are the most frequently reported chromosomal aberration in individuals with autism Thie region includes the Prader-Willi/Angelman syndrome (PWS/AS) critical region, wich is subjet to genomic imprinting. Most duplications of this interval are caused by supernumerary chromosomes formed by the inverted duplication of proximal 15q, know as isodicentric chromosome 15. Intersticial duplications of this region are less frequent, but many cases have been reported in association with autism. The majority of cases are associated with maternally derived duplications, whereas paternal inheritance usually leads to normal phenotypes.We describe here a female patient in wich autism segregates with maternal inherance of a proximal 15q duplication. The patient was born at 37 gestation weeks with a weigh of 3150 gr. and no incidences in neonatal period. In posterior pediatric revission was detected language and cognitive delayed, supected due to autistic disorder (AD), at 3 years age preseted epilepsy episodes. The familiar history include fater and maternal grandmother with epilepsy, maternal uncle with autism and a sister healty.Comparative Genomic Hybridization (CGH-Array) with the Nimblegen CGX Cytogenetic Microarrays platform, suplied by PerkinElmer, and karyotype was performed for the patient and parentsThe CGH- Array was normal in the father, but both mother and patient presented a duplication of 5,56 Mb in 15q11.2-q13.1 PWS/AS region (arr(hg19)15q11.2-q13.1(22,822,019-28,379,369)x3). No others chromosomal anomalies were detected.Karyotype was normal in the patients and parents.The Array-CGH and karyotype from paternal grandmother, maternal uncle and sister were no done.This results are according with previous studies that show the correlation between this duplication and autistic disorder when have been maternal in origin. The family history with the maternal uncle diagnosed of autistic disorder also agree this posibility. The epilepsy, presented in some members of father`s family, is possible that can be originated for another unknow genetics alteration, without any correlation with the microduplication in PSW/AS region described in the patient.

867F

Co-existence of a complex, three-way translocation with a 4.6 Mb deletion in 8q22.3-8q23.1. *K. Swisshelm[1], S. Toomey[1], J. LeRoux[1], R. Rowe[1], K. Ha[1], B. Carstens[1], E. Elias[2].* 1) Dept Pathology, Colorado Genetics Laboratory, Univ Colorado Denver Anschutz Medical Campus, Aurora, CO; 2) Department of Pediatrics and Colorado Childrens Hospital, Aurora, CO.

   We present a case of a non-verbal 18 year old male with skeletal abnormalities, including mild scoliosis, severe intellectual disability, autism and generalized convulsive and intractable epilepsy.   Initial high resolution chromosome studies revealed a complex karyotype involving a three-way translocation of chromosomes 7, 11 and 12, with an insertion of 12p material into the short arm of chromosome 7. The ISCN for this finding is: 46,XY,t(7;11;12)(12pter->12p12.2::7p15.1->7qter;11pter->11q22.3::7p15.2->7pter;11qter->11q22.3::7p15.1->7p15.1::12p12.2->12qter).   Single nucleotide polymorphism chromosomal microarray testing revealed no gains or losses of genomic material involving chromosomes 7, 11 and 12. However, an additional finding of a 4.6 Mb loss within the long arm of chromosome 8, at 8q22.3-8q23.1 (101,930,909-106,510,518; hg19) was observed. Upon inspection of the high resolution chromosomes, this finding could be visualized at the 450-550 band level. Parental studies were negative for a rearrangement of chromosomes 7, 11 and 12 and were negative for the 8q22.3-8q23.1 loss by fluorescence in situ hybridization. Therefore, the findings of a complex chromosomal rearrangement and an 8q deletion in this patient are *de novo*.   An overlapping region of deletion within 8q has been reported in the literature in a case of an 8 year old female with intellectual disability and epilepsy (Kuroda Y et al., Am J Med Genet 164A:2104-2108, 2014), and in five patients with similar deletions, all with intellectual disability and dysmorphic features, and 4 of 5 with epilepsy (Kuechler A et al., Am J Med Genet 155A:1857-1864, 2011). Our patient's deletion involved seven disease genes, including *GRHL2, RRM2B, FZD6, CTHRC1, SLC25A32, DPYS,* and *ZFPM2.* In this case, the complex three-way translocation appears to be balanced, with no gain or loss of genomic material. While disruption of genes involved in the rearrangement of chromosomes 7, 11, and 12 cannot be excluded, our patient's phenotype can be attributed to the 4.6 Mb loss within 8q. Our findings underscore the importance of a complete genomic laboratory testing to include both karyotype and chromosomal microarray in the absence of other molecular finding.

868W

What can go wrong in the molecular assays when the results conflict the clinical diagnoses. *C. Tsai.* pediatrics/genetics, childrens Hospital colorado, Aurora, CO.

BACKGROUND: Molecular genetics testing have been applied to our daily medical practice. Current methods for single gene disorders including Sanger sequencing and high through-put next generation sequencing (NGS): PCR or captured based panels as well as exome sequencing. The predictive value and clinical applications are variable from one condition to the other. Numerous questions remain including technology deficits, data interpretation and unpredicted phenotypes in complex disorders.OBJECTIVE: In this study, the author reviewed all patients with conflicting results between molecular results and clinical diagnosis. Addition testing on or include the suspected genes were studied which subsequently revealed or confirmed the diagnosis.DESIGN/ METHODS: From 2011-2015, 22 patients with classic or highly suggestive clinical diagnosis of congenital malformation syndrome yet initial molecular assay did not identify an anomaly were reviewed and offered additional study. 15 patients were able to establish a final diagnosis.RESULTS: A patient with Pompe disease had 2 mutations missed by Sanger but picked up by NGS and microarray due to allele dropout and a partial exon deletion. 2 siblings with MELAS mutation each has a ratio of 19 % and 13% mosaicism originally missed by sanger but picked up by NGS. 1 patient with classic Noonan syndrome due to PTPN missense mutation was missed by Sanger and picked up by NGS due to allele dropout. 2 patients with FOXG1 mutation missed by NGS panel but picked up by exome sequencing due to script and filtering errors. 4 Angelman syndrome pt with normal Sanger sequencing of UBE3A were found to have CRIN2B, SLC6A9, CTNNB1 and PQBP1 mutations by panel assay. 2 patient thought to have Waardenburg syndrome and NF1 respectly were proved to have KIT mutations, 1 patients with retinopathy were missed by captured based NGS panel but picked up by PCR based NGS ones. CONCLUSIONS: Most capture based panel assays continue to miss gene changes from the capturing process, exon 1 mutations, GC rich genes and pseudogenes. Bioinformatics analysis remain critical for calling predicting the consequences of the variant. The author demonstrated a series of cases of laboratory pitfalls. Clinicians need to recognize that a mutation can be missed by one reputable lab and detected by another using a different platform/methodology; understand the limitations of each testing is critical in making the correct diagnosis. .

Microarray comparative genomic hybridization analysis (aCGH) in patients with multiple congenital abnormalities and global developmental delay. *R.I. Ursu[1,2], V.E. Radoi[1,2], G.P. Chelu[2], C. Arsene[2], R.E Bohiltea[1], L.C. Bohiltea[1].* 1) "Carol Davila" University of Medicine and Pharmacy, Faculty of General Medicine, Bucharest, Bucharest, Romania; 2) SYNEVO Romania, Central Laboratory, Medical Genetics Department, Bucharest, Romania.

Background: The array comparative genomice hybridization technique (aCGH, molecular karyotype) has become one of the most important diagnostic tools in identifying genomic abnormalities associated with developmental disabilities (congenital malformations, cognitive impairment and behavioral disorders, microdeletion and microduplication syndromes). **Purpose:** The purpose of this presentation is to describe the optimal medical genetics evaluation and diagnosis of the child with intellectual disability and global developmental delay. **Material. Method:** Study group consists of 8 children with epileptic enephalopathy, hypotonia, psychomotor impairment, different forms of epilepsy, microcephaly, intellectual disability. Constitutional karyotyping has been performed in all the cases with normal findings. The next diagnostic step in the management of the patients has been the molecular karyotype (aCGH) on an Agilent platform using SurePrint G3 CGH ISCA v2 Microarray, 8X60K. Data analysis and clinical interpretation have been completed using the Agilent CytoGenomics 3.0.2.11 Software, ADM2 algoritm. **Results:** The results revealed pathogenic variants in 4 cases: Microduplications with pathogenic significance (correlated with the clinical indications): 2 cases, 1p36.32; 8p23.1 Microdeletions with pathogenic significance (correlated with the clinical indications): 2 cases, 14q31.1; 1p36.33p36.23 Microdeletions and microduplications with benign or uncertain significance *(according to current genetics knowledge):* 4 cases. **Conclusions:** Although arrayCGH is currently being used as a complementary test to standard cytogenetic techniques, it is likely to become the genetic test of choice, especially in cases of idiopathic developmental delays, epilepsy, multiple congenital anomalies microdeletion and microduplication syndromes.

870F

22q11.2 duplication: Medical co-morbidities, intellectual functioning and neurodevelopmental concerns in probands and non-proband carriers.

M.T. Carter[1], B. McConnell[2], B. Mackinnon[2], S. Jilderda[2], J. Falcon[2], S. Saleh[2], G. Kamboj[2], A. Noor[3], A.S. Bassett[4], M. Speevak[5], D.J. Stavropoulos[6], I. Drmic[2]. 1) Regional Genetics Program, The Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Autism Research Unit, SickKids Hospital, Toronto, ON, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada; 4) Dalglish Family 22q Clinic, University Health Network & Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 5) Department of Genetics, Trillium Health Partners Credit Valley Site, Toronto, ON, Canada; 6) Department of Pathology and Laboratory Medicine, SickKids Hospital, Toronto, ON, Canada.

   A wide range of phenotypic manifestations have been described in probands with duplication of the 22q11.2 (LCR-a to LCR-d) region in case reports. Non-proband carriers of the duplication (i.e. parents and siblings of probands) are very rarely described, despite the fact that this duplication is usually inherited. We collected medical history information on 46 probands and 12 non-proband carriers of the 22q11.2 duplication; we also collected psychometric data on 10 of the probands and all 12 of the non-proband carriers. While 28% had one or more major congenital anomalies, no specific pattern of anomalies emerged. Dysmorphic facial features were absent in non-probands and rare in probands. One-quarter of the individuals tested had no clinically significant findings based on best-estimate clinical diagnosis that included file review and psychological testing (which included standardized measures of intelligence, academic achievement, adaptive functioning, social communication, attention, anxiety and depression). Thirty-three percent had a significant split between verbal IQ (VIQ) and performance IQ (PIQ); all but one individual had significantly higher VIQ. Of the remaining individuals for whom a Full Scale IQ was calculated, the majority were within the Average range. Similarly, reading and math skills were in the average range for the majority (58 and 70%, respectively). Learning disability and attention deficit-hyperactivity disorder symptoms were more common in probands versus non-probands, while anxiety and depression showed the reverse trend. In conclusion, our results show that most individuals with 22q11.2 duplication have average intellectual functioning, and those with an uneven cognitive profile tend to have stronger verbal reasoning skills. They may be at slightly elevated risk for congenital anomalies, but no specific pattern of anomalies is characteristic. Future studies will examine whether congenital anomalies and/or intellectual deficits are correlated with the presence of additional copy number variants.

871W

***De novo* 17q21.31 microdeletion in two girls with intellectual disability detected by Chromosomal Microarray Analysis.**

I.P. Pinto[1,2], L.B. Minasi[2,3], G.R. Nascimento[2,3], A.V. de Melo[1,2], D.M.C. Cunha[2], C.L. Ribeiro[1,2], C.C. da Silva[1,2,3,4,5], A.D. da Cruz[1,2,3,4]. 1) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Pontifical Catholic University of Goias, Genetics Master's Program, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Brazil.

   The Chromosome 17q21.31 Deletion Syndrome (MIM 610443) is a genomic disorder caused by the microdeletions between 500-650 Kb that are mediated by non-allelic homologs recombination between flaking low-copy repeats regions. The deletion at 17q21.31 shows clinical recognizable manifestation characterized by intellectual disability, hypotonia, a friendly or amiable behavior, distinctive facial features, epilepsy, heart defect and urogenital malformation. Here, we report two cases of girls who presented moderate intellectual disability, friendly behavior, mild facial dysmorphisms with long face and tubular or "pear shaped" nose with bulbous nasal tip, and epileptic seizure with de novo 17q21.31 microdeletion in Central Brazil. Conventional cytogenetics analysis by GTG banding using the software IKAROS® (Metasystems Corporation, Germany) showed the normal female karyotype 46,XX for both girls. Chromosomal Microarray Analysis (CMA) using GeneChip® CytoScan-HD™ array revealed in all two girls a de novo microdeletion spanning ~ 500 kb in 17q21.31, encompassing 9 genes (*CRHR1, MGC57346, CRHR1-IT1, MAPT-AS1, SPPL2C, MAPT, MAPT-IT1, STH, KANSL1*). The evaluation of progenitor's CMA confirmed de novo genomic imbalances in their each child. *CRHR1* and *MAPT* genes are known to be highly expressed in brain and have been implicated in behavioral phenotypes and several neurodegenerative disorders, and *KANSL1* gene is expressed in human tissues, including in the central nervous system. Haploinsufficiency of one or more of these genes within the deleted region in both girls is the most probable cause of the probands phenotype and is responsible for the phenotype seen in the Chromosome 17q21.31 Deletion Syndrome. The CMA analysis has proving to be a powerful tool to carry out genetic diagnostic and it was useful method to identify at the first time in Central Brazil the 17q21.31 microdeletion associated with intellectual disability phenotypes. The authors believe that the rare and complex phenotypes need to be investigated to allow specify phenotypes classification. Therefore, the CMA is an efficient strategy to help in delineating phenotypic variation and allow adequate clinical management and better follow up of the probands and the family.

872T

Identification of a *KAT6B* mutation in a family with developmental delay and intellectual disability leading to the diagnosis of SBBYSS syndrome via diagnostic exome sequencing. *H. Kim[1], Y. Kim[2], J. Park[2], J. Jang[3], E. Cho[3].* 1) Dept.of Medical Genetics, Konyang University Hospital, Deajon, South Korea; 2) Dept. of Rehabilitation Medicine, Konyang University College of Medicine, Daejon, South Korea; 3) Green Cross Genome, South Korea.

Developmental delay (DD) and intellectual disability (ID) are major neuropsychological disorders in children, which affect 1-3% of the general population and substantial portion of cases of DD/ID are proven to be genetic.(17.4-47.1%) Recently, heterozygous *de novo* mutation of the histone acetyltransferase encoding gene KAT6B has been recognized to cause a syndrome with congenital anomalies and intellectual disability, namely Say-Barber-Biesecker/Young Simpson syndrome (SBBYSS). Here, we present a SBBYSS syndrome of a Korean Family affected in three generations with a missense mutation in *KAT6B*, c.2292C>T (p. His767Tyr) identified by diagnostic exome sequencing(DES), which has not been reported in Korea yet. The proband was 3years old female with facial dysmorphism of bilateral blepharophimosis and strabismus and microcephaly in addition to DD. And she was diagnosed as SBBYSS syndrome with the identification of mutation in KAT6B and subsequentcy, the same mutation was found in her father, uncle, and grandmother. Thus SBBYSS syndrome was diagnosed in four affected members in three generations in the family with DD/ID. DES was useful diagnostic tool for the identification of molecular diagnosis of DD/ID and leading to accurate and appropriate genetic counseling for the family with DD/ID.

873F

Severe intellectual disability in a patient with Turner syndrome features. *U. Kappes[1,2], D.G. Basel[3], D.P. Bick[4], B. Chirempes[5], L. Weik[3], P. van Tuinen[6], J.F. Peterson[6].* 1) Department of Medicine, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Pediatrics, Division of Genomic Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 3) Department of Pediatrics, Division of Genetics, Medical College of Wisconsin, Milwaukee, WI; 4) Hudson-Alpha Institute for Biotechnology, Huntsville, AL; 5) The Advanced Genomics Laboratory, Children's Hospital of Wisconsin, Milwaukee, WI; 6) Department of Pathology, Medical College of Wisconsin, Milwaukee, WI.

Turner syndrome and its variants typically result in short stature, premature ovarian failure, and variable dysmorphic features. We report a 20-year-old female patient with a history of short stature, premature ovarian failure, sacral teratoma, neurogenic bladder, and severe intellectual disability. At age 18 classical cytogenetic analysis (50 PHA-stimulated cells) revealed a terminal Xq24 deletion in 37 cells, a ring X chromosome in 6 cells, and monosomy X in 7 cells. At that time a diagnosis of Turner syndrome was rendered. Two years later further cytogenetic studies were initiated to better understand the etiology of a phenotype that surpasses the characteristic features of Turner syndrome. Array comparative genomic hybridization (aCGH) analysis was performed on purified DNA from the proband using the CytoScan HD microarray (Affymetrix, Santa Clara, CA), and scanned with a Genechip Scanner 3000 (Affymetrix). Microarray analysis revealed a concomitant 38.5-Mb duplication of 3q25.33-q29, and an 82.9-Mb heterozygous Xq13.2-q28 deletion. The 3q25.33-q29 duplication contained 420 genes, and the Xq13.2-q28 deletion contained 962 genes including *XIST*. To confirm the location of the 3q25.33-q29 duplication, FISH analysis was performed on metaphase cells using a *BCL6* (3q27) break-apart DNA probe (Abbott Molecular, Des Plaines, IL). Positive hybridization for *BCL6* was observed on both copies of chromosome 3, in addition to the long arm of the abnormal X chromosome. The duplicated 3q segment located on the abnormal X chromosome accounts for the widely discrepant Xq breakpoints seen by the classical cytogenetic (Xq24) and microarray (Xq13.2) analyses. The mosaic cell lines observed in the patient's karyotype likely indicate a *de novo* event. Parental chromosome studies have yet to be performed to investigate balanced translocation carrier status. The intellectual disability together with a Turner-like phenotype is due to an unbalanced partial X;autosome translocation resulting in partial trisomy 3q. Genes on the abnormal X chromosome remain activated due to loss of the X-inactivation center (*XIST*). This case demonstrates that a multifaceted molecular approach may be necessary to resolve complex constitutional disorders.

874W

Functional disomy of Xp22 and *de novo* t(X;3). *A. Mohamed[1], A. Kamel[1], M. Zaki[2], M. Mekkawy[1], P. Safwat[1], I. Fadel[1].* 1) Human cytogenetics, National Research Centre, Cairo, Egypt; 2) Clinical Genetics, National Research Centre.

We report on a female patient aged 2 years complaint of delayed milestones and abnormal facies. She is the third child of healthy non consanguineous parents and had normal sibs. Since birth there were dysmorphic facial features. On examination the weight was 10.5 Kg (-1SD), Ht. 88 (mean) and head circumference 46cm(-1SD). She had hypertrichosis, depressed nasal bridge,sagging lower eye lids and low set ears. She had hypotonia and the reflexes were present. MRI, EEG and Echo were normal, abdominal sonar was normal. Her karyotype showed 46,XX,t(X;3)(3q12;Xp22.1). FISH analysis using whole chromosome paint for chromosomes 3 and X, subtelomeres 3p and q, Xp subtelomere, approved that translocation is a reciprocal translocation which is apparently balanced one. Chromosomes of both parents were normal.X chromosome inactivation performed using Late replicating chromatin technique in order to detect the pattern of X inactivation. The abnormal X chromosome revealed that the normal X chromosome is the active one in all analyzed cells and the translocated X is the inactive one, the translocated 3q part to the X chromosome escape X inactivations**.** The Xp22.1 segment translocated to 3q is out of XIST gene control and escaped X inactivation. In this patient the delayed milstones and dysmorphic features bay be due to functional disomy of Xp22,1 or other cryptic chromosome abnormalities involving Xp and 3q.

875T

Impact of long contiguous stretches of homozygosity in three girls with intellectual disability. *D.C. Silva[1,6], I.P. Pinto[1,3], L.B. Minasi[1,2], D.M.C. Cunha[1], C.L. Ribeiro[1,3], C.C. da Silva[1,2,3,4,5], A.D. da Cruz[1,2,3,4].* 1) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Genetics Master's Program, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Brazil; 6) Federal University of Goias, Animal Science PhD Program, Campus Samambaia, Goiânia, GO, Brazil.

The genetic causes of intellectual disability (ID) and autism include almost all types of genomic variations (chromosomal rearrangements, copy number variations and single gene mutations). Epigenetic alterations due to genomic variations affecting genes involved in epigenomic regulation and uniparental disomy resulting from chromosomal or segmental homozygosity are shown to contribute to the etiology of neurodevelopmental disease. Probably the commonest type of epigenomic variations in humans is long contiguous stretches of homozygosity (LCSH), and the presence of LCSH can be indicative for parental consanguinity, uniparental disomy, or segmental homozygosity for single gene recessive mutations. Herein, we report three girls with moderate intellectual disability who presented LCSH at Xq11.1q13.1 detected by Chromosomal Microarray Analysis (CMA). Karyotyping at > 550 band resolution for both three girls showed a female karyotype (46,XX). Affymetrix's GeneChip® CytoScanHD™ array revealed the same alteration in all three girls, LCSH spanning ~ 6.20 Mb in Xq11.1q13.1, with 21 genes (*SPIN4, LOC92249, ARHGEF9, MIR1468, AMER1, ASB12, MTMR8, ZC4H2, ZC3H12B, LAS1L, FRMD8P1, MSN, MIR223, VSIG4, HEPH, EDA2R, AR, OPHN1, YIPF6, STARD8, EFNB1*). Epilepsy and ID are the common phenotypic effects of all *ARHGEF9* mutations. Point mutations, rearrangements, and small deletions of *ZC4H2* gene cause a clinically variable broad-spectrum neurodevelopmental disorder of the central and peripheral nervous systems. Mutations in the *OPHN1* gene are responsible for OPHN1-related X-linked mental retardation with cerebellar hypoplasia and distinctive facial dysmorphisms. Clinically, LCSH of any size can aid in diagnosis of autosomal recessive disease through homozygosity mapping. Furthermore, it is now recognized that the effect of LCSH is not only significant for monogenic recessive disorders, but there is a role for recessive variants in complex genetic disorders. In several ways, LCSH loci appear comparable to large genomic CNVs that are well known to be associated with autism and ID, and some LCSH loci can have features of a contiguous gene disorder. Therefore, the CMA with polymorphic and non-polymorphic markers is an important diagnostic tool to identify both CNV and LCSH in patients with a wide variety of clinical indications. However, the mechanisms and consequences of LCSH are poorly understood, and the interpretation of these epigenetic mutations can represent a challenge.

Use and application of chromosome microdissection technique to isolate the 4p16.3 region. *A.P. Amancio[1,2], I.P. Pinto[1,2], C.C. da Silva[1,2,3,4], A.D. da Cruz[1,2,3].* 1) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 4) State University of Goias, UnU Eseffego, Brazil.

Around 5% of pregnancies result in the birth of a child with some congenital disorder, disability or genetic disease that compromises the development and the quality of life. Monogenic diseases or chromosomal alterations cause more than 40% of severe intellectual disability cases. The Wolf-Hirschhorn Syndrome (WHS) is a genetic disorder characterized by severe growth retardation, severe intellectual disability, severe facial dimorphism and seizures. This syndrome is caused by a terminal microdeletion at 4p16.3 region from the short arm of chromosome 4, in which the size of deletion varies among affected individuals. Conventional cytogenetics analysis by GTG banding does not have enough resolution to diagnosis of WHS. On the order hand, molecular cytogenetic techniques such as FISH and Chromosomal Microarray Analysis (CMA) are necessary for full characterization of chromosomal rearrangements associated with WHS. The aim of this study was to perform chromosome microdissection technique to isolate the chromosomal segment from 4p16.3 region. A total of 5 mL of peripheral blood was drawn using a standard vacuum extraction blood-collecting system containing heparin from a non-syndromic individual with intellectual disability to obtain the chromosomes using the cell culture. The sample from cell culture was dripped on glass coverslips for scraped chromosomal, and while manipulating the coverslip and microscope table, the needle was maintained at the high position to avoid breakage. Detachment of the chromosomes from the coverslip was achieved by gently scraping the chromosome along its vertical axis, causing the chromosome to fold around itself and finally bind to the needle. The microdissection was performed using an inverted microscope (Zeiss, Germany) with the manipulator (Eppendorf, Germany). The 4p16.3 region from chromosome 4 was isolated by chromosome microdissection method for further development and validation of the DNA probe using the FISH technique. The chromosome microdissection technique is an important approach to isolate the chromosome and construction of DNA probe that can detect many genetic syndromes and hematological disorders. Furthermore, this technique is useful for decreasing the cost of production of probes, allowing access to detection of genetic syndromes caused by microrearrangements in public health service.

Microarray analysis of an infant with a rare *de novo* 1p31.3p31.1 deletion from Central Brazil. *C.C. da Silva[1,2,3,4,5], I.P. Pinto[1,3], D.M.C. Cunha[1], C.L. Ribeiro[1,3], L.B. Minasi[1,2], A.D. da Cruz[1,2,3,4].* 1) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Genetics Master's Program, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Brazil.

The Chromosome 1p32-p31 Deletion Syndrome (MIM 613735) is rare disorder and at least 19 cases have been reported. Patients with 1p interstitial microdeletions display a number of clinical features due to a phenotype expressivity and deletion size be variable including intellectual disability, craniofacial anomalies, seizures, tooth abnormalities, urinary tract anomalies, and skeletal, cardiac as well as limb defects. Here, we report an 8 years old girl who was born to non-consanguineous parents at 37 weeks gestation, and her birth weight was 2095 g and length of 44 cm. Physical examination revealed small nose and bulbous nasal tip, low-set ears, small chin, tooth abnormalities, hypotonia, moderate intellectual disability, behavioral disturbs, and seizures requiring the use of phenobarbital. The family history revealed that her paternal relatives had intellectual disability and epileptic seizures. Karyotyping at > 550 band resolution showed a female karyotype (46,XX). Chromosomal Microarray Analysis using Affymetrix GeneChip® CytoScanHD™ array revealed a *de novo* pathogenic 10.89 Mb microdeletion at 1p31.3p31.1 (68,693,129-79,580,916) x1. This region encompassing 49 genes (*WLS, RPE65, DEPDC1, LRRC7, PIN1P1, LRRC40, SRSF11, ANKRD13C, HHLA3, CTH, PTGER3, ZRANB2-AS1, ZRANB2, MIR186, ZRANB2-AS2, NEGR1, NEGR1-IT1, LRRIQ3, FPGT, FPGT-TNNI3K, TNNI3K, C1orf173, CRYZ, TYW3, LHX8, SLC44A5, ACADM, RABGGTB, SNORD45C, SNORD45A, SNORD45B, MSH4, ASB17, ST6GALNAC3, ST6GALNAC5, PIGK, AK5, ZZZ3, USP33, FAM73A, NEXN, FUBP1, DNAJB4, GIPC2, MGC27382, PTGFR, IFI44L, IFI44,* and *ELTD1*). The progenitor's CMA confirmed *de novo* genomic imbalances in their child. Definition of chromosomal deletions can help to identify genes contributing to pathological phenotypes. The *AK5* gene is likely candidate gene that could contribute to the intellectual disability phenotype. This gene encodes a member of the adenylate kinase and is expresses exclusively in brain, thus, is associated to a specific needs of different cellular functions. The other genes in the deleted region did not appear to play a causative role for the phenotype, but we cannot exclude their involvement. Genetic evaluation of patients with intellectual disability using microarray analysis allowed obtain precise information about CNVs, identifying candidate genes contained within these regions, and provided knowledge about the clinical implications of these CNVs.

878T

Identification of microdeletion at 15q11.13 using fluorescence *in situ* **hybridization in Brazilian probands from public health service.** *V.C.P. Santos[1], S.S.S. Pereira[1,2], L.S. Teodoro[1,2], D.M.C. Cunha[1], C.L. Ribeiro[1,3], I.P. Pinto[1,3], C.C. da Silva[1,2,3,4,5], L.B. Minasi[1,2], A.D. da Cruz[1,2,3,4].* 1) Pontifical Catholic University of Goias, Department of Biology, Replicon Research Group, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 2) Pontifical Catholic University of Goias, Genetics Master's Program, Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Pesquisa e Inovação, Campus Samambaia, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Brazil.

   Prader-Willi (PWS) and Angelman (AS) syndromes are two distinct neurogenetic disorders associated with multiple anomalies and intellectual disability. Three genetics mechanisms are known to be involved in the pathogenesis: microdeletions, uniparental disomy (UPD) or loss of the imprinted gene expression in paternally or maternally 15q11-q13 region. Both disorders have clinically overlapped features with other diseases during infancy, which makes them difficult to diagnose solely relying on the clinical manifestations, therefore, definite diagnosis of PWS/AS is dependent of genetic tests. The aim of this study was report 32 cases from public health system in Central Brazil to confirm the suspect of PWS and AS. Fluorescence *in situ* Hibridization (FISH) analysis were performed using Prader-Willi/Angelman Probe that include 15q11.13 (spectrum red) and 15qter (spectrum green) according to the standard FISH protocols (Cytocell, USA), and chromosomes were counterstained with 4,6-diamino-2-phenyl-indole (DAPI). Capture and analysis of metaphases and interphase nuclei were released by Epifluorescence Microscope (Carl Zeiss, Germany) and the software ISIS® (Metasystems Corporation, Germany). Since 1997, assistant physicians from Goiás state public health system referred 32 patients with clinical indication of PWS/AS to our genetic service at both the Laboratory of Human Cytogenetic and Molecular Genetics and the Biology Department at Pontifical Catholic University in Central Brazil to perform FISH test. FISH analysis of 15q11.13 microdeletion revealed 6 (18.75%) patients with positive FISH results and 26 (81.25%) patients with negative FISH results. The method that is commonly used for PWS/AS detection is fluorescence *in situ* hybridization because 75% of the cases occurring by microdeletion and the remaining 25% could be due to UPD and imprinting gene mutation. In our cases, only 18.75% were diagnosed with 15q11.13 microdeletion, on the other hand, 81.25% of cases without 15q11.13 microdeletion could present different genetics mechanisms for PWS/AS. Therefore, it is recommended to carry on others techniques to identify these disorders such as methylation-specific PCR, multiplex ligation-dependent probe amplification, short tandem repeat linkage analysis, DNA sequencing, array comparative genomic hybridization, and chromosomal microarray analysis. In addition, it is important the correct diagnose for accurate genetic counseling for the patients and their family.

879F

The diagnosis experience for Cockayne syndrome-Complex *ERCC8* **variants in two Chinese sibings.** *H. Xie.* Capital Institute of Pediatrics ,Beijing Municipal Key Laboratory of Child Development and Nutriomic, BeiJing, China.

   Cockayne syndrome is an autosomal recessive disorder principally characterized by postnatal growth failure and progressive neurologic dysfunction. Mutations of the *ERCC6* and *ERCC8* genes are the predominant cause of Cockayne syndrome. We reported the diagnosis experience for two clinical suspected Cockayne syndrome patients in a Chinese family. Using multiple molecular techniques including whole exome sequencing, array comparative genomic hybridization and Quantitative polymerase chain reaction, we identified a maternal splicing mutation (chr5:60195556, NM_000082:c.618-2A>G) and a paternal complex exonic deletion (chr5:60211534-60213756, chr5:60212086-60217114) of the *ERCC8* and confirmed that is the pathogenesis of the two suspected patients. The microhomologies (TAA and AGCT) at the breakpoints proved microhomology-mediated FoSTeS events were involved in this complex *ERCC8* deletion. Our diagnosis experience also demonstrated the advantage of high-throughput genomic technologies in the clinical genetic diagnosis.

880W

Deep phenotypic and genetic investigation of array-CGH data reveals novel genomic disorders, position effects and refines genotype/phenotype correlations. *A. Brusco[1,2], E. Di Gregorio[1,2], E. Pasini[1,2], S. De Rubeis[11,12], G.B. Ferrero[3], Neurowes.* 1) Medical Sciences, University of Turin, Torino, TO, Italy; 2) Città della Salute e della Scienza University Hospital, Medical Genetics Unit, 10126, Turin, Italy; 3) University of Torino, Department of Public Health and Pediatrics, 10126, Turin, Italy; 4) Molecular Biotechnology Center (MBC), Computational Biology Unit, Turin, Italy; 5) University of Torino , Department of Molecular Biotechnology and Health Sciences, CAP, Turin, Italy; 6) Martini Hospital, Maternal and Infantile Department, ASL TO1, Torino, Italy; 7) Adult Autism Center, ASL TO2, CAP, Torino, Italy; 8) Hospital "Santa Croce e Carle", Cuneo, Italy; 9) University of Torino, Department of Neuro-psychiatry, 10126, Turin, Italy; 10) University of Torino, Department of Clinical and Biological Sciences, and Medical Genetics, San Luigi Gonzaga University Hospital, Orbassano (TO), Italy; 11) Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, CAP, New York, USA; 12) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, CAP, New York, USA; 13) Max Planck Institute for Molecular Genetics, Ihnestr. 63–73, Berlin, 14195, Germany.

Using an array-CGH 60K platform, we analyzed 1,023 children with unexplained developmental delay/intellectual disability (DD/ID) or multiple congenital anomalies (MCA). We identified 11.1% of pathogenic, 4.4% of possibly pathogenic and 13.8% of unknown significance deletions/duplications. We recognized rare genomic disorders, such as 4q35 duplication (Coat's like disease), 2q24.2 deletion, 18q12.2 deletion, centromeric 3q29 deletion, and 17p13.1 duplication. We detected CNVs spanning genes associated with single gene disorders in ten cases, among which deletions of *CAMTA1, NRXN1* and *WAC* genes. Lack of phenotypic segregation for a deletion in the 5'UTR region in *MBD5*, together with similar cases described in DGV, suggested rearrangements involving this part of the gene are irrelevant to *MBD5* associated phenotype. We deeply investigated our CNVs to dissect possibly novel candidates for ID/DD. We searched for FMRP mRNA targets, synaptic proteins, histone-modifying enzymes, GO ontology enrichment. We identified 62 remarkable genes, 16 of which showed strong constraints both for missense and loss-of-function mutations (*ACTR3B, BCL11B, BRSK1, BRWD3, CACNA1D, EP400, GRIA2, KIF2A, LRRC41, NAA15, NR2E1, NRXN3, OTUD7A, U2AF2, ZNF536* and *ZNF628*). We also considered strong candidates such as *DLG2* and *ASTN2* based on literature data. We identified two potential Topological Associated Domain (TAD) boundary deletions: i) a *de novo* CNV overlapped the mesomelia-synostoses syndrome critical region (MIM 600383) in a patient without skeletal anomalies. We suggest that this disease is due to a position effect rather than to *SULF1* and/or *SLCO5A1* haploinsufficiency; ii) in a family with three cases associated with psychiatric disturbances, we showed the segregation of small deletion upstream *CTNND2* possibly altering its regulatory landscape. In conclusion, deep phenotypic and genetic analyses of our cohort allowed identifying complex cases, possibly rare disease genes involved in ID/DD, and novel position effects.

881T

Identification of *PSMD12* and *PITPNC1* as candidate genes for 17q24.2 microdeletion syndrome. *T. Gambin[1,2,3], J.A. Rosenfeld[1], B. Yuan[1], C.D. Luzzi[4], A. Gomez Gutierrez[5], E. Roeder[6], K. Stringer[7], S. Sachorow[8], C.A. Bacino[1,9,10], F. Xia[1], C.A. Shaw[1], Y. Yang[1], A. Patel[1], P. Stankiewicz[1].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 3) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 4) Memorial Behavioral and Developmental Pediatrics, South Bend, IN; 5) Instituto de Referencia Andino, Bogota, Columbia; 6) Departments of Pediatrics and Molecular and Human Genetics, Baylor College of Medicine, San Antonio, TX; 7) University of Mississippi Medical Center, Jackson, MS; 8) Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 9) Department of Medicine, Baylor College of Medicine, Houston, TX; 10) Department of Pediatrics, Texas Children's Hospital, Houston, TX.

Large genomic deletions involving 17q24.2 have been reported in patients with intellectual disability (ID) truncal obesity, mood swings, and hallucinations (PMID: 22166941, 24297458), and *PRKCA, CACNG5, CACNG4, CACNG1,* and *HELZ* have been proposed as candidate genes. In our CMA database of 59,092 patients who underwent exon targeted aCGH testing, we have found four individuals with smaller-sized deletions on 17q24.2 (including three *de novo* events). These four patients presented with variable features of developmental delay/ID, dysmorphic features, hypotonia, and failure to thrive. The smallest deletion of ~ 125 kb only involved exons 5-8 of *PITPNC1*; its inheritance is unknown. The smallest region of overlap for the two *de novo* deletions (220 kb and 580 kb) and one *de novo* del-norm-del rearrangement (620 kb) contained two genes: *PSMD12* and the first exon of *PITPNC1*. By exploring our database of >7000 clinical exomes analyzed, we found a *de novo* splicing variant g.17:65340898A>G in *PSMD12* in a patient with seizures, ADHD, learning/developmental delays, autistic features, dysmorphic features, velopharyngeal insufficiency, cryptorchidism, chordee, lymphangioma, and pineal cyst. In summary, we have identified one critical region responsible for abnormal neurodevelopment in the 17q24.2 microdeletion syndrome, which contains two candidate genes, although functional information about these genes is limited. *PSMD12* encodes a non-ATPase subunit of the 19S regulator which is a part of 26S proteasome, was found to be highly expressed in frontal cortex and has very high haploinsufficiency score (HI index=0.0557). *PITPNC1* encodes a phosphatidylinositol transfer protein that plays important roles in cell signaling and lipid metabolism, and the probability of this gene being haploinsufficient is lower (HI index=0.147).

882F

Further clinical delineation of PACS1-related syndrome due to a recurrent *de novo* **pathogenic variant.** *T. Funari[1], D. Stern[2], M. Cho[1], R. Chikarmane[1], J. Hoffman[1], R. Willaert[1], K. Retterer[1], H. Crawford[3], F. Kendall[4], M. Deardorff[5], S. Hopkins[6], E. Bedoukian[7], A. Slavotinek[8], S. Vergano[9], B. Spangler[9], M. McDonald[10], A. McConkie-Rosell[10], B. Chung[2,11].* 1) GeneDx, Gaithersburg, MD; 2) Department of Pediatrics, Columbia University Medical Center, New York, NY; 3) Clinical and Metabolic Genetics, Cook Children's Health Care System, Fort Worth, TX; 4) VMP Genetics, Roswell, GA; 5) Department of Pediatrics, Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 6) Division of Neurology, The Children's Hospital of Philadelphia, The University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 7) Individualized Medical Genetics Center, Division of Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 8) Department of Pediatrics, UCSF Benioff Children's Hospital, University of California, San Francisco, San Francisco, CA; 9) Division of Medical Genetics and Metabolism, Children's Hospital of The King's Daughters, Norfolk, VA; 10) Division of Medical Genetics, Duke University Medical Center, Durham, NC; 11) Department of Medicine, Columbia University Medical Center, New York, NY; 12) Division of Genetics, Birth Defects & Metabolism, Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL.

Identifying the etiology of intellectual disability (ID) is challenging due to the genetic heterogeneity and clinical variability associated with these disorders. Whole exome sequencing (WES) has proven to be an effective tool for identifying the genetic etiology of ID in many patients. Using WES, *PACS1* was recently recognized as a novel gene for ID associated with autosomal dominant mental retardation syndrome 17 (MRD17) (MIM#615009). A recurrent, *de novo PACS1* pathogenic variant, p.Arg203Trp, has been reported in 19 individuals with a similar phenotype including ID, dysmorphic facial features, and urogenital abnormalities. Using WES, we have identified seven additional unrelated individuals who were heterozygous for this *de novo* missense variant in *PACS1.* All seven probands in our series also have ID, impaired language development, and overlapping dysmorphic facial features , such as hypertelorism, downslanting palpebral fissures, full/arched eyebrows, down-turned corners of the mouth, long eyelashes, simple ears, bulbous nasal tip, and widely-spaced teeth. Other common features shared among this cohort and the previously reported patients include seizures (in 6/7 and 12/19, respectively), structural brain abnormalities (3/5 and 12/16 who had imaging studies), oral aversion (3/7 and 11/19), hypotonia (5/7 and 8/19), aggressive outbursts (3/7 and 10/19), cryptorchidism (3/5 and 6/12 males), eye abnormalities (3/7 and 8/19), gastroesophageal reflux (5/7 and 6/19), and congenital heart disease (3/7 and 8/19). Two of the seven individuals also have hypertonia of the extremities in addition to central hypotonia, which has not been previously reported in affected individuals. PACS1 protein is a trans-golgi-membrane traffic regulator responsible for localization of protein cargo and several viral envelope proteins. PACS1 is up-regulated during fetal brain development and down-regulated after birth. The p.Arg203Trp variant is located in the furin cargo binding domain, adjacent to a CK2-binding motif necessary for PACS1 autoregulation. Previous studies in zebrafish embryos demonstrate that PACS1 plays a role in cranial neural crest migration. Currently, no other missense variants in the *PACS1* gene have been reported as pathogenic, suggesting a specific disease mechanism for p.Arg203Trp, possibly due to a gain of function. In summary, our results add to the clinical delineation of this new syndromic form of ID (MRD17).

883W

Understanding Xp22.31 duplication. *Y. Qiao[1], F. Tang[2], C. Badduke[1], S. Martell[1], H. Bagheri[1], S. Lewis[3], W. Robinson[3], L. Arbour[4], E. Rajcan-Sepaorivc[1].* 1) Dept. Pathology (Cytogenetics), BC Child and Family Research Institute, University of British Columbia (UBC), Vancouver, BC, Canada; 2) University of Calgary, Alberta, Canada; 3) Dept. Medical Genetics, UBC, Vancouver, BC, Canada; 4) Dept. Medical Genetics, University of Victoria, BC, Canada.

Xp22.31 duplications are reported in subjects with neurodevelopmental delay (NDD) and variable phenotypic abnormalities, including seizures. However, they can also be present in controls. In order to understand the role of the Xp22.31 duplication in NDD we preformed multifaceted studies in a family with an affected boy with NDD and an Xp22.31 duplication (7515787-8123310, hg19). This duplication encompasses only the *PNLPN4* and *VCX* genes and is inherited from his normal grandfather. The proband had significant NDD, verbal apraxia and facial dysmorphism including a short forehead, bitemporal narrowing, hypertelorism, wide palpebral fissures, flattened supraorbital ridges, a broad nasal root, thin upper lip, long philtrum, a high arched palate, malar hypoplasia, and posteriorly placed and low set ears. Digits and toes were widened distally with short distal phalangeal creases and prominent finger pads, mildly splayed distal phalanges, and pes planus. He also had central hypotonia, hyperextensibility of joints, thin torso, prominent scapulae, a pectus excavatum and prominence of the lower ribs. His mother had seizures, which were controlled in pregnancy with valproic acing (1000mg/day). The proband's phenotype had overlaps with the prenatal effect of valproic acid, but was overall considered to be more severe. The expression of the *PNLPN4* gene from Xp22.31 was increased in the proband and his mother. Exome sequencing revealed that the proband also carried a *de novo* missense mutation in *PURA,* and an X-linked missense mutation in *TMLHE,* inherited from the maternal grandmother. Both genes are associated with NDD, and *TMLHE* is also linked with seizures. Skewed X-chromosome inactivation (XCI) (94:6) was observed in the mother with preferential inactivation of maternal X (*TMLHE* mutation) and activation of the paternal X (Xp22.31 duplication). The *TMLHE* mutation carrier grandmother also showed skewed XCI (91:9). We propose that a combination of dosage sensitive genes in the Xp22.31 duplication (e.g. *PNLP4* is a lipase with a role in retinoid homeostasis, critical for development and growth), as well as additional genetic "hits" (e.g. mutations in NDD genes) contribute to the severity of the phenotype in some of the subjects with Xp22.3 duplication. More widespread use of next generation sequencing and functional analysis of Xp22.31 genes in cells from carriers could contribute to better understanding of phenotypic variability in subjects with Xp22.31 duplication.

884T

Fragile-X Syndrome: Advances in diagnosis in the public health system in central Brazil. *T.C. Vieira[1,3,4], M.A.D. Gigonzac[1,2,3], L.S. Teodoro[4], L.B. Minasi[4], C.C. Da Silva[1,2,3,4], A.D. Da Cruz[1,2,4].* 1) Human Cytogenetics and Molecular Genetics Laboratory (LaGene) Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 2) Biotechnology and Biodiversity Graduate Program, Federal University of Goiás, Campus Samambaia, Goiânia, Goiás, Brazil; 3) State University of Goiás (UEG), UnU Goiânia, Avenida Anhanguera, Goiânia, Goiás, Brazil; 4) Graduate Program in Genetics (MGene)/Replicon Research Center, Catholic University of Goiás (PUC-GO), Setor Universitário, Goiânia, GO, Brazil.

Fragile X Syndrome (FXS) is the most common cause of Intellectual Disability inherited, with an estimated prevalence of 1/4000 male births. The most common etiology of the syndrome is associated with a CGG trinucleotide expansion and methylation Xq27.3 region involving the *FMR1* gene. This disorder is commonly underdiagnosed in children and adolescents, given the high clinical variability. This study aimed to describe the implementation of a method of molecular diagnosis in patients with intellectual disability suggestive of FXS from the Public Health System in Central Brazil. Genomic dsDNA of patients was isolated and amplified by polymerase chain reaction using the *FMR1* Amplidex® Kit. The fragments were separated by capillary electrophoresis in the ABI 3500 Genetic Analyzer (Applied Biosystems®), and analyzed using GeneMarker® program. It was possible to detect changes in the *FMR1* gene, like full mutation and pre-mutations, consistent with the phenotypes observed in patients. Our study reports the results of TP-PCR of 26 unrelated individuals, 9 females and 17 males, with aging ranging from 3 to 18 years old. The normal CGG range was 8–35 repeats, and 29, 28 and 30 repeats represented the most common alleles corresponding to 20%, 11.5% and 11.5%, respectively. Two (7.7%) full mutation was identified in a male individual. The size of the fragments was 977pb with 249 CGG expansions, and 927pb with 233 CGG expansions. Moreover, pre-mutation was identified in another male patient who showed a fragment with 632pb involving an expansion of 134 CGG copies. Thus, the proposed method proved to be rapid and effective for the diagnosis of FXS, permitting genetic counseling suitable for families. On the other hand, the inclusion of this molecular testing in a Brazil public health service has allowed bridge the gap between the available technologies and effective diagnosis, universalizing access to genetic testing in central Brazil.

Küry[1].* 1) CHU Nantes, Service de Génétique Médicale, Nantes, France; 2) CHU Angers, Département de Biochimie et Génétique, Angers, France; 3) UMR INSERM 1083 - CNRS 6214; 4) CHRU Brest, Génétique médicale, Brest, France; 5) CHU Poitiers, Service de Génétique, EA 3808 Université Poitiers, Poitiers, France; 6) CHU Rennes, Service de Génétique Clinique, CNRS UMR6290, Université Rennes1, Rennes, France; 7) CHU Tours, Service de Génétique, Tours, France; 8) Inserm, UMR 1087, l'institut du thorax, CHU Nantes, Nantes, France; 9) CNRS, UMR 6291, Université de Nantes, Nantes, France; 10) Western France consortium, HUGODIMS is the French acronym standing for "Projet inter-régional Français des Hôpitaux Universitaires du Grand Ouest pour l'exploration par approche exome des causes moléculaires de Déficience Intellectuelle isolée ou syndromi.

Background: Intellectual disabilities (ID) constitute a heterogeneous group of syndromic and non-syndromic disorders of variable prevalence. The number of genes accounting for the vast majority of ID is so important that a targeted analysis is questionable. Numerous studies pointed to the relevancy of exome sequencing of patients/parents trios to increase diagnostic yield. **Purpose:** Our goal was to determine the efficiency of exome sequencing to unravel the molecular cause of ID in patients with severe phenotype seen by clinical geneticists from Western France hospitals. Method: Following a trio-based exome sequencing strategy, we investigated 75 patients with severe ID which could not been explained by fragile X syndrome, copy number variations (CGH array) or even by known candidate genes. **Results:** For almost 50% of the cases tested so far, we have been able to explain the molecular cause of the disease or highlight new ID candidate genes. **Conclusions:** Our work confirmed that the trio-based whole-exome sequencing is a powerful approach for diagnosis and research. New identified genes highlighted the importance of several signaling pathways such as the NMDAR one, in the occurrence of neurodevelopmental disorders.

The evaluation of CNV in an infant with intellectual disability prenatally exposed to crack-cocaine detected by Chromosomal Microarray Analysis. *A.S. da Cruz[1,2], L.G. Oliveira[1,2], D.M.C. Cunha[1], C.L. Ribeiro[1,3], I.P. Pinto[1,3], L.B. Minasi[1,2], E.O.A. Costa[1,2], C.C. da Silva[1,2,3,4,5], A.D. da Cruz[1,2,3,4].* 1) Biology, Pontifícia Universidade Católica de Goiás, Department of Biology.Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 2) Genetics Master's Program, Pontifical Catholic University of Goias , Rua 235, n. 40, Bloco L, Área IV Setor Universitário, Goiânia, GO, Brazil; 3) Federal University of Goias, Biotechnology and Biodiversity PhD Program, Rede Centro Oeste de Pós-Graduação, Campus Samambaia, Goiânia, GO, Brazil; 4) Human Cytogenetics and Molecular Genetics Laboratory, Secretary of Goias State for Public Health, Goiânia, GO, Brazil; 5) State University of Goias, UnU Eseffego, Av. Anhaguera, N° 3228, Setor Leste Vila Nova.

Prenatal crack-cocaine exposure affected brains are characterized with widespread structural and functional alterations, and are associated with deficits in intelligence, language skills, executive functioning, impulse control and attention, and evidence of internalizing and externalizing behavioral traits. Herein, we reported the genomic imbalances in a boy who his parents were prenatally crack-cocaine dependent users referred by assistants from public health system of Central Brazil. A 2-years old male proband born to non-consanguineous parents, at 39 weeks gestation and his birth weight was 2800 g. Physical examination of the proband reveled difficulty of gait in his left leg, claw left hand deformity, mild intellectual disability, and a height of 94 cm, a weight 1400 g. Both parents are crack depends users and even during the proband's pregnancy. Conventional cytogenetics analysis at about 550 band resolution using the software IKARO® (Metasystems Corporation, Germany) showed the proband with a male karyotype (46,XY), without any suggestion of chromosome alteration. Chromosomal Microarray Analysis (CMA) using Affymetrix GeneChip® CytoScanHD™ array with the reduced standard segments filters recommended by manufacturer, comprising for losses and gains a minimum of 25 and 50 markers, respectively, in a > 1kb length. The CMA revealed small CNVs between 1 to 17 kb. Three *de novo* microduplications at Xq13.3, Xq24 and Xq28 regions, and three *de novo* microdeletions involving 2q33.2, Xq26.1 and Xq27.1 regions were identify. None genes were identified in Xq13.3, Xq26.1 and Xq27.1 regions. The 17 kb microduplication in the *SLC25A43* gene at Xq24 region is widely expressed in the central nervous system, and the 10 kb microduplication in the *MECP2* gene at Xq28 region is required for maturation of neurons and mutations in this gene can cause Rett Syndrome, mental retardation, encephalopathy, and have been implicated in autism susceptibility. *De novo* small CNVs are also observed in different types of exposure to ionizing radiation and chemical agents. The authors suggest that the exposure before and during the pregnancy of crack-cocaine could increase the genomic instability and if not adequately repaired, these DNA damage would cause high frequency of small CNVs seeing in the proband.

887T

***De novo* single nucleotide and structural variants in the *CACNA1C* gene detected with array and WES in a diagnostic cohort of 10,731 patients with intellectual disability: Disease-causing or incidental findings?** *N. de Leeuw[1], L. Vissers[1], H.G. Yntema[1], C. Marcelis[1], T. Rinne[1], M. Ruiterkamp-Versteeg[1], W.M. Nillesen[1], N. Leijsten[1], S.J. Stevens[2], A.P.A. Stegmann[2], A.D.C. Paulussen[2], C. Gilissen[1], J.Y. Hehir-Kwa[1], R. Pfundt[1].* 1) Department of Human Genetics; Radboud Institute for Molecular Life Sciences and Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, the Netherlands; 2) Department of Clinical Genetics, Maastricht University Medical Center+, Maastricht, the Netherlands.

The *CACNA1C* gene is a known dominant disease gene associated with Timothy syndrome and Brugada syndrome, both characterized by heart arrhythmias with a high incidence of sudden death. So far, only missense variants have been reported in this gene that encodes the alpha-1C subunit of voltage-sensitive calcium channels present in cardiac muscle, skeletal muscle and brain. There is evidence that *CACNA1C* plays a role in brain morphology and function and genetic variations in *CACNA1C* have been found to be associated with neuropsychiatric disease, in particular schizophrenia and autism. So far, no disease-causing *CACNA1C* variants have been described in the aetiology of intellectual disability (ID). We report a total of 10 *de novo* variants involving *CACNA1C*, including one nonsense, one frameshift and three missense variants as well as one terminal and four interstitial copy number losses encompassing *CACNA1C* in five males and five females from a total of 10,731 patients with ID who were tested in our diagnostic laboratory by genome wide SNP-based array analysis (n=8,480) or Whole Exome Sequencing (WES) trio analysis (n=2,251), including Copy Number Variant (CNV) analysis in WES data. The three missense variants were detected with WES in three unrelated patients with ID, without a cardiac phenotype being reported. Because none of these missense variants had been reported in literature and were not listed in the ExAC database, these variants were considered as incidental findings (IFs) and hence anonymously discussed in our multidisciplinary committee of IFs. All three were classified as a Class 3 variant and therefore none of these were reported back to the requesting clinician by the committee, but were labelled as potential candidate gene variants for ID. Subsequent analysis of >2,000 control trio studies using WES or Whole Genome Sequencing did not reveal any *de novo* variants in *CACNA1C*. Moreover, this gene has a Residual Variation Intolerance Score of -2.09, a probability of Loss-of-Function (LoF) intolerance of 1.00, a high Z score of 6.41 (for synonymous and missense variants), and a high rank Haploinsufficiency Index score of 8.42, all indicating that the *CACNA1C* gene is (extremely) intolerant to variation. Based on our diagnostic data from genome wide array and WES analysis in a total diagnostic cohort of more than 20,000 individuals, we conclude that both structural and nucleotide LoF variants leading to *CACNA1C* haploinsufficiency are likely to cause ID.

888F

Genetic testing of idiopathic intellectual disability patients with the 505 gene custom NGS panel DI GeneProfile.

Sistemas Genomicos, Valencia, Valencia, Spain; 3) New Technologies Lab. Sistemas Genomicos, Valencia, Valencia, Spain.

Intellectual disability (ID) is the most common developmental disorder with a prevalence of 1-3% of the population worlwide and a lifetime estimated cost of $1 million/individual. Benefits to establishing a diagnosis for both primary care providers and families include prognosis and treatment options, as well as genetic counselling. To date, 60% of ID patients remain without a diagnosis. Most severe forms have a genetic basis, with underlying mutations occurring at scales of resolution ranging from large cytogenetic anomalies to point mutations. At this level, there is a high heterogeneity, with >500 genes associated to ID. **Statement of purpose:** With the aim to achieve a higher diagnostic yield in patients with ID, we have designed a NGS gene panel targeting 505 genes asocciated with ID. Our bioinformatics pipeline allows the detection of SNVs and indels, as well as CNVs at a single exon resolution. **Methods & samples:** The design interrogates 2.1 Mb of 505 genes, including the entire coding region plus the intronic adjacent regions. Probes were captured using SureSelect (Agilent); sequencing was performed in MiSeq/HiSeq Illumina platforms. Nucleotide variants were confirmed by Sanger. CNVs were confirmed by MLPA, QMPSF and/or variant allele ratio observation when possible. Samples included both syndromic and non-syndromic patients, as well as one couple with offspring affected with lissencephaly, and a prenatal sample with clinical suspicion of Meckel syndrome. **Summary of results:** Before testing the clinical samples, the panel was technically validated with 8 control samples (HapMap) obtaining a sensibility >99% and a specificity of 97% for SNVs/indels. Since March 2015 to date, 51 patient samples have been analyzed, including a prenatal case that in spite of its previous assumption of Meckel syndrome, was finally diagnosed as McKusick-Kaufman. Out of the total, 15 positive diagnosis have been made so far (29%) including both nucleotide variants and CNVs, represented among some of them Mental retardation-hypotonic facies syndrome , Rett syndrome, Kabuki syndrome, Bohring-Opitz syndrome, Coffin-Siris syndrome, Lissencephaly, XL Hydrocephalus, Treacher Collins, or Mental Retardation XL 90. **Conclusions:** Our NGS gene panel proves to be a reliable and efficient diagnostic platform to detect CNVs and nucleotide variants, to well oriented cases and to not so clear ones, and hence helps the diagnosis of ID patients, which has a positive impact in their lifes.

The Intellectual Disability (ID) is one of the most prevalent development disorders, which appears before 18 years of age, characterized by adaptive and cognitive limitations with significant impairment in intellectual functioning. Due to its heterogeneity, the etiology of ID is variable and difficult to identify, often referred as idiopathic intellectual disability. Several studies highlight the genetic changes as factors that significantly contribute to this condition. The aim of this study was to investigate the genomic alteration of idiopathic intellectual disability in an 11 years-old female proband. Initially we conducted the conventional cytogenetic analysis by GTG banding using the software Ikaros® (Metasystems Corporation, Germany) to identify potential chromosomal abnormalities. Subsequently, Chromosomal Analysis of Microarrays (CMA) using GeneChip® CytoScanHD (Affymetrix, USA) was carry on to identify microrearrangements. In additional, the molecular analysis of the promoter region of the *FMR1* gene at Xq27 chromosome was performed by capillary electrophoresis genetic analyzer ABI3500 (Applied Biosystems®) to check possible CGG expansions. The karyotype showed the normal female karyotype 46,XX. Chromosomal microarray analysis revealed a *de novo* microdeletion spanning ~ 4.18 Mb in Xq27.3-q28, encompassing 33 genes (*SLITRK2, TMEM257, MIR890, MIR888, MIR892A, MIR892B, MIR891B, MIR891A, CXorf51A, CXorf51B, MIR506, MIR507, MIR508, MIR514B, MIR509-2, MIR509-1, MIR509-3, MIR510, MIR514A1, MIR514A3, MIR514A2, FMR1-AS1, FMR1, FMR1NB, AFF2, IDS, LINC00893, CXorf40A, MAGEA9, MAGEA9B, HSFX2, HSFX1, TMEM185A*). The progenitor's CMA confirmed *de novo* genomic imbalances in their child. Five genes (*TMEM257, FMR1, FMR1NB, IDS,* and *TMEM185A)* presented direct relation with the phenotype of ID and neurological disorders. Furthermore, molecular analysis of the region of the *FMR1* gene identified an allele with 28 repeats and the absence of the other allele on chromosome X. This study reinforces the importance of holding the chromosomal microarray analysis and the fragile X test for detecting CGG repeats as a diagnostic method in patients with idiopathic intellectual disabilities, contributing to the description of rare chromosomal changes or not previously described in the literature.

890T

De novo KCNH1 **mutations in four patients with syndromic developmental delay, hypotonia and seizures.** *N. Matsumoto, R. Fukui, N. Miyake.* Yokohama City University Graduate School of Medicine, Yokohama, Japan.

   The voltage-gated Kv10.1 potassium channel, also known as ether-a-go-go-related gene 1, encoded by *KCNH1* (potassium voltage-gated channel, subfamily H [eag-related], member 1) is predominantly expressed in the central nervous system. Recently, de novo missense *KCNH1* mutations have been identified in six patients with Zimmermann-Laband syndrome and in four patients with Temple-Baraitser syndrome. These syndromes were historically considered distinct. Here, we report three de novo missense *KCNH1* mutations in four patients with syndromic developmental delay and epilepsy. Two novel *KCNH1* mutations (p.R357Q and p.R357P), found in three patients, were located at the evolutionally highly conserved arginine in the channel voltage sensor domain (S4). Another mutation (p.G496E) was found in the channel pore domain (S6) helix, which acts as a hinge in activation gating and mainly conducts non-inactivating outward potassium current. A previously reported p.G496R mutation was shown to produce no voltage-dependent outward current in CHO cells, suggesting that p.G496E may also disrupt the proper function of the Kv channel pore. Our report confirms that *KCNH1* mutations are associated with syndromic neurodevelopmental disorder, and also support the functional importance of the S4 domain. Acknowledgements: Saitsu H, Tsurusaki H, Sakai Y, Haginoya K, Takahashi K, Hubshman MW, Okamoto N, Nakashima M, Tanaka F are highly appreciated for their contribution to this study.

Application of a targeted next generation sequencing (TNGS) strategy for the molecular diagnosis of intellectual disability. *G. Royer[1], S. Hanein[2], A. Elmorjani[1], M. Rio[1,2], C. Fourrage[1,2], J. Amiel[1,2], V. Cormier-Daire[1,2], G. Baujat[1,2], C. Bole-Feysot[2], P. Nitschke[2], S. Lyonnet[1,2], J.P. Bonnefont[1,2], A. Munnich[1,2], L. Colleaux[2], J. Steffann[1,2], G. Barcia[1,2]. 1) Genetics Dept, Hosp Necker-Enfants Malades, Paris, France; 2) Imagine Institute for Genetic Diseases, Paris, France.*

   Purpose: Intellectual disability (ID) represents the leading cause for referral in the Genetics Department of the Necker Hospital with about 7000 patients every year. Trio whole exome sequencing (WES) is a powerful approach to gain insight into the genetic bases of ID, but it remains costly and time consuming. Moreover, it can be a source of uncertain or incidental findings, and is therefore less relevant for the diagnostic setting. We developed a custom targeted next generation sequencing (TNGS) strategy for the molecular diagnosis of ID, including all genes whose mutations have already been reported in at least two unrelated patients. Methods: Genomic DNA libraries were performed using SureSelect XT Target Enrichment Reagent Kit according to the suppliers' recommendations, and were subjected to custom targeted DNA panel enrichment. 4615 regions of interest of 253 ID genes were captured with the 120-pb cRNA baits designed using the SureDesign software (Agilent). The targeted regions, encompassing 1,556 Mb of DNA, were sequenced by synthesis on an Illumina HiSeq2500, and data were analysed through the Imagine Bioinformatics core facilities. Results: We analysed 167 patients including 32 patient-parents trios, and 135 index cases. We identified pathogenic or probably pathogenic variants in 39/167 patients (23%) and variants of unknown significance in 25/167 (15%). Pathogenic or probably pathogenic variants affected genes involved in autosomal dominant ID in 32/39 cases and in X-linked ID in 7/39. Considering the variants of unknown signification, the majority affected genes involved in X-linked ID (13/25) and was associated with atypical phenotypes. Conclusions: With a diagnostic yield of 23%, TNGS is an efficient strategy for the first-step genetic screening of ID, avoiding incidental findings, and at a lower cost compared to WES. Even if targeted approaches are restricted to a few hundred genes, interpreting variants generated by TNGS is challenging. A dynamic interaction between physicians and molecular biologists is necessary to interpret TNGS results and to draw genotype-phenotype correlations. TNGS, enabling a comprehensive screening of all known genes involved in ID, offers a rapid, cost effective and relevant selection of patients available for the identification of novel genes by WES and WGS in the research setting. .

892W

Further clinical delineation of SATB-2 associated syndrome and its possible therapeutic interventions. *A.L. Williamson[1], M. Kano-Lueckerath[2], K. Oishi[1].* 1) Departments of Genetics & Genomic Sciences, Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Departments of Internal Medicine, Pediatrics, Mount Sinai Beth Israel, New York, NY.

Introduction: SATB2–associated syndrome (MIM 612313), a rare and recently recognized genetic disorder, is associated with expressive speech delay, intellectual disability and facial dysmorphism. This condition is caused by either heterozygous mutations in the *SATB2* gene or contiguous chromosomal deletion of 2q33.1 that includes *SATB2*. SATB2 is a DNA binding protein with a role in chromatin remodeling and its haploinsufficiency causes SATB2–associated syndrome. **Case:** The patient is a Japanese female who developed severe progressive hypotonia, postnatal growth restriction, and developmental delay particularly with language difficulties in early infancy. At the age of 9, she was enrolled in extensive physical, occupational, and speech therapies. On our exam at 11 years old, she had short stature (4 %ile) with low weight (0.01 %ile) with intellectual disability, mild hypotonia, and facial dysmorphism including large frontal incisors. She was able to walk and run without difficulties and communicated with well-preserved receptive language skills. **Objective:** To identify and characterize molecular cause of the patient's condition and review the clinical outcome from the interventions she received. **Methods:** Genomic DNA from the patient and her mother were used for next generation and Sanger sequencing. Retrospective chart review was done. **Results:** Whole exome sequencing identified a heterozygous variant c.715C>T, p.R239X in the *SATB2* gene, which was predicted to be a pathogenic variant with an introduction of a stop codon. This variant was presumed to be *de novo.* The review of her clinical history and physical exam revealed that the extensive therapies remarkably improved her muscle strength, emotional expression and communication skills including recognition of written words, while she is still not able to speak meaningful words. **Discussion:** This variant has been described in two out of the eight patients with mutations in *SATB2*, suggesting that the p.R239X is a recurrent hotspot mutation in SATB2-associated syndrome. Abnormal tooth development is a part of the clinical features of this syndrome. As observed in our patient, macrodontia was seen in three previously reported cases, indicating that macrodontia should a part of the clinical phenotype of the disorder. While no large-scale Cohort studies have been employed, it is speculated that intensive interventions may be beneficial to restore social and physical functions in patients with SATB2-associated syndrome.

893T

Haploinsufficiency of E3 ubiquitin-protein ligase gene *TRIP12* **causes syndromic intellectual disability.** *J. Zhang[1,2], T. Gambin[1,3,4], J. Rosenfeld[1], M. Albalwi[5], L. Al-Gazali[6], A. Lalani[1,2], Y. Yang[1,2], A. Patel[1,2], F. Xia[1,2], P. Stankiewicz[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 2) Baylor Miraca Genetics Laboratories, Houston, TX; 3) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 4) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 5) King Abdulaziz Medical City, Riyadh, Saudi Arabia; 6) Department of Paediatrics, College of Medicine and Health Sciences, United Arab Emirates University, Al Ain, United Arab Emirates; 7) Departments of Pediatrics and Molecular and Human Genetics, Baylor College of Medicine, San Antonio, Texas; 8) UT Southwestern Medical Center, Children's Health Children's Medical Center Dallas, Texas; 9) Tripler Army Medical Center, Honolulu, Hawaii; 10) Genetics & Metabolism, Children's Hospital, Aurora, Colorado; 11) Lauren E. King, Vanderbilt Children's Hospital, Nashville, Tennessee; 12) Department of Pediatrics, Baylor College of Medicine, Houston, Texas; 13) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 14) Texas Children's Hospital, Houston, Texas.

Whole exome sequencing (WES) and chromosomal microarray analysis (CMA) in individuals with intellectual disabilities (ID) and autistic spectrum disorders (ASDs) have facilitated discoveries of many novel neurodevelopmental disease genes. Here, we report eight unrelated patients referred for clinical WES or CMA in whom we identified pathogenic heterozygous variants involving the *TRIP12 (*thyroid hormone receptor interactor 12) gene, encoding a member of the HECT domain E3 ubiquitin ligases family. Most recently, variants in *TRIP12* have been reported in few patients with developmental delay (DD), ASDs, language delay, macrocephaly, hypotonia, and facial dysmorphism (PMID: 24768552, 25418537, 26777411). *TRIP12* has been classified as category 3 (suggestive evidence) in SFARI autism gene scoring. A 4-year-old boy (pt 1) with global psychomotor delay, ASDs, hyperactive and destructive behavior, and dysmorphic features carried a *de novo* c.3446_3447delCA (p.S1149X). In a 2.8-year-old male (pt 2) with speech delay, dysmorphic features, and aggressive behaviors, WES revealed c.1145-2A>C; his mother was negative for this pathogenic variant, while the father was not available for study. A 9-year-old male (pt 3) with a *de novo* c.2979dupA (p.G994fs) manifested delayed motor milestones, delayed speech, autism, intellectual disability, dysmorphic features, and obesity. Clinical evaluation of a 15-year-old male (pt 4) with a *de novo* 18 kb deletion encompassing 9 exons of *TRIP12* detected by exon targeted aCGH revealed moderate DD, minor dysmorphic features, and obesity. 7-year-old boy (pt 5) presenting with cognitive delay, autism, speech delay, and learning problems had a 29 kb deletion overlapping 17 exons of *TRIP12*. Four exon deletion of *TRIP12* was identified in a 15-year-old male (pt 6) with DD. In a 4-year-old girl (pt 7) with DD, dysmorphic features, unilateral sensorineural hearing loss, and mild obesity CMA revealed a *de novo* 940 kb deletion encompassing *TRIP12* and 7 adjacent genes. Finally, 22-month-old girl (pt 8) with ID, epilepsy, autism, mixed receptive and expressive speech delay had a *de novo* deletion of 1.7 Mb, involving *TRIP12* and 3 other genes. Our data implicate *TRIP12* as playing an important role in neurodevelopment, and its haploinsufficiency resulting in ID*,* autism, and dysmorphic features.

894F

Clinical findings in a girl with 8p23.1-p22 duplication. *I.O Focsa[1], I. Streata[2], S. Serban Sosoi[2], L.C Bohiltea[1], M. Ioana[2], M. Budisteanu[3,4,5].* 1) Carol Davila University of Medicine, Bucharest, Romania; 2) University of Medicine and Pharmacy, Craiova, Romania; 3) Prof. Dr. Alex. Obregia Clinical Hospital of Psychiatry, Bucharest, Romania; 4) Victor Babes National Institute of Pathology, Bucharest, Romania; 5) Titu Maiorescu University, Bucharest, Romania.

Introduction: Unique to chromosome 8 is a region in the p arm of about 15 Mbp, which has an abnormally high mutation rate and is genetically very divergent between humans and chimpanzees. This strongly implies that the region may be implicated in the evolution of the human brain. Many of its genes and their protein products are involved in critical process of proper brain development and function: neurogenesis, neuronal migration, and synaptic connectivity. Aim: We present a case report on 9 years-old female patient with 8p23.1-p22 duplication and complex phenotype. Material and method: The child was referred in the pediatric neurology department at 2 ½ years for global developmental delay. After a full evaluation including: clinical, neuropsychiatric and psychological examinations, biological tests, EEG, heart ultrasound, cerebral CT scan, we noted: dysmorphic features (skin pigmentary anomalies, hypertelorism, low inserted columella, micrognathia, broad malformed fingers), intellectual disability, speech delay and language development. Heart ultrasound showed atrio-ventricular septal defect and left ventricular hypertrophy. CT scan revealed a mild supra- and infratentorial cortical atrophy. Cytogenetic investigation karyotype and array-based comparative genomic hybridization (aCGH) on a 60K Agilent platform have been performed. Results and discussion: A 3.97 Mb duplication at 8p23.1-p22 was identified by aCGH investigation, as a sole aberration. The duplicated region, with genomic boundaries 12039930 - 16010296 (hg19) contains about 51 genes several listed as pathogenic in OMIM: *TUSC3* (OMIM 601385) encodes a protein involved in the vertebrate plasma membrane magnesium ion transport system and has been associated with mental retardation; *DLC1* (OMIM 604258) gene playing a critical role in biological processes such as cell migration and proliferation. Only few cases with similar duplications that partially overlap the region detected in our patient have been reported so far. Some characteristics: delayed speech and language development, intellectual disability, are reported in most of the patients. Conclusion: Our patient brings new insight in the phenotype of this rare chromosomal imbalance. The phenotype of our patient will be compared with those of other patient with the same duplication previously described to further delineate the phenotype-genotype relationship.

895W

Mosaic supernumerary marker chromosome containing euchromatin 1q21.1q24.2 in a patient with global developmental delay, facial dysmorphism and diffused nevoid hypermelanosis. *H. Li[1], A. Bibb[1], J. Sloan[2], D.G. Castillo[2], W. Kim[2], B. Bunke[2], M. Hegde[2], Z.Y. Dai[2].* 1) Division of Medical Genetics, Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Emory Genetics Laboratory, Department of Human Genetics, Emory University, Decatur, GA.

Objective: To investigate the genetic etiology in a 20 month-old boy with global developmental delay, facial dysmorphism, strabismus, laryngomalacia, diffused linear and whorled nevoid hypermelanosis. Brain MRI revealed mild brainstem dysplasia. **Methods:** Given his characteristic skin finding suggesting mosaicism, we performed skin biopsy with mixed hyperpigmented and normal skin region for cytogenetic study, including single nucleotide polymorphism (SNP) microarray, chromosome analysis and Fluorescence *In Situ* Hybridization (FISH). **Results:** A low-level mosaic (~18%) 26.6 megabase (Mb) duplication of chromosome 1q21.1q24.2 was detected by Affymetrix CytoScan HD microarray. This mosaic duplication may be even larger since there are no microarray probes for the heterochromatin region of chromosome 1q12 and the first microarray probe distal to the centromere of chromosome 1 had low-level duplication. FISH using a probe RP11-137A12 located at 1q23.3 confirmed an extra signal present in approximately 34% (17/50) interphase cells analyzed. Chromosome analysis revealed a mosaic small marker chromosome, interpreted as a supernumerary chromosome containing the centromere of chromosome 1 to chromosome 1q24.2. Therefore, the low-level duplicated region is from chromosome 1q10 to chromosome 1q24.2. **Conclusion:** This is the first reported patient carrying a mosaic small supernumerary maker chromosome containing euchromatin 1q21.1q24.2. Our study emphasizes the need of combining different techniques for low-mosaicism marker identification. It also contributes to the delineation of the partial proximal trisomy 1q phenotype.

896T

Chromosomal translocation, cnv deletion and missense mutations associated with intellectual disability in consanguineous families from Jordan. *T. Froukh[1,2], X. Zhu[2], V. Shashi[3], D. Goldstein[2], E. Heinzen[2].* 1) Biotechnology and Genetic Engineering, Philadelphia University, Amman, Jordan; 2) Institute for Genomic Medicine, Columbia University Medical Center, New York, NY; 3) Duke University School of Medicine, Durham, NC.

Intellectual disability (ID) is primarily diagnosed based on IQ less than 70 and usually associated with global developmental delay. The prevalence of ID is 1 to 3% which tends to be higher in low-income countries and in inbred communities with high consanguinity. In Jordan, the genetic bases of ID are largely unstudied, however approximately 40% of marriages are consanguineous suggesting that recessive disease may be a major contributor. In this study, we used whole exome sequencing (WES) and homozygosity mapping to identify the genetic causes of ID in ten consanguineous families from Jordan with one or more intellectually disabled progeny. In a multiplex family, paternal translocation t(5;11) (p15.33-15.1; q23.3-q25) has led to two groups of aneuploid progeny due to malsegregation. While the two groups of the progeny are intellectually disabled, they have distinct phenotypes due to the distinct deletion/duplication. A *de novo* CNV deletion with 3.5Mb on 17p11.2, previously associated with Smith Magenis Syndrome was detected in another family with clinical features in the affected child consistent with this syndrome. Two intellectually disabled probands from two different families were found to have a homozygous missense variant in genes previously implicated with ID: (1) pA710V in *GUCY2D* associated with Leber congenital amaurosis 1, and (2) p.D312N *NAGLU* causing Mucopolysaccharidosis type IIIB; both were found to have similar phenotypic features associated with these disorders. We also highlight new candidate genes in six families with autosomal recessive inheritance pattern. This study is one of the first studies to look at the genetic bases of ID in Jordan, further demonstrates the power of consanguineous families to reveal the genetic basis of disease in small patient populations, and strongly motivates larger gene discovery endeavors in the Jordan population.

897F

Use of a cen (2) CY3 PNA probe together with an FITC telomere probe for detecting telomere size differences in T-lymphocyte interphases from older people with Down syndrome with and without mild cognitive impairment. *E.C. Jenkins[1], L. Ye[1], E. Marchi[1], S. Krinsky-McHale[1], W. Zigman[1], N. Schupf[1,2], W. Silverman[3].* 1) Human Genetics, NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Taub Institute for Alzheimer's Disease and Aging Research, Columbia University, New York, NY; 3) Kennedy Krieger Institute and Johns Hopkins Hopkins University School of Medicine, Baltimore, MD.

Jenkins et al. (2006, 2008, 2010, 2012, and 2016) have shown that it is possible to detect reduced telomere number and size (quantified by light intensity as well as physical lengths) in short-term T-lymphocyte cultures from older people with Down syndrome (DS) with mild cognitive impairment (MCI-DS) or dementia. For all of these studies, as well as for the cases described below, dementia status was determined based on longitudinal assessments of cognition and function explicitly appropriate for this population and able to distinguish adult-onset impairment from pre-existing developmental disability. In the course of our studies using a MetaSystems image analyzer in combination with ISIS software and a Zeiss Axioskop 2 plus microscope, we obtained a centromere 2 FITC probe that provided a non-telomere standard. This enabled us to develop light intensity ratios from telomere intensities/cen2 intensities, using FITC probes with metaphase chromosome preparations. However, we could not distinguish the cen (2) FITC probe from telomere FITC probes in interphase. We have now obtained a cen (2) CY3 probe (gift from DAKO/Agilent), and can measure the FITC telomere light intensity (blue green) units/cen(2)CY3 (red) light intensity units ratio as well as total FITC fluorescence (as we had previously) in interphase . We used FITC/CY3 light intensity ratios to analyze telomere length in interphases in those with compared to those without MCI-DS. Four age- and sex-matched female pairings and four age and sex-matched male pairings all showed evidence of MCI-DS associated telomere shortening ($p<.0094 – p<.000000$). This suggests the usefulness of adding the CY3 probe in studies of telomere length in this and other populations.   This paper has no conflicts of interest relating to money or contents of the article. Inheritance patterns may not always be as expected: Diagnostic exome sequencing (DES) uncovers alterations in X-linked genes in equal amounts in males and females with intellectual disability. *S. Tang, K. Hagman, T. Cain, H. Newman, Z. Powis.* Ambry Genetics, Aliso Viejo, CA.

Diagnostic exome sequencing (DES) uncovers a positive finding in a characterized gene in roughly 30% of patients with a broad range of underlying Mendelian disorders.   Among the first 2,000 patients undergoing DES, 1,364 (68.2%) patients were referred for intellectual disability (ID). Overall among patients with ID, a positive finding in a characterized gene was identified in 28.4% (388).   The rate of positive findings in characterized genes at the time of original analysis was higher in females (30.8%; 178/578) than in males (26.7%; 210/786) (p = 0.01, chi-square test). Interestingly and unexpectedly, the rate of positive findings in characterized X-linked genes was similar in males (4.3%; 34/786) vs females (4.7%; 27/578). All the heterozygous mutations on the X chromosome identified in females arose *de novo* (when both parents are available for testing) or are *bona fide* mutations (in which at least one parent was unavailable for testing). Recurrent causative XLID genes seen in females include *MECP2*, *HDAC8*, and *WDR45*. For males, a *de novo* occurrence accounts for 41.2% (14/34) of the detected mutations and the rest 58.8% (20/34) inherited the mutation from their mother. In the latter 20 male probands, there were no strong indications of an X-linked condition in any family.   It is possible that males with ID (and unlikely that females with ID) underwent testing for X-linked genes prior to DES and thus the most prevalent and best known XLID genes have already been excluded. Alternatively, these data may support the concept of a "female protective model" for neurodevelopmental disorders. For example, an increase in number of identifiable pathogenic CNVs and SNVs in female vs male probands with autism spectrum disorders has been observed, despite the increased prevalence in males (Jacquemont, *et al.* AJHG 2014).   Our data demonstrate that the chance to find an X-linked molecular etiology is similar in males and females undergoing DES and highlight the utility of DES to detect unanticipated inheritance patterns. The data have implications for genetic counseling; highlighting that pre-test counseling should include a review of all applicable inheritance patterns. .

899T

Novel compound heterozygous variations of *FKRP* **in patient with myopathy.** *H. Galehdari[1], G. Shariati[2,3], A.H. Saberi[2,3], M. Hamid[2,4].* 1) Departments of geneticsshahid chamran uinversity, ahvaz, iran, ahvaz, Iran; 2) Narges genetic diagnostic lab; 3) Ahvaz Jundishapour University of Medical Sciences; 4) Pasteur institute, Tehran, Iran.

Myopathy is a group of muscle disorders.   We applied whole exome sequencing for detection of genetic role for a patients with symptoms including muscle weakness, motor delay, elevated CPK and muscular dystrophy. At result screening of whole exome of peripheral blood mononuclear cells genome revealed two heterozygous variation g.10504A>T and g.10663T>C in FKRP. Both variations are disease causing according to the mutation taster analysis and are pathogenic depend on predictSNP analysis. Sanger sequencing and pedigree allele segregation approved these variations as potential causative candidates. This gene has role in posttranslational modification. Previous studies demonstrated mutations in this gene have been associated with congenital muscular dystrophy, mental retardation and cerebellar cysts.

RNA-seq as a tool for diagnostically intractable cases of Duchenne Muscular Dystrophy. *E. Douine[1,2], R.T. Wang[1,2], A. Eskin[2,3], H. Lee[1,3], V. Arboleda[3], C.G. Bönnemann[4], N. Khanlou[3], C.M. McDonald[6], P.B. Shieh[2,5], S. Donkervoort[4], B.L. Wong[7], J.R. Nance[4], S.F. Nelson[1,2,3].* 1) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA, USA; 2) Center for Duchenne Muscular Dystrophy, University of California Los Angeles, Los Angeles, CA, USA; 3) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA, USA; 4) National Institutes of Health, National Institute of Neurological Disorders and Stroke, Neurogenetics Branch, Neuromuscular and Neurogenetic Disorders of Childhood Section, Bethesda, MD, USA; 5) Department of Neurology, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA, USA; 6) Department of Rehabilitation, University of California Davis Medical Center, Sacramento, CA, USA; 7) Division of Pediatric Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA.

   Duchenne muscular dystrophy (DMD) is an X-linked progressive muscle wasting disease. Roughly 1:5000 male births are affected, making it one of the most common pediatric genetic disorders. Disease progression begins with delayed walking and muscle weakness in early childhood. Boys become wheelchair bound around age 10. Death occurs in the 20's due to cardiorespiratory failure. DMD is caused by defects in the *DMD* gene which encodes the structural protein dystrophin. Commonly observed mutations include large exonic deletions (72%) and duplications (10%), indels (5%), splice site mutations (3%) and point mutations (9%). Multiplex ligation-dependent probe amplification (MLPA) and Sanger sequencing of *DMD* exons are the most common genetic tests and collectively find a cause for 85-95% of cases. However, roughly 5% of cases remain diagnostically intractable after conventional testing. We employed RNA-Seq on a series of clinically diagnosed DMD cases where standard testing failed to identify the molecular cause despite dystrophin negative muscle biopsy and characteristic clinical presentation. RNA-Seq identified two *DMD* structural variations—a large inversion on the X chromosome which disrupted the *DMD* transcript and a translocation between intron 44 of *DMD* and chromosome 15. We also found intronic mutations leading to pseudoexon inclusion and frame shifts in two other DMD cases. Lastly, one case of genomic duplication that included exon 44 was identified despite prior normal clinical testing which leads to an out-of-frame transcript. Detection of duplication events is challenging with existing methods and highlights strength of unbiased RNA-Seq analysis. All the above allowed the creation of family specific DNA diagnostics essential for carrier testing in females within each family. Further, the results of RNA-Seq are now highly relevant for personalized genetic therapies such as emerging exon skipping treatment for DMD as the exact mRNA produced is essential to the mechanism of action of the new drugs. For instance, in two boys with different partial exonic deletions where the consequence of their genomic deletions were unclear, we found strong evidence from RNA-Seq that an unpredicted splicing event created a frame-preserving transcript in one mildly affected boy with substantial dystrophin on muscle biopsy and the introduction of a stop codon in all transcripts in a second boy with no dystrophin on muscle biopsy. These data now have therapeutic implications.

Univ., Saitama, Japan; 5) Dept. of Metabolism, Chiba Children's Hospital, Chiba, Japan.

   Mitochondrial disorder has the highest incidence among congenital metabolic disorders characterized by biochemical respiratory chain complex deficiencies. It occurs at a rate of 1 in 5,000 births, and has phenotypic and genetic heterogeneity. More than 250 genes that cause mitochondrial disorder have been reported to date. However exact genetic diagnosis for patients still remained largely unknown. Recently, we published genomic analyses for 142 juvenile patients with mitochondrial respiratory chain complex deficiencies. We identified 37 novel mutations in known mitochondrial disease genes and 3 mitochondria-related genes (*MRPS23*, *QRSL1*, and *PNPLA4*) as novel causative genes, and also achieved genetic diagnoses in 49 of 142 patients (34.5%). The high proportion of novel mutations indicates the different ethnicity in Japanese population compared with those so far reported mainly by studies on Caucasian patients. Genetic causes for a large number of cases are still unknown. Therefore, to further clarify these unsolved cases, we are currently focusing on the analysis of exonic deletions as well as SNVs/INDELs/CNVs. By increasing the number of cases analyzed by exome sequencing, we will present our latest results and discuss about the contribution of these variants for the pathogenesis of mitochondrial disorder.

902T

Diagnosis of mitochondrial deletion syndromes by concurrent mitochondrial genome and whole exome sequencing. *A.M. Balog[1], H. Cui[1], J. Higgs[1], L. Carey[1], A. Dameron[1], K. Baldwin[2], R.A. Heidenreich[2], J. Cohen[3], A. Fatemi[3], R. Bai[1].* 1) GeneDx, Gaithersburg, MD; 2) University of New Mexico School of Medicine, Albuquerque, NM; 3) Kennedy Krieger Institute, Baltimore, MD.

   Background: The diagnosis of a mitochondrial DNA (mtDNA) deletion syndrome has important implications for surveillance, prognosis, and recurrence risk. Mitochondrial disorders represent a unique diagnostic challenge due to their variable clinical features and genetic heterogeneity. Due to the phenotypic overlap between primary mitochondrial disorders and other single gene disorders, whole exome sequencing (WES) in conjunction with whole mitochondrial genome sequencing (WMGS) has proved a valuable tool for evaluation of these disorders (PMID: 26633542). While methods have been developed to extract mtDNA reads from WES sequence data, these methods are unable to detect large mtDNA deletions associated with mtDNA deletion syndromes that can be detected by independent WMGS using next-generation sequencing of long range PCR amplified DNA with two sets of tail-to-tail primers (PMID: 24901348). **Patients and Methods:** In a retrospective study, 4,000 consecutive cases submitted for WES and WMGS were reviewed for the presence of a mtDNA deletion. WES and WMGS was performed by previously published methods (PMID: 26633542). **Results:** Out of 4000 cases, 5 patients harbored diagnostic mtDNA deletions and non-diagnostic WES results. One patient, presenting with growth retardation, ptosis, thrombocytopenia, and iron deficiency anemia with a family history significant for consanguinity, harbored a 5kb deletion at approximately 43% heteroplasmy in blood, consistent with a diagnosis of Pearson syndrome. Three patients, presenting with primarily non-specific neurodevelopmental phenotypes, including autism, seizures, and developmental delay, harbored deletions between 3.9 and 10.5kb at less than 15% heteroplasmy in blood consistent with a diagnosis of a mtDNA deletion syndrome. For the fifth patient who had a history of muscle weakness, exercise intolerance, and an abnormal muscle biopsy, a muscle biopsy was submitted for WMGS. This individual harbored a 12.8 kb deletion at less than 15% heteroplasmy . None of the five patients presented with chronic progressive external ophthalmoplegia, a symptom highly suspicious for mtDNA deletion syndromes. **Conclusion:** Concurrent WMGS and WES allowed for the diagnosis of 5 patients with atypical presentation of mtDNA deletion syndromes while excluding other potential diagnoses, supporting the benefit of this approach for evaluation of patients with complex presentations, even in the absence of mitochondrial disease-specific symptoms.

903F

***De novo DNM1L* variants associated with development delay, seizures and extended lifespan.** *H. Cui[1], A. Balog[1], J. Higgs[1], L. Carey[1], E. Heise[1], D. McKnight[1], J. Juusola[1], F. Zamora[1], S. Bale[1], M. McDonald[2], A. Irani[3], L. Escobar[3], M. Tarnopolsky[4], A. Kim[5], E. Leeth[5], J. Charrow[6], A. Qais[1], S. Suchy[1], R. Bai[1].* 1) GeneDx, Inc., Gaithersburg, MD; 2) Department of Pediatrics, Duke University, Durham, NC; 3) Medical Genetics & Neurodevelopmental Center, St. Vincent's Peyton Manning Children's Hospital, Indianapolis, IN; 4) Department of Pediatrics, McMaster University Medical Center, Ontario, CA; 5) Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL.

   Dynamin-like protein 1, encoded by the *DNML1* gene, is a dynamin superfamily member that regulates mitochondrial fission and has a role in normal mitochondrial function. *DNM1L* is composed of a GTPase domain, a middle domain, and a GTPase effector domain (GED). *De novo* variants in *DNM1L* have been reported in association with autosomal dominant lethal encephalopathy due to defective mitochondrial and peroxisomal fission. A dominant-negative disease mechanism has been proposed. All reported missense variants are in the middle domain of *DNM1L*, the domain that may be responsible for dimerization. Compound heterozygous loss-of-function variants in *DNM1L* were reported in two siblings with profound hypotonia at birth, who died in early infancy, indicating that complete loss of *DNM1L* function is incompatible with life. With only a few *DNM1L* variants published to date, the phenotypic and mutational spectrum of pathogenic variants in the *DNM1L* gene needs further study. Our clinical laboratory has identified 4 likely pathogenic variants in *DNML1* from 5 unrelated patients referred for whole exome sequencing. All patients presented with developmental delay and seizures or abnormal movements. Variants from 4 patients for whom parental samples were available were *de novo*, and three variants were novel. An R403C variant, published in two unrelated patients, was detected twice in our patient cohort, suggesting this amino acid is a mutation hot spot. Three identified variants, A395G, R403C and C431Y, are located in the middle domain, which has a relatively low frequency of benign variants compared to the GTPase and GED domains according to ExAC database. A Y691C variant within the GED domain was also identified in a 21 year old patient with history of hypotonia and global developmental delay during infancy, suggesting the biological importance of other *DNM1L* domains is yet to be fully understood. Although the clinical features of patients in this cohort were consistent with previously published cases, most previously reported patients with *DNM1L*-related disorders died in early infancy, whereas at the time of testing, the mean age of patients in this cohort was 9.1 years. In summary, we have detected 3 novel *de novo* variants and a recurrent pathogenic variant in *DNM1L*. This cohort doubles the number of cases reported, and indicates that the life expectancy for this disorder may be significantly greater than reported previously.

904W

Can whole genome sequencing end the diagnostic odyssey for paediatric mitochondrial disorders? *L. Riley[1,2], M. Cowley[3], V. Gayevskiy[3], T. Roscioli[3], D. Thorburn[4,5], M. Bahlo[6,7], C. Sue[3,8], S. Balasubramaniam[9], J. Mitochondrial disorders are the most common inherited metabolic disease. They are a heterogeneous group of disorders caused by mutations in either the mitochondrial or nuclear genome. Diagnosis is often a lengthy process and usually relies on both clinical evidence and detection of a mitochondrial respiratory chain enzyme deficiency. We are investigating the utility of whole genome sequencing (WGS), which can detect both nuclear and mitochondrial variants, in diagnosis of paediatric mitochondrial disorders. We studied an Australian cohort of 41 patients with clinical features of mitochondrial disorders, from 4 state-based paediatric genetic metabolic service centres. Mitochondrial respiratory chain enzyme deficiencies had been reported in 25 cases and normal mitochondrial respiratory chain enzyme activities in 5 cases, the remaining cases have not had enzymology. DNA was extracted from blood samples from the patients, and their parents where available. WGS was performed at the Kinghorn Centre for Clinical Genomics, Sydney, Australia. WGS sequencing libraries were prepared using Illumina TruSeq NanoHT v2.5 sample preparation kits and sequenced on Illumina HiSeq X sequencers, via 2 × 150 bp reads, with 95% of the nuclear genome covered to > 15× depth. Alignment, annotation and identification of SNVs and indels were performed using VEP and the in-house Seave pipeline. Sanger sequencing was used to confirm variants. Data analysis has been performed on 29 families to date. Presumptive causal variants have been identified in 14 cases (48%) and involved the known mitochondrial disease genes *ACAD9* (2 unrelated cases), *ECHS1*, *GFM1*, *NDUFB11*, *RARS2*, *SERAC1* and mitochondrial-encoded *MT-ATP6*, *MT-CO2,* and *MT-TL1*. A putative novel mitochondrial disease gene has been identified in one case. The remaining cases all had evidence of a mitochondrial respiratory chain disorder however, variants were identified in disease genes with no previous evidence of causing a mitochondrial disorder (*ARX*, *G6PC*, *SKIV2L*, *SLC39A8*), but causing other symptoms consistent with the patient phenotypes. These 4 cases suggest that the primary diagnosis of a mitochondrial disorder may be incorrect or that in these cases the respiratory chain enzyme deficiency may be a secondary effect. Our preliminary data indicate that WGS rapidly and efficiently identifies variants in known mitochondrial disease genes of both nuclear and mitochondrial origin, with a positive detection rate approaching 50%.

905T

Development of a targeted next generation sequencing (TNGS) strategy for the genetic diagnosis of mitochondrial diseases in paediatric population. *G. Barcia[1,2], Z. Assouline[1], M. Rio[1,2], M. Bernardelli[1], M. Magen[1], S. Hanein[2], C. Fourrage[1,2], C. Bole-Feysot[2], P. Nitschke[2], J.P. Bonnefont[1,2], A. Munnich[1,2], A. Rotig[2], J. Steffann[1,2].* 1) Genetics Unit, Necker Hospital, Paris, France; 2) Imagine Institut of genetic diseases, Paris, France.

Purpose: Mitochondrial diseases (MD) are a clinically and genetically heterogeneous group of disorders caused by mutations of nuclear DNA (nDNA) or mitochondrial DNA (mtDNA) and resulting in mitochondrial respiratory chain dysfunction. The global incidence of MD is estimated 1/4000 live birth, corresponding to 200 new patients/year in France. Clinically, childhood MD differ from adult MD because they are characterized by a more severe phenotype and by a frequent brain involvement. In childhood MD, mutations in nDNA are more frequent than in adult MD. Mitochondrial DNA mutations account for less than 10% of paediatric MD patients. As a collaborative work of the Imagine Institute and the Clinical and Molecular Genetics Unit of the Necker Hospital, we developed a custom targeted next generation sequencing (TNGS) strategy for the molecular analysis of nuclear and mitochondrial genes involved in MD. Considering the technical complexity linked to heteroplasmy and tissue specificity of mtDNA mutations, we decided to develop two separate strategy for nDNA and mtDNA TNGS. Methods: In 2015-2016, we studied by TNGS 160 patients with a clinical, biochemical, metabolic and radiological work-up suggestive of MD. The sequencing of 212 genes involved in MD was performed by capture (SureSelectXT Target Enrichment Reagent Kit, Agilent, Illumina HiSeq2500). The sequencing of mtDNA was performed for 56 patients (long range PCR, Illumina MiSeq). Results: We identified de novo pathogenic or probably damaging nDNA variants in 58/160 patients (36%), including point mutations, large deletions (8 patients) and large duplications (2 patients) affecting genes involved in mtDNA transcription and protein synthesis (18/58 patients), mitochondrial DNA maintenance (13/58 patients) and assembly of the respiratory chain complexes (13/58). Mitochondrial DNA mutations were found only in 2/56 patients (3.5%). Conclusions: With a diagnostic yield of 36% in a cohort of 160 patients, nDNA TNGS is an efficient strategy for the genetic studies of MD. Our results suggest that, in a paediatric setting, nDNA TNGS can be used as a first step in the genetic diagnosis of MD and mitochondrial DNA sequencing can be performed as a second step in patients with a negative mtDNA result. .

GeneMatcher facilitates the diagnosis of an autosomal-recessive mitochondrial disease caused by biallelic mutation of the tRNA isopentenyltransferase (*TRIT1*) gene. *. E.G. Farrow[1,2], K.D. Kernohan[3], D.A. Dyment[3,4], M. Pupavac[6], A. McBride[3], T. Hartley[3], E. Sell[5], J. Majewski[6], D.S. Rosenblatt[6], E. Shoubridge[6], A. Mhanni[7], T. Myers[1], J. Kussman[8], N. Safina[2,8], C.J. Saunders[2,9], K. Boycott[3], I. Thiffault[2,9], Care4Rare Consortium.* 1) Department of Pediatrics, Children's Mercy Hospital, Kansas City, MO; 2) University of Missouri-Kansas City School of Medicine, Kansas City, MO; 3) Care4Rare Consortium, Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON, Canada; 4) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Division of Neurology, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 6) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 7) Department of Paediatrics and Child Health, College of Medicine, Faculty of Health Sciences, University of Manitoba, Winnipeg, Manitoba, Canada; 8) Department of Genetics, Children's Mercy Hospital, Kansas City, MO; 9) Department of Pathology, Children's Mercy Hospital, Kansas City, MO.

The myriad of important roles assumed by mitochondria in cellular function such as energy production, metabolism, signaling pathways and the regulation of apoptosis, are contributing factors of the clinical diversity of human mitochondrial diseases. From a clinical standpoint, mitochondrial disorders are often suspected on the basis of clinical presentations, but the diagnostic workup is often difficult, requiring complex and extensive clinical and laboratory evaluation. Typical clinical features often include, but are not limited to myopathy, diabetes mellitus, liver failure, ataxia, seizures, encephalopathy, sensorineural deafness and bone marrow failure. The minimum prevalence of isolated or combined, genetically defined OXPHOS defects is approximately 1:5000 live births, considering only the most recurrent mutations of mtDNA. Additionally, given the extensive locus and allelic heterogeneity present in mitochondriopathies, it is not surprising that over 1,300 nuclear genes are implicated in mitochondrial function and 265 disease genes identified to date. With the growing use of whole exome sequencing (WES), genetic diagnoses of both nuclear and mitochondrial mitochondriopathies, including novel disease genes is possible. However without functional data, the demonstration of causality in a novel gene candidate, in a single family, can be challenging. One efficient method to show evidence in favor of causality is to identify two or more unrelated individuals with the same candidate gene and sharing the similar phenotype. To facilitate connections of similarly affected individuals several matching platforms have been developed (MatchMaker Exchange, Genematcher). Here we describe three unrelated individuals "matched" by candidate gene, the mitochondrial tRNA isopentenyltransferase (*TRIT1*), with the use of GeneMatcher. A disorder characterized by microcephaly, profound developmental delay, hypotonia, epilepsy and brain anomalies. Functional studies revealed decreased levels of mitochondria complex III and complex IV proteins. Importantly, we find that TRIT1 is present in patient cells in the appropriate quantity and location, indicating the effects in patient cells are due to defective TRIT1 protein function. Our findings identify a human mitochondrial tRNA isopentenyltransferase defect syndrome linked to *TRIT1*, providing insight into the roles of defective modification of mitochondrial and cytosolic tRNAs in *TRIT1*-related diseases.

Novallele™ HRM-based genotyping assays for detection of mitochondrial DNA mutations. *L. Jiang, L. Papazisi, R. Ndongo, F. Mokeyo, M. Cai, J. Huuskonen, I. Knight.* R&D, Canon US Life Sci, Inc, Rockville, MD.

Background: More than fourteen diseases and other disorders are identified as potentially related to mutations of mitochondrial DNA (mtDNA). Each human cell can contain thousands of copies of mtDNA, which are highly susceptible to mutations. While homoplasmic mtDNA can be normal or mutated, heteroplasmic mutations occur only in some copies of mtDNA. Even though methods exist for mtDNA mutation detection, such as next-generation sequencing and Sanger sequencing, there is still a need for a fast, sensitive, and cost-effective detection method. The goal of our research is to develop highly sensitive and specific assays using PCR followed by high-resolution melting (HRM) analysis. **Methods**: We designed and developed five new genotyping assays targeting mutations in the mitochondrial genome. We focused on mutations associated with Leber's hereditary optic neuropathy (LHON), mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), and myoclonic epilepsy with ragged red fiber (MERRF) disease. For each target, four assays were designed and the most robust assay was selected using gradient PCR. Testing was performed using an HRM-enabled thermocycler with both genomic DNA and synthetic constructs. One small-amplicon and four unlabeled-probe assays were selected. In order to determine assay sensitivity with regards to heteroplasmic mutations, two targets were studied by varying the amount of mutant DNA from 5–100% to mimic heteroplasmy. **Results**: Our assay selection process resulted in robust and specific PCR amplification. All assays yielded unambiguous genotyping. Fast results were achieved as the high copy number of mtDNA lowered the PCR amplification threshold (approximately 15 cycles) as compared to genomic DNA. The mutant DNA detection limit in the heterozygous samples was 10% for the small-amplicon assay and 15% for the unlabeled-probe assay. **Conclusion**: Our results demonstrate that HRM has potential over Sanger sequencing, which has a mutant DNA detection limit of 15–20%. Novallele genotyping assays provide a sensitive, fast, and cost-effective method to genotype various mtDNA mutations. HRM is useful for detecting heteroplasmic mutations and provides a viable alternative to other more-costly, labor-intensive technologies. The Novallele genotyping assays are for Research Use Only. Not for use in diagnostic procedures.

Next-generation sequencing analysis for mitochondrial disorders in adult Japanese patients. *Y. Okamoto, J. Yuan, A. Yoshimra, Y. Hiramatsu, M. Ando, A. Hashiguchi, H. Takashima.* Dept Neurology & Geriatrics, Kagoshima Univ Grad Sch Medical & Dental Sci, Kagoshima City, Kagoshima, Japan.

Mitochondrial disorders have a reported incidence of 1 in 5000 live births and are a clinically and genetically heterogeneous group of diseases. A correct diagnosis is challenging mainly because of the absence of clear phenotype– genotype correlations. In addition, these diseases are attributed to the mutations in the 16.6-kb mitochondrial genome, with approximately 1500 genes encoded in the nuclear genome. The development of next-generation sequencing (NGS) has revolutionized diagnostic approaches, enabling faster, more sensitive, and more efficient genetic analyses. We developed a targeted NGS-based assay of the mitochondrial DNA (mtDNA) and 180 nuclear genes associated with mitochondrial disorders. We specifically designed and performed a three-step strategy, comprising clinical and pathological screening, long-range PCR using muscle DNA and whole mtDNA sequencing with Illumina MiSeq, and gene panel analysis following whole-exome sequencing (WES). We detected mtDNA deletions in approximately 45% of our cases. Nuclear gene mutations were identified in *RRM2B*, *POLG*, *C10orf2*, and *ABCB7* in five (14.3%) of 35 cases who underwent WES. Multiple cases had mild renal failure, external ophthalmoplegia, and neuropathy. A case with an *ABCB7* mutation had sideroblastic anemia, mental retardation, and mitochondrial myopathy, which is a rare symptom. Further studies should include investigating additional nuclear genes and pathological examinations to clarify the pathophysiology. Our results indicate that neuropathy might be an important symptom of adult mitochondrial disease caused by mutations in nuclear genes. We speculate that a noticeable number of mildly symptomatic patients with a mitochondrial disease are adults. This study shows that NGS can play a major role in the molecular diagnosis of mitochondrial disorders. .

Detection and analysis of partial *USH2A* deletions in patients with hearing loss. *C.A. Austin-Tse[1], D.L. Mandelker[2], S.S. Amr[1,3].* 1) Laboratory for Molecular Medicine, Partners Personalized Medicine, Cambridge, MA; 2) Memorial Sloan Kettering Cancer Center, Department of Pathology, New York, NY; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Usher syndrome (US) is an autosomal recessive disorder characterized by hearing loss and retinitis pigmentosa, which accounts for up to 50% of all deaf-blindness. While patients can benefit from early diagnosis, the most common form of the disease, Usher syndrome type II (USH2), presents as isolated hearing loss in childhood and is thus not immediately identifiable in the clinic. As a result, detection is largely dependent upon molecular diagnostics. The *USH2A* gene is the largest contributor to USH2: To date, more than 700 putative disease-causing SNVs and small indels in the *USH2A* gene have been reported in patients with US. However, in about 20% of US probands that undergo *USH2A* sequencing at our laboratory, only a single, heterozygous, disease-causing variant in *USH2A* is identified. This finding supports the presence of variants that are not detectable by clinical sequencing assays (which usually target the coding and splice site regions of the gene), such as variants in intronic and promoter regions, as well as deletions or duplications spanning 1 or more exons. To better understand the contribution of copy number variants (CNVs) to the genetic etiology of US, we screened for *USH2A* CNVs in 91 probands, who were divided into 1 of 3 groups: 1) individuals carrying only a single heterozygous clinically significant variant in the *USH2A* gene, 2) those with *USH2A* variants of uncertain significance, and 3) individuals with no *USH2A* variants who had clinical features highly suggestive of US. In total, 9 large deletions (including 3 previously reported and 6 novel deletions) were identified in 11 patients (12% of the cohort). The detection rate for large deletions was highest in individuals with a previously detected pathogenic variant (45%; 9/20 individuals in Group 1). The remaining 2 deletions were identified in individuals without previously identified *USH2A* variants (Group 3). Precise mapping of the deletion breakpoints provided evidence for a template switching mechanism underlying a recurrent exon 27 deletion. Although the remainder of the breakpoints were not enriched for homologies or repetitive elements, pooling of our data with previously reported *USH2A* CNVs revealed a concentration of breakpoints within 4 introns, raising the possibility of "fragile" regions within the gene. We hypothesize that deep sequencing of these introns in US probands may uncover a new class of *USH2A* variants that evade detection by standard assays: intragenic inversions.

910W

CDH23 and MYO7A mutations identified by targeted NGS approach in an Italian cohort with non-syndromic hearing loss. *F. Cesca[1], E. Bettella[1], R. Polli[1], E. Leonardi[1], B. Sicilian[2], D. Croatto[2], A. Murgia[1,3].* 1) Department of Salute Donna e Bambino, Laboratory of Molecular Genetics of Neurodevelopment. University of Padua, Padua, PD, Italy; 2) Medical Center of Phoniatrics, Casa di Cura Trieste, Padua, PD, Italy; 3) Department of Neuroscience. University of Padua, Padua, PD, Italy.

Hereditary sensorineural Non-Syndromic Hearing Loss (NSHL) is characterized by clinically indistinguishable phenotypes and genetic heterogeneity that until recently have hampered effective early etiological diagnoses. Next Generation Sequencing (NGS) technologies offer unprecedented diagnostic capacities and hold the promise of a significant increase in knowledge about the pathogenic role of many disease-genes. With the aim of developing advanced diagnostic tools to investigate the genetic bases of hearing impairment in a population of Italian individuals mainly of pediatric age, we designed a targeted NGS panel including 59 genes strongly associated, in Caucasians, with NSHL or with syndromes (i.e. Pendred and Usher) with onset as seemingly isolated deafness. In a cohort of 16 highly selected subjects, negative for *GJB2/GJB6* mutations, we have identified 3 cases (18%) with pathogenic mutations in genes involved both in NSHL and Usher's syndrome. In two sisters, aged 16 and 11, with profound pre-lingual hearing loss, we identified compound heterozygous *CDH23* (MIM #605516; NM_022124) mutations: a missense mutation c.6530C>A (p.P2177H) and a novel splice-site mutation c.8966-1G>C in intron 59-60, that cause the complete skipping of exon 60. In a second case two novel *CDH23* alterations, c.893T>C (p.L298P) and c.924-926del, and a novel *MYO7A* (MIM #276903; NM_000260) variant, c.808C>G (p.L270V) were detected in a 12 year-old boy with moderate hearing loss and referred post-lingual onset. In the third case we detect two *MYO7A* alterations, one of which already described as pathogenic, while the second one a novel variant, c.730C>T (p.R244C) in a 12 year-old girl with post-lingual moderate hearing loss, In all the three cases, the individuals do not have family history of deafness, nor retinal alterations or vestibular dysfunction and have a normal neurodevelopment, so we can exclude a syndromic form of hearing loss. Even though from a small cohort of individuals, our data are in agreement with previous reports about the relative frequency of *CDH23* mutations in NSHL. We show how a truncating mutation, in combination with a missense mutation of *CDH23* cause autosomal recessive NSHL (DFNB12 MIM #601386). We would like to stress the value of an NGS targeted gene panel as a first tier molecular genetic tool and the great importance of combining molecular and clinical data to reach a final correct diagnosis and provide appropriate counseling.

Identification of POU3F4 defects in Chinese subjects with congenital hearing loss using MPS. *J. Cheng[1], Y. Zhao[2], Y. Lu[1], H. Yuan[1].* 1) Medical Genetics Center, Southwest Hospital, Chongqing, China; 2) Peking University People's Hospital, Beijing, China.

DFNX2 is the most common form of X- linked hearing loss, which caused by various types of mutations of *POU3F4*, accounting for up to 50% of X- linked hearing loss cases. In this study, the combination of targeted exome capture and massive parallel sequencing (MPS) with 685 hearing loss-related genes was performed to identify the underlying genes for 10000+ samples with hearing loss. We identified 49 distinct *POU3F4* mutations in 57 males with congenital hearing loss. Ten reported pathogenic mutations were identified in 17 cases. Among the 39 identified novel variants, there are 17 frameshift mutations, 5 nonsense mutations and 17 missense mutations. In 57 male subjects, 11 cases exhibited typical DFNX2 temporal bone anomalies and the others did not conduct CT scan. In a three-generation Chinese family with X-linked progressive nonsyndromic hearing loss, the proband, a six years old boy, is characterized with specific nonsyndromic low-frequency sensorineural hearing loss (LFSNHL) and showed typical IP III. A novel mutation (c.1074delC) in the *POU3F4* gene causes a frameshift extension mutation(p. C358fs) which located outside of POU domain and nuclear localization signal (NLS) at the C-terminus. This mutation was found to consistently cosegregate with the deafness phenotype in the family by Sanger sequencing. All the samples with novel mutations will be validated by CT. This study expends the genetic and phenotypic spectrum of DFNX2.

912F

Collaboration of different pathogenic variations can cause Retinitic Pigmentosa. *G. Shariati[1,2], H. Galehdari[3], A.H. Saberi[1], M. Hamid[4].* 1) Ahvaz Jundishapur University of Medical Sciences, Ahvaz, KHUZESTAN, Iran; 2) Narges Genetic Diagnostics lab; 3) department of Genetics, Shahid Chamran University, Ahvaz, Iran; 4) Institute Pasteur, Tehran, Iran.

Retinitis pigmentosa (RP) is a heterogeneous group of inherited degenerative eye diseases affect the retina's ability to respond to light subsequently causes severe vision impairment.Common symptoms of RPare difficulty seeing at night and a loss of peripheral vision.Various genes variations linked to the RP etiology. Here we applied exome sequencing to a patient with RP.At result we found two single nucleotide variation g.102775563C>T in PDZD7 and g.89971970C>G in GPR38. Although GPR98/PDZD7 mutation with digenic inheritance have been reported for Usher syndrome, type 2C, surprisingly Sanger sequencing and pedigree allele segregation checking approved these variations as potential causative candidates. Bioinformatics analysis using mutation taster showed these mutation are diseases causing. Notably according to the Exome Aggregation Consortium report allele frequencies of these variations respectively is 0.001318 and 0.0004415. Both variations (GPR98 - ENST00000405460- p.Ser1796Cys and PDZD7 - ENST00000433616-p. Glu102Lys) are pathogenic according to the SIFT and PolyPhen2 tools. Diagnosis can be challenging as variouscausative genes are related to non-syndromic RP and phenotypic symptoms significantly differ between patients. In conclusion we can emphasize exome sequencing as an opportunityfor obtaining a genetic diagnosis and characterize the comprehensive spectrum of RP.

913W

Heterozygous frame shift mutation and a three exon gain in *EYS* causing Retinitis Pigmentosa detected with whole exome sequencing. *L.H. Hoefsloot[1], V.J.M. Verhoeven[1], C.C.W. Klaver[2], T. Brands[1], M. van Tienhoven[1], A. de Klein[1], W.Y. Cheung[1], B. Eussen[1], A. Kievit[1], J. Knijnenburg[1].* 1) Dept Clinical Genetics, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2) Dept Ophthalmology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands.

Retinitis Pigmentosa (RP) is an inherited degenerative ocular disease that causes progressive vision impairment by retinal photoreceptor degeneration. The genetic disorder is estimated to show an autosomal recessive inheritance in 50 to 60% of patients, an autosomal dominant inheritance in 30 to 40% and an X-linked inheritance in 5 to 15%[1]. Mutations in more than 60 genes are currently known to cause a monogenic form of RP. A 74 year-old male patient, affected with RP with an onset at 16-17 years, was investigated using whole exome sequencing (WES) with filtering for a set of genes known to be involved in the genetic cause of vision disorders (333 genes). Analysis revealed a heterozygous pathogenic frame shift mutation in the *EYS* gene on chromosome 6q12. Biallelic homozygous or compound heterozygous mutations in this gene are known to cause autosomal recessive Retinitis Pigmentosa-25 (RP25) (OMIM #602772). No other pathogenic single nucleotide variation was found. Subsequent copy number variation analysis of the WES data using CoNVex[2] showed a three exon gain in *EYS*, which was confirmed using SNP-array analysis. Segregation studies in the daughter of the patient showed only the inheritance of the frame shift mutation, proving the biallelic presence of the two mutations in the patient. Although the presence of a three exon gain in the genome is not sufficient evidence to conclude pathogenicity of the event, the segregation studies support the contribution of the event to the phenotype. Characterisation of the position of the duplication, in combination with expression studies of the EYS gene in the patient will provide further evidence of its pathogenicity. [1]Hartong, D. T., Berson, E. L., Dryja, T. P. Retinitis pigmentosa. Lancet 2006; 368: 1795-1809. Exome sequencing in a Turkish family revealed an autosomal dominant juvenile pulverulent cataract. *A.S. Dogan[1], A. Yesilyurt[2], B. Yurteri[2], O. Altintas[3], A. Karalezli[4], C. Gurdal[1]. 1) Ophthalmology, Diskapi Yildirim Beyazit Training and Research Hospital, Ankara, Turkey; 2) Genetics, Diskapi Yildirim Beyazit Training and Research Hospital, Ankara, Turkey; 3) Kocaeli University, Faculty of Medicine, Kocaeli, Turkey; 4) Mugla Sitki Kocman University, Training and Research Hospital, Mugla, Turkey.*

  Introduction: Cataract is the opacity in the crystalline lens. Juvenile forms appear from birth upto 16 years old. This study was aimed to identify the mutation in a Turkish family with juvenile autosomal dominant pulverulent cataract. Phenotypically identical cataracts may result from mutations at different genetic loci and may have different inheritance patterns as well as phenotypic variability may be seen in a single family. **Methods:** The family members underwent full ophthalmic examination and systemic evaluation. There were no ocular lesions other than the cataracts, and the patients were healthy intelligently, neurologically and metabolically. Pedigree of 3 generations revealed the presence of autosomal dominant inheritance with a complete penetrance pattern. The form of the cataracts was pulverulent, in a progressive behavior. Blood samples were collected from 5 members of this family and whole exome sequencing was carried out in proband. Sanger sequencing was performed for the rest of the family members to show segregation analysis as well as confirmation of NGS result. **Results:** Whole exome sequencing in the proband revealed the c.143G>A (p.R48H) heterozygous mutation in exon 2 of the *CRYGC* gene. Rests of the affected members of the family were revealed as bearing the same mutation in *CRYGC* gene by Sanger sequencing. **Conclusions:** In the present study, we described a family with pulverulent juvenile cataract that segregated the c.143G>A mutation (p.R48H) in the *CRYGC* gene. But, the mutation has conflicting interpretation whether it is pathogenic or a SNP. A few mutations so far have been described in the *CRYGC* gene leading to autosomal dominant cataract. Mutations in the *CRYGC* gene in literature have been shown as related to different types of cataract. Only two of them have been reported associated with pulverulent cataract. Ren et al. has shown a heterozygous 5-bp duplication in exon 2 of the CRYGC gene leading to zonular pulverulent cataract (CTRCT2; 604307). González-Huerta et al. have reported the same mutation associated with autosomal dominant pulverulent cataract. Mutation segregation in the affected family members as well as previous report by González-Huerta et al. suggested that p.R48H should be considered as a disease-causing mutation and not a SNP. **Acknowledgement:** Founded by Scientific Research Project Office of Diskapi Training and Research Hospital.

Phenotype-driven analysis of whole genome sequencing to find missing alleles in retinal disease. *A.P. DeLuca[1,2], S. Hiatt[3], K. Bowling[3], J.L. Andorf[1,2], D. Gray[3], C. Finnila[3], M. Thompson[3], A.V. Drack[1,2], G. Cooper[3], T.E. Scheetz[1,2], V.C. Sheffield[1,4], E.M. Stone[1,2]. 1) Stephen A. Wynn Institute for Vision Research, University of Iowa, Iowa City, IA; 2) Dept of Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 3) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 4) Stead Family Dept of Pediatrics, University of Iowa, Iowa City, IA.*

  There are well over one hundred genes that cause inherited retinal diseases. While comprehensive exome-based genetic testing has enabled diagnoses for many across this highly heterogeneous space, there remain cases where one or more disease alleles cannot be identified. We focused on a subset of these unsolved cases where a combination of genotypic and phenotypic information reduced the hypothesis to a single gene with a single missing allele. These cases include, for instance, dominant monogenic disorders such as *PRPH2*-associated pattern dystrophy, and recessive genetically heterogeneous disorders including *USH2A*-associated retinitis pigmentosa where a single disease-causing allele has already been identified. All cases were required to have a clinical phenotype consistent with the hypothesized gene. Whole Genome Sequencing (WGS) with 30x coverage was obtained in 27 such cases, including four where we suspected Copy Number Variants (CNVs) based on exome coverage data. Breakpoints for suspected CNVs were discovered in each of these four cases. Putative disease causing variants have been identified in 12/23 of the remaining cases. Of these 16 cases, 3 had exonic single nucleotide variants (*ACO2*, *OPA1*, *PRPH2*), 10 had CNVs that removed or added exons (*ACO2*, *CERKL*, *CHM*, *CNGB3*, *FRDMD7*, *GPR98*, *MAK*, *NMNAT1*, *PRPH2, USH2A*), 3 had structural variants disrupting regulatory sequences (*PAX6*, *TYR* x2). All identified variants were confirmed via Sanger sequencing. Segregation and phase were established by sequencing family members when available. Additional work is underway on the 11 unresolved cases to establish the pathogenicity of deep intronic or intergenic SNVs and/or small indels. With a current solve rate of 16/27 (59%), WGS has proven to be a very successful tool in identifying missing disease alleles in retinal disease patients where the available phenotypic and genotypic information can narrow the pre-test hypothesis. Additionally, the narrowed hypothesis allows additional scrutiny including even manual inspection of the sequence data that would not be possible with a genome-wide hypothesis. This additional scrutiny allowed the discovery of several variants that current bioinformatic tools failed to detect. Overall, this work emphasizes the increasing importance of high-quality clinical data as WGS becomes more readily available.

Newborn deafness genetic screening of 142,417 neonates in Wuhan, China. *Z. Hao, D. Fu, Q. Zuo, Y. Ming, J. Yang, Q. Huang, H. Ring, B. Ring.* Huazhong University of science and technology, Wuhan, Hubei, China.

   Objective: Almost one third of the three million people in China suffering severe deafness are children, and 50% of these cases are believed to have genetic components to their etiology. Newborn hearing genetic screening can complement Universal Neonatal Hearing Screening for the diagnosis of congenital hearing loss, as well identifying children at risk for late-onset and progressive hearing impairment. The aim of this joint academic and Ministry of Health project was to prototype a newborn genetic screen in a community health setting on a city-wide level, and to ascertain the prevalence of variation in three genes that have been associated with non-syndromic hearing loss. Methods: With the participation of 143 local hospitals in the city of Wuhan, including both maternity and general hospitals, we screened 142,417 newborns born between May 2014 and Dec. 2015. The variants GJB2 235delC, SLC26A4 919-2A>G, and mitochondrial variants in the MT-RNR1 gene 1555A>G and 1494C>T were assayed using real time PCR. Newborns found to carry a variant were re-assayed by sequencing in duplicate.Results: We developed a high throughput genetic screening process and applied it to a total of 142,417 newborns delivered at 143 hospitals in Wuhan. About 98.7% of newborns at the contributing hospitals participated in this screen. The concordance between variants found in the genotyping screen and resequencing was >99.99%. The most frequent hearing loss associated allele detected in this population was the 235delC variant in GJB2 gene. In total, 4241 (2.98%) newborns were found to carry at least one allele of either GJB2 235delC, SLC26A4 919-2A>G or the two assayed MT-RNR1 variants. 3999 (2.8%) newborns were positive for at least one of the non-mitochondrial variants, and 242 (0.17%) newborns carried a mitochondrial DNA variant. In addition, sequencing found novel mutations in the GJB2 region.Conclusions: We performed the first large scale genetic screening in central China for alleles associated with hearing loss. This study shows that GJB2 mutation is a potential important contributor to prelingual deafness in the Wuhan newborns. Further collaboration with the participating hospitals will determine the specificity and sensitivity of the association of the studied variants with hearing loss at birth and arising in early childhood, allowing an estimation of the costs and benefits of delivering newborn hearing genetic screening in a large scale community setting.

917T

Novel *ACTG1* mutation in a Mexican patient with Baraitser-Winter syndrome. *T. Barragan, J.C. Zenteno, O. Chacon, D. Lozano, I. Hindi, B. Fuerte.* Genetics, Instituto de Oftalamologia Conde de Valenciana, Mexico City, Mexico, Mexico.

   INTRODUCTION   Baraitser-Winter syndrome is a rare autosomal dominant developmental disorder characterized by brain malformations, microcephaly, ridged metopic suture, congenital ptosis, high-arched eyebrows, hypertelorism, ocular coloboma, postnatal short stature and intellectual disability. Mutations in *ACTB* and *ACTG1* genes have been associated to this entity. In this work, non previously reported clinical features are described in a Mexican patient. A novel mutation in *ACTG1* is identified   METHODS AND MATERIALS   A 1-year old male child was referred for evaluation due to psychomotor delay and congenital eye and brain anomalies. He is the child of healthy, nonconsanguineous parents, and was delivered at term. General examination showed dysmorphic features that included microcephaly with ridged metopic suture, hypertelorism, bilateral ptosis, high-arched eyebrows and short nose with a broad bridge. On ocular examination, iris, retinal and optic nerve coloboma in both eyes, and an aparent extra ocular muscle insercion anomaly were observed; cerebral malformations were identified using CTscan. Conventional karyotype analysis was normal. *ACTB* and *ACTG1* gene analysis was performed using exon-by-exon PCR amplification and direct Sanger sequencing on genomic DNA from the patient.   RESULTS   This patient presented all cardinal features of Baraitser-Winter syndrome; moreover, we identified congenital anomalies which have not been previously reported. A novel *ACTG1* transition c.176 A>G: p.Q59R was identified in probands DNA. In silico analysis, its absence in population database (ExAC Browser, 1000 Genomes and EVS) and parental DNA, and familial segregation analysis, support the pathogenicity of this variant.   CONCLUSION   This is the first clinical and molecular analysis of a Baraitser – Winter syndrome patient from Latin America. Our patient presented typical features of this entity, and to our knowledge extra ocular muscle anomalies have not been described previously. The actin gene family consists of six different isoforms with a protein sequence similarity greater than 93%. *ACTB* and *ACTG1* differ by only four biochemically similar amino acids within the 10N-terminal residues. Interestingly, p.Q59R is described as a pathogenical variant in *ACTB* gene, which suggests that due to the great homology between these protein isoforms, this amino acid position could have important functions. Our results expand the clinical and mutational spectrum of Baraitser-Winter syndrome .

918F

Identification of a novel splice mutation in choroideremia patients involved in clinical trial. *R. Mah, A. Radziwon, S. Hume, I. MacDonald. University of Alberta, Edmonton, Alberta, Canada.*

  Purpose: Choroideremia (CHM), an X-linked disorder, causes eventual vision loss in affected male patients. Although there is no effective treatment for choroideremia, gene therapy trials are in progress in two locations. Currently patients are identified through clinical examination and sequencing and copy variant analysis of the only known gene, *CHM*. Patients with the appropriate phenotype but who lack a *CHM* pathogenic variant, can have immunoblot analysis done in a research setting as a lack of the corresponding REP-1 protein is also diagnostic for choroideremia. Because immunoblot analysis is not possible for most diagnostic laboratories future gene therapy patients will require a highly sensitive diagnostic test. To promote this we are investigating REP-1 negative patients who do not have a CHM coding variant. **Methods:** Primary fibroblasts cells from two patients were grown until fully confluent. Cells were washed with PBS and RNA extraction performed. cDNA was synthesized from these RNA extractions along with gDNA extracted from the same patients' blood samples. CHM coding region primers were designed in Geneious using the *Primer3* design tool. Product size was assessed used a 1% agarose gel. Sanger sequencing of both cDNA and gDNA was performed and sequences were then aligned to CHM gene using Seqpilot software. Splice predictions performed using Alamut Visual software. **Results:** To improve our test sensitivity, we chose to examine the RNA from two patients who were confirmed both clinically and by immunoblot analysis to have CHM. Scanning the exons of the cDNA it was noted that appropriately sized products were obtained from all exons up to exon 10. The larger fragment size for exon 10 suggested an insertion of approximately 100 bp. Sequencing of the cDNA revealed a variant, c.1245-521A>G. This variant was predicted by Alamut to cause a more favourable splice acceptor and as a result, 114 bases of intronic sequence is introduced into the mRNA transcript prior to exon 10. **Conclusions:** RNA transcript analysis of two unrelated individuals revealed a novel pathogenic splice variant, c.1245-521A>G. Because these individuals are unrelated; it is proposed that this is a hotspot for mutations to spontaneously occur. This 114 bp insertion is proposed to be sufficient to cause non-sense mediated RNA decay and therefore, no REP-1 protein is produced. Inclusion of this region in a diagnostic CHM test will considerably help the overall test sensitivity.

919W

PCR SNP assay for analysis of 22q11 region in Tunisian population. *O. Kaabi, R. Louati, N. Abdellaoui, N.B. Abdelmoula. Histology, Medical University, Sfax, Tunisia.*

  22q11.2 deletion syndrome is a genomic disorder with a broader clinical and genetic spectrum. Microalterations at the 22q11.2 locus include the most frequent 3 Mb deletion and the smaller nested 1.5 Mb deletion. Non-allelic recombination events between LCRs A to H are responsible of 22q11.2 genomic rearrangements. Molecular diagnosis of 22q11.2 microdeleletion is usually made by FISH, MLPA, chromosome microarray analysis or by qPCR. Since 2003, it has been shown that a three step PCR–RFLP analysis can be useful to exclude the presence of 22q11.2 microdeletion in the typically deleted 22q11 region of 1.5 Mb with less cost and high specificity (Huber et al. 2014) and with benefit of reducing the number of patients who must be screened for 22q11.2 microdeletion (from 100 to 1 pc). But this method was developed in the basis of the presence of polymorphism in consecutive selected SNP markers located in the 1,5 Mb 22q11.2 microdeleted region and with a high heterozygosity rate in Brazilian population. Heterozygosity excluded 22q11.2 deletion, whereas homozygosity cannot exclude deletion and leaded to subsequently analysis of 22q11 region by FISH or MLPA. Here, we perform this efficient PCR SNP assay for analysis of 22q11 region in a small cohort (n=10: deleted n=2 and not deleted n=8) of Tunisian patients having a known status of 22q11 deletion by karyotyping, FISH or/and MLPA. Interrogation of SNP database showed no information about allelic polymorphisms of the 3 first steps selected SNP (rs4819523, rs4680 and rs5748411) in North African population. PCR amplification was conducted using primers designed by Huber et al. PCR amplification reactions and conditions were optimized using in Silico PCR tools and gradient melting assays. One touch down PCR reaction was finally designed for a simultaneous amplification of the first step three markers. It was possible via Nebcutter to validate rs4819523 and rs5748411 digestion profiles, using respectively HaeIII and BsrI restriction enzymes. Digestion of rs4680 by BclI as described by Huber et al. was not valid and another enzyme CviAII was then considered. Fragments generated were visualized on 4 pc agarose gel. PCR-RFLP results were concordant with FISH/ MLPA status of deleted (homozygous) and not deleted (heterozygous) patients. Further population studies for determination of heterozygosity rate of 22q11 region markers are needed before setting up such interesting method of 22q11 deletion screening in our population.

920T

Novel mutations including a large deletion in the *ARSB* gene causing mucopolysaccharidosis type VI. *K. Suphapeetiporn[1,2], C. Ittiwut[1,2], S. Boonbuamas[1], C. Srichomthong[1,2], R. Ittiwut[1,2], V. Shotelersuk[1,2].* 1) Department of Pediatrics, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; 2) Excellence Center for Medical Genetics, King Chulalongkorn Memorial Hospital, the Thai Red Cross Society, Bangkok, 10330, Thailand.

Mucopolysaccharidosis type VI (MPS VI; Maroteaux-Lamy syndrome), a rare autosomal recessive lysosomal storage disease, is caused by mutations in the *N*-acetylgalactosamine-4-sulfatase (*arylsulfatase B*, or *ARSB*) gene resulting in a deficiency of ARSB activity. Here we report on clinical and molecular features of four unrelated Thai patients with MPS VI. Two were products of consanguineous marriages. The diagnosis was confirmed by biochemical and genetic tests. We performed mutation analysis by PCR-sequencing the entire coding region of the *ARSB* gene. The causative mutations were detected in all cases. Of four different mutations identified, three have never been previously described which included two missense mutations (p.C155Y and p.R388T) and a deletion encompassing exons 2 and 3. Both missense mutations were absent in 110 unaffected ethnic-matched control chromosomes and an in-house database of 180 Thai exomes. The p.C155Y and p.R388T mutations were located in the highly conserved residues. Array CGH analysis combined with direct sequencing identified the breakpoints of the large 13,788 base-pair deletion. It is the largest deletion of *ARSB* described to date in patients with MPS VI. In conclusion, this study successfully characterized four unrelated Thai patients with MPS VI and identified causative mutations in all cases. Three novel mutations in *ARSB*; two missenses and one large deletion, were reported, expanding the mutational spectrum of *ARSB* causing MPS VI. This study is also the first to characterize the largest deletion encompassing exons 2 and 3 of the *ARSB* gene.

921F

A *de novo* terminal 4.5 Mb duplication of chromosome 16q24.1-q24.3 associated with atrial septal defect, dysmorphic features and severe speech and learning disabilities. *R. Singh[1], W.A. Khan[1], C. Simotas[2], A. Babu[1], B. Xiang[1], S.A. Scott[1], N. Cohen[1].* 1) Genetics and Genomic Sciences, Mount Sinai, New York, NY; 2) Department of Pediatrics, Elmhurst Hospital Center, New York, NY.

Distal trisomy 16q is a rare disorder associated with a spectrum of clinical features and limited postnatal survival. The variability in clinical presentation is due to both the size of the 16q duplication and the partial monosomy of an additional chromosome, since the majority of reported cases have been the result of an unbalanced translocation involving chromosome 16q. We report a child with an atrial septal defect, dysmorphic features including esotropia, microcephaly, a prominent lower lip, periorbital fullness, and shortened palpebral fissures. In addition, the patient had mild central hypotonia, developmental delay, severe speech delay, and learning difficulties. Microarray-based comparative genomic hybridization (aCGH) testing of the proband detected a previously unreported terminal 4.5 Mb duplication of chromosome 16q24.1-q24.3 that includes ~90 genes, 19 of which are known Mendelian disease genes. Interestingly, metaphase fluorescence *in situ* hybridization (FISH) using probes specific to the subtelomeric region of 16q and 22q revealed that the duplicated region was localized to the acrocentric arm of chromosome 22 as a result of an unbalanced 16;22 translocation. The derivative chromosome 22 could not be unequivocally identified by standard karyotyping, and additional FISH testing using AcroP (Cytocell) probes revealed that the chromosome 22p material was intact. Notably, parental analysis by aCGH and FISH determined that neither parent was a carrier of a balanced chromosomal rearrangement involving chromosomes 16 and 22, indicating that this unbalanced 16;22 translocation occurred *de novo*. In addition to the 4.5 Mb duplication of chromosome 16q24.1-q24.3, a *de novo* 665.2 kb deletion on chromosome 5q12.1 was detected in the proband by aCGH, which includes four genes (*KIF2A, DIMT1L, IPO11,* and *LRRC70*). Larger deletions that include *KIF2A* have been reported among patients with developmental delay; however, the identified 5q12.1 deletion was determined to be of uncertain clinical significance based on copy number variation coverage in the Database of Genomic Variation. Our patient shared some common dysmorphic features with reported partial trisomy 16q cases; however, the microcephaly, atrial septal defect, severe speech, and learning difficulties unique to this informative case implicate potential candidate genes within chromosome 16q24.1-q24.3 in the pathogenesis of these specific clinical features.

922W

Langer-Giedon syndrome with 8q23.1-q24.13 large deletion caused by 3-way translocation. *K. Yeon[1], E. Seo[1,2], H. Yoo[1,3], J. Lee[1], J. Lee[4].* 1) Medical Genetics Center, Asan Medical Center, Seoul, South Korea; 2) Department of Laboratory Medicine, Asan Medical Center, Seoul, South Korea; 3) Department of pediatrics, Asan Medical Center, Seoul, South Korea; 4) Asan Institute for Life Sciences, Asan Medical Center, Seoul, South Korea.

　　Langer-Giedion syndrome, also called trichorhinophalangeal syndrome type (TRPS2) or LGCR is a very uncommon autosomal dominant genetic disorder caused by the deletion or mutations of at least two genes on chromosome 8. The missing portion of the chromosome is 8q23-q24 that includes the genes TRPS1 and EXT1. It is a condition that causes bone abnormalities and distinctive facial features. The characteristic appearance of individuals with Langer-Giedion syndrome includes multiple exostoses, short stature, epiphyses, sparse scalp hair, rounded nose, philtrum, and a thin upper lip. Now we present a case of Langer-Giedion syndrome. Case was a 5-month-old girl with bending Lt.thumb, Hypolastic digits, brachycephaly, bulbous nose, prominent alae nasi, thick nasal septum, prominent ears, and missing uvula. Cytogenetic analysis was performed according to standard procedures. Karyotype was 46,XX,der(4)t(4;19)(q27;q11),der(8)t(4;8)(q27;q22.3),der(19)t(8;19)(q22.3;q11)del(8)(q23q24.1). This patient had 3-way translocation with 8q23-q24.1 interstitial deletion. Chromosome analysis of her parents was normal. We could know that in result, her abnormality of chromosome was de novo. Multiplex Ligation-Dependent Probe Amplification (MLPA) also was performed using MLPA probemix (P064, MRC Hollans) and P245 probemix. The patient was found to have a heterozygous deletion at 8q23-q24, rsa 8q24(P064)x1 and rsa 8q24(P245)x1, that include probes for TRPS1 and EXT1. The deletion was confirmed and visualized at the molecular level by array comparative genomic hybridization (array CGH). Array CGH showed a very large deletion of 17 Mb at 8q23.1-q24.13, arr 8q23.1q24.13(108,685,855-125,700,000)x1. Most patients of Langer-Giedion syndrome are caused by the interstitial deletion of 8 to 13 Mb. But this case was 17 Mb deletion at 8q23.1-q24.13 caused by 3-way translocation. This large deletion with Langer-Giedion syndrome is first reported.

923T

Distal trisomy 15q26.3-qter: Report of three familial cases and review of the literature. *S. Basalom, M.D. D'Agostino, S. Drury, L. Russell.* Medical Genetics, McGill University Health Center, Montreal, Canada.

　　Background: Pure duplication of distal 15q is a rare chromosome anomaly characterized by pre and postnatal overgrowth, mild to moderate intellectual deficiency and speech impairment, facial dysmorphisms, renal and cardiac anomalies and cranial synostosis. We report the clinical features of three patients in one family having pure duplication of distal 15q26.3-qter. **Clinical cases:** The proband, patient A, is an 8-year-old male. His birth weight was above the 85th %, length at 99.9th % and head circumference ~ 97th %. He presented at 5 years of age with severe expressive and receptive language delay and delayed motor skills. On physical exam the weight was ~ 85th %, height above the 85th % and head circumference ~ 75th %. Minor dysmorphic features included long face, pointed chin, tall/prominent forehead and deep-set eyes. Abdominal ultrasound was normal while echocardiography showed insignificant cardiac anomalies. The proband's father, patient B, reported symptoms of attention deficit hyperactivity disorder. His height was at the 90th % and head circumference at the 98th %. He also had mild scoliosis, myopia and astigmatism. The proband's paternal half-sister, patient C, reportedly had a mild expressive language delay that has not yet been formally assessed. Her birth weight was at the 75th %, birth length 97th % and head circumference 90th %; at 3 1/2 years her weight was again at the 75th % with height at the 85-98th % and head circumference at the 90th %. She was mildly, diffusely hypotonic and had a prominent forehead and frontal hair upsweep. Echocardiography and abdominal ultrasound were normal. The proband's chromosome microarray revealed a 3.084 Mb duplication of 15q26.3-qter (97004262-100088571). These results were confirmed by fluorescence in situ hybridization (FISH). The same duplication was found in the father (patient B) by FISH and in the sister (patient C) by aCGH and FISH. **Discussion:** We have identified three members of one family with pure trisomy 15q26.3-qter, a region that includes the *IGF1R*. To the best of our knowledge, these cases have the smallest region of distal trisomy 15q reported. Each of these cases exhibits overgrowth and/or macrocephaly, with variable dysmorphic features. We compared these cases to the cases of pure trisomy 15q reported by Chen et al, 2011, and Roggenbuck, et al, 2004. Overgrowth was noted only in those cases in which the trisomic region appeared to include *IGF1R*.

924F

***POLR1D* deletion causes Treacher-Collins syndrome 2 in a family with incomplete penetrance.** *M.J. Alshammari[1,2], S. Zeesman[1], M.J Nowaczyk[1].* 1) McMaster University, Hamilton, ON, Canada; 2) King Saud University, Riyadh, Saudi Arabia.

Treacher Collins syndrome is a mandibulofacial dysostosis that resultes from mutations in genes that contribute to ribosomal synthesis and function. *TCOF1* mutations are detected in the majority of the patients. Recently, *POLR1D* and *POLR1C* genes have been reported in *TCOF1* negative patients. with different manner of inheritance. We report a 30 year-old woman who was diagnosed with Treacher-Collins syndrome at age 18 months: she had micrognathia, zygomatic depression, partial cleft palate, bilateral small, dysplastic posteriorly rotated, low seat ears with poor development of superior pinna and chronic ears infection. She had hearing impairment that required hearing aids (Fig.1). She had normal appearing eyelids with no coloboma and no reduction of her eyelashes. Her growth was normal and she had good academic performance. Her mother had recurrent ears infection but otherwise normal. She had three apparently healthy sisters. However, her nephew had multiple ear infections, narrow ear canals and facial features suggesting a mild form of TCS (Fig. 2). *TCOF1* sequencing was normal. SNP oligonucleotide array analysis identified a 52-kb deletion within chromosomal region 13q12.2, extending from 28,192,790 to 28,245,365 that resulted in the deletion of the entire *POLR1D* gene and partial deletion of *LNX2* gene. This finding was further confirmed by quantitative PCR using primers targeted to chromosome region chr13:28,192,790-28,245,365. Quantitative PCR showed one copy of the loci examined that consistent with SNP oligonucleotide array. High density targeted array revealed a deletion of at least 47.1 kb (g.28195500_28242550) including *POLR1D* gene and this deletion extends from 5' of the *POLR1D* gene to 3' of the gene therefore all *POLR1D* exons are deleted. The same molecular result was found in the proband's mother, her phenotypically normal sister, and her affected nephew. This is the third report of *POLR1D* mutation causing an autosomal dominant inherited Treacher-Collins syndrome and it reinforces the concept of genetic heterogeneity and incomplete penetrance of Treacher-Collins syndrome. It emphasizes in the importance of testing apparently phenotypically normal TCS first degree relative for appropriate genetic counseling and to investigate further the possible factors that contribute in *POLR1D* expression.

925W

13q22.2q34 tetrasomy mosaicism due to an inverted duplication with a neocentromere. *T. Hattori[1], T. Togawa[2], Y. Togawa[1], H. Kawabe[1], T. Kato[3], H. Kurahashi[3], S. Saitoh[2], M. Kouwaki[1], N. Koyama[1].* 1) Department of Pediatrics, Toyohashi Municipal Hospital, Toyohashi, Japan; 2) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 3) Division of Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Japan.

Small supernumerary marker chromosomes (sSMC) comprise a heterogeneous group of structurally rearranged chromosomes origin of which is not determined by conventional cytogenetics. sSMCs lacking endogenous centromere regions are supposed to be maintained during mitosis through a neocentromere formation. Partial tetrasomy 13 due to inverted duplication with a neocentromere has been rarely reported in literature. Here, we report a patient with partial tetrasomy 13 mosaicism due to an inverted duplication of 13q22.2q34 with a neocentromere, which has never been reported. The patient, a Japanese male neonate, was born at 38th gestational age from a 23-year-old healthy mother. His birth weight, length, and head circumference were 3370g, 50cm, and 33cm, respectively. He showed hemangioma on the mid-forehead, low set ears, cleft lip and palate, postaxial polydactyly of the right hand and bilateral feet, laryngomalacia, and umbilical hernia. A brain MRI showed hypoplasia of cerebellar vermis and no sign of holoprosencephaly. G-banding chromosomal analysis from his peripheral blood leukocytes demonstrated 47,XY,+mar[2]/46,XY[28]. Both parents showed normal karyotypes, indicating that sSMC arose de novo. Multicolor fluorescent in situ hybridization (FISH) revealed that the sSMC was derived from chromosome 13. Because inverted duplication was suspected by the G-banding staining pattern of the sSMC, we further performed FISH analysis with dual probes detecting 13q14 and 13q34 on skin fibroblasts established from the patient. Forty of 50 analyzed cells showed four signals of 13q34, while no 13q14 signal was detected on the sSMC. Remaining 10 analyzed cells appeared normal having both 13q34 and 13q14 signals. Therefore, the sSMC did not have an endogenous centromere and was supposed to have a neocentromere. We performed Affymetrix's CytoScan™ HD SNP array to evaluate the range of duplication. Copy number elevation of approximately 39Mb corresponding to 13q22.2 to the q-terminal was identified. Accordingly, we confirmed the cytogenetic diagnosis of 47, XY,+inv dup(13)(q34→q22.2::q22.2→q34).arr[hg19]13q22.2q34(76,134,983-115,107,733)x4. To our knowledge, this is the first report of 13q22.2q34 tetrasomy due to an inverted duplication with a neocentromere. Clinical features of the patient are well corresponding to those with trisomy 13. Our findings can offer additional information to understand phenotype-genotype correlation in patients with partial tetrasomy 13.

926T

Partial trisomy 5q and partial monosomy 13q result in developmental delay with characteristic facial features. *L. Dupuis[1], M. Shago[2], R. Mendoza-Londono[1].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Ontario, Canada.

We report a 12 year old female of Chinese descent with trisomy 5q33.3q35.3 and monosomy 13q34 derived from a paternal t(5;13)(q33.3;q34). Genomic microarray analysis revealed an estimated 23.2 Mb terminal duplication of chromosome region 5q33.3 to 5qter that involved approximatively 217 RefSeq genes and 27 OMIM genes. The terminal deletion of chromosome regions 13q34 to 13qter was estimated to be 1.765 Mb. This deletion resulted in the loss of one copy of 33 RefSeq genes including 5 OMIM genes (*F7, F10, PROZ, GRK1*, and *CHAMP1*).   A review of the literature revealed one case of a 2 year old female of Japanese descent with distal trisomy 5q and monosomy 13q from a maternal translocation (Shiihara *et al*., 2004). Phenotypic similarities between these two cases are striking. Craniofacial findings shared with patients with distal trisomy 5q include hypertelorism, flat midface, thin upper lip with a long simple philtrum, low set posteriorly rotated ears, and small mouth. Syndromic craniosynostosis and skull deformity have been linked to chromosome 5q35 and are due to duplication of the *MSX2* gene in the region. Interestingly, congenital heart disease has been associated with trisomy of 5q distal to 5q31. Our patient exhibited a small patent foramen ovale, whereas the previously reported patient had an ASD and PDA. Both of the patients had moderate developmental delay, particularly in areas of language and fine motor skills, but no major neurological deficits. Congenital heart defects have also been associated with 13q terminal deletions, including one patient with a deletion of 1.1Mb (*Yang et al*., 2013).   Recognition of this characteristic clinical phenotype may facilitate the diagnosis, understanding of the natural history and provision of adequate counseling to parents with similar balanced translocations.

927F

Copy number variation analysis identifies novel genomic regions associated with aberrant developmental phenotypes. *S. Chettiar[1], A. Patel[2], J. Dattani[3], D. Jhala[4], V. Sharma[5], U. Radhakrishna[6], M. Rao[4], N. Jain[1].* 1) Department of Life Science, Gujarat University, Ahmedabad, Gujarat, India; 2) GeneXplore Diagnostics and Research Centre, Ahmedabad, India; 3) NVBDP, Ministry of Health and Family Welfare, Government of India; 4) Department of Human Genetics, Gujarat University, Ahmedabad, India; 5) Department of Bioscience, Veer Narmad South Gujarat University, Surat, India; 6) Department of Obstetrics and Gynecology, Oakland University- William Beaumont School of Medicine, Royal Oak, MI, USA.

Copy-number variation (CNV) is the most common type of genomic structural variation in humans, and plays an important role in the etiology of many diseases such as cancers, psychiatric disorders, *congenital anomalies, r*ecurrent pregnancy loss and developmental disorders. These variations due to deletions and/or duplications of chromosomal segments alter the genome structure and also significantly affect gene expression levels. Twenty five amniotic fluid samples from individuals with a history of various developmental anomalies observed during radiological examination were analyzed. The average age of mothers was 30 years. Conventional cytogenetic analysis was performed, followed by high-resolution array Comparative Genomic Hybridization (aCGH) for the identification of copy number variations (CNVs). Using these combined techniques for the detection of structural variation, we discovered eight *genomic regions* associated with developmental disorders. In two cases with *echogenic intracardiac focus,* duplication of Chr19p13.11-p12*,* was detected and in three cases with short nasal bone, *retrognathia*, and *symmetrical intrauterine growth retardation,* a microdeletion on chromosome 4q35.2 and a duplication at chromosome 15q11.1-11.2 were observed. In addition, one case with atrioventricular septal defect showed a deletion at Chr8p11.22 region. Three different cases with bilateral *Ventriculomegaly* and facial dimorphism had a deletion at Chr3p26.2-26.1, ChrX22.33 and a duplication of Chr10q26.3. The present data suggest these copy number variations are one of multiple factors contributing to the development of *developmental* disorders in children. The current study emphasizes the utility of microarray based analysis in aberrant radiological observation.

928W

Identification of deletions during diagnostic massive parallel NGS gene panel sequencing. *S. Hinreiner[1], M.R. Hehr[1], N. Koch[1], A. Schweiger-Kabesch[2], I. Bader[3], B. Schmitt[4], S. Gebre-Medhin[5], S.M. Herbst[1], U. Hehr[1].* 1) Center for and Department of Human Genetics , Regensburg, Bayern, Germany; 2) Department of Pediatric Neurology, Klinik St. Hedwig, University Children's Hospital, Regensburg, Germany; 3) Division of Clinical Genetics, Department of Pediatrics, PMU Salzburg, Austria; 4) Department of Neurology, Children's Hospital, Zürich, Switzerland; 5) Department of Clinical Genetics, Skane University Hospital, Lund, Sweden.

   Introduction Massive parallel sequencing of multi gene panels (MGPS) allows fast and cost-effective genetic diagnostic testing including sequence analysis of genes with small contribution for a wide variety of phenotypes. The additional detection of copy number variations (CNVs) by MGPS within the analyzed genes can be expected to further improve the diagnostic yield, but so far is limited due to technical and bioinformatic aspects.   **Methods** 81 patients were sequenced with phenotype specific gene panels on a MiSeq platform (Illumina) and analyzed with our bioinformatic diagnostic workflow including a quantitative data assessment using our *in house* JAVA based bioinformatic script to search for gene or exon deletions. Detected deletions were confirmed by an independent method (e.g. MLPA, PCR amplification of the junction fragment), if available.   **Results** We here report details for five suspected deletions in six patients detected by our *in house* bioinformatic workflow, five of them currently independently confirmed: heterozygous gene deletions of *PAFAH1B1, Spastin* or *ARFGEF2,* respectively; two heterozygous *CFTR* deletions of exon 2 and 3 and one homozygous partial *SFTPB* deletion. The average coverage for the respective target reads was 84.16 for the controls (standard deviation 28.78) and 47.28 within the assumed heterozygous deletions. The complete gene deletions of *PAFAH1B1* and *Spastin* as well as the *CFTR* deletion of exon 2 and 3 could be confirmed by MLPA. For the partial *SFTPB* deletion both breakpoints could be precisely located within the read-out, allowing determining correct deletion size and design of primers to amplify the junction fragment.   **Discussion** Diagnostic multi gene panel sequencing after Nextera enrichment allows sufficient homogeneity of the obtained patient and control data per target to quantitatively search for constitutional deletions covering two or more adjacent targets. Combined data assessment considering the individual clinical data will not only further increase the diagnostic yield but can also be expected to further delineate the mutational spectrum for specific phenotypes by the simultaneous detection of clinically relevant sequence variants as well as copy number variations.

929T

Research reanalysis of clinical whole exome sequencing: Opportunities and discoveries. *E. Bhoj[1], D. Li[1], M. Harr[1], E. Chishom[2], S. Vergano[2], E. Zackai[1], H. Hakonarson[1].* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) Children's Hospital of the King's Daughters, Norfolk, VA.

   Clinical whole exome sequencing (WES) has entered the mainstream of genetic testing recently with thousands of patients testing in dozens of laboratories. There is some variability in the rates of achieving a diagnosis using exome sequencing, but regardless of testing laboratory, indication for testing, and analysis methodology, over half of the tests are non-diagnostic. Therefore, there are likely patients with a molecular diagnosis who are not being captured in their original exome sequencing analysis. These extra findings may be related to strengths and weakness of a particular analytic pipeline, or the result of undiscovered genes that contribute to the phenotype. Additionally, there is not a clear recommendation governing periodic reanalysis of the sequencing data, or a universal forum for collection of this valuable data. Therefore, clinicians are left with few options when a patient does not achieve a diagnosis through exome sequencing. At the Center for Applied Genomics at the Children's Hospital of Philadelphia we have an IRB-approved program to provide research-based reanalysis of whole exome/genome sequencing that was non-diagnostic at a clinical reference laboratory. After the families are consented, the bam and vcf files from the original sequencing are requested from the reference laboratory. We then analyze those data using a pipeline optimized both for known genes, and especially for gene discovery. Over thirty families from multiple references laboratories and clinical centers have been enrolled in the project to date. In our initial analysis we have found about a 20% diagnostic or strong candidate gene identification rate. In addition, we have been able to identify trends in those cases with a newly positive result, including application of phenotypic information to the analysis, and integration of multiple scientific databases during the analysis. We will highlight strategies for referring clinicians to communicate effectively with sequencing laboratories to improve diagnostic efficiency. Also, options to partner with laboratories that can provide follow up functional testing of novel variants will be discussed. Two informative cases from the project will be presented (with blinding of the original reference laboratories); one with the identification of a known gene and one with the discovery of a confirmed novel disease gene, TBCK-related intellectual disability.

930F

Miller-Dieker syndrome due to a 5.5 Mb 17p deletion from a Y-17 dicentric chromosome. *F.T. Bellucco[1], N. Nunes[1], M.E. Colovati[1], A.C. Malinverni[2], T.P. Caneloi[1], M.F. Soares[3], A.B. Perez[1], M.I. Melaragno[1].* 1) Department of Morphology and Genetics, UNIFESP - Universidade Federal de São Paulo, São Paulo, Brazil; 2) Department of Pathology, UNIFESP - Universidade Federal de São Paulo, São Paulo, Brazil; 3) Department of Diagnostic Imaging, UNIFESP - Universidade Federal de São Paulo, São Paulo, Brazil.

Miller–Dieker syndrome (MDS; OMIM 247200) is a contiguous gene deletion syndrome characterized by a severe type of lissencephaly, significant facial dysmorphism and, occasionally, other congenital anomalies, such as renal, gastrointestinal, and cardiac defects. We report a male infant with clinical phenotype of MDS including lissencephaly, corpus callosum hypoplasia, microcephaly, bitemporal hollowing, prominent forehead, short nose/upturned nares, broad nasal bridge, epicanthal folds, low-set ears, protuberant upper lip, high-arched palate, prenatal and postnatal growth deficiency, heart malformation, genital anomalies and transverse palmar creases. The patient presents 45 chromosomes and a derivative Y-17 chromosome. Array-CGH showed a *de novo* 5.5 Mb 17p13.3 deletion and no deletion in chromosome Y. C-banding showed the Yq distal heterochromatin attached to the 17p breakpoint. Fluorescent in situ hybridization (FISH) with *SRY* probe showed positive signal in the extremity of the dicentric chromosome revealing the fusion of Yq to 17p. The final cytogenomic result is: 45,X,dic(Y;17)(Ypter→Yq12::17p13.2→17qter). arr[hg19] 17p13.3p13.2(59,739-5,464,323)×1. The deletion involves more than 100 genes including the *PAFAH1B1* gene and the CRK and *YWHAE* genes, which contribute to cortical development and the severity of MDS. Almost all patients with MDS present *de novo* cytogenetic visible 17p13.3 deletions or microdeletions encompassing the *PAFAH1B1* gene along with several nearby genes including the *YWHAE* gene. Our patient presents a large deletion, a rare finding in the literature in MDS patients. Most patients with 17p deletion and unbalanced translocations show a combination of MDS and additional phenotypes because of the involvement of segments of various autosomes. Pure partial monosomy derived from balanced translocation is relatively rare in the literature. Our patient presents a Y-autosome translocation, a rare cytogenetic finding with frequency of 0.01%. At least 34 cases of 45,X male with Y-autosome translocation have been reported in the literature, none of them involving the chromosome 17. Only four cases with Y-autosome translocation associated with genetic syndromes were described: Jacobsen syndrome, DiGeorge syndrome, cri-du-chat and Dandy-Walker malformation with cerebral atresia. This is the first case of Miller-Dieker syndrome that showed a pure 17p deletion, derived from a t(Y;17) translocation.

931W

Molecular karyotyping in patients with SRS features: A powerful tool to increase diagnostic yield. *K. Eggermann[1], J. Sachwitz[1], R. Meyer[1], G. Fekete[2], M. Elbracht[1], T. Eggermann[1].* 1) Inst Human Genetics, RWTH Aachen, Aachen, Germany; 2) Dept. of Pediatrics, Semmelweis University, Budapest, Hungary.

Silver-Russell syndrome (SRS, RSS) is a growth retardation syndrome characterized by intrauterine and postnatal growth retardation, relative macrocephaly and protruding forehead, body asymmetry and feeding difficulties. Nearly 50% of cases with a characteristic phenotype show a hypomethylation of ICR1 in 11p15.5; maternal uniparental disomy of chromosome 7 (upd(7)mat) can be detected in 10% of patients. After exclusion of ICR1 hypomethylation and upd(7)mat, we analysed 44 individuals referred for SRS genetic testing by molecular karyotyping. Pathogenic variants were detected in six of them, including a duplication of the maternal Prader-Willi/ Angelman region (PWAS-CR) in 15q11.2-12, a duplication of NSD1 in 5q35 and a 14q32 microdeletion. The clinical picture of patients with 15q11.2-12 microduplications may vary considerably but among other features growth retardation, hypotonia, macrocephaly, epicanthus and clinodactyly are reported, all features are also described in SRS patients. NSD1 deletions lead to overgrowth syndromes and vice versa NSD1 duplications lead to growth retardation. The 14q32 deletion is typically associated with Temple syndrome (TS14) and this reflects the clinical overlap between TS14 and SRS. Determination of the molecular subtype is crucial for a directed counselling and therapy. Using molecular karyotyping, we identified pathogenic variants in >13% of unclassified patients referred for SRS testing. Among those with a characteristic SRS phenotype more than 16% showed pathogenic variants. We therefore conclude that in addition to 11p15.5 alterations and upd(7)mat, 6-7% of all SRS patients carry submicroscopic chromosome aberrations and we strongly suggest applying molecular karyotyping after exclusion of the more frequent aberrations.

932T

The presence of two rare genomic syndromes, 1q21.1 deletion and Xq28 duplication, segregating independently in a family with intellectual disability. *K. Ha*[1,2]*, H.G. Kim*[2,3]*.* 1) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX; 2) Section of Reproductive Endocrinology, Infertility & Genetics, Department of Obstetrics & Gynecology, Augusta University, Augusta, GA; 3) Department of Neuroscience and Regenerative Medicine, Augusta University, Augusta, GA.

1q21.1 microdeletion syndrome is a rare contiguous gene deletion disorder with *de novo* or autosomal dominant inheritance patterns and its phenotypic features include intellectual disability, distinctive facial dysmorphism, microcephaly, cardiac abnormalities, and cataracts. *MECP2* duplication syndrome is an X-linked recessive neurodevelopmental disorder characterized by intellectual disability, global developmental delay, and other neurologic complications including seizures later in life. Since these two syndromes are genetically unrelated, it has not been reported for these two different genetic syndromes segregating independently in a same family. Here we describe two siblings carrying a chromosome 1q21.1 microdeletion and chromosome Xq28 duplication, respectively. Using a comparative genomic hybridization (CGH) array, we identified a 1.24 Mb heterozygous deletion at 1q21.1 from position 146.5-147.78 Mb resulting in the loss of 12 genes in a girl with hypothyroidism, short stature, sensory integration disorder, and soft dysmorphic features including cupped ears and a unilateral ear pit. We also characterized a 508 kb duplication at Xq28 encompassing *MECP2* in the younger brother with hypotonia, poor speech, cognitive and motor impairment. The parental CGH and quantitative PCR (qPCR) analyses revealed that the 1q21.1 deletion in the elder sister is *de novo*, but the Xq28 duplication in the younger brother was originally inherited from maternal grandmother through the mother, both of whom as an asymptomatic carrier. RT-qPCR assays revealed that the affected brother has almost double amount of *MECP2* mRNA expression compared to other family members of both genders including maternal grandmother and mother who have the same Xq28 duplication with no phenotype, suggesting the X chromosome with an Xq28 duplication in the carrier females is preferentially silenced. We also discussed the possible involvement of other genes in the phenotypes of these two rare syndromes according to the relevant literature.

933F

Mosaicism identified by SNP array analysis in a large cohort of pediatric patients. *M. Luo*[1,2]*, J. Fan*[2]*, S. Mulchandani*[2]*, J. Chen*[2]*, B. Thiel*[2]*, M. Dulik*[2]*, E. Zackai*[3,4]*, N. Spinner*[1,2]*, L. Conlin*[1,2]*.* 1) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Philadelphia, PA 19104; 2) Division of Genomic Diagnostics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 3) Department of Genetics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA 19104; 4) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104.

Mosaicism denotes the presence of two or more populations of cells with different genomic contents. Abnormalities can arise from either a post-zygotic error or a pre-zygotic error corrected post-zygotically. Mosaicism complicates the clinical interpretation and following genetic counseling. We have previously demonstrated the clinical utility of single-nucleotide polymorphism (SNP) array analysis in the detection of mosaicism involving ≥5% of cells. In order to investigate the contribution of mosaicism in pediatric genetic diagnostics, we reviewed the SNP array data from patients received by our clinical laboratory for the diagnosis of suspected constitutional genetic disorders since May 2008. In this retrospective analysis of 11,659 patients, mosaic changes were detected in 195 cases (1.67%). Of these 195 cases, 161 carried the mosaic abnormalities associated with the patients' phenotypes, which also accounted for about 10% of all our positive cases. The remaining 34 cases were found to have mosaic findings with unknown significance. Among all the cases, seven cases were characterized as a genome wide mosaicism, caused by genome-wide uniparental disomy (UPD), chimerism or twin-twin transfusion. Aneuploidy with or without additional chromosomal abnormalities was the most common finding and was detected in 69 cases, with 42 cases involving only sex chromosomes, 26 involving only autosomes, and 1 affecting both. Single or multiple copy number variations affecting only part of a chromosome, either as an interstitial or a terminal change, were identified in 58 cases. Three cases involved mosaic unbalanced translocations. Partial chromosome loss of heterozygosity (LOH) suggesting segmental UPD was identified in 48 cases with the majority involving the short arm of chromosome 11. Whole chromosome UPD was seen in 7 cases, with two of them also associated with aneuploidy. In addition to these proband samples, three parents with germline mosaicism were identified. The possible structural abnormalities associated with the mosaic findings, the underlying mechanisms, and their tissue distribution were further investigated by additional clinical tests including chromosome and FISH studies. Our analysis provides an overview of the mosaic disorders detected in pediatric patients. This study demonstrates that mosaicism is much more frequent than previously recognized and the detection of mosaicism increases the diagnostic yield of chromosome array analysis.

934W

Molecular dissection of germline chromothripsis in a developmental context. *S. Middelkamp[1], S. van Heesch[1,2], K. Braat[1], J. de Ligt[1], M. van Iterson[3], M. Simonis[1], M. van Roosmalen[1], M. Kelder[4], E. Kruisselbrink[1], R. Hochstenbach[1], N. Verbeek[1], E. Ippel[1], Y. Adolfs[1], J. Pasterkamp[1], W. Kloosterman[1], E. Kuijk[1], E. Cuppen[1].* 1) University Medical Center Utrecht, Utrecht, The Netherlands; 2) Cardiovascular and Metabolic Sciences, Max-Delbrück-Center for Molecular Medicine (MDC) in the Helmholtz Association, Berlin, Germany; 3) Leiden University Medical Center, Leiden, The Netherlands; 4) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UK.

Chromothripsis causes complex genomic rearrangements that are likely to affect multiple genes and their regulatory contexts. The contribution of individual rearrangements and affected genes to the phenotypes of patients with complex germline genomic rearrangements is generally unknown. To dissect the impact of germline chromothripsis in a relevant developmental context, we performed trio-based RNA expression analysis on blood cells, induced pluripotent stem (iPS) cells and iPS-cell derived neuronal cells from a patient with *de novo* germline chromothripsis and both healthy parents. Sixty-seven genes are located within one megabase of the complex chromothripsis rearrangements involving seventeen breakpoints on four chromosomes. We find that three of these genes, *TWIST1*, *FOXP1* and *DPYD*, are both differentially expressed in the cells of the patient and associated with developmental disorders resembling the phenotype of the patient. Interestingly, the effect on *TWIST1* expression was exclusively detectable in the patient's iPS-derived neuronal cells, stressing the need for studying developmental disorders in the correct context. Analysis of the regulatory landscape around *TWIST1* by Hi-C indicates that deregulation of *TWIST1* expression is caused by gains and losses of patient- and cell type specific enhancer interactions near *TWIST1*. We demonstrate that a combination of patient-derived iPS cell differentiation and trio-based molecular profiling is a powerful approach to improve the interpretation of pathogenic complex genomic rearrangements. Here we have applied this approach to identify misexpression of *TWIST1, FOXP1* and *DPYD* as key contributors to the complex congenital phenotype resulting from germline chromothripsis rearrangements.

935T

***De novo* interstitial duplication 5q31.2q31.3 associated with microcephaly, growth restriction and global developmental delay.** *L. Schultz, E. McCready, C. Li.* McMaster Children's Hospital, Department of Genetics, 1200 Main St W, Hamilton, ON L8N3Z5.

We report a 19 months old female patient who presented with intrauterine growth restriction with a birth weight of 2.26kg at 37 weeks gestation and a postnatal history of failure to thrive. At 19 months, her weight was less than 5th percentile, height was at the 5th percentile and her head circumference was less than -3SD. She also had global developmental delay, unable to crawl or finger-feed herself and had no words. Physical examination also revealed subtle dysmorphic features that included a prominent forehead and nose with hypoplastic nares. A *de novo* duplication on 5q31.2q31.3 was found on microarray. The deletion is 2.98Mb in size and encompasses 50 RefSeq genes, including six that are catalogued in the Morbid OMIM: *KLHL3, MYOT, REEP2, SIL1, MATR3, TMEM173*. Interstitial duplication of 5q31.2q31.3 is rare. Larger duplications involving this region have been described [Giardino et al., 2004; Faguer et al., 2011] without a clear phenotypic pattern. We found only one interstitial duplication in 5q with similar breakpoints and size to our case [Rosenfeld et al., 2011]. Overlapping phenotype included microcephaly, developmental delay and a prominent forehead. However, congenital heart defect and ear anomaly are not present in our patient, and seizure/abnormal EEG has not been observed to date. By sharing our findings, we hope to contribute to the molecular and phenotypic delineation of a rare duplication 5q31.2q31.3.

936F

Lions and tigers and bears, oh my! Technically challenging variants are prevalent and require new approaches to NGS test development and validation. *S. Lincoln[1], R. Truty[1], J. Zook[2], B. Funke[3,4], C. Huang[5], J. Dickens[5], M. Ghent[1], S. Yang[1], A. Rosendorff[1], S. Aradhya[1], J. Park[6], M. Salit[2], R. Nussbaum[1].* 1) InVitae, San Francisco, CA; 2) National Institute for Standards and Technology, Gaithersburg, MD; 3) Laboratory for Molecular Medicine, Cambridge, MA; 4) Department of Pathology, Harvard Medical School, Boston, MA; 5) Seracare Life Sciences, Gaithersburg MD; 6) UT Southwestern Medical Center; Dallas, TX.

Most sequencing efforts currently focus on the detection of SNVs and small indels in accessible coding regions, although these methods can miss a significant fraction of variants with clinical importance. We examined clinical test results for over 30,000 patients across 1000 genes associated with cancer, cardiovascular, neurological and pediatric disorders. We found that technically challenging variants were a substantial fraction of the potentially actionable findings: Of roughly 5000 patients with a pathogenic variant, 2.9% had CNVs affecting only a single-exon,1.8% a large indel or complex sequence change, and 5.8% a variant in a region of high-GC, low complexity or poor short-read mapability. Even at >250x average depth, 3-4% of target bases in these genes had, by clinical testing standards, low (<20x) coverage in standard exome sequences, compared to 0.0% - 0.1% for coverage-optimized panels at similar depths. Also, 20% of target bases were outside the published Genome in a Bottle (GIAB) high-confidence regions, and very few examples of "hard" GIAB variants are present in these genes. Developing and validating tests that include these regions and variant types is challenging, in part because of the relative scarcity of positive and negative controls. Steps are being taken to improve this. Multiple assays including linked reads and long-read single molecule sequencing are being used to improve the GIAB reference, and the latest draft GIAB data increase the high-confidence regions from 78% to 89% of the genome. To increase the number of "hard" variants we developed sets of large plasmid inserts bearing specific, known variants engineered into the GIAB reference sequences. These were spiked into GIAB genomic DNAs at concentrations that mimic heterozygous variants and sequenced using standard NGS protocols. We compared the resulting BAM files against those from patients with the same variants and found them to be highly similar. Most currently published validation studies include few, if any, of the most challenging types of variants, which are indeed clinically important and are prevalent across a range of genetic disorders. We believe that clinical test validation standards should increasingly focus on this issue. To help labs do so, new GIAB data and GIAB samples with engineered plasmids will be available to the ASHG community by the 2016 Annual Meeting. Variant prevalence data will be available in ClinVar.

937W

Improving coverage of poorly sequenced regions in clinical exomes. *E. White, N. Chennagiri, E. Lopez, A. Frieden, J. Thompson.* Claritas Genomics, Cambridge, MA.

We have previously reported an orthogonal sequencing approach for clinical whole exome sequencing in which results of two next-generation sequencing platforms are combined for rapid variant confirmation. This both reduces the Sanger sequencing confirmation burden by ~90% and increases overall assay sensitivity since each platform uniquely sequences thousands of exons. In the current orthogonal approach, we sequence the Agilent Clinical Research Exome (CRE) libraries on the Illumina NextSeq and combine variants with those identified from AmpliSeq Exome libraries sequenced on the Ion Torrent Proton. Although the orthogonal platform increases exome variant sensitivity, there are still poorly covered regions that remain and may result in missed pathogenic variants. To minimize this problem, we have designed new sets of primers for low coverage AmpliSeq amplicons and amplified these independently at lower multiplicity than the highly multiplexed standard amplicons. Independent pools are designed for up to hundreds of genes in a phenotypically-driven manner. These are used as a supplement to the standard amplicons and sequenced together with them. We find that many of the low coverage regions are enhanced to the point that variants can be called and sensitivity in those regions is substantially improved so that patients receive a higher quality analysis.

938T

Rapid clinical WES in critically ill infants. *Y. Yang[1,2], M. Walkiewicz[1,2], F. Xia[1,2], R. Xiao[1,2], W. Bi[1,2], P. Liu[1,2], C. Qu[2], Y. Ding[3], J. Chandarana[2], P. Stankiewicz[1,2], A.M. Breman[1,2], J. Smith[1,2], S. Lalani[1,2], J. Smith[1,2], A. Patel[1,2], S.W. Cheung[1,2], N. Narayanan[2], A. Braxton[2], P. Ward[1,2], J.R. Lupski[1,3,5], A.L. Beaudet[1,2], S.E. Plon[1,4], R.A. Gibbs[1,3], D.M. Muzny[1,3], C.M. Eng[1,2].* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Baylor Miraca Genetics Laboratories, Houston, TX; 3) The Human Genome Sequencing Center, Baylor Col Med, Houston, TX; 4) Texas Children's Hospital, Houston, TX; 5) Department of Pediatrics, Baylor Col Med, Houston, TX.

Clinical whole exome sequencing (WES) has been integrated into healthcare in recent years. Initially, WES was used primarily on patients who had previously tested negative for specific genes, karyotype, and/or microarray studies, and the turnaround time (TAT) was usually several months. With the improvements of NGS methodologies and analysis tools, the TAT of WES can be reduced to about two weeks. The short TAT enables new clinical applications especially in the molecular diagnosis of prenatal patients or patients who are at high risk for potentially life-threatening conditions and are therefore considered critically ill. Here, we present the rapid clinical WES of 61 patients who were under 12 months of age. The patients were referred by multiple institutions; most of them had been admitted into intensive care units. Twenty-two out of the 61 cases had both WES and chromosomal microarray (CMA) tests ordered concurrently. The CMA/WES ordering status for the remaining cases is unknown. Overall, approximately 56% (34/61) of the patients received a molecular diagnosis from rapid WES. Twelve of the 22 (55%) patients with concurrent CMA/WES received a molecular diagnosis including 1 diagnosis of a large heterozygous deletion identified by both tests. No additional diagnoses were made by CMA. The molecular diagnosis rate from our data is consistent with the approximately 50% reported from other studies on critically ill young patients. The collective data to date suggest that rapid exome sequencing should become a standard of care and the first-tier NGS test for NICU or PICU patients whose phenotypic features suggest an underlying genetic etiology. However, accessibility to clinical exome sequencing has remained challenging due to low reimbursement and authorization rates from insurance plans. It is therefore critical to further evaluate the clinical utility of rapid WES and establish practice guidelines leading to efficient and cost effective molecular diagnoses for NICU and PICU patients. .

939F

A novel mutation of *ROBO3* in horizontal gaze palsy with progressive scoliosis. *S. Tug Bozdogan[1], E. Dinc[2], A. Sari[2], A. Ozgur[3], A. Bisgin[1].* 1) Medical Genetics, Cukurova University Medical School, Adana, Turkey; 2) Mersin University Medical School, Ophthalmology; 3) Mersin University Medical School, Radiology.

INTRODUCTION Horizontal gaze palsy with progressive scoliosis (HGPPS), is a rare autosomal recessive disorder with oculomotor and general disturbances in innervation. The *ROBO3* gene mutation was described as a responsible gene of HGPPS. Here we present a case of HGPPS with a novel mutation of *ROBO3.* **CASE REPORT** A 22-year-old female patient was admitted to clinic with dysmorphic features and strabismus in both eyes. She was the fifth child of 8 siblings of first cousins. Her two elder sisters have a history of basic esotropia surgery. Her motor development was delayed, thoracolumbar scoliosis was diagnosed at the age of 2 years and had been progressive. Her physical examination revealed short stature, short neck, pectus carinatum with left thoracic scoliosis extending from T6 to L1 with a quite prominent hump to the right. MR imaging of the brain depicted a hypoplastic pons with a cleft, a hypoplastic medulla oblongata with butterfly morphology and the fourth ventricle with a tent-shaped roof. There was severely limited abduction and adduction in both eyes; vertical movements were unimpaired. Because the patient presented with clinical features suggestive of HGPPS, the coding regions of *ROBO3* was subjected to sequence analysis. She carried a homozygous p.R842* (c.2524C>T) mutation in exon 16 of *ROBO3.* However the mutation has not been reported previously, in-silico analyses revealed as a disease making mutation. Only the mother accepted to involve in the genetic testing, that resulted as a carrier of this novel mutation; heterozygous p.R842* (c.2524C>T). **DISCUSSION** HGPPS is a rare congenital disorder characterized by defective horizontal eye movements and progressive scoliosis during childhood and adolescence. Brain stem malformation and defective crossing of brain stem neuronal pathways are also seen in HGPPS. Our patient presented with severe left thoracic scoliosis extending from T6 to L1 vertebrae, exotropia and defective horizontal eye movements with normal vertical movements. *ROBO3* gene play a role in the regulation of hindbrain axonal midline crossing and helps cell migration. To date, 33 different mutations of *ROBO3* have been described and related to HGPPS. In our case, we determined a novel homozygous mutation p.R842* (c.2524C>T) causing a premature stop codon which is a disease making mutation. Much remains to be learned about this condition despite the advances in our understanding.

940W

Analysis of chromosome 22q11.2 copy number variations by multiplex ligation-dependent probe amplification. *T. Alarcon Martinez[1], S. Kabacam[2], A.C. Ceylan[3], O.P. Simsek Kiper[2], M. Alikasifoglu[3], K. Boduroglu[2], G.E. Utine[2].* 1) Department of Pediatrics, Hacettepe University, Ankara, Turkey; 2) Division of Pediatric Genetics, Hacettepe University, Ankara, Turkey; 3) Department of Medical Genetics, Hacettepe University, Ankara, Turkey.

Introduction: Genomic copy number variations (CNVs) at 22q11.2 are associated with several syndromes, characterized by different combinations of clinical manifestations. The traditional molecular diagnostic procedure for CNVs of the region is chromosomal analysis coupled with fluorescence *in situ* hybridization (FISH). However, atypical deletions and duplications may be missed by these methods. Multiplex ligation-dependent probe amplification (MLPA) was herein investigated as an alternative to FISH for molecular diagnosis and more precise delineation of CNVs at 22q11.2. Methods: MLPA analysis was performed in a total of 83 patients, in search for higher resolution molecular results and also for possible genotype-phenotype correlations. Of these, 30 patients had FISH-confirmed 22q11.2 deletion syndrome (22q11.2DS), and 53 patients had clinical diagnoses previously not supported by FISH. Results: MLPA confirmed the diagnosis of 22q11.2DS in 30 patients with positive FISH. Among 30 patients, 27 (90%) showed typical 3-Mb deletion, while 2 (6.6%) displayed proximal 1.5-Mb deletion. Patients with 1.5-Mb deletion were monozygotic twins, demonstrating only velopharyngeal insufficiency. One patient (3.4%) had a deletion encompassing cat-eye region and LCRA, while her sister exhibited duplication in the same region. Parental karyotyping results showed 46, XX,t(13;22)(q12.1;q12.1), balanced translocation in their mother. MLPA analysis of 53 patients with negative FISH results revealed mosaic 3-Mb deletion in one, *TBX1* duplication in one and *TBX1* deletion in three patients. *TBX1* deletions are confirmed by real time PCR, whereas *TBX1* duplication is also detected by comparative genomic hybridization. Conclusions: MLPA is more sensitive than FISH in molecular diagnosis and delineation of CNVs at 22q11.2, with a yield in the current study of 9.4% (5/53) in patients with previously negative results. Moreover, patients with duplications and atypical deletions showed different clinical characteristics than 22q11.2DS.

941T

Nonrecurrent *PMP22-RAI1* contiguous gene deletions arise from replication-based mechanisms and result in Smith-Magenis syndrome with evident peripheral neuropathy. *J. Neira[1], B. Yuan[1], S. Gu[1], T. Harel[1], P. Liu[1], I. Briceño[2,3,4], S. Elsea[1], A. Gómez Gutiérrez[2,3], L. Potocki[1,7], J.R. Lupski[1,5,6,7].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, 77030, USA; 2) Instituto de Genética Humana, Facultad de Medicina, Pontificia Universidad Javeriana, Bogotá, Colombia; 3) Instituto de Referencia Andino, Bogotá, Colombia; 4) Facultad de Medicina, Universidad de La Sabana, Chía, Colombia; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas, 77030, USA; 6) Department of Pediatrics, Baylor College of Medicine, Houston, Texas, 77030, USA; 7) Texas Children's Hospital, Houston, Texas, 77030, USA.

Hereditary neuropathy with liability to pressure palsies (HNPP) and Smith-Magenis syndrome (SMS) are genomic disorders associated with deletion copy number variants (CNVs) involving chromosome 17p12 and 17p11.2, respectively. Nonallelic homologous recombination (NAHR)-mediated recurrent deletions are responsible for the majority of HNPP and SMS cases; the rearrangement products encompass the key dosage sensitive genes *PMP22* and *RAI1*, respectively, and result in haploinsufficiency for these genes. Less frequently, nonrecurrent genomic rearrangements occur at this locus. Contiguous gene duplications encompassing both *PMP22* and *RAI1*, i.e. *PMP22-RAI1* duplications, have been investigated, and replication-based mechanisms rather than NAHR have been proposed for these rearrangements. In the current study, we report molecular and clinical characterizations of six subjects with the reciprocal phenomenon of deletions spanning both genes, i.e. *PMP22-RAI1* deletions. Molecular studies utilizing high-resolution array comparative genomic hybridization and breakpoint junction sequencing identified mutational signatures that were suggestive of replication-based mechanisms. Systematic clinical studies revealed features consistent with SMS, including features of intellectual disability, speech and gross motor delays, behavioral problems and ocular abnormalities. Five out of six subjects presented clinical signs and/or objective electrophysiologic studies of peripheral neuropathy. Clinical profiling may improve the clinical management of this unique group of subjects, as the peripheral neuropathy can be more severe or of earlier onset as compared to SMS patients having the common recurrent deletion. Moreover, the current study, in combination with the previous report of *PMP22-RAI1* duplications, contributes to the understanding of rare complex phenotypes involving multiple dosage-sensitive genes from a genetic mechanistic standpoint. .

942F

Comprehensive assay to detect DNA sequence variants in the muco-polysaccharidoses related genes using next generation sequence. *A. Brusius-Facchin[1,2], M. Siebert[3], D. Leão[3], D. Malaga[1,2], G. Pasqualim[2,4], U. Matte[2,3,4,5], R. Giugliani[1,2,5], S. Leistner-Segal[1,6].* 1) Hospital de Clinicas de Porto Aelgre, Porto Alegre, Brazil; 2) Post-Graduation Program in Genetics and Molecular Biology (PPGBM) – Universidade Federal do Rio Grande do Sul (UFRGS), Brazil;; 3) Unidade de Análises Moleculares e de Proteínas (UAMP) – Centro de Pesquisa Experimental, HCPA, Brazil; 4) Gene Therapy Center, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 5) Department of Genetics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 6) 6.Post-Graduation Program in Medicine: Medical Sciences (PPGCM) – Universidade Federal do Rio Grande do Sul (UFRGS), Brazil.

The mucopolysaccharidoses (MPS) a group of rare genetic disorders caused by mutations in any of the eleven genes that encode enzymes responsible for the stepwise degradation of glycosaminoglycans (GAGs). The abnormal accumulation of these substrate inside the lysosomes of most cells, induce progressive cellular damage and multiple organ failure, with consequent reduction of the quality of life and life expectancy. Over the past 30 years Sanger sequencing technology was the gold standard approach to identify sequence alterations in the target region analyzing individual genes, usually exon-by-exon. Currently, the Next Generation Sequence, a fast tool with high capacity of sequencing, allows the mutation detection of multiple genes and patients at same time improving the molecular diagnosis. In order to evaluate the NGS technology for MPS diagnosis, eleven genes related to MPS diseases were divided into three different custom panels according to the overall clinical presentations. DNA samples from 70 patients with previous biochemical diagnosis of MPS and already genotyped with Sanger sequencing, were analyzed by Ion Torrent semiconductor technology. Using this new approach, we could identify different types of pathogenic mutations distributed across all exons of MPS related genes. We were able to identify 96% of all gene variants previously identified by Sanger, showing high sensitivity in detecting several types of mutations. As no new variations were detected, the NGS method presented 100% specificity. This comprehensive assay for the identification of the disease causing mutations in the MPS is an attractive option for the genotyping of MPS patients. Indeed, with the incorporation of NGS to clinical laboratories, we could consider that the present diagnostic flow could even be inverted, with biochemical tests becoming confirmatory methods to prove the functional consequences of a genetic abnormality detected by NGS.

943W

Combined genetic analyses with targeted next-generation sequencing, multiplex ligation-dependent probe amplification and microarray comparative genomic hybridization for Alagille syndrome and biliary atresia. *K. Ohashi[1], T. Togawa[1], T. Sugiura[1], K. Ito[1], T. Endo[1], K. Aoyama[1], Y. Negishi[1], T. Kudo[2], R. Ito[2], S. Saitoh[1].* 1) Department of Neonatology and Pediatrics, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 2) Department of Hepatology, National Medical Center for Children and Mothers, National Center for Child Health and Development, Tokyo, Japan.

Introduction Alagille syndrome (ALGS) is an autosomal dominant multisystem disorder, and is caused by mutations in *JAG1* or rarely in *NOTCH2*. Biliary atresia (BA) is the representative differential diagnosis of ALGS. We aimed to evaluate combined genetic analyses with targeted next-generation sequencing (NGS), multiplex ligation probe amplification (MLPA) and microarray comparative genomic hybridization (CGH) in subjects with ALGS, atypical ALGS and BA. **Method** We recruited subjects with ALGS, atypical ALGS, and BA. All subjects were tested by targeted NGS analysis including *JAG1* and *NOTCH2* using the AmpliSeq and Ion Torrent Personal Genome Machine (Ion PGM, ThermoFisher Scientific) system. If no mutations were detected in *JAG1* or *NOTCH2*, we performed MLPA analysis covering entire exons of *JAG1*. MLPA was also applied to confirm the possible CNVs called by NGS. We further performed microarray CGH analysis to subjects with whole exon deletion detected by the MLPA analysis. **Result** We analyzed 56 subjects (28 with ALGS, 6 with atypical ALGS, and 22 with BA), and detected mutations in *JAG1* or *NOTCH2* in 23/28 (82.1%) subjects with ALGS, in 4/6 (66.7%) subjects with atypical ALGS, and in 1/22 (4.5%) subjects with BA. The mutation type was as follow; 3 missense mutation, 5 nonsense mutation, 2 splice site mutation, 8 small insertion or deletion, 1 single exon deletion, 3 whole exons deletions in *JAG1* and 1 missense mutation in *NOTCH2* in subjects with ALGS, 1 missense mutation, 1 nonsense mutation, 1 small deletion, 1 single exon deletion in *JAG1* in subjects with atypical ALGS, and 1 missense mutation in *JAG1* in a subject with BA. Distribution of *JAG1* mutations was missense mutation 18.5%, nonsense mutation 22.2%, splice site mutation 7.4%, small indels 33.3%, single exon deletion 7.4%, and whole exons deletion 11.1%. The targeted NGS analysis detected 26/28 (92.9%) of mutations, and MLPA analysis of *JAG1* detected 2/28 (7.1%) of mutations. **Conclusion** Combined molecular genetic analyses, using targeted NGS, MLPA of *JAG1*, and microarray-CGH can achieve efficient diagnostic yields for the subjects with typical and atypical ALGS as well as subjects with BA phenotypically overlapping with ALGS.

944T

Supplemental CNV analysis in diagnostic NGS gene panel data. *J.J. Saris, M.A. van Slegtenhorst, R. Minkelen, M. Wilke, A.M.W. van den Ouweland, H.T. Brüggenwirth, L.H. Hoefsloot.* Clinical Genetics, Erasmus MC, Rotterdam, Zuid-Holland, Netherlands.

Standard diagnostic laboratory flows based on PCR and Sanger sequencing often include MLPA analysis when available and relevant. Introducing NGS gene panels in a clinical setting promises a higher diagnostic yield due to scanning more genes, while reducing costs, but is usually designed only for sequence variant detection. Normalized Depth-of-Coverage (DOC) calculation can indicate exon copy number variation (CNV) and might replace MLPA. Our lab has established a NGS sequencing flow using JSI SeqNext software (www.jsi-medisys.de). Recently we validated the effectiveness and usability of a DOC-CNV submodule using data from genes located on chromosome X and positive controls. Type and number of reference files (1-on-1 and n=12), signal-to-noise ratio and detection cut-off were evaluated in SeqNext and independent via Z-score analysis. Aim: Retrospective analysis of 27 gene panel experiments (324 samples), comparison to validation results and prospective analysis of future cardiomyopathy experiments (±12) for exon-CNV and wet lab confirmation of calls ≥ 2 exons and <5% frequency, using an internal database, including a filter of "noisy" ROI. Results: In 324 samples (incl. 116 cardiomyopathy) DOC based gender determination using chromosome X located genes, calling was concordant with the recorded clinical gender. Seven multi-exon (a.o. NEXN-e2e11 & B9D2-e2e4) and 10 whole gene CNV (a.o. NPHP1, ACTB) were detected, of which 8 confirmed (Known True Positives), 7 new variants of which confirmation is ongoing, and 2 polymorphic CNV based of occurrence frequency. Manual curation of single exon CNV (124 events) indicates deep intronic sequence variation near certain exons influencing accuracy of DOC results on capturing and/or read mapping level, e.g. 5' ANKRD1-exon4 (MAF ±30%) with Mendelian appearance. Conclusion: Exon CNV detection using DOC-analysis in SeqNext promises to be an possible replacement of MLPA in diagnostics. Validation, update on results and lessons learned will be presented.

Acute Myeloid Leukemia-associated *DNMT3A* **p.Arg882His mutation in a patient with Tatton-Brown-Rahman Overgrowth Syndrome as a constitutional mutation.** *R. Kosaki[1], H. Terashima[2], M. Kubota[2], K. Kosaki[3].* 1) Division of Medical Genetics, National Center for Child Health and Development, Tokyo, Japan; 2) Division of Neurology,National Center for Child Health and Development, Tokyo, Japan; 3) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan.

DNA methylation plays a critical role in both embryonic development and tumorigenesis and is mediated through various DNA methyltransferases. Constitutional mutations in the *de novo* DNA methyltransferase *DNMT3A* cause a recently identified Tatton-Brown-Rahman overgrowth syndrome (TBRS). Somatically acquired mutations in *DNMT3A* are causally associated with acute myeloid leukemia (AML), and p.Arg882His represents the most prevalent hotspot. So far, no patients with TBRS have been reported to have subsequently developed AML. Here, we report a live birth and the survival of a female infant with the TBRS phenotype who had a heterozygous constitutional *DNMT3A* mutation at the AML somatic mutation hotspot p.Arg882His in her DNA from peripheral blood and buccal tissue. Her characteristic features at birth included hypotonia, round face, narrow palpebral fissures, ventricular septal defect, umbilical hernia, sacral cyst, Chiari type I anomaly, and intellectual disability. At the age of 6 years, she exhibited overgrowth(+3SD). The documentation of the same variant (*DNMT3A* p.Arg882His) as both the constitutional mutation associated with TBRS and the somatic mutation hotspot of AML supports a notion that mutations responsible for TBRS and those for AML share the same mode of action. Surveillance for hematologic abnormalities may be considered in patients with TBRS. .

A new syndrome associated with compound heterozygous changes in
NCOR2 **gene.** *C. Li, M. Szybowska, G. Cowing.* Dept of Genetics, McMaster Children's Hospital, Hamilton, ON, Canada.

We report the clinical phenotype of a case with multiple congenital anomalies and profound intellectual disability in association with compound heterozygous changes in *NCOR2*, c.3322C>T (p.L1108F) and c.4621C>G (p.L1541V). The patient presented antenatally with increased nuchal, two-vessel cord, polyhydramnios and hydronephrosis. Postnatally she was noted to have glaucoma, cloudy cornea, kyphoscoliosis, hip dysplasia, pulmonary lymphangiectasia, interstitial glycogenosis and multiple dysmorphic features. These include brachycephaly, well-defined arched brows, shallow orbits with wide palpebral fissures and long lashes. She has a bulbous nose with hypoplastic nares. The mouth is small with thin lips and the tongue is protruding which in infancy led to obstruction of the airway and difficulty with intubation. She has small and tightly spaced teeth. The facial profile is flat. The ears are crumpled and flat against the skull. She has thin extremities with narrow hands and feet and slender fingers and toes. Reduced range of motion is noted of the hips, knees and elbows. Camptodactyly of the fingers and overlapping toes with hypoplastic nails are also noted. There is generalized hypotrophy of the muscles. Brain MRI showed thinning of the corpus callosum, periventricular white matter volume loss and exvacuo dilation of the ventricles. Spine MRI showed tethered cord and query segmentation defects. At her last assessment at 10 years of age, she was not able to sit unsupported and had only few signs for communication. Her parents each carry one of the genetic changes in the NCOR2 gene. The family history is non-contributory otherwise. The *NCOR2* gene encodes SMRT (silencing mediator for retinoid and thyroid hormone receptors). NCOR-family plays central roles in the timing of embryo and stem cell differentiation [Short et al., 2015]. SMRT is a transcription co-suppressor that, in concert with MeCP2 protein (involved in Rett syndrome), allows non-liganded nuclear receptors to remain inactive [Pei et al., 2011]. Studies in mice showed *Ncor2* to be essential for normal neural and cardiac development. Aberrant expression of SMRT in Xenopus also resulted in abnormal head development [Malatre et al., 2006]. However, pathogenic mutations have not been reported in the *NCOR2* gene in association with a constitutional disease condition in humans. We hope to share our findings and draw attention to the potential role of *NCOR2* in human disease conditions.

The NIH Undiagnosed Diseases Program: A mystery solved at long last.
A.P. Liebendorfer[1], G. Nesterova[1], C. Wahl[1], B.P. Brooks[2], W.M. `[2], C.C. Chan[2], J. Balow[3], D. Adams[1], W. Gahl[1], T. Markello[1]. 1) National Human Genome Research Institute, Bethesda, MD; 2) National Eye Institute, Bethesda, MD; 3) National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD.

Introduction: The NIH Undiagnosed Diseases Program (UDP) enrolls participants who have illnesses that remain undiagnosed despite extensive medical workup. In 2008, a 32 y/o woman presented to the UDP with h/o seizures, weakness in her lower extremities with abnormal gait, exudative retinopathy leading to right eye enucleation, multiple intestinal bleedings without ulceration and eventually chronic renal failure, starting at age 8-10. MRIs revealed multiple cavernous hemangiomas. The patient started peritoneal dialysis at age 27 due to ESRD after renal injury with preeclampsia. The patient died from intractable intestinal bleeding, acute renal failure and pneumonia seven months after evaluation. Overall the presentation was multisystemic involving GI, skin, bone, eye and CNS. **Methods:** Evaluation included neurological, dermatological, ophthalmological, hematological, and radiological exams and autopsy. Discussions focused on evidence of diffuse basement membrane defects. Her exome was analyzed in 2016 because population and disease variant databases had matured; the biologic mother also became available for study. **Results:** Postmortem, the patient exhibited anterior scalp poliosis, depigmented macules on her arms and chest, patches of hyperpigmentation on the abdomen and left thigh, and hard nodules bilaterally affecting the distal two thirds of her legs. Retinal telangiectasia was found. Calcification was noted intracranially and in her lower extremities, and osteopenia was noted in much of her lower body. SNP chip analysis suggested a de novo or compound heterozygous model for disease. Exome analysis revealed two phased variants in *CTC1*: c.2959C>T, p.R9087W and c.1603T>C, p.C535R. *CTC1* is associated with Coats Plus Syndrome (OMIM 612199). **Conclusions:** The case illustrates the rapid changes in genetic diagnostics and discovery using genome-scale sequencing as a diagnostic tool. When our patient was first seen, no exome sequencing was available and connection between *CTC1* and Coats disease was unknown. The case also provides an extensive description of advanced Coats Plus Syndrome and further characterizes the phenotype of this rare disorder. This research is supported by the Intramural Research Program of the National Human Genome Research Institute and the Common Fund of the National Institutes of Health.

Detection of copy number variants by whole exome sequencing. *J.M. Meck, L.B. Henderson, G. Douglas, O. Cano, G. Li, J. Scuffins, G. Richard, K. Retterer, J. Juusola.* GeneDx, Gaithersburg, MD.

Whole exome sequencing (WES) is typically utilized to identify sequence variants in the human exome, while genomic copy number variants (CNVs) are detected by chromosomal microarray (CMA). Our clinical laboratory developed an algorithm for identifying CNVs including multi-genic, whole, or partial gene deletions (dels)/duplications (dups) directly from the WES next generation sequencing (NGS) data [1]. Overall, the positive rate of WES in our cohort of over 11,000 affected individuals was 26.4%. Almost 5% of the positive findings were pathogenic CNVs confirmed by array, MLPA, qPCR or PCR. We reviewed 146 pathogenic CNVs identified from WES NGS data in 143 probands (including 3 with presumed unbalanced translocations) to determine their type, size, inheritance, and associated disease spectrum. Reported CNVs included 127 (87%) dels and 19 (13%) dups ranging from a single exon (10 cases) to 16.3 Mb. Seventy-seven (54%) probands had whole or partial del/dup of a single gene, while 66 (46%) had multi-genic aberrations. Most (35/66; 53%) multi-genic CNVs were associated with recurrent microdel/dup syndromes, such as 16p11.2 del or dup (n=5), classic and distal 22q11.2 dels (n=4), 15q13.3 del (n=2), 17p12 dup (n=2) and monosomy 1p36 (n=2). Although most reported CNVs act in a dominant fashion, 1/3 were either homozygous (22; 15%) or heterozygous CNVs (26; 18%) in *trans* with a pathogenic sequence variant in a gene associated with an autosomal recessive (AR) disorder. Five AR disorders with at least one pathogenic CNV were detected recurrently: Cohen syndrome (*VPS13B*, n=4); juvenile neuronal ceroid lipofuscinosis (*CLN3*, n=3); *TBCK*-related disorder (*TBCK*, n=2); 3-methylglutaconic aciduria with deafness, encephalopathy, and Leigh-like syndrome (*SERAC1*, n=2); and myopathy with extrapyramidal signs (*MICU1*, n=2). Analysis of inheritance pattern showed that 59 (41%) CNVs occurred *de novo*, 54 (38%) were inherited, and 30 (21%) had no or uninformative parental testing. Prior or concurrent CMA was performed in at least 66/143 (46%) cases, with results known to us in 59. In 42/59 (71%) cases the pathogenic CNV was not detected by CMA; most of these (38/42; 90%) had intragenic CNVs. In summary, our data demonstrate the significant contribution of pathogenic CNVs to the mutational spectrum identifiable by WES, and highlight the utility of WES NGS for identifying single gene and exon-level CNVs not detected by routine CMA testing. [1] Retterer et al. PMID 25356966.

Accurate molecular diagnosis is critical for the clinical management, counselling and prognosis of individuals with suspected monogenic diseases, particularly where early diagnosis and intervention would drastically influence decision making by the clinician or family. Rare causes of disease are often overlooked following traditional genetic testing routes, as many conditions have a highly variable clinical presentation, present as part of a phenotypic spectrum or are difficult to distinguish from other, very similar, disorders. Use of whole exome or genome sequencing (WES/WGS) technologies circumvents many of these problems, since these are agnostic to the underlying genetic cause. Here we evaluated the use of WES (n=37) or WGS (n=3) in a consecutive series of 40 patients with craniosynostosis (premature fusion of the cranial sutures), who had been identified as priority cases by either clinical geneticists with particular expertise in craniosynostosis (n= 22) or by specialist clinical laboratory scientists (n= 18), and in whom standard diagnostic testing had failed to reveal an underlying cause. To date we have identified a likely causative mutation in 15 families (37.5%). All associated genes were mutated in single families, except for *IL11RA* (2 families), a recently recognised recessive cause of craniosynostosis that has now been added to our diagnostic panel. We classified the other positive diagnoses as follows: known craniosynostosis gene with atypical presentation (*EFNB1*, *TWIST1*); genes for which mutations are only rarely associated with craniosynostosis (*FBN1*, *KRAS*, *MSX2*, *STAT3*); genes that represent very recently recognised associations with craniosynostosis (*CDC45*, *HUWE1*, *ZIC1*); and known disease genes for which the causal relationship with craniosynostosis is currently uncertain (*AHDC1*, *NTRK2*). In two further families, likely novel disease genes are currently undergoing functional validation. In 5 of the 15 positive cases, the (previously unanticipated) molecular diagnosis had immediate, actionable consequences for either genetic or medical management of the families (mutations in *EFNB1*, *FBN1*, *KRAS*, *STAT3*, *NTRK2*), which we will discuss. In summary our findings illustrate the molecular diversity of causes of craniosynostosis and the considerable added value provided by WES/WGS for the precise diagnosis of patients suspected to have a genetic cause, where the underlying mutation would have otherwise eluded routine clinical testing.

950T

Secondary actionable findings identified by whole-exome sequencing: Frequency and potential consecutive medical recommendations and organisation: Study on 653 consecutive tests. *C. Thauvin-Robinet[1], J. Thevenon[1], S. Nambot[1], P. Kuentz[1], A.-L. Bruel[1], A. Chassagne[1], E. Cretin[1], O. Putois[1], A. Pelissier[1], C. Peyron[1], E. Gautier[1], J. Skrzypski[2], D. Lehalle[1], N. Jean-Marçais[1], P. Callier[1], A.-L. Mosca-Boidron[1], C. Poé[1], T. Jouan[1], M. Chevarin[1], M. Lefebvre[1], E. Tisserant[1], C. Binquet[3], J. Deleuze[4], Y. Duffourd[1], L. Faivre[1].* 1) Clinical genetics centre, FHU-TRANSLAD, Dijon, France; 2) Centre Georges François Leclerc Dijon, France; 3) CIC-EC, Dijon, France; 4) Centre national de génotypage, Évry, France.

In whole exome sequencing (WES) integrated into the practice of medicine, there is potential for the recognition and reporting of incidental or secondary findings unrelated to the indication for ordering the sequencing but of medical value for patient care. In 2013, the American College of Medical Genetics and Genomics (ACMG) examined the issue of incidental findings in WES/WGS, and introduced recommendations to search for, evaluate and report medically actionable variants in a minimal set of 56 genes. In order to evaluate the implications in organization of care, we have conducted a retrospective study evaluating the frequency of variants in a list of actionable genes in a cohort of 653 consecutive probands with multiple congenital anomalies explored by WES. The 174 genes of interest comprised the list of the ACMG, extended to further cancer predisposition genes (n=154), and 3 genes of the most frequent autosomal recessive diseases in France leading to the screening of heterozygote in relatives (*CFTR*, *HFE*-p.C282Y, *CYP21A2*-classical form). Variants in 110 genes implicated in X-linked intellectual deficiency (XLID) were also searched to detect female carriers for genetic counselling issues. We looked for all the variants with known Clinvar status and considered only pathogenic and likely pathogenic variants following the interpretation recommendations of the ACMG and Association for Molecular Pathology. We identified 19 cases (2,9%) with autosomal dominant heterozygous pathogenic variant (0,9%, in a gene responsible for a cancer predisposition, 1,4% in a hereditary cardiac disease, 0.6% in polycystic kidney disease) (11/19 variants in the ACMG actionable 56 genes), 1 DMD *carrier*, no XLID carrier, 21 *CFTR* heterozygous cases (3,2%), 55 HFE-pC282Y heterozygous cases (8,4%) and 1 *CYP21A2* heterozygous case (0,1%). *SMN1* deletion and the majority of *CYP21A2*-classical form variants could not be detected. If returned to patients (14,9%), these results should induce 653 pre-test and 97 post-test genetic consultations, as well as 11 cardiologic, 7 nephrology, 5 gynecologic, 4 dermatologic, 2 gastroenterological, and endocrine evaluations. Additional family evaluations should also be anticipated. The study is in progress to also include the additional impact of 17 genes with actionable pharmacogenetic alleles and genes leading to coagulation defects.

951F

Detection of low level mosaic mutations in a gene panel for segmental overgrowth. *M. Alders, M.A. Haagmans, O.R. Mook, M.M.A.M. Mannens.* Department of Clinical Genetics, AMC, Amsterdam, the Netherlands.

Somatic mutations in genes of the PI3K/AKT/mTOR pathway causing segmental overgrowth may be present in a very low percentage. This can hinder the identification of causal mutations. Sanger sequencing, but also standard NGS diagnostic pipelines are able to identify mosaic mutations with a detection limit of approximately 10%. Targeted analysis of specific sites is usually used for more sensitive detection of mutations. With the growing number of known mutations there is a need for a high sensitive mutation scanning method to analyze the complete coding sequences of the genes involved rather than analysis of hotspots. We have developed a NGS based gene panel test for segmental overgrowth (AKT1, AKT3, MTOR, PIK3CA, PIK3R2, PTEN, TSC1 and TSC2) especially for the detection of low level mosaicism. Samples are sequenced with high coverage (average 1500-2000 reads, minimum 500 reads) and an analysis pipeline was developed that is able to detect mosaic mutations as low as 1%.

The CAUSES Research Clinic: A pediatric sequencing initiative in British Columbia. *C. du Souich[1,2,3], A.M. Elliott[1,2,3], C. van Karnebeek[2,4], S. Adam[3], J. Gillis[4], J.C. Mwenifumbo[2], T.N. Nelson[2,5], A. Lehman[1,2,3], J.M. Friedman[1,2,3].* 1) Provincial Medical Genetics Program, BC Women's Hospital and Health Centre, Vancouver, BC, Canada; 2) Child and Family Research Institute, Vancouver, BC, Canada; 3) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Division of Biochemical Diseases, Department of Pediatrics, University of British Columbia, Vancouver, BC, Canada; 5) Department of Pathology and Laboratory Medicine, BC Children's Hospital, Vancouver, BC, Canada.

   Background: The CAUSES study, a 3 year translational research initiative to sequence 500 BC pediatric patients with suspected genetic disorders, began in June 2015. Inclusion criteria and a clinical genomic consultation service were developed to select patients suitable for enrollment. Patients are referred from various pediatric subspecialties throughout the province. Genetic counselling is a critical component throughout the study. Telehealth is available for families from remote areas and interpreters for non-English speaking families. Genetic counseling and health economic research are embedded in the program. *Methods:* A comprehensive list of issues and implications of sequencing is discussed and informed consent is obtained by a genetic counselor prior to testing. Exome sequencing (ES; Agilent All Exon V5+UTR) is performed on the proband and both parents using an Illumina platform. A customized bioinformatics pipeline is used to align sequencing reads to the reference human genome (Bowtie 2) and call good quality SNVs & indels (samtools/bcftools). Ensembl transcript set annotation identifies functional variants, which are then filtered against public & in-house databases. A list of rare variants compatible with Mendelian inheritance patterns is annotated with diagnostically relevant information, and delineated by genes in the OMIM compendium as disease-causing (clinome) or not (non-clinome). The annotated variant list produced is reviewed by a panel that includes clinical geneticists, genetic counselors, bioinformaticians, clinical molecular geneticists and the referring physician. Putative causal variants are confirmed by the clinical laboratory, including Sanger sequencing and clinical variant interpretation, prior to return of results. Genetic counseling is provided to families with result interpretation. *Findings:* To date, 82 families have undergone ES and bioinformatic analysis. Thirty-four patients received a probable or definite diagnosis (40%). The majority were *de novo* autosomal dominant disorders. Three patients had variants in *EP300*, 3 in *ARID1B* and 2 in *DDX3X*. Treatment/management has been impacted in several patients. *Conclusions:* The CAUSES clinic demonstrates the clinical utility of ES and the importance of utilizing trios in patients with undiagnosed genetic disorders. It also shows the importance of a comprehensive approach to genome sequencing, which includes a strong genetic counseling component.

953T

Clinical features of 28 patients with presumptive diagnosis of *PIK3CA*-**related overgrowth spectrum (PROS) in a tertiary hospital in Brazil.** *C.H. Chung, R.S. Honjo, D.R. Bertola, C.A. Kim.* Unidade de Genética, Instituto da Criança - Hospital das Clínicas da FMUSP, São Paulo, Brazil.

   PIK3CA-related overgrowth spectrum (PROS) is a group of segmental overgrowth disorders usually caused by somatic mosaic mutation in *PIK3CA*. It has been associated to Megalencephaly-capillary malformation (MCAP) syndrome, Hemimegalencephaly, CLOVE syndrome (Congenital Lipomatous Overgrowth, Vascular Malformations, and Epidermal Nevi), fibroadipose hyperplasia, Klippel-Trenaunay syndrome and isolated macrodactyly. We report the clinical findings of 28 patients with presumptive diagnosis of PROS, from the Genetics Unit of Instituto da Criança - HCFMUSP (São Paulo, Brazil). 15/28 were initially diagnosed as Klippel-Trenaunay syndrome; 3/28 as Klippel-Trenaunay-Weber syndrome; 3/28 as CLOVE syndrome; 2/28 as Isolated macrodactyly; 2/28 as Proteus syndrome; 3/28 were suspected of Proteus syndrome or Klippel-Trenaunay syndrome. Their clinical manifestations were: hemangioma (82.1%), body asymmetry (67.8%), vascular malformations (46.4%), macrodactyly (39.3%), learning disability (21.4%), seizures (17.8%), renal abnormality (17.8%), high stature (14.3%), macrocephaly (14.3%), lipomas (14.3%), skeletal involvement (14.3%), eye involvement (14.3%), CNS malformation (10.7%), thromboembolic events (7.1%), short stature (3.6%) and polydactyly (3.6%). Prenatal ultrasound detected alterations in 17.8% of the cases. Even though a few patients were initially evaluated for clinical suspicion of Proteus syndrome, none fulfilled the diagnostic criteria for this syndrome. Due to the overlapping phenotypes in segmental overgrowth disorders, the molecular testing in the affected tissues is crucial to establish the correct diagnosis. It may also contribute to a better understanding of the clinical characteristics and complications of this group and, maybe in the future, open a pathway to therapeutic strategies.

954F

Next generation sequencing illuminates genetic heterogeneity in infantile cholestatic disorders. *S.M. Herbst[1], S. Hinreiner[1], C. Posovszky[3], F. Jochum[4], T. Rödl[1], J.A. Schroeder[6], T.F. Barth[5], M. Melter[2], J. Vermehren[2], U. Hehr[1].* 1) Center for and Department of Human Genetics, Regensburg, Bayern, Germany; 2) KUNO - Children´s University Hospital Regensburg, Regensburg, Germany; 3) University Medical Center Ulm, Department of Pediatrics and Adolescent Medicine, Ulm; 4) Department of Pediatrics and Adolescent Medicine, Evangelisches Waldkrankenhaus Spandau, Berlin; 5) University of Ulm, Institute of Pathology, Ulm; 6) Department of Pathology, University of Regensburg.

   Introduction A wide variety of genetic and non-genetic conditions may result in infantile cholestasis. The differential diagnosis is especially challenging due to their similar clinical presentation including biochemical parameters and often non-specific liver histology. More than 90 genes are associated with infantile cholestasis, ranging from monogenic forms to multisytemic disorders, which can primarily manifest as hepatic disease in infancy with or without cholestasis, thus preventing routine genetic workup by Sanger sequencing. However, rapid identification of an underlying genetic disease is essential (1) to discriminate patients who might benefit from liver transplantation in the long term, (2) to facilitate optimal treatment algorithms and (3) to prevent unnecessary and potentially harmful diagnostic procedures. **Method** Massively parallel sequencing of 93 genes associated with cholestatic disease in infancy was prospectively performed for 12 clinically well characterized patients in whom common causes of infantile cholestasis had already been excluded. **Results** Seven novel and nine known pathogenic mutations were identified in our patient cohort. The identified underlying diseases included for example one case of progressive familial intrahepatic cholestasis type 2 (PFIC2) (*ABCB11*: p.Gly628Trpfs*3, c.611+1G>A), one case of Niemann-Pick Disease Type C1 (*NPC1*: p.Glu391Lys, p.Arg116*), one case of atypical PFIC (*LBR*: p.Arg372Cys, *ABCB11*: p.Val1112Phe) and one case of autosomal recessive polycystic kidney disease (ARPKD) (*PKHD1*: p.Thr777Met, p.Tyr2260Cys). Three exemplary clinical cases of infants with cholestasis are presented and discussed in the context of their genetic, histopathological and electron microscopic findings (ARPKD, PFIC and NPC). **Conclusion** Our data confirm the power of massive parallel sequencing by targeted multi gene panels for infantile cholestasis. This testing strategy overcomes the complexity of the phenotype-based, candidate gene approach. Furthermore, our data highlight the critical impact of integrating clinical, histopathological and genetic data during the process of multi gene panel testing to ultimately pinpoint rare genetic diagnoses.

955W

Partial uniparental disomy results in homozygous 2p21 deletion in a male newborn with hypotonia-cystinuria syndrome. *L. Mao[1], A. Janssen[1], Y. Li[1,2], C. Dvorak[1], H. Andersson[1,2], T. Chen[1,2].* 1) Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA; 2) Department of Pediatrics, Tulane University School of Medicine, New Orleans, LA.

   Hypotonia-cystinuria syndrome (2p21 deletion syndrome, OMIM606407) is a contiguous gene syndrome caused by a homozygous deletion on chromosome 2p21 with clinical features including hypotonia, cystinuria, neonatal seizures, developmental delay, facial dysmorphism, and lactic acidosis. This syndrome has been reported from 11 families with 20 patients up to date. All of these patients were from families with consanguineous history. In this report, a male newborn was born by induced vaginal delivery at 38 weeks gestation to a 21-year-old mother, G2P1. The infant had low calcium related to low parathyroid hormone and severe hypotonia with poor feeding. Physical exam revealed no remarkable facial dysmorphology except for micrognathia, mildly flattened ears, and mildly abnormal palmer creases. Biochemical profile indicated that excretion of arginine and ornithine in urine was increased but cysteine level was normal. This patient may be too young to manifest other reported clinical features. There is no history of consanguinity in the family. The parents each have a healthy child with another partner. Cytogenomic analysis identified a homozygous 91 Kb microdeletion located within a 4.09 Mb region of copy-neutral loss of heterozygosity at 2p21 by CGH+SNP array. This alteration results in partial deletion of SLC3A1 and CAMKMT, as well as full deletion of the PREPL gene, consistent with the diagnosis of 2p21 deletion syndrome. Results from PCR amplification using primers against exon 7 and exon 10 of SLC3A1 and exon 2 of CAMKMT confirmed the loss of both copies of these two genes in this patient. Parental genetic analysis is pending to discover the origin of the deletion. To our best knowledge, this is the first case of 2p21 deletion syndrome identified from a family without consanguineous history. The homozygous deletion is very likely due to the location of the deletion within a partial uniparental disomy region.

956T

Evaluation of the parental origin of the chromosomes by using SNP genotype data from CGH+SNP microarray: Two cases with multiple congenital abnormalities. *K. Wakui[1,2], K. Takano[1,2], T. Kosho[1,2], T. Yamaguchi[1], Y. Takahashi[2], R. Kawamura[1], Y. Fukushima[1,2].* 1) Medical Genetics, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 2) Clinical and Molecular Genetics, Shinshu University Hospital, Matsumoto, Nagano, Japan.

Cytogenomic microarray is useful to detect pathogenic copy number changes in the subjects with birth defects, and copy-number-neutral absence of heterozygosity (AOH) and uniparental isodisomy can also be detected by SNP array. In addition, the data of SNP genotype can be used effectively to evaluate the parental origin of the chromosomes in some cases as shown below. Platform of the analysis: CGX™-SNP array (108K CGH + 60K SNP, PerkinElmer) and CytoGenomics software (Agilent) Case 1: No pathogenic CNVs, but a chromosome 20 has two AOH regions. One is 6.5-6.8Mb from pter, and the other is 10.9-11.6 Mb from qter. The SNP genotype data showed this subject was maternal uniparental disomy; uniparental isodisomy in both ends and uniparental heterodisomy in the middle of the region of chromosomes 20. Case 2: Gain CNVs in whole chromosome 14 in blood cells, but the average value of log2 ratio was 0.25. Metaphase FISH analyses showed that the subject had about 12% of mosaic trisomy 14. But fibroblasts of the subject had only around 1% of mosaic trisomy 14. We compared the SNP genotype data between the blood cells and fibroblasts. The results were that the chromosomes 14 in the cells of disomy 14 were biparental, and the additional chromosome 14 in the cells of trisomy 14 were paternal.

957F

Detection of copy number variation using shallow whole genome sequencing (CNVseq) as a cost-effective alternative to genomic microarrays. *B. Menten, M. De Smet, T. Sante, S. Vergult, A. Dheedene.* Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Genomic Copy Number Variations (CNVs) are an important cause of several human genetic disorders. Conventional karyotyping has been the gold standard for many years, but has been replaced by genomic microarrays, enabling a higher throughput and more important, a much higher resolution. More recently, next generation sequencing has been introduced in genetic diagnostics by means of targeted resequencing such as (clinical) exome sequencing. Despite the big advantage of whole exome sequencing (WES) to interrogate patient genomes at the nucleotide level to identify disease-associated single nucleotide variants, additional testing is still warranted to unequivocally detect, or rule out, CNVs. Although it has been proven that microarrays perform well for detecting submicroscopic CNVs, throughput is still rather limited, consumable cost is high, and resolution is fixed depending on the probe density of the microarray used. We therefor investigated whether genomic microarrays can be replaced by shallow whole genome sequencing for the detection of submicroscopic copy number variants (CNVseq) in a diagnostic setting. First, a statistical model was built to predict the theoretical amount of sequence reads necessary for a certain resolution. Subsequently, this model was evaluated by shallow whole genome sequencing at several read depths and bin sizes for several patient samples with clinically relevant genomic aberrations. We defined the number of reads necessary to achieve the same resolution as with commonly used microarrays and a thorough comparison between genomic microarrays and CNVseq was made. Moreover, we show that CNVseq results in a higher dynamic range and is more sensitive for the detection of low-grade mosaicism. Since library preparation is completely automatable and many samples can be pooled on one sequencing run, the hands-on time diminishes. Together with the plummeting cost of sequencing, this results in a more cost-effective workflow and a higher throughput. Furthermore, resolution is merely dependent on sequencing depth and is not limited to the probes present on the array, hence CNVseq enables more flexibility compared to genomic microarrays.

A case of maternal UPD 20 in an infant with severe feeding difficulties, postnatal growth delay and mild developmental delay. *J.E. Watt[1], V.B. Bickley[1], K. Doudney[1], A.M. Kidd[1], G. Poke[2], M.D. Robertson[1], R.I. King[1].* 1) Genetics, Canterbury Health Laboratories, PO Box 151, Christchurch , New Zealand; 2) Genetic Health Service NZ, Wellington , New Zealand.

Maternal uniparental disomy for chromosome 20 [UPD(20)mat] is an emerging imprinting disorder. Characterisation of the phenotype has been hindered by case reports in patients with complete or partial trisomy 20 mosaicism, with only nine cases of isolated UPD(20)mat reported to date. The emerging phenotype is characterised by failure to thrive, profound difficulty feeding often requiring gastric tube intervention and growth retardation. Here we present a further case of isolated UPD(20)mat. Our case, a female infant, presented with postnatal growth delay, poor feeding, mild developmental delay - particularly gross motor skills, plagiocephaly and eczema. Birth weight was on the 25th centile, and poor feeding from birth resulted in a drop in weight to the 0.4th centile by 4 weeks. At 6 months of age a gastrostomy tube was inserted to improve nutrition. Chromosomal microarray analysis undertaken at 4 months showed no significant copy number change. However SNP analysis identified long continuous stretches of homozygosity (LCSH) confined to the terminal arms of chromosome 20. This pattern typifies UPD(20) resulting from a meiosis I nondisjunction error. Fluorescent in situ hybridisation (FISH), performed on cultured peripheral blood, excluded trisomy 20. Analysis of parental SNP data confirmed the UPD(20) to be of maternal origin. This case adds to the phenotypic data on this emerging disorder and is consistent with previously reported cases, with profound feeding difficulty leading to postnatal growth retardation being the predominant feature. .

Opportunity and challenge of applying clinical exome for critical newborn patients: 1,000 clinical exome cases from a neonatal clinic. *H. Wang[1], L. Yang[1], B. Wu[1], Y. Lu[1], B. Sun[1], Z. Li[1], B. Liu[1], Z. Wei[2], Q. Zhao[2], H. Sun[2], F. Xia[3], W. Zhou[1].* 1) Pediatrics Research Institute, Children's Hospital of Fudan University, Shanghai, Shanghai, China; 2) Wuxi NEXTCODE ,288 Fute Zhong Road, Waigaoqiao Free Trade Zone, Shanghai 200131, China; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, USA.

Background Birth defects are estimated to affect 3-6% of newborns worldwide, and are frequently caused by genetic factors. Accurate molecular diagnosis holds the key to prevent and treat congenital diseases. However, routine prenatal/newborn screens can only detect a small fraction of newborn disorders. On the other hand, many genetic diseases only manifest partially, or show higher variability at infant stage, which leaves little clue for clinician to cherry-pick a short list of genes to test. A more comprehensive approach, such as exome or genome sequencing, is desirable to cover all genetic possibilities. Methods At Children's Hospital of Fudan University, we continuously evaluated ~12,000 patients with critical conditions referred to our neonatal clinic by a systemic protocol. About 20% of them are suspected to have underlying genetic causes. If the patient with possible genetic disorder did not display distinctive clinical features, we will recommend the case for exome sequencing test. For each exome, the total targeted region is 50MB, and average coverage is more than 100X with 97% of targets covered by 20X or more. Parental studies were performed on candidate variants detected by exome test, if the parents are available. Results More than 1,000 of probands have been tested by clinic exome sequencing. Neuromuscular disorders are the largest group, and account for 43% of cases. 30% have structural anomalies. 14% of them have complex endocrine or immunology disorders. Due to the sample availability and economic issues, 27% of the cases are tested as Trio exome, and 64% of them have both parents available as familial controls. In total, about 46% of cases received diagnosis or possible diagnosis, and more than 75% have notable findings related. For cases received positive findings, 18% had improved treatment plan; 96% of them did further consultation of family planning on prenatal and preimplantation options. Conclusion Clinic exome is a valuable diagnostic tool in neonatal clinics, with optimal results from trio exome and prepared families. Patient management and family planning can greatly benefit from exome testing results. Pre-test counseling is challenging to convince both parents involved, especially for families with less-educated backgrounds.

Evaluation of non-invasive prenatal testing for fetal aneuploidies in Korean population. *D.J. Kim[1], D.E. Lee[1], H.J. Kim[1], S.Y. Kim[1], S.Y. Park[1], J. Park[3], S. Ji[3], T. Yun[3], B.C. Lee[3], H.M Ryu[1,2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, South Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Dankook University College of Medicine, Seoul, Korea; 3) Molecular Diagnostics Team, IVD Business Unit, New business Division, SK telecom, Seongnam, Korea.

Background: Non-invasive Prenatal Testing (NIPT) usingcell-free fetal DNA from maternal plasma for fetal aneuploidies is expanding worldwide. In this study, we developed and validated a NIPT technology using cell-free fetal DNAfor fetal aneuploidy detection in Korean population. **Methods:** This preliminary study was performed at Cheil General Hospital and Women's Healthcare Center, Seoul, Korea. Only pregnant women who underwent both NIPT and amniocentesis were included in this study. NIPT results were compared with those of karyotype analysis. **Results:** Among 202 cases, 19 cases of fetal aneuploidies, including T21 (n=14), T18 (n=4), and T13 (n=1), were identified by NIPT and confirmed by karyotyping of amniotic fluid cells. There were no false-positiveand false-negativeresults. In the 101 male pregnancies, the median fetal DNA fraction was 10.65% and there was a trend towards an increasing fetal fraction from 15.0 to 22.5 weeks' gestation. The majority (98%) of pregnancies had a fetal DNA fraction>4%, which is generally the limit for accurate aneuploidy detection by NIPT. **Conclusion:** NIPT is highly reliable and accurate whenapplied to maternal DNA samples collected frompregnant women in the second trimester. Further large prospective studies are needed to adequately *assess* the performance of NIPT in first trimester pregnancies.

Non-invasive prenatal detection of fetal aneuploidies by targeted semiconductor sequencing: A technical feasibility study. *Y. Xi[1,2], A. Arbabi[3,4], A. McNaughton[5], A. Hamilton[6], D. Hull[7], H. Perras[6], T. Chiu[6], S. Morrison[6], C. Goldsmith[6], E. Creede[6], C. Honeywell[6], M. Cloutier[6], N. Macchio[7], C. Kiss[7], X. Liu[5,8], S. Crocker[5,8], G.A. Davies[5,8], M. Brudno[3,4], C.M. Armour[6,9].* 1) Molecular Diagnostics Laboratory South, Alberta Health Services, Calgary, AB, Canada; 2) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 3) Department of Computer Science, University of Toronto, Toronto, ON, Canada; 4) Center for Computational Medicine, Hospital for Sick Children, Toronto, ON, Canada; 5) Queen's University Genomics Laboratory at Ongwanada, Kingston, ON, Canada; 6) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ottawa, ON, Canada; 7) Kingston General Hospital, Kingston, ON, Canada; 8) Queen's University, Kingston, ON, Canada; 9) Regional Genetics Unit, Children's Hospital of Eastern, Ottawa, ON, Canada.

With the discovery of fetal cell-free DNA (cfDNA) in maternal plasma and the development of massively parallel sequencing techniques, non-invasive prenatal testing (NIPT) for common chromosomal aneuploidies has become possible and has been widely tested for clinical use with high sensitivity and specificity. However, it remains a relatively expensive test compared to traditional serum screening methods and expensive in many parts of the world. Thus there remains significant interest in developing other approaches that may utilize less costly sequencing approaches. Here, we designed a customized AmpliSeq panel, including 1067 primer pairs targeting specific regions on chromosome 21, 18, 13 and other chromosomes. Maternal plasma cfDNAs from a total of 235 pregnancies at high risk, including 30 affected with Trisomy 21 (T21) were extracted, and sequenced with Ion Torrent Proton sequencer using the custom panel. Analysis of the data and applying the derived risk score yields a bimodal distribution with the affected samples clustering near 1.0 and the unaffected near 0. For a risk score cut-off of 0.345, above which all would be considered 'high risk', all 30 T21-positive pregnancies were correctly predicted to be affected and 200 of the 207 non-T21 samples were also correctly predicted. At this cut-off there were 7 false positives (7/207; 3.3%) and no false negatives. With the described targeted sequencing approach on the semiconductor platform using a custom designed library and probabilistic statistical approach, we have demonstrated a feasible method to assess for fetal T21. Such an approach could be further developed for the common aneuploidies, potentially providing a cost and resource effective alternative to current methods.

Autism spectrum disorder (ASD) is a group of common neurodevelopmental disorders defined by deficits in social skills, behavioral regulation, and communication. Although the cause of ASD is still largely unknown, copy number variations (CNVs) significantly contribute to the genetic causes of ASD. However, the contribution of these polymorphisms in non-European populations with ASD has not been well characterized. In this study, we aim to identify novel ASD-associated CNVs and to evaluate the diagnostic yield of a high-resolution genome-wide SNP-based microarray in a cohort of Thai patients with ASD of unknown cause. Illumina CytoSNP-850K BeadChip, which contains approximately 850,000 probes spanning the whole genome, was used to identify CNVs in the 114 patients who met the DSM-IV or DSM-5 criteria for ASD. The microarray data were analyzed using GenomeStudio and BlueFuse Multi v4.1 software. Multiple large curated CNV databases including Thai CNV database, which contains CNVs of the 3,017 general Thai individuals were utilized for interpretation of clinical significance. We detected pathogenic CNVs and variants of uncertain clinical significance (VUS) in 29 of 114 patients (25.4%), including five *de novo* CNVs, eighteen inherited CNVs, and six of unknown inheritance. Of the 29 patients, pathogenic CNVs were identified in 7 patients (6.1%) and VUS were found in 22 patients (19.3%). Of the VUS group, 7 CNVs were likely pathogenic and 15 CNVs were likely benign. Among the five *de novo* CNVs, one was a large deletion associated with the known 9q21.13 microdeletion syndrome, while the other four were rare duplications of 100-300 Kb in size. These gains contained both known ASD-associated genes such as *DPP10* and *CHL1*, and genes that are highly expressed in brain but have not yet been linked to ASD, namely *CNDP1* and *SERINC2*. In conclusion, this is the first SNP-based microarray study in a large cohort of Thai patients with ASD. Our findings provide supportive evidence that chromosomal microarray should be considered as a first tier genetic analysis for Thai patients with ASD of unknown cause. Additionally, CNV analysis using ancestry-matched controls in diverse population is a valuable tool for identification of novel ASD-associated genes. The CNVs detected in our study suggest a number of ASD candidate genes that warrant further investigation.

963F

MMP-8 and TIMP-1 expression in pressure ulcer management through negative pressure wound therapy in spinal cord injury patients. *R. Srivastava, M. Dwivedi, A. Bhagat, S. Raj.* Orthopaedic Surgery, KG Medical College, CSM Medical University, Lucknow, UP, India.

Introduction: Pressure ulcer (PU) is devastating co morbidity in SCI subjects. Our aim was to assess the concentrations of matrix metalloproteinase-8 (MMP-8) and tissue inhibitor of metalloproteinase-1 (TIMP-1) between PU treated with negative pressure wound therapy (NPWT) and PU treated with standard wound care and correlates it with healing outcomes. **Methods:** 44 patients of stage 3 & 4 pressure ulcers were randomized into two treatment groups. Group 1 (n=21) received NPWT and Group 2 (n=23) received conventional method of dressing. The tissues from base of PU were taken at week 0, 3, 6 and week 9 for analysis of MMP-8 and TIMP-1 by enzyme linked immune sorbent assay (ELISA). **Results:** Significantly reduced level of MMP-8 was observed in NPWT group at week 3 (p=0.014), week 6 (p=0.0007), week 9 (p=0.0001) as compared to standard wound care. Significant higher value of TIMP-1 was observed at week 6 (p=0.03) and week 9 (p=0.003) in NPWT group as compared to standard wound care. Significantly reduced length of PU in NPWT group was observed at week 6 (p=0.01), which further reduced more at week 9 (p=0.0001) as compared to standard wound care. Similarly significant reduction of width (p=0.0006) and depth (p=0.001) of PU was observed in NPWT at week 9 as compared to standard wound care group. Correlation analysis revealed that reduction of length, width and depth were positive correlated with MMP-8 and negatively correlated with TIMP-1. **Conclusion:** Negative pressure wound therapy leads to early wound healing by decreasing the concentration of MMP-8 and may increased the concentration of TIMP-1 as compared with standard wound care. New treatment strategies for chronic pressure ulcer healing could be directed towards molecular factors including maintenance of matrix metalloproteinases.

964W

Successful detection of pathogenic copy number variations in patients with neonatal/infantile cholestasis by next generation sequencing with Ion Torrent Personal Genome Machine system. *T. Togawa, T. Sugiura, K. Ito, T. Endo, K. Aoyama, Y. Negishi, K. Ohashi, S. Saitoh.* Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Copy number variation (CNV) substantially underlies the pathogenesis of genetic disorders, and has become of much greater interest in a clinical setting. Array comparative genomic hybridization and multiplex ligation-dependent probe amplification (MLPA) analysis are the standard methods of detecting CNVs. Recently, next generation sequencing (NGS) technologies provide an alternative method of detecting CNVs by comparing the number of sequence depth. We developed a diagnostic panel of causative genes for neonatal/infantile intrahepatic cholestasis using the AmpliSeq and Ion Torrent Personal Genome Machine (Ion PGM, ThermoFisher Scientific) system. The panel included 18 genes, and number of amplicons, total targeted bases and exons were 551, 53.426kb, 355, respectively. Sequenced reads were analyzed through Ion Reporter software (IR, ThermoFisher Scientific) version 4.0/5.0. The IR could call CNVs by computational prediction according to two scores; the confidence score (CS) and the precision score (PS). Candidates of pathogenic CNV were collected as follows; 1) CS or PS indicated >10 points and called CNVs were expected to be potentially pathogenic, or 2) CS or PS < 10 points, however, called CNVs were strongly suspected of disease-causing. We analyzed 331 patients who were suspected of having a colestatic syndrome, such as Alagille syndrome (ALGS), progressive familial intrahepatic cholestasis type 1 (PFIC1), or Dubin-Johnson syndrome (DJS). The IR called 6 candidates of pathogenic CNVs; 3 *JAG1* CNVs in 3 patients with ALGS, 2 *ATP8B1* CNVs in 2 patients with PFIC, or 1 *ABCC2* CNV in 1 patient with no definitive etiology. In the candidates of *JAG1*, the IR predicted heterozygous whole gene deletions encompassing the length of 34 kb, and CS/ PS showed 296/296, 294/294, and 213/213 in respective patient. Regarding *ATP8B1*, each of two patients was predicted harboring a heterozygous deletion of exon 2 to 6 or exon 13, and CS/PS showed 48/48 or 3.2/3.2, respectively. In *ABCC2*, one homozygous deletion of exon 7 was predicted as CS/PS indicated 7.4/23. All candidates CNVs were successfully confirmed by MLPA analysis for *JAG1* using the SALSA MLPA probemix P184-C2 JAG1 (MRC-Holland), by quantitative polymerase chain reaction by LightCycler Nano system (Roche Diagnostics) for *ATP8B1*, or by Sanger sequencing for *ABCC2* detecting the break point. In conclusion, IR analysis using sequence depth by Ion PGM system successfully.

965T

Accurate detection of copy number variants in *ADME* **genes using PharmacoScan™ Assay.** *R. Varma, D. Black, J. Gollub, C. Bruckner, J. Law, M. Mittmann, T. Webster, A. Roter, M. Shapero, J. Schmidt.* Affymetrix, part of Thermo Fisher Scientific, Santa Clara, CA.

Copy number variations (CNVs) in genes relevant to drug absorption, distribution, metabolism, and excretion (ADME) have been characterized using several technologies. CNV detection using a standard single-nucleotide polymorphism (SNP) genotyping assay is efficient and advantageous because the genotypes of these genes are of utmost importance. We report here on the development of a CNV detection method for five ADME genes using PharmacoScan Assay, a cost-effective, high-throughput pharmacogenetics analysis solution. Copy number calls are compared to TaqMan® copy number assays, published data, or both, when available. We focus on CNV calling in five genes: CYP2A6, CYP2D6, GSTM1, GSTT1, and UGT2B17. CYP2A6 and CYP2D6 are particularly difficult to characterize because of the presence of closely related pseudogenes, which may form hybrids with their respective genes. Copy number states called include gains and homozygous and hemizygous losses. Both SNP and non-polymorphic probes are used for copy number detection and were selected based on sequence homology and response to copy number. Data analysis steps include signal summarization and normalization; calculation of log-ratios using normal diploid reference; correction of signals based on GC content and other covariate factors; median log-ratio calculation; and CNV calling based on thresholds for each region. Several hundred samples from the HapMap and 1000 Genome projects were analyzed using PharmacoScan Assay, and CNVs were called in eight regions: GSTM1, GSTT1, UGT2B17, two CYP2D6 sub-regions, and three CYP2A6 sub-regions. The predicted copy number states were compared to TaqMan results, and to sequencing results reported by the 1000 Genomes project. Results show high concordance in copy number calls for all eight regions between PharmacoScan Assay and other technologies. For CYP2D6 and CYP2A6, many samples were identified with differing copy number calls in the sub-regions, demonstrating the ability to distinguish copy number changes that are likely due to complex recombination events. In order to obtain equivalent results using TaqMan, multiple assays probing different locations within the gene are required. In contrast, the method presented here has the advantage of using a single assay to call CNVs in multiple sub-regions while also providing comprehensive genotypic information in genes of interest.

966F

Mechanistic analysis of interchromosomal insertional translocation.
T. Kato[1], Y. Ouchi[1,2], H. Inagaki[1,2], Y. Makita[3], S. Mizuno[4], H. Kurahashi[1,2]. 1) Divison of Molecular Genetics, Fujita Health University, Toyoake, Japan; 2) Genome and Transcriptome Analysis Center, Fujita Health University, Aichi, Japan; 3) Education Center, Asahikawa Medical University, Hokkaido, Japan; 4) Department of Pediatrics, Central Hospital, Aichi Human Service Center, Aichi, Japan.

   Interchromosomal insertional translocation is relatively rare chromosomal structural aberration, since they require at least three breaks followed by a segment from one chromosome is inserted into as interstitial region of different chromosome. Although several mechanisms such as double-strand-repairs via non-allelic homologous recombination or non-homologous end joining, and replication-based pathway have been implicated as mechanisms of chromosomal structural aberrations, the mechanisms of the insertional translocation is still unknown. In this study, we analyzed breakpoints and rearranged fragments by means of FISH, SNP array and next generation sequencing, to gain insight into their mechanisms of formation. To characterize the breakpoint diversity and insertion site complexities, we applied whole genome sequencing and mate-pair sequencing using next generation sequencer. All insertion cases are not simple structural aberration mediated by three breakages and three repairs. Inserted fragments are consisted of multiple pieces of genomic segments with a disorderly array and copy number alternations. All of the junctions have short microhomology or short insertional nucleotides. Polymorphism analysis revealed that insertion site sequences are of the same parental origin with normal counterpart homologous chromosome. One case showed that an insertion event is intermingled, i.e. maternal insertion site is inserted into another paternal chromosome. These data imply that the interchromosomal insertional translocation results from a meiotic nondisjunction event followed by a trisomic rescue at early post-zygotic stage with anaphase lag. Micronucleus that is formed from anaphase lagging chromosomes might undergo chromoanasynthes-like rearrangements. Pulverized chromosomes might be then inserted into another chromosome. It is likely that insertional translocation might be formed by several independent processes across pre- and post-zygotic events.

967W

Nomenclature matters: A collaboration to bridge the gap between ISCN and HGVS. *J. McGowan-Jordan[1,2], A. Simons[3], J. den Dunnen[4].* 1) Genetics, CHEO, Ottawa, ON, Canada; 2) University of Ottawa, Canada; 3) Human Genetics, Radboud University Medical Center, Nijmegen, The Netherlands; 4) Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

   Clear descriptions of clinical and experimental findings are essential for consistent communication amongst individual scientists, clinicians, and groups. In laboratory genetic studies this has happened in two distinct ways. For decades, the Standing Committee of the International System for Human Cytogenetic Nomenclature (ISCN) has established a standard scheme for the description of numerical and structural chromosome abnormalities. Detection of aberrations began with methods describing unbanded, then banded chromosomes, and later using technological advances including FISH, microarray and region-specific assays. When the molecular basis of various human diseases began to be identified, the need for a standard system of describing variants at a base-pair level became evident. The Human Genome Variation Society (HGVS) established such guidelines and continues to update and improve the originally proposed scheme, enabling the description of variants based on different reference sequences and covering the DNA, RNA and protein levels.   With widespread uptake of advanced sequencing technologies large rearrangements, well beyond those typically identified by more classical sequencing, are being identified. Nomenclature to describe these changes, both within and between chromosomes, was outside the scope of the existing ISCN and HGVS schemes and required the establishment of a scheme that would be useful for both the Cytogenetics and Molecular Genetics communities. In a unique and historic collaboration, the ISCN Standing Committee and HGVS Working Group on Sequence Variant Description and Nomenclature have worked together to draft a scheme that will meet the needs of both communities and provide consistent description of large intra- and inter-chromosomal rearrangements. This scheme, published as a new chapter in ISCN (newly renamed as An International System for Human Cytogenomic Nomenclature) 2016, combines aspects of both HGVS and ISCN, so that information on both the chromosomal and base-pair level is readily evident. Elements and examples of the combined scheme will be presented to illustrate its utility.

968T

Molecular genetic analysis of 30 families with Joubert syndrome and related disorders. *T. Suzuki[1,2], N. Miyake[1], Y. Tsurusaki[3], M. Nakashima[1], H. Saitsu[1,4], S. Takeda[2], N. Matsumoto[1].* 1) Depertment of Human Genetics, Yokohama City University Graduate School of Medicine, yokohama, Japan; 2) Department of Obstetrics and Gynecology, Juntendo University Faculty of Medicine, Tokyo, Japan; 3) Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Department of Biochemistry, Hamamatsu University School of Medicine, Hamamatsu, Japan.

Joubert Syndrome and Related Disorders (JSRD, MIM 213300) are rare recessive disorders characterized by hypoplasia/aplasia of cerebellar vermis and a deep posterior interpeduncular fossa, thickened and elongated superior cerebellar peduncles known as "molar tooth sign" on brain MRI. JSRD is genetically highly heterogeneous and at least 28 disease mutant genes have been found in JSRD so far. To elucidate genetic causes in JSRD, we performed whole exome sequencing (WES) in 24 JSRD families newly recruited. Including six families which we previously reported, genetic and clinical aspect of 30 JSRD families (27 Japanese families, two Omani families, and one family of half-Japanese and half-Paraguayan mother and Paraguayan father) were analyzed. We run the exon-captured samples on Genome Analyzer IIx or HiSeq (Illumina platform). Candidate pathogenic variants were validated by Sanger sequencing, and the mutation segregation was checked when familial samples were also available. In addition, we analyzed copy number variations (CNV) using the eXome Hidden Markov Model and Nord program which are WES-based CNV detection tools. As a result, we identified the causative mutations in 25 out of 30 families (83.3%). We did not detect any pathogenic CNVs. Among eight genes which mutations were identified in 27 Japanese families, mutations of *TMEM67* (7/27, 25.9%) and *CEP290* (6/27, 22.2%) were most frequent. Interestingly, nine of 12 disease alleles of *CEP290* were c.6012-12T>A (75.0%), while it has never been reported in other ethnic studies. Additionally, we found compound heterozygous mutations with *C5orf42* in two Japanese families. Among of them, three mutations (c.3577C>T, c.3557delA, and c.3599C>T) in *C5orf42* were previously reported in Japanese families, but not in other ethnic groups. Therefore, c.6012-12T>A in *CEP290* and c.3577C>T, c.3557delA, and c.3599C>T in *C5orf42* could be founder alleles in a Japanese population. Furthermore, in two families (2/30, 6.7%), we found concomitant mutations consisting of compound heterozygous mutations in *TMEM67* and *RPGRIP1L* in one Japanese family, and homozygous mutations in *TMEM67* and *BBS1* in an Omani family. *BBS1* is a causative gene with Bardet-Biedl syndrome. Since they showed severe and/or complex clinical features, the dual effects of different mutant genes are suggested.

969F

Detection of constitutional copy number variation in saliva DNA using the Affymetrix Cytoscan HD array. *J. Reiner[1], L. Karger[1], G. Mamtora[2], R. Duttagupta[2], E. Fung[2], L. Mehta[1], L. Edelmann[1], S.A. Scott[1].* 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Cytogenetics Research and Development, Thermo Fisher Scientific, Santa Clara, CA.

Chromosomal microarray (CMA) analysis is considered a first-tier test for the detection of constitutional abnormalities in individuals with idiopathic developmental conditions and/or congenital anomalies. Currently, postnatal clinical CMA testing is most commonly performed using DNA extracted from lymphocytes in whole blood. However, the collection of saliva samples for downstream molecular testing can offer several advantages over blood, including a non-invasive collection procedure and increased sample stability. Previous studies using saliva or buccal samples for single nucleotide polymorphism (SNP) genotyping microarrays have reported mixed results with respect to SNP calling and copy number variation (CNV) detection, likely due to the presence of variable concentrations of bacterial DNA among the saliva samples. As such, further investigation is warranted before implementing saliva DNA for clinical CMA testing. In order to test the effect of high bacterial content on CMA performance, we tested DNA from six saliva samples collected using the Oragene Dx kit (OGD-500; DNA Genotek) with a broad range of PCR-quantified bacterial DNA content (3.1-20.8%) on the Affymetrix CytoScan HD array. No significant differences in mapd values were detected between samples, suggesting that bacterial mass does not adversely affect Cytoscan HD array quality metrics. We also compared the performance of matched blood and saliva DNA from 10 healthy adult controls and an additional 10 postnatal cases with clinically-significant copy number aberrations previously detected by clinical CMA analysis on blood DNA. Analysis of the aggregate blood and saliva samples showed comparable mapd and snpQC values, as well as a similar number of absence of heterozygosity (AOH) calls. Despite a trend towards increased CNV call rate in saliva, concordance between the matched blood and saliva samples was greater than 80% for all CNV and AOH calls. Importantly, the clinical utility of using saliva DNA for CMA testing with the Cytoscan HD array was further validated by the detection of all clinically-significant copy number aberrations in saliva that were originally identified in blood DNA.

970W

Triaging complex cases for genomic tests in South Australia: A multi-disciplinary team approach. *P.A. Kaub, K.S. Kassahn, J.M. Fletcher.* Genetics & Molecular Pathology, SA Pathology, Adelaide, South Australia, Australia.

New genetic testing platforms offer much promise, but are still a relatively limited resource in clinical diagnostic settings in Australia. Our clinical diagnostic service uses a multi-disciplinary team (MDT) forum, where medical scientists and bioinformaticians performing genetic testing and analysis directly interact with primary clinicians and pathologists to determine the most appropriate testing for complex clinical cases. Routine genetic tests are sent directly to relevant laboratories. For complex cases however, we have developed a systematic approach for case presentations and decision criteria to assist determination of the most appropriate testing for each case, based on both clinical and laboratory information. We consider the management implications, evidence supporting genetic testing indication and utility, test availability, service capacity and in-house expertise, as well as expected turnaround time. A recommendation for each case is formed after open and robust discussion between the MDT meeting members. Outcomes include recommendations for phenotype-targeted next generation sequencing (NGS) gene panels, clinical exome, whole exome or whole-genome sequencing, array-based testing and MLPA. Where there are issues of capacity or lack of expertise, samples have been referred to research colleagues or external laboratories. In just under two years, this consensus-based, open discussion platform has reviewed approximately 100 complex clinical cases. The majority have been Paediatric patients, with the greatest number referred from Clinical Geneticists, however Immunologists, Neurologists, Cardiologists, Metabolic, Renal and General Physicians have also been represented. Common phenotypes include neurological, syndromic, dysmorphic/anatomic, developmental/intellectual delay or metabolic conditions. This process is scaleable as each new panel moves from the complex to standard pathway. The MDT meeting format has been key to our successful implementation of NGS and ability to meet increased demand through optimised test selection that is phenotype-driven. Scientists, researchers, clinicians & bioinformaticians are all essential members of our MDT meeting format, maximising the utility of diagnostic services and assisting best clinical outcome for patients.

971T

Assessing the clinical genomic load and outcome within the eMERGE III network. *M. Leduc[1], D. Muzny[2], K. Walker[2], E. Venner[2], E. Kudalkar[3], F. Funke[3,4], A. Gordon[5], G. Jarvik[5], H. Rehm[3,4], Y. Yang[1,6], C. Eng[1,6], R. Gibbs[2] on behalf of the Electronic Medical Records and Genomics (eMERGE) Network.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Laboratory for Molecular Medicine at Partners Health-Care Personalized Medicine, Cambridge, MA; 4) Department of Pathology, Harvard Medical School/Massachusetts General Hospital, Cambridge, MA; 5) Dept. of Medicine (Medical Genetics), University of Washington, Seattle, WA; 6) Baylor Miraca Genetics Laboratories, Houston, TX.

The eMERGE (Electronic Medical Records and Genomics) network is a NHGRI funded national consortium that aims to advance medical care by implementing genomic medicine and integrating Electronic Medical Records (EMR) systems. In eMERGE III, we will resequence 109 genes in a CAP and CLIA environment in addition to testing ~1,500 unique single nucleotide variants. The test will use a CARE seq DNA capture panel to test 25,000 DNA samples from a cohort submitted by the 9 eMERGE clinical sites, including symptomatic and asymptomatic individuals. The 109 eMERGE genes include the 56 ACMG medically actionable genes and 53 genes of interest selected by the clinical sites, 92 of which are of clinical significance and 66 of which are medically actionable. Two core clinical laboratories will perform the sequencing, clinical assessement of the variants and provide an individualized clinical report with pathogenic (P) and likely pathogenic (LP) variants. Carrier status will not be reported. The clinical report will be linked to the patient's EMR while the vcf datafile will be transmitted to the clinical sites for further research. As a preliminary analysis, we used our internal clinical exome (WES) databases to assess the performance of our DNA capture panel reagent and predict the number of positive clinical reports to likely be required for 'healthy' asymptomatic individuals. Based on data from 647 test samples, only 14 exons had no or low coverage using the criteria of 10% of samples with coverage <20X, illustrating the overall high quality of the capture reagent. We then catalogued all known P and LP variants detected and/or curated by our laboratory within the 92 eMERGE genes and 1,500 variants (n=5,663 P/LP variants). We investigated 6,000 WES patients for P/LP variants and identified 1,835 P/LP variants in 1,591 patients (28%). Since the clinical WES population is pediatric and symptomatic, we removed the variants related to the patient's phenotype and interrogated the medically actionable genes and variants. We identified 166 patients with either one P/LP heterozygous variants in autosomal dominant disorders (n=163) or a hemi and homozygous variants in autosomal recessive and X-linked disorders (n=3). While additional variant curation and harmonization of this categorization is underway between the two core laboratories, we estimated that approximately 3% of asymptomatic participants enrolled in the eMERGE consortium will require a positive reportable finding.

972F

The Wessex Clinical Exome Pilot: A comprehensive service evaluation of focussed exome sequencing in clinical diagnostics. *R. Pengelly[1], D. Ward[2], E. Baple[3], S. Thomas[2], D. Hunt[3], C. Mattocks[2], S. Ennis[1], Wessex Clinical Exome Pilot.* 1) Human Genetics & Genomic Medicine, University of Southampton, Southampton, United Kingdom; 2) Wessex Regional Genetics Laboratory, Salisbury District Hospital, Salisbury, UK; 3) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton, UK.

Next-generation sequencing (NGS) has revolutionised the practice of medical genetic research, allowing the massively parallel sequencing of DNA, and is now increasingly applied to clinical diagnostics. Focussed-exome sequencing (FES), the sequencing of the exonic regions of ~4,500 genes previously implicated in human disease (the 'morbidome') offers an intermediate option between the sequencing of all genes and small targeted gene panels. The Wessex Clinical Exome Pilot (WCEP) is a partnership between academia and healthcare, involving the University of Southampton, University Hospital Southampton NHS Foundation Trust and Salisbury District Hospital NHS Foundation Trust. The WCEP aims to perform a comprehensive service evaluation of FES in routine clinical diagnostics. A through evaluation of FES kits was performed and the Illumina TruSight One focussed exome kit will be applied to a cohort of individuals with molecular diagnoses previously determined by routine clinical diagnostic methods. Furthermore, we will investigate ~150 diverse cases for which clinical targeted gene panels were being performed in parallel. We will comprehensively evaluate these cohorts for operational parameters including diagnostic rate, turn around time and cost, as well as determining the robustness of the technology in clinical diagnostics and improving our bioinformatics tools to allow maximal utility of these data and conducting further research utilising this dataset. The development during the WCEP will lay strong foundations for ongoing commercial clinical diagnostic FES testing in the Wessex region, leading to improved economy and better patient outcomes for those undergoing genetic testing.

973W

Evaluation of the truXTRAC™ DBS DNA Kit for extraction of DNA from dried blood spot samples for use in NGS library preparation. *K. Ramachandran[1], R. Daber[1,2], J. Jackson[1], L. Vu[1], J. Adigun[1].* 1) GeneDx, 205 Perry Parkway, Gaithersburg, MD 20877; 2) Bio-Reference Laboratories, Inc, 481 Edward H. Ross Drive Elmwood Park, NJ 07407.

Dried blood spots (DBS) provide an easy and inexpensive way to collect and store peripheral blood specimens from infants, children and adults. The ability to run molecular or clinical assays on this type of specimen allows for easier specimen shipments and less invasive procedures for patients. This is also a convenient method for the long term room temperature storage of materials suitable for molecular assays and also minimizes storage and archival space. The truXTRAC DBS DNA Kit from Covaris® is designed for controlled and efficient extraction of NGS-grade DNA from DBS samples using Adaptive Focused Acoustics (AFA™). According to the manufacturer, Covaris® AFA enables sample rehydration while providing simultaneous cell lysis and DNA shearing resulting in high-yield and high-quality DNA. Here we report the successful use of the truXTRAC DBS DNA Kit to extract DNA from a single 3mm punch of a DBS cards for generation of NGS libraries. Hybridization based capture was then performed on the libraries to assay for germline mutations in an inherited cancer panel. Downstream data analysis showed that data quality and variant calling for libraries prepared from DBS DNA were indistinguishable from those prepared from DNA extracted from 1ml of whole blood. This new protocol provides more evidence for the efficacy of DNA extracted from DBS cards in the molecular diagnostics of genetic disorders.

974T

Toward objective interpretation of sequence variants in clinical testing. *J. Weber[1], Z. Ye[2], Z. Wang[1].* 1) PreventionGenetics, Marshfield, WI; 2) Marshfield Clinic Research Foundation, Marshfield, WI.

Interpretation of sequence variants is certainly one the greatest current challenges in clinical genetics. To date, variant interpretation has been a highly subjective exercise. In an effort to make interpretation more objective, we have utilized several simple, quantitative measures of pathogenicity. These measures include allele frequency differences between cases and controls, and the fraction of times a particular variant occurs together with a second plausible pathogenic variant in patients affected with recessive disease. We demonstrate the utility of these approaches with several examples including autosomal dominant Malignant Hyperthermia Susceptibiltiy via *RYR1* variants and Autosomal Recessive Polycystic Kidney Disease via *PKHD1* variants. Our approaches have limitations and potential pitfalls and therefore must be used with caution. These approaches also require quantitative definitions of Pathogenic, Likely Pathogenic, Likely Benign and Benign. Nevertheless, these approaches are important first steps in transforming sequence interpretation from an art to a science.

975F

A pathogenicity/phenotype correlation dual-scoring system for precise clinical interpretation of genetic variants: In the setting of expanded sequencing-based carrier screen for 20,000 individuals. *F. Xia, L. Meng, J. Zhang, R. Xiao, C. Eng, A. Beaudet.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background Population-based carrier testing is in the process of transitioning from targeted mutation analysis on a small number of genes to full sequencing of all exons for hundreds of targeted genes. This represents a major challenge where large numbers of variants need to be interpreted very rapidly, for both pathogenicity and phenotype correlation.   Methods Since 2015, Baylor Miraca Genetics Laboratories launched the GeneAware® comprehensive carrier screen test. The main component is sequencing the coding regions of a 159-gene panel associated with autosomal recessive and X-linked conditions. As the candidate pool, we collected over 30,000 variants from locus specific mutation databases, including HGMD®, ClinVar. For accurate interpretation, we developed a scoring system giving each variant both pathogenicity ranks resembling the new ACMG 5-category system, and phenotype scores including four phenotype categories: classic severe (1), atypical mild (2), subclinical condition (3) and to-be-determined (4). The evidence for scoring is classified into types as clinical cases, population genetics, and functinoal data and theoretical predictions. Variants scored as pathogenic/likely pathogenic are reported.   Results To date, over 20,000 clinical cases have been analyzed, and >10,000 variants have been curated and assigned with both pathogenicity and phenotype correlation scores. Among the variants scored as pathogenic or likely pathogenic, 95.7% of them have classic phenotype score. Atypical mild and subclinical are 3.9% and 0.4%, respectively. However, in 1000 genome and ExAC databases, the atypical and subclinical variants are 250% more frequent than the severe ones. The observation is consistent with that mild alleles may survive better during natural selection. For variants associated with classic severe phenotype, evidence from clinical cases and functional data are consistent; population variant frequencies are in general supportive. For variants of mild and subclinical categories, clinical cases become dominantly important, while other types of evidence show ambiguity.   Conclusion The pathogenicity/phenotype correlation dual scoring system allows us to give precise interpretation of clinical testing results. Given the wide and expanding phenotypic spectrum of genetic disorders, professional curation in combination of informatics tools is crucial to achieve the optimal results for complex genetic testing like panel, exome and whole genome sequencing.

976W

Variant classifications are highly concordant in ClinVar, but with variability in genes from different disease areas. *S. Yang, S. Lincoln, K. Nykamp, T. Hambuch, Y. Kobayashi, S. Topper, R. Nussbaum.* Invitae, San Francisco, CA.

As the number of laboratories offering genetic tests grows, the potential for inconsistent variant classifications increases. Public databases of clinically classified variants afford us, for the first time, the ability to systematically evaluate this issue. We evaluated pathogenicity assessments in the ClinVar April 2016 XML file. We included all unique variants from genes Invitae currently offer with at least 2 classifications submitted by established clinical laboratories including data from Myriad Genetics submitted via the Sharing Clinical Reports Project (SCRP). 24,455 total classifications of 10,000 unique variants were available for comparison. The largest data sets exist for hereditary cancer (48%) and cardiovascular (33%) genes, with smaller data sets available in: neurology, excluding epilepsy (7%), epilepsy (7%) and inherited metabolic disorders (4%). We first focused on differences between putatively disease causing variants classified as Pathogenic (P) or Likely Pathogenic (LP), as opposed to those which are not clinically actionable: Variant of Uncertain Significance (VUS), and Likely Benign (LB), or Benign (B) variants. Counting each unique variant as a data point, concordance among different labs was high: variants in cancer genes had the highest agreement (98.9%) while inherited metabolic disorder variants had the lowest (92.7%). However, when the concordance is defined with finer detail as pathogenic (P/LP), vs. uncertain (VUS) vs. benign (B/LB), we see lower agreement. Variants in cancer, neurological and inherited metabolic disorder genes maintain over 90% concordance; while cardiology and epilepsy are the least concordant at 85.7% and 76.1% respectively. The major diagnostic labs we investigated generally agree on the clinical significance of potentially actionable (P) vs. not actionable (NP) findings. Classification of variants in genes in different disease areas, however, does vary in their concordance. This may arise from differences in the depth and sophistication of knowledge about these diseases, the complexity and diversity of genetic causes of the disease, the number of labs participating in that area and other factors. The small number of differences is important to resolve collaboratively through peer-review of such data, and serves as an important form of laboratory quality control. The learning from such comparisons helps to improve standards and knowledge among all clinical genetics professionals.

977T

Segmental genomic deletions and splicing mutations causing tuberous sclerosis complex (TSC). *L. Almeida[1], J.P.G. Almeida[2], L. Masulk[3], M. Richartz[3], N. Miranda[3], I.M.W. Silva[1], S. Chiavegatto[4], M.R. Passos-Bueno[1], S.A. Antoniuk[3], S. Rosemberg[2], L.A. Haddad[1].* 1) Department of Genetics and Evolutionary Biology, Instituto de Biociências, Universidade de São Paulo, São Paulo, Brazil; 2) Department of Pediatrics, Division of Child Neurology, Faculdade de Medicina da Santa Casa de São Paulo, São Paulo, Brazil; 3) Department of Pediatrics, Universidade Federal do Paraná, Curitiba, Brazil; 4) Department of Pharmacology, Instituto de Ciências Biomédicas, Universidade de São Paulo, São Paulo, Brazil.

Tuberous sclerosis complex (TSC) is an autosomal dominant hamartomatosis with variable expression, affecting notably the brain, kidneys, heart, skin, lungs, and retina. Mutations in either tumor suppressor genes *TSC1* (9q34) or *TSC2* (16p13.3) are responsible for TSC. The proteins expressed by those genes, respectively hamartin and tuberin, form a heterodimer that inhibits the mammalian target of rapamycin complex 1 (mTORC1), controlling cell growth and proliferation. Comprehensive screening for *TSC1* and *TSC2* DNA variants are well established, and disclose in average 70% of pathogenic (loss-of-function) DNA variants in the *TSC2* and 30% in the *TSC1* genes. Different clinical and research groups worldwide have reported that 75-90% of TSC-causing mutations lie in the *TSC1* and *TSC2* coding regions (frameshifting, nonsense and missense DNA variants). Increasing evidence indicates that DNA variants in non-coding sequence and copy number variations (CNV) may be responsible for *TSC1* and *TSC2* gene inactivation, including patients previously classified with no-mutation identified (NMI) (Nellist, M *et al.*, 2015, *BMC medical genetics*). Here we report on segmental genomic deletions and splicing mutations detected altogether in 24% of TSC patients from a Brazilian cohort. Forty-one patients with definite clinical diagnosis of TSC had leukocyte DNA previously analyzed by Sanger sequencing (Almeida, L. *et al.*, 2015, *Am Soc Hum Genet*). Deletions identified by multiplex ligation-dependent probe amplification (MLPA) analyses were submitted to quantitative PCR (qPCR), and *TSC1* and *TSC2*-targetted exome sequencing. Data from the latter approach were analyzed using a set of statistical and computational tools named XHMM (Frommer *et al.*, 2012; *Am J Hum Genet*). A high rate of mutation detection (97.6%) was observed for this group of patients (N=41) that had been referred to our laboratory from Neurology services from two tertiary referral hospitals in Brazil. Three patients (7%) had segmental deletions (two in *TSC1*, and one in *TSC2*); one of them with a mosaic pattern confirmed by different techniques. The *TSC2* gene presented splicing mutations in seven patients (17%). No splicing mutation was detected in the *TSC1* gene. In addition, the only patient that remained NMI had a single nucleotide variant in one *TSC2* intron, which needs to be functionally evaluated.

978F

High-throughput copy number variation detection in the application of clinical carrier testing. *L. Meng[1], C. Shaw[1], T. Chiang[3], W. Jin[2], T. Luong[2], T. Zhang[2], Z. Chen[1,2], F. Xia[1,2], J. Zhang[1,2], C.M. Christine[1,2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Baylor Miraca Genetics Laboratories, Houston, TX; 3) Human Genome Center, Baylor College of Medicine, Houston, TX.

Statement of purpose: We developed a novel 500 kb clinical carrier testing panel which includes full gene next-generation sequencing for 152 genes, triplet repeat analysis for FMR1, and analysis for recurrent CNVs in 15 genes. As of May 2016 we have reported over 10,000 clinical samples for this test. We continually optimize our pipeline to improve data quality and overall efficiency. Here, we explored the possibility of using NGS data to perform CNV analysis for non-homologous genes as part of the clinical carrier testing panel. Methods used: Normalized read depth from NGS data are computed for each target exon in the given sample and copy number was calculated by reference it to the median read depth within the capture midpool. To compare the NGS CNV pipeline with the current system, Fluidigm qPCR assay, we performed CNV analysis by both methods and compared the results for *CFTR* and *DMD* from 5000 de-identified clinical samples. Summary of results: The Fluidigm qPCR assay were designed to target for *CFTR* exon2 and 3 only, and detected only 1/5000 samples with exon2 deletion. By expanding the detection region to full gene by NGS, CNV detection rate was increased to 4/5000 (1 case with exon19 deletion, 1 case with exon 19-21 deletion, and 1 case with complex deletion with exon 4-8 and exon 12-21), without significantly affecting the false positive rate (0.21% by qPCR assay versus 0.45% by NGS). Since Fluidigm qPCR assay covers a great majority of the *DMD* gene, both methods successfully detected samples with CNVs over the *DMD* region (eight cases with copy number loss and three cases with copy number gain). But it should be noted that NGS analysis still has higher coverage (79 exons from the major isoform and 6 exons from other important isoforms) than Fluidigm qPCR assay (54 exons). Even with our best effort for analysis improving, false positive samples remained as high as 12.16% for Fluidigm qPCR assay, while only 0.57% samples were called false positive by standard NGS algorism. A great majority of false positive deletions in qPCR testing are caused by rare SNV located in the primer/probe region resulting in allele drop out, while these SNPs have little effect in NGS-based CNV results. In summary, compared to qPCR-based testing, NGS-based CNV analysis is superior in coverage, detection rate, and specificity, and may replace dedicated CNV assays in clinical carrier testing.

979W

The clinical application of exome CNV detection in a large cohort of patients with various genetic disorders. *R. Pfundt[1], M. del Rosario[1], L.E.L.M. Vissers[1], M.P. Kwint[1], I.M. Janssen[1], H.G. Yntema[1], M.R. Nelen[1], D. Lugtenberg[1], E. Kamsteeg[1], N. Wieskamp[1], A.P.A. Stegmann[2], S.J.C. Stevens[2], R.J.T. Rodenburg[3], A. Simons[1], A.R. Mensenkamp[1], T. Rinne[1], C. Gilissen[1], H. Scheffer[1,2], N. de Leeuw[1], J.A. Veltman[1,2], J.Y. Hehir-Kwa[1].* 1) Human Genetics, Radboud University Nijmegen Medical Center, Nijmegen, Gelderland, Netherlands; 2) Department of Clinical Genetics, GROW School for Oncology and Developmental Biology, Maastricht University Medical Centre, Maastricht, The Netherlands; 3) . Nijmegen Center for Mitochondrial Disorders, Department of Pediatrics, Radboud university medical centre, Nijmegen, The Netherlands.

Copy number variation (CNV) is a common source of genomic variation and an important genetic cause of disease. Microarray based CNV analysis has become a first tier diagnostic test for patients with intellectual disability, with a diagnostic yield of 10-20%. However, for most other genetic disorders the role of CNVs is less clear and genetic studies are generally limited to the study of single nucleotide variations (SNVs) and other small variants. With the introduction of exome and genome sequencing it is now possible to detect both SNVs and CNVs in a single test. Here, we have performed exome based CNV screening on data from 2,603 patients affected by a range of 14 different genetic disorders for which exome sequencing was performed in a diagnostic setting. Using read depth analysis we identified 131 clinically relevant CNVs ranging in size from 729bp – 15.3 Mb. This results in over 50 conclusive diagnoses, with an overall average diagnostic yield of ~2%. CNVs were found exerting both dominant and recessive effects, as well as CNVs unmasking a recessive mutation that results in pathogenic compound heterozygous events. This study shows that CNVs play an important role in a broad range of genetic disorders and illustrates how these CNVs can be readily detected from exome sequencing, without the need for additional genetic laboratory testing. Combining SNV and CNV analysis maximizes the diagnostic yield of whole exome sequencing, making it very suited as a first tier genetic test for many disorders. This brings us closer to single test genomics.

980T

What have genes got to do with it? Analyzing gene content across interpreted CNVs in the Clinical Genome Resource Structural Variation Interpretation Working Group. *D.I. Ritter[1], E. Riggs[2], E. Anderson*[3], A. Cherry[4], S. Kantarci[5], H. Kearney[6], C.P. Lorentz[6], J.M. Meck[7], A. Patel[8], S.E. Plon[1], G. Raca[9], S. South[10], E. Thorland*[6], R. Vanzo[11], D. Pineda-Alvarez**[12], S. Aradhya**[13], C.L. Martin[2] on behalf of the Clinical Genome Resource, Co-chairs of ClinGen *Dosage WG & **SV Interpretation WG.* 1) Baylor College of Medicine, Texas Children's Hospital, Houston, TX; 2) Geisinger Health System, Danville, PA; 3) ARUP Laboratories, University of Utah, Salt Lake City, UT; 4) Departments of Pathology and of Pediatrics, Stanford University Medical Center; 5) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA; 6) Mayo Clinic, Rochester, MN; 7) GeneDx, Gaithersburg, MD; 8) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX; 9) Department of Pathology and Laboratory Medicine, Children's Hospital Los Angeles, Keck School of Medicine, University of Southern California; 10) 23andMe, Mountain View, CA; 11) Lineagen Inc, Salt Lake City, UT,; 12) Courtagen Life Sciences Inc, Woburn, MA; 13) Invitae, San Francisco, CA.

Structural variation (SV) through copy number variants (CNVs) is an important disease mechanism implicated in phenotypes ranging from developmental delay to cancers. The Clinical Genome Resource (ClinGen) SV Interpretation Working Group represents a team of investigators from multiple institutions and diagnostic laboratories collaborating with the American College of Medical Genetics and Genomics (ACMG) to update and revise clinical CNV interpretation guidelines. To understand the impact of gene content in interpreting CNVs for pathogenicity, we solicited CNVs that were evaluated in the last 5 years from participating diagnostic laboratories. CNVs requested included deletions of >200kb and <5MB or duplications >500kb to <10MB, with inheritance information and interpreted as: "pathogenic", "likely-pathogenic", "VOUS" (variant of unknown significance), "likely-benign" or "benign." Additionally, we supplied a questionnaire to obtain general reporting practices. We annotated CNVs with RefSeq genes (hg19) and converted all relevant information into a standardized 4-field BED format. We have completed one round of analysis on a subset (~500 CNVs) and expect to collect ~5K interpreted CNVs from reporting laboratories. We found that the median gene content was significantly higher (using a pairwise t-test) between pathogenic and VOUS CNV deletions (p<2e-16; 20 and 8 genes, respectively) with a similar trend for CNV duplications (p<2e-16; 42 and 9 genes, respectively), although the minimum number of genes in a pathogenic CNV could be one in cases of a well-known disease gene. However, likely-pathogenic and VOUS CNVs were not as easily separable by gene content. Ongoing analysis of the larger set will exclude CNVs containing well-documented disease genes by intersection with three databases of gene dosage or truncating variant tolerance: ClinGen Dosage Sensitivity Map, DECIPHER Haploinsufficiency Index and ExAC Loss of Function Intolerance. Inheritance information, such as gene content of *de-novo* vs inherited CNVs will also be analyzed. This work is revealing how current diagnostic laboratories are using gene content in CNV interpretation. The results will inform suggested gene content windows for CNV interpretation, particularly critical for cases of CNVs lacking clearly causal genes. We will incorporate this work into the larger ClinGen SV Interpretation Working Group effort to systematically update and revise the ACMG guidelines for CNV interpretation.

981F

CentoMD®, a comprehensive genotype-phenotype database for rare diseases. *G.E. Oprea[1], D. Trujillano[1], Y. Schmitz[1], A.M. Bertoli-Avella[1], R. Abou Jamra[1,2], O. Brandau[1], P. Bauer[1], A. Rolfs[1,3].* 1) Centogene AG, Rostock, Germany; 2) Institute of Human Genetics, University of Leipzig Hospitals and Clinics, Leipzig, Germany; 3) Albrecht-Kossel-Institute for Neuroregeneration, Medical University Rostock, Rostock, Germany.

Our ability to discover genetic variants in a patient runs far ahead of our ability to interpret them medically. Databases with accurate and curated descriptions of the causal relationship between the variants and the phenotype are valuable since these are critical tools in clinical genetic diagnostics. Here we introduce CentoMD®, a comprehensive genotype-phenotype database with the main focus on rare diseases. CentoMD® is browser based software that enables access to a comprehensive, curated, and growing repository of genetic and clinical information. Its main goals are to aid medical professionals in the evaluation of genetic variants and to enhance the validity of the genetic analytical workflow. CentoMD® correlates the clinical information of consented patients and probands of different racial and ethnic backgrounds (>100 countries) with a large dataset of genetic variants and, when available, biomarker information. More than 74,000 genetically screened individuals are documented in CentoMD®, resulting in more than 200 million variant detections. Approximately 56% of the clinically relevant and uncertain variants in CentoMD are novel. Since every variant retrieval is systematically logged, we have implemented an automated re-contacting tool informing users whenever a variant classification has changed to allow them updating their clinical reports if necessary. Taken together, these unique features, fully embedded in a CLIA/CAP accredited quality management system, allow for excellent data quality and thus enhance patient safety in genetic testing.

982W

Data-driven Sanger confirmation guidelines for next generation sequencing calls. *S.H. Askree[1,2], C. da Silva[1,2], L. Bean[1,2], C. Collins[1,2], A. Tanner[1,2], J. Alexander[1,2], Z. Dai[1,2], A. Ankala[1,2], M. Hegde[1,2]*. 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) EGL Genetic Diagnostic, Decatur, GA.

Sanger confirmation in accurate variant reporting of next generation sequencing (NGS) data has burdened molecular diagnostics laboratories. In order to minimize unnecessary cost and labor, while not compromising on accuracy, we sought to generate guidelines for careful selection of variant calls that truly need confirmation. At EGL genetic laboratory, 4011 variants were targeted for confirmation via Sanger sequencing in the first year of NGS testing alone. All data was generated using HiSeq 2500 in rapid run mode and variants were called with NextGENe software and annotation processed by EGL bioinformatics pipeline. Out of the 2973 that were single nucleotide variants, 85% (2512) confirmed to be true calls, while 15% (461) were determined to be false calls. We first grouped the NGS calls according to percent reads that constitute the non-reference call. Next, data was analyzed for coverage, NextGENe mutation score, presence of pseudo-exon and the frequency of observation in our internal data as well as population databases. It was quickly evident that calls with 35-75% non-reference reads that fulfil a defined quality criteria for coverage and score, were all confirmed as true heterozygous variants by Sanger sequencing. Similarly, calls >90% non-reference reads and above a definable quality criteria, confirmed as true homozygous variants. Zygosity confirmation is needed for all calls with 75-90% non-reference reads. For calls with <35% non-reference reads, Sanger sequencing is necessary, especially considering possibility of mosaicism. The guidelines presented here include quality criteria for each group of calls stratified for percent reads. Since the implementation of these guidelines we have been able to decrease Sanger confirmation by 74%. In addition, we have been able to test the system with a number of variants and have not found an outlier. In summary, NGS data accuracy is more reliable than originally feared and variant calls pipeline can be set up to minimize Sanger confirmation.

983T

***APAF1* and *CASP9* implicated in recurrent folate-resistant neural tube defects.** *C.J. Spellicy[1], C. Bupp[2], P. Mester[3], T. Reynolds[1], C. Schwartz[1], E. Alexov[4], J. Norris[1], R. Stevenson[1], M.J. Friez[1]*. 1) Greenwood Genetic Center, Greenwood, SC; 2) Spectrum Health, Grand Rapids, MI; 3) University of South Carolina School of Medicine, Columbia, SC; 4) Clemson University, Clemson, SC.

Neural tube defects (NTDs) are among the most serious of birth defects, contributing significantly to prenatal and postnatal morbidity and mortality. Although a number of risk factors have been identified and a risk-lowering intervention (including maternal intake of folic acid in the periconceptional period) is available, NTDs continue to occur at a baseline rate of about 5 cases per 10,000 pregnancies. Approximately 200 genetic mouse models of NTDs have been produced, implicating genes in several pathways as risk factors for NTDs. However, specific Mendelian causes of NTDs in humans have remained elusive. Using whole exome sequencing (WES) and trio analysis, we have identified potentially deleterious variants in key apoptotic genes in two families with recurrent folate-resistant NTDs. Sequencing revealed that affected fetuses in Family 1 have compound heterozygous missense changes in the *APAF1* gene, and affected fetuses in Family 2 have compound heterozygous changes in the *CASP9* gene. The phenotype of the fetuses with NTDs is consistent between these two families, which included open NTDs (lumbar spina bifida in two fetuses in Family 1, and craniorachischisis in two fetuses in Family 2) and unusual rib anomalies (rib bifurcation and irregular placement in the two fetuses in Family 1, and abnormal rib morphology and number in one fetus in Family 2 with craniorachischisis). The open NTD phenotypes observed in Family 1 and Family 2 resemble those observed in knockout mouse models of *Apaf1* and *Casp9*, which typically exhibit exencephaly. Other knockout mouse models of apoptotic pathway genes display phenotypes including rib anomalies and NTDs, indicating the importance of the apoptotic gene family in development of these structures. *In silico* analyses of the missense alterations in these families suggest a potential loss-of-function and/or loss of stability compared to the wild type protein. This is the first report of an association of NTDs in humans with mutations in apoptosis genes.

984F

Monitoring for low-level contamination of extracted DNA. *S. Taylor, R. Tomaszewski, K. Baptista, K. Sprysak, L. Vicen, M. Somerville, S. Hume.* Molecular Diagnostic Laboratory, Genetic Laboratory Services, Alberta Health Services, Edmonton, AB, Canada.

The use of robotic extraction systems has greatly improved sample through-put in molecular diagnostics laboratories. A custom TECAN EVO-CHEMAGEN Robotic DNA Extraction system is used in our laboratory to extract DNA from whole blood. While initial validation of this system suggested cross contamination between specimens was not a concern we decided, as part of our lab quality assurance program, to monitor for such an event during all extractions. As extracted DNA is used for a variety of purposes from simple PCR based assays such as HFE genotyping to NGS assays for low level genetic variants it was important to establish a measure of allowable contamination and a value above which would require corrective action. To this end, dilutions from 0 to 2000X of 15 ng/ul male and female DNAs used routinely as controls in our assays were run in triplicate for a quantitative PCR assay of three loci (HIRA, TBX and COMT) within the DiGeorge Chromosome Region (DGCR) on chromosome 22q11.2. A standard curve of DNA concentration was plotted against the cycle change from the undiluted sample. The amplification efficiency of the 22q11 deletion assay is calculated at 88%. Our findings suggest that a 10 cycle difference, roughly equivalent to a dilution of 300X, would not interfere with interpretation of assay results. Corrective action and a repeat extraction would be initiated if the cycle difference was less. This level of contamination was confirmed to be acceptable on a range of assays, including, quantitative PCR for 22q11 deletions, allelic discrimination for HFE, allele specific PCR for Y chromosome deletions and the AmpFLSTR® Identifiler® PCR kit. We have implemented as part of our standard extraction protocol the inclusion of a 3 ml sample of water in each batch of samples extracted. The water samples are monitored post extraction using the PCR assay for 22q11 deletions. To date amplification has only been detectable in a small portion of extraction contamination controls. We recommend that all molecular diagnostic laboratories monitor for extraction contamination using a quantitative assay and define through assay validation, acceptable contamination limits.

985W

Comparative assessment of Sanger sequencing and targeted next generation sequencing (NGS) for molecular diagnoses of patients with alterations in gonadal axis. *M.N. Nishi[1], L.R. Montenegro[1], M.F.A. Funari[1], M.M. França[1], A.M. Narcizo[2], S.M. Oba-Shinjo[3], A.C. Latronico[1], B.B. Mendonca[1].* 1) Laboratório de Hormônios e Genética Molecular LIM42, HCFMUSP, Sao Paulo, Brazil; 2) SELA, FMUSP, Sao Paulo, Brazil; 3) Laboratório de Investigação em Neurologia, LIM15, FMUSP, Sao Paulo, Brazil.

Introduction: NGS has been widely used for targeted sequencing of candidate genes for diagnosis and research. More than 100 genes are associated with the etiology of isolated hypogonadotropic hypogonadism (IHH) and disorders of sex development (DSD). A comparison of cost and time of execution by Sanger method and targeted NGS can help the researchers choose which methodology best applies to the financial resources and urgency of the study. **Objective:** To compare the cost and execution time between Sanger sequencing and targeted NGS panel for molecular diagnoses of patients with gonadal axis disorders. **Material and Methods:** Genomic DNA was isolated from peripheral blood leukocytes from all patients using salting out method. Sanger sequencing was performed using 60 bp flanking region primers for each exon of candidate genes, 11 for IHH and 11 for 46,XY DSD). A total of 431 patients were evaluated (283 IHH and 148 DSD) by Sanger method. A group of these patients without molecular defects were assessed by NGS (96 IHH and 17 DSD patients). This study used a custom SureSelectXT DNA target enrichment panel (Agilent Technologies Inc) designed to capture 100 known candidate genes involved in gonadal axis. All exons, the 25 base pairs of intronic flanking region and 5' and 3' untranslated region of each gene were sequenced. Sequence capture was performed according to the SureSelectXT Target Enrichment Protocol using Agilent Bravo Automated Liquid Handling Platform. Sequencing was performed on a NextSeq 500 (Illumina, Inc). Allelic variants were considered as causative molecular defect if they had a minor population allele frequency <0,001, segregated with the phenotype in an appropriate inheritance pattern and were found damaging by several prediction sites. **Results:** The cost of NGS, considering only the reagents was around US$370 per patient. To study only the coding region of all genes present on the target panel by Sanger sequencing, it will be necessary around 866 PCRs with an estimated cost of US$14,095 *per* patient. The study by targeted NGS was complete in 3 months and by Sanger in 25 months. 111 molecular defects were identified by Sanger method and 46 by NGS considering both groups. **Conclusion:** The cost and execution time of targeted NGS panel for molecular diagnosis of patients with gonadal axis disorders are better than Sanger method and should be considered for routine diagnosis.

986T

Analysis of exome filtering techniques for the prioritization of clinically relevant genes. *K.D. Kernohan[1], T. Hartley[1], D.A. Dyment[1,2], K.M. Boycott[1,2], Care4Rare Canada Consortium.* 1) Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON, Canada; 2) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

Whole exome sequencing is a next-generation sequencing based technique which selectively sequences DNA from the ~1% of the genome that codes for proteins. This cost efficient and effective technology has revolutionized rare disease research as a tool for novel disease gene identification, and has already begun to transition into the clinical realm for diagnostics. However, one of the challenges for clinical exome sequencing is variant interpretation; each exome contains ~20,000 variants, ~300-500 of which are rare (seen in <1% of the population). Clinical labs must interrogate this data to identify the pathogenic variants in genes related to an individual's phenotype, a task which is difficult given the constantly evolving rare disease literature. Efficient exome filtering also allows for control over the identification of incidental findings. We conducted a strategic assessment of 50 exomes with known disease variants using a number of available rare disease datasets as filters: Online Mendelian Inheritance in Man (OMIM), Orphanet, Human Phenotype Ontology (HPO) annotation files and the gene panels curated at Radboud University Medical Center. Each participant was phenotyped using HPO in PhenomeCentral. Projects were then evaluated for the total number of variants which would need to be assessed with the application of each filter as well as their success rate, defined as the presence of the causal variant following filtering. We found that the clinically-curated panels from Radboud produced the fewest variants requiring assessment, however it also resulted in the lowest success rate. OMIM and Orphanet produced the largest variant lists, but with a high success rate. Personalized panels produced using the HPO terms for each participant's PhenomeCentral profile and the HPO annotation files had the same success rate as the OMIM and Orphanet panels, while providing a significantly smaller pool of variants to individually assess. We conclude that HPO term derived gene panels are an efficient and effective way to prioritize and identify clinically relevant exome variants.

987F

Candidate genes evaluated in patients with stomatocytosis and hyperbilirubinemia using whole-exome sequencing. *Y. Kim[1], Y.G. Sung[1], J. Kim[1], K-A. Lee[2].* 1) Department of Laboratory Medicine, Yonsei University Wonju College of Medicine, Wonju, Seoul, South Korea, MD; 2) Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea, MD.

Here we reported the case of Korean female with stomatocytosis, hyperbilirubinemia and vitamin D deficiency. A 31 years old female was admitted to the gastroenterology and hepatology department in 16 July for evaluation of hyperbilirubinemia and anemia which had been detected incidentally at 2003. The peripheral blood count revealed that WBC, hemoglobin, MCV, MCHC and platelet count were 3.69 x 10^3/uL, 11.4 g/dL, 113.7 fL, 33.2g/dL and 304 x 10^9/L, respectively. And serum level of total bilirubin, direct bilirubin, calcium, LDH, vitamin D3 and PTH were 5.08 mg/dL, 0.56 mg/dL, 10.6 mg/dL, 238 U/L, <4.20 ng/mL and 181.8 pg/mL, respectively. Peripheral blood smear findings showed stomatocytosis. *UGT1A1* genotype was wild type (*1/*1). To evaluate genetic alternations related patient's phenotype, we performed whole exome sequencing with Illumina Hiseq2500 and Agilent Sureselect exome kit. The sequence reads were aligned to the reference genome (NCBI b37) using the software BWA and subsequent identification of genetic variants was done with the Genome Analysis Toolkit (GATK version 2.8.1). Annotation was performed using SnpEff (version 3.3h). Alignments are visually verified with the Integrative Genomics Viewer (IGV) v2.3. Database of dbSNP, ExAC, 1000 genomes, KRGDB, KOMIM, NCBI, ClinVar and literate review were used for mutation interpretation. In silico analysis were performed using Align-GVGD, Shift, Polyphen-2, splicing prediction programs. After filtering according to analysis steps, we obtained the lists of candidate gene and SNPs. We will perform confirmatory study using sequencing with patients and unaffected family DNA samples.

988W

Sample collection for saliva DNA may influence results from next generation sequencing for microbiome research. *M.G. Kibriya, F. Jasmine, J. Shinkle, M. Sabarinathan, H. Ahsan.* Public Health Sciences, University of Chicago, Chicago, IL.

   Background: Observations from microbiome studies in both healthy and diseased individuals are considered to be affected by factors including sample collection, handling, library preparation and next generation sequencing (NGS) platform. In this study, we evaluate the role of methods of saliva collection and processing for DNA extraction on microbiome NGS results. **Material and Methods:** This pilot study was designed to address situations that are commonly encountered in large-scale epidemiological studies: (a) Duration between saliva collection and processing, i.e., saliva collected at clinic and processed right away versus saliva collected at home and transported or shipped to the laboratory for processing; (b) Time of the day for saliva collection, i.e., first morning sample in fasting state versus randomly collected samples during the day; (c) Saliva collection with or without preservative. Saliva samples were collected from four individuals. Each individual gave saliva (fasting and random) in different tubes (Plain, Oragene, IsoHelix). Samples were processed with different gap between collection and DNA extraction. We had a total of 44 DNA samples from 4 individuals, processed for metagenomics using Illumina Nextera XT and KAPA Biosystems kits for 16S rRNA gene V3 and V4 region sequencing on MiSeq. **Result:** Each sample had a median 250165 reads passing the filter and only ~250 reads per samples were unclassified. For analysis, we focused on the bacterias (n=26) at genus level which had at least 2% reads in at least one of the 44 DNA samples. The factors that influenced the relative abundance of a specific genus included (a) person, (b) collection time within a day, (c) collection tube, as well as, (d) different days of collection. No statistically significant difference was observed arising from (a) immediate DNA extraction vs. extraction of DNA after storage at -86C; (b) extraction of DNA with or without bead beating; and (c) gap between sample collection and heat treatment - between 6 hrs and 7 days. **Conclusion:** Relative microbial abundance in saliva is different from person-to-person. However, there is day-to-day variation in relative abundance within an individual. For a particular study, uniformity in saliva sample collection protocol (in terms of collection time within a day, collection tube with preservative) is essential to compare microbial abundance between groups.

989T

Integration of copy number variation analysis with custom gene panel next-generation sequencing diagnostics. *J.M. Ellingford[1,2], C. Campbell[1], S. Barton[1], S. Bhaskar[1], S. Gupta[3], S.C. Ramsden[1], B. Panda[3], G.C.M. Black[1,2].* 1) Manchester Centre for Genomic Medicine, Central Manchester Hospitals NHS Foundation Trust, Manchester Academic Health Science Centre, St Mary's Hospital, Manchester, United Kingdom; 2) Institute of Human Development, University of Manchester, United Kingdom; 3) Ganit Laboratories, Bio-IT Centre, Institute of Bioinformatics and Applied Biotechnology, Bangalore, India.

   Introduction: Copy number variants (CNVs) are increasingly identified as a cause of human genetic disease. Next-generation sequencing (NGS) techniques are a routine diagnostic test for many such disorders, but the interrogation of CNVs in targeted NGS data is limited in comparison to whole genome sequencing (WGS) techniques. Consequently, CNV detection is seldom undertaken in a clinical context. **Methods:** We benchmarked the accuracy of CNV detection in targeted NGS datasets through (i) comparison to events detected by WGS for 25 individuals, and (ii) a validated simulation methodology. Using quality assurance metrics determined through these assessments, we applied CNV detection for 133 individuals without molecular diagnoses through clinical NGS testing. High coverage targeted NGS data was generated using standard diagnostic procedures and CNV detection was performed using ExomeDepth v.1.1.6. **Results:** In comparison to WGS data, we determined a sensitivity and specificity for CNV detection of 100% and 99.8%, respectively. We found 97% of simulated events (*n*=2749), and identified that the extent of sequencing coverage, the inter- and intra-sample variability in the depth of sequencing coverage, and the composition of analysis regions are all important determinants of successful CNV surveillance. Clinical integration of CNV detection identified 17 CNVs contributing to the onset of a Mendelian disorder, and ruled out several clinical diagnoses. These findings were verified through additional molecular techniques. **Conclusions:** Our findings support the integration of CNV detection with routine targeted NGS diagnostic services for Mendelian disorders. Implementation of this strategy has transferred this from the research environment, has increased diagnostic yields and is enhancing clinical care.

The SickKids Genome Clinic is a multidisciplinary research project that conducts clinical whole genome sequencing (WGS) for children who are undergoing genetic evaluations. With parents' permission, we systematically search children's genomes for diagnostic variants that explain the patient's known phenotype and predictive secondary variants (PSVs) associated with occult or future disease. PSVs for childhood onset disorders are always returned. ~65% of parents also request return of their child's adult onset PSVs.   For our first 100 patients bioinformatics analysis of WGS data for candidate PSVs affecting 2800+ disease genes yielded 154 CNVs and 571 SVs that overlapped disease genes as well as 2957 SNVs in 1132 disease genes (~30 SNVs/genome). Two thirds of the SNVs were listed in HGMD, but manual assessment eliminated >90% of these PSVs as well as all CNVs and SVs. Using 2015 ACMG variant classification guidelines we found 24 pathogenic/likely pathogenic SNVs. An additional 12 SNVs were deemed returnable PSVs based on more limited evidence of pathogenicity. All 37 PSVs were inherited and 25% predicted adult onset disease. The majority were rare (MAF<0.0001) variants in genes that cause dominant Mendelian disorders. The rest included variants linked to attenuated Mendelian phenotypes, common disease risk variants, an X-linked variant and a protective variant.   30/100 children had at least one PSV, including 4 children with 2 PSVs and one child with 3. For children whose genomes had no reportable PSVs structured family histories obtained at the time of result disclosure were generally negative. Of note, pedigrees collected by the referring clinician rarely identified disease states predicted by a secondary PSV found in the child. This is likely due to inadequate reporting of family history, incomplete penetrance, and/or undiagnosed disease. *E.g.,* for some families reassessing a negative family history following disclosure of a secondary PSV uncovered family members who had the predicted phenotype, while in other families we found children and parents who carried a pathogenic/likely pathogenic PSV but lacked the predicted phenotype.   Comprehensive genomic searching can identify PSVs in 25-30% of children and most PSVs are rare familial mutations associated with disorders that occur in childhood. While WGS yields more false positives, it appears more sensitive than family history for identifying familial genetic disorders and can uncover occult disease states.

991W

Phenotype-based matching in mendeliangenomics.org. *J. Krier[1], A. Hamosh[2], F. Schiettecatte[3], N. Sobreira[2].* 1) Brigham and Women's Hospital, Boston, MA; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) FS Consulting, LLC; Marblehead, MA.

Introduction. Matchmaking initiatives such as GeneMatcher have demonstrated the utility of gene-based matching for identifying unrelated individuals with similar phenotypes and pathogenic variants in the same gene. Phenotype-based matching has been attempted less widely. **Methods**. As part of the Baylor-Hopkins Center for Mendelian Genomics, users submit cases to mendeliangenomics.org using phenotypic terms from the PhenoDB ontology, enabling the use of semantic-similarity based phenotype matching algorithms. We compared the following methodologies: SimUI, Distance, Wang, Jacquard, Resnick, SimGIC, PhenoDigm. For information content calculations, corpora based on phenotypic features in OMIM and mendeliangenomics.org were each tested. We used pair-based testing in which one case of a known phenotype is used as a query case, and another case is "planted" in the test set. We tested the matching algorithms on a) 44 published cases with detailed phenotypic descriptions of four known syndromes and b) 1,152 unrelated probands with 37 different OMIM phenotypes in the mendeliangenomics.org database who had been annotated with at least 5 phenotypic terms. To simulate a real-life matching query, we evaluated the ability of the algorithms to identify all cases of the same syndrome as a query case within the top 5th percentile of the complete case set based on phenotypic similarity. **Results.** We validated the algorithms by demonstrating strong matching performance using the 44 case testing set. Using data from mendeliangenomics.org, the best performing algorithm (SimGIC) successfully matched the "planted" case to the query case of the same syndrome within the top 5 phenotypic matches in 56% of matching tests. Across six selected syndromes, the SimGIC algorithm successfully identified 80% of cases sharing the same diagnosis within the top 5th percentile of the database, and above 95% for 3/6 phenotypes. **Conclusions.** Applying semantic-similarity based matching algorithms to the mendeliangenomics.org database resulted in mixed success at identifying "planted" cases of the same syndrome, but shows promise in stratifying cases of the same syndrome within the top 5th percentile large data set based on phenotypic similarity. We will next explore if the combination of phenotype-based matching and pathway-based matching offers the potential to identify novel Mendelian genes in the same pathway that cause similar phenotypes.

992T

Expanding the clinical sensitivity of shole genome sequencing – Validation of copy number variation. *R.J. Taft[1], A. Ajay[1], A. Gross[1], D. Perry[1], J. Avecilla[1], A. Chawla[1], A. Khouzam[1], E. Thorpe[1], S. Chowdury[1,2], S. Kruglyak[1], S. Tanner[1], M. Eberle[1], D. Bentley[3].* 1) Illumina Inc, San Diego, CA, USA; 2) Rady Children's Institute for Genomic Medicine, San Diego, CA USA; 3) Illumina Cambridge Ltd, Cambridge, UK.

Single nucleotide and small indel variant calling and interpretation are routine components of clinical exome and whole genome sequencing (WGS) pipelines. Traditionally, large copy number variants (CNVs) have been assessed by orthogonal technologies such as chromosomal microarrays. Here we report on the integration of large and small variant calls on a single WGS platform, and the validated deployment of copy number variants greater than 10kb as a component of the Illumina Clinical Services Laboratory's rare and undiagnosed disease WGS test offering. Using a set of 20 Coriell samples with well-characterized pathogenic CNVs, spanning from less than 50kb to trisomies, we performed a head-to-head comparison of large variants called from WGS using the Canvas algorithm and those detected by an independent clinical microarray laboratory using the Infinium CytoSNP-850k microarray. We found greater than 80% sensitivity of Canvas-called events, which exceeded that of microarrays. To assess specificity, we compared WGS Canvas calls against PacBio and BioNano data sets derived from CEPH NA12878 genome, and found a maximum false positive rate of ~20-40%. To enable rapid triaging of potential candidate CNVs, we developed a set of family-based analysis algorithms that, in the context of a proband in a family trio, typically delivers 8-10 CNVs that require manual interpretation. Up to half of these variants may be ruled out by filtering against common CNVs identified in public data sets, or an in-house database of more than 2,000 genomes, suggesting that the CNV interpretation burden from WGS data may be low. Initial CNV deployment has increased diagnostic yield - resolving both X-linked and autosomal CNVs, and complex scenarios including conditions caused by combinations of single nucleotide and CNV events. Ongoing efforts to improve our clinical CNV calling indicate that variants as small as 50bp – 10kb are tractable, suggesting that WGS can provide the complete range of variants from a single assay.

993F

The variable phenotype of heterozygous form of β-thalassemia and α-triplication. *F. Moosavi[1], A. Moosavi[1], A. Amirian[1], S. Zeinali[1,2], M.S. Fallah[2], M. Karimipoor[1].* 1) Pasteur institute of Iran, Tehran, Iran; 2) Kawsar Human Genetics Research Center, Tehran, Iran.

Objectives: Different types of thalassemia and hemoglobinopathies are common in Iran. Therefore, the combination of two or more globin chain aberrations in families is not uncommon. The clinical symptoms of β-thalassemia are modified by some genetic determinants like the number of α-globin genes. **Methods:** In this report, the prevalence of α-globin gene triplication was investigated in 550 Iranian β-thalassemia carriers. Multiplex PCR and MLPA methods were used in this study. In addition two families were referred to our center for further study of their children with intermediate forms of β-thalassemia. **Results:** Fourteen cases (2.54%) were heterozygote for α-triplication. Investigation of mentioned families revealed the combination of heterozygous form of β-thalassemia and α-triplication. **Discussion:** The results emphasizes that uncertainty still exist about the phenotypic prediction of excess of α-globin genes in combination with β- thalassemia heterozygote carriers and these issues should be concerned in genetic counseling. **Keywords:** α-triplication; α-quadruplication; β-thalassemia; thalassemia intermedia; Alpha-hemoglobin-stabilizing protein (AHSP).

994W

Genetic variations of *AKAP4* gene in infertile patients with immotile short-tail sperm defect. *E. Zare Mehrjardi[1], M. Sabbaghian[2], A. Mohseni Meybodi[3], S.M. Seifati[1], M.A. Sadighi Gilani[2], J. Hoseini[2].* 1) Islamic Azad University of Ashkezar branch, Yazd, Yazd, Iran; 2) Department of Andrology at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran; 3) Department of Genetics at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran.

Ehsan Zare Mehrjardi[1], Marjan Sabbaghian[2], Anahita Mohseni Meybodi[3], Seyed Morteza Seifati[1], Mohamad Ali Sadighi Gilani[2], Jalil Hoseini[2] 1. Medical Biotechnology Research Center, Ashkezar Branch, Islamic Azad University, Ashkezar, Yazd, Iran 2. Department of Andrology at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran. 3. Department of Genetics at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran. **Introduction**: The immotile short tail sperm (ISTS) defect is an autosomal recessive disease that causes male infertility. A Kinase Anchoring Protein 4 (AKAP4) in the fibrous sheath (FS) of sperm flagella provides scaffold for the correct assembly of FS. The main goal of this research was to assess *AKAP4* gene variation in ISTS patients. **Material and Methods**: In this study, which was performed from 2010 to 2013, 32 infertile men with ISTS defect (>80% short tail sperm cells in at least two spermograms) and 50 normozoospermic men as control were enrolled. Semen analysis was performed for each specimen. After DNA extraction from peripheral blood samples, PCR-Sequencing was done for two regions of exon 5 in *AKAP4* gene. **Results**: Semen analysis showed significant differences in sperm concentration, normal morphology, progressive motility, and short tail sperm count between patients and controls. Sequence analysis did not show any single nucleotide polymorphisms (SNPs) in the target regions. But, a deletion related to the potential AKAP4/AKAP3 binding region was found in one patient. GAPDH was applied as internal control. Four primers were designed (with 700 base pair distance) that did not show any PCR products. Karyotype showed normal status revealed that the banding pattern of chromosomes were not affected by this deletion. **Conclusions**: Our data did not reveal any SNP in exon 5 of the gene, but further studies with more sample size and determination of levels of mRNA and protein from the *AKAP4* gene are suggested in order to elucidate final conclusion. *Key words*: Male infertility, Short tail sperm, *AKAP4* gene.

995T

The validation of pharmacogenetics in the identification of patients with Fabry disease for treatment with migalastat. *E.R. Benjamin[1], C. Della Valle[1], X. Wu[1], E. Katz[1], K.J. Valenzano[1], D.G. Bichet[2], D.P. Germain[3], R. Giugliani[4], D. Hughes[5], R. Schiffmann[6], W. Wilcox[7], J. Yu[1], J. Kirk[1], J. Barth[1], J. Castelli[1].* 1) Amicus Therapeutics,, Cranbury, NJ, USA; 2) Hôpital du Sacré-Coeur, University of Montreal, Montreal, Quebec, Canada; 3) Division of Medical Genetics, University of Versailles–St. Quentin en Yvelines (UVSQ), Montigny, France; 4) HCPA/UFRGS Porto Alegre, Porto Alegre, Brazil; 5) Royal Free Hospital, University College London, London, UK; 6) Baylor Research Institute, Dallas, TX, USA; 7) Department of Human Genetics, Emory University, Atlanta, GA, USA.

Fabry disease is an X-linked lysosomal storage disorder caused by *GLA* mutations, resulting in deficient lysosomal α-galactosidase A (α-Gal A) activity and progressive cellular accumulation of globotriaosylceramide (GL-3). Migalastat is a pharmacological chaperone that stabilizes specific mutant forms of α-Gal A (termed amenable), leading to increased physical stability, lysosomal trafficking, and intracellular activity of the enzyme. Each of 600 Fabry disease-causing mutations were expressed in HEK-293 (HEK) cells, and increases in α-Gal A activity in response to migalastat were measured using a Good Laboratory Practice (GLP)-validated *in vitro* assay (GLP HEK/migalastat amenability assay). In total, 268 migalastat-amenable mutant forms of α-Gal A were identified, defined by a relative increase of ≥1.20-fold and an absolute increase of ≥3.0% wild-type α-Gal A activity in the presence of 10 μM migalastat. Clinical validation was assessed using pharmacodynamic responses in phase 2/3 studies (73 unique amenable and nonamenable mutations in 160 male and female patients with Fabry disease). Comparison of mutant α-Gal A responses in the GLP HEK/migalastat amenability assay to responses in white blood cells from male patients in phase 2 and 3 studies to treatment with migalastat exhibited high sensitivity, specificity, and positive and negative predictive values (PPV and NPV, respectively; ≥0.875). GLP HEK/migalastat amenability assay results were predictive of decreases in kidney GL-3 in males and plasma globotriaosylsphingosine in both males and females (sensitivity: 1.0 and 0.93, respectively; specificity: 1.0 and 0.69; PPV: 1.0 and 0.84; NPV: 1.0 and 0.85). The clinical study subset of amenable mutations (n=51) were representative of all 268 amenable mutations identified by the GLP HEK/migalastat amenability assay. The GLP HEK/migalastat amenability assay is a clinically validated method of identifying male and female patients with Fabry disease who are candidates for treatment with migalastat.

"SMRTer Confirmation": Scalable clinical read-through variant confirmation using the Pacific Biosciences SMRT® Sequencing Platform. *S. McCalmon, K. Konvicka, N. Reddy, J. Whittaker, C. Kautzer, J. Risinger, J. Sorenson, R. Lewis, M. Kennemer, E. Olivares, A. Shinohara, I. Melnick, A. Rosendorff.* Invitae Corporation, San Francisco, CA.

Next-generation sequencing (NGS) has significantly improved the cost and turnaround time for diagnostic genetic tests. ACMG recommends variant confirmation by an orthogonal method, unless sufficiently high sensitivity and specificity can be demonstrated using NGS alone. Most NGS laboratories make extensive use of Sanger sequencing for secondary confirmation of single nucleotide variants (SNVs) and indels, representing a large fraction of the cost and time required to deliver high quality genetic testing data to clinicians and patients. Despite its established data quality, Sanger is not a high-throughput method by today's standards from either an assay or analysis standpoint as it can involve manual review of Sanger traces and is not amenable to multiplexing. Toward a scalable solution for confirmation, Invitae has developed a fully automated and LIMS-tracked assay and informatics pipeline that utilizes the Pacific Biosciences SMRT® sequencing platform. Invitae's pipeline generates PCR amplicons that encompass the variant(s) of interest, which are converted to closed DNA structures (SMRTbells) and sequenced in pools of 96 per SMRTcell. Each amplicon is appended with a 16nt barcode that encodes the patient and variant IDs. Per-sample demultiplexing, alignment, variant-calling, and confirmation resolution are handled via an automated pipeline. The confirmation process was validated by analyzing 243 clinical SNVs and indels in parallel with the gold standard Sanger sequencing method. Amplicons were sequenced and analyzed in technical replicates to demonstrate reproducibility. In this study, the PacBio-based confirmation pipeline demonstrated high reproducibility (97.5%), and outperformed Sanger in the fraction of primary NGS variants confirmed (PacBio = 93.4% and 94.7% confirmed across two replicates, Sanger = 84.8%) while having 100% concordance of confirmation status among overlapping confirmation calls.

Mutation spectrum of *ACADS* gene in Korean patients with short-chain acyl-coenzyme A dehydrogenase deficiency. *C.K. Cheon[1], Y.M. Kim[1], J.M. Ko[2].* 1) Pediatrics, Pusan National University, Yangsan, Yangsan, South Korea; 2) Pediatrics, Seoul National University Children's Hospital, Seoul, Korea.

Purpose: Short-chain acyl-CoA dehydrogenase deficiency (SCADD; OMIM # 201470) is an autosomal recessive inborn error of mitochondrial fatty acid β-oxidation, presenting with a variety of clinical signs and symptoms. We sought to investigate the mutation spectrum of *ACADS* gene and associated clinical manifestations in Korean patients with confirmed SCADD. **Methods:** The study included 9 patients with SCADD from 7 unrelated families as diagnosed by biochemical profile and DNA testing. Clinical features, biochemical data, growth, and neurodevelopmental state were reviewed retrospectively. **Results:** Seven patients were found during newborn screening using tandem mass spectrometry, and 2 were diagnosed by family screening after their siblings were diagnosed. Their mean age at diagnosis was 14.1 ± 31.9 months. During follow-up ranging from 9 months to 4.5 years, no hypoglycemic event was observed, and the development and growth of the patients was normal, except in 2 siblings showing mild hypotonia and delayed gross motor development. In addition, one girl showed cyclic vomiting until the age of 2 years. We analyzed the *ACADS* genotype in all patients, identifying 7 different mutations. Of these, p.E344G was the most frequent mutation with an allele frequency of 42.8%, followed by p.P55L with 21.4%. p.G108D, and 4 novel mutations were identified: p.L93I, p.E228K, p.P377L, and p.R386H. **Conclusions:** While the *ACADS* genotype was heterogeneous, Korean patients with SCADD detected during newborn screening generally showed mild clinical manifestation without severe metabolic crisis. These data contribute to a better understanding of the distinct molecular genetic characteristics and clinical manifestations of SCADD in Korean patients.

998T

Will the real chromosome anomaly please stand up. *L. Richards, M. Chung, J. Castelli, J. Kogan, D. Rita.* ACL Laboratories, 5400 Pearl Street, Rosemont, IL 60018.

The implementation of whole genome SNP microarray copy number analysis along with fluorescence in situ hybridization (FISH) techniques in the clinical laboratory setting has had an impact on the quality and accuracy of diagnoses provided. We present three unique cases in which traditional chromosome analysis detected derivative or marker chromosomes that were later shown through the use of microarray and FISH techniques to be quite different than originally reported. We introduce the first case, where chromosome analysis was initially evaluated to be a derivative chromosome 15 involving an unbalanced translocation between chromosomes X and 15. However, microarray analysis revealed a duplication of chromosome 4, which changed the original analysis to der(15)t(4;15). In the second case chromosome analysis initially revealed an apparent derivative chromosome 2 involving an unbalanced translocation between chromosomes 2 and 14. Microarray was later performed and confirmed a derivative chromosome 2 bearing two separate interstitial deletions of the short arm of chromosome 2, but no evidence of an unbalanced translocation. The third case involved mosaicism with three different cell lines consisting of: monosomy X, monosomy X with an extra marker chromosome of unknown origin, and two apparent centric fissions of chromosome X. Microarray and multiple FISH analyses were performed that identified the marker as material from chromosome Y, and the presumed X fissions were actually one normal Y chromosome and one inverted duplicated Y chromosome. Knowing the exact origins of these chromosomal abnormalities is essential for accurate prognosis for patients and for genetic counseling. These cases illustrate that there is no simple answer in terms of which technique will most accurately provide this knowledge. G banded chromosome analysis alone is subject to interpretation error. These cases highlight the need for laboratories to employ all available techniques to attain the highest quality results for their patients. .

999F

Autozygosity mapping using SNP based chromosomal microarray: Opportunity to increase the clinical diagnostic yield in populations with high consanguinity. *S. Sampath[1], A.W. El-Hattab[2].* 1) PreventionGenetics, Marshfield, WI; 2) Pediatrics Department, Tawam Hospital, Al-Ain, United Arab Emirates.

Chromosomal microarray (CMA) test has been used as first-tier diagnostic test for the clinical diagnosis of genetic disorders in individuals with unexplained developmental delay/intellectual disability, autism spectrum disorder, and multiple congenital abnormalities, with an overall yield of 15-20%. Because of its enhanced clinical utility and impact on medical management, copy number detection using CMA test has largely replaced conventional cytogenetic tests such as chromosome and FISH analysis, although some of its limitations over these traditional tools have been exemplified in the last few years. Moreover, the use of single nucleotide polymorphism (SNP) based CMA test using aCGH + SNP microarrays conferred additional clinical utility in a) detection of allele specific copy-number, b) detection of polyploidy, and c) detection of excess homozygosity on single and multiple chromosomes. The presence of excess homozygosity in the form of uninterrupted regions/blocks of homozygous SNP alleles, may indicate, depending its total size, extent and its distribution on chromosomes, ancestral relationship, uniparental disomy (UPD) or parental consanguinity. Although the presence of excess homozygosity is by itself not diagnostic of any specific disorder, it increases the likelihood of recessive traits. Autozygosity mapping following CMA has been successfully used to identify genes underlying numerous recessive disorders in consanguineous families. Despite the success of CMA-based autozygosity mapping, its overall burden in out-bred populations significantly limits its use in a clinic setting. In this study, we describe the use of autozygosity mapping in 227 patients referred for CMA from a population with high levels of consanguinity, and demonstrate its clinical utility and overall increase in the diagnostic yield. We show that the diagnostic yield of CMA increased by at least 10% by using freely-available online tools for the detection of candidate genes and associated conditions mapping to regions of homozygosity. We also demonstrate the successful implementation of a diagnostic workflow for the routine analysis of AOH regions in a clinical diagnostic lab. Finally, using specific examples, we identify potential limitations of our approach, and make recommendations to increase the diagnostic yield by enhancing tools that automate phenotype-genotype based prioritization of gene candidates.

1000W

Validation of the OneOme RightMed™ pharmacogenomic test using the IntelliQube® to demonstrate an accurate method for pharmacogenomic genotyping. *R. Higgins, K. Bauer, B. Ramey Hartung, Ph. D., D. Bailey, Ph.D., J. Odegaard, M.D., Ph.D.* OneOme, Minneapolis, MN.

Imprecise medication can lead to delay of treatment, re-hospitalization, adverse events and increased mortality. Adverse drug reactions are the fourth leading cause of death in the United States leading to 2.2 million hospitalizations and $136 billion in costs annually.[1] Genetic factors have been shown to account for up to 95% of drug response variability.[2] Pharmacogenomics (PGx) can identify which inherited genetic variations a person has to predict how an individual will or will not metabolize a drug, ultimately guiding more effective treatment. We have developed the OneOme RightMed™ pharmacogenomic test that combines a patient's genetic profile, prescription history, and current medications with a proprietary algorithm-based platform co-developed and exclusively licensed from Mayo Clinic. The RightMed PGx test panel includes 22 genes and 90 alleles that cover more than 300 common drugs. The genotype analysis is performed using probed-based quantitative PCR assays. Here we review the results of 75 SNP genotyping assays and 4 copy number variation (CNV) assays as part of the RightMed analytical validation. The validation study included a comparison of genotype results from a collection of samples from the NIGMS Human Genetic Cell Repository at the Coriell Institute for Medical Research in addition to 12 donor samples which were sent for Sanger sequencing confirmation. Sanger sequencing was completed at an independent laboratory, Eurofins Clinical Molecular Testing Services in Louisville, Kentucky. Results for the sequenced donor samples and reported genotypes for the Coriell samples were compared to the genotype calls generated by several intra- and inter-run precision studies performed at OneOme to assess concordance. The results of this validation study suggest that the methods for running the OneOme RightMed pharmacogenomic test panel produces both accurate and reproducible genotyping results. These findings provide confidence in the analytical validity of the RightMed test and may subsequently further the widespread adoption of the test panel to guide better prescribing decisions based on evolving pharmacogenomics evidence. 1) Johnson JA, Bootman JL. Drug-related morbidity and mortality. A cost-of-illness model. Arch Intern Med 1995;155(18):1949–1956. 2) Kalow W, et al. Pharmacogenetics 1998;8:283-289.

1001T

The Iowa Institute of Human Genetics Drug Metabolism Test: A pharmacogenomics platform to predict adverse drug response. *A.E. Kwitek[1], N.C. Smith[2], T.B. Bair[1], C.A. Campbell[1], M.S. Chimenti[1], M.J. Kimble[1], K.L. Knudtson[1], D.L. Kolbe[1], M.A. Mansilla[1], S.O. Mason[1], C.J. Nishimura[1], M. Sorenson[3], R.J. Smith[1].* 1) Iowa Institute of Human Genetics, University of Iowa, Iowa City, IA; 2) Institute for Clinical & Translational Sciences, University of Iowa, Iowa City, IA; 3) University of Iowa Hospitals and Clinics, University of Iowa, Iowa City, IA.

Approximately 5% of all hospital admissions are due to adverse drug responses (ADRs), resulting in over 100,000 deaths annually and $177.4 billion in related healthcare costs. Some of these ADRs are due to known inherited genetic variation. A goal in the Iowa Institute of Human Genetics (IIHG) is to identify patients with genetic risk for adverse drug responses, prior to being given the drug. Toward this goal, we developed a targeted genome enrichment and massive parallel sequencing (TGE+MPS) panel of 280 genes involving drug metabolism, transport, and action. The Drug Metabolism Test (DMT) is clinically available test through the IIHG CLIA certified, CAP accredited Clinical Diagnostics Division. Initial clinical implementation focused on reporting variants in two genes (*CYP2C19* and *CYP2D6*) affecting metabolism of clopidogrel and opioids (http://www.medicine.uiowa.edu/humangenetics/pharmacogenomic/provider). To support the clinical utility of the DMT, we performed a cost analysis of patients going to the Emergency Department (ED) at the University of Iowa Hospitals and Clinics (UIHC) for an adverse drug event. The aim of the study was to determine if preemptive testing for genes causing ADRs could have predicted patients at risk for an ADR. All patients visiting the UIHC ED for the past three years were identified and screened for ICD9 codes indicating an adverse drug response. We identified 1019 visits to the ED by 951 patients having an ADR, with related costs of nearly $52 million. Adverse response to chemotherapy drugs corresponded to over 20% of the ED visits, incurring nearly $20 million in total costs. Currently we are validating and implementing a test for inherited risk of chemotoxicity in *DPYD*, *G6PD*, *TPMT*, and *UGT1A1*. This test will be offered to the patients suffering an ADR to common chemotherapy agents (fluorouracil, capecitabine, tegafur, mercaptopurine, azathioprine, thioguanine, nilotinib, and rasburicase), to determine if their ADR could have been predicted. The DMT is a tool that can assist healthcare providers in minimizing adverse drug reactions, ideally prior to the start of therapy, and strongly complements established cancer mutation profiling.

PGx1: An assay for actionable genes in pharmacogenetics. *T. Wiltshire, O. Dong, O. Suzuki.* School of Pharmacy, University of North Carolina, Chapel Hill, NC.

Currently there are over 120 drugs that have genetic information in their package labeling and deemed as being actionable by FDA guidelines, some with "black box" warnings where an action is assigned. Of these drugs, 23 fall within the top 200 most commonly prescribed drugs. The Clinical Pharmacogenetics Implementation Consortium (CPIC) and the FDA provide guidelines that enable the translation of genetic laboratory test results into actionable prescribing decisions that promote the safe and effective use of specific drugs. It is estimated that during a person's lifetime 96% of consumers will be prescribed a drug that has actionable PGx information, **yet few of these tests are currently used in any clinical settings**. There have been a number of major barriers to implementation of pharmacogenetic diagnostics, including lack of knowledge by clinicians, but **a major factor is the availability and cost of tests, reimbursement, and delay in return of results.** Here, we address how to capture PGx data efficiently, in a cost-effective and broadly applicable manner. We have designed an assay set that covers the pharmacogenetic "actionable genome", that is genes that have guidance (CPIC) for the use of the genetic information. We have used a molecular inversion probe (MIP) platform to develop a custom pull-down sequencing assay (PGx1). Designs were performed for twenty-one genes using MIPgen resulting in 1800 probes, with each probe optimized to specifically capture 112 bp of sequence. MIP sets were tested and re-designed or re-balanced for optimal performance. The resultant set covers all coding regions, exon/intron boundaries, and 1 kb of upstream sequence (amounting to 120 kb of sequence). PGx1 tests in a 48 DNA sample multiplexed MiSeq sequence run show that the assay provides greater than 35X average coverage. As a clinical diagnostic tool however, there are only specific polymorphisms that have direct guidance; sequencing depth was optimized for these polymorphisms. 42 polymorphisms have been validated in a CLIA/CAP environment such that the genotypes can be directly reported as a clinical result. These genes/polymorphisms cover pharmacogenetic impact across a number of different disease/drug indications, eg. cardiovascular, pain, psychiatric. We have used this assay as an educational tool with PharmD students, and in high-risk populations (cath lab patients) to explore pharmacoeconomic analysis.

Retrospective comparison of traditional single gene testing and massively parallel sequencing-based gene panels in the diagnosis of pulmonary arterial hypertension. *K. Sumner[1], D.H. Best[1,2,3].* 1) Inst. for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Dept. of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 3) Dept. of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Background: Pulmonary arterial hypertension (PAH) is a rare, but lethal disorder most commonly caused by autosomal dominant (with reduced penetrance) mutations in the *BMPR2* gene. PAH can also result from mutations in the *ACVRL1*, *ENG*, *CAV1*, *KCNK3*, and *EIF2AK4* genes. **Method:** A retrospective analysis was performed to determine the mutation detection rate in (n=68) PAH patients submitted for diagnostic testing of the *BMPR2* gene using traditional testing modalities (i.e. Sanger sequencing, MLPA). Similarly, the mutation detection rate was determined for (n=41) PAH patients referred for a massively parallel sequencing (MPS)-based PAH gene panel containing multiple PAH related genes combined with deletion/duplication analysis by comparative genomic hybridization array (aCGH). **Results:** Sanger sequencing of the *BMPR2* gene detected a clinically significant sequence variant in 10 out of 68 patients (14.7%).Testing by the MPS-based PAH gene panel identified a clinically significant variant in 14 out of 41 patents (34.1%). The PAH panel detected eight mutations in the *BMPR2* gene and six in the other PAH genes tested *ENG* (n=1), *KCNK3* (n=1), *ACVRL1* (n=2), *EIF2AK4* (n=2). **Conclusion:** Diagnostic testing in PAH patients using traditional testing modalities is ultimately more time-consuming and costly than those utilizing MPS.

1004T

Transcriptomic profiles in peripheral blood between women with unexplained recurrent implantation failure and recurrent miscarriage and the correlation with endometrium. *J. Huang[1], H. Qin[2], X. Shi[1], W. Cheung[1], C. Wang[1,3], T. Chan[2], T. Li[1].* 1) Department of Obstetrics and Gynaecology, the Chinese University of Hong Kong, Hong Kong SAR, China; 2) School of Life Sciences, The Chinese University of Hong Kong, Hong Kong SAR, China; 3) Li Ka Shing Institute of Health Sciences, The Chineses University of Hong Kong, Hong Kong SAR, China.

The gene expression profiles are different in the endometrium of RIF, RM and fertile women during the window of implantation. Women with RIF and RM have both been reported to have altered expression of endometrial receptivity markers. But it is not known whether any difference in transcriptome in peripheral blood during the window of implantation between women with recurrent implantation failures (RIF) and unexplained recurrent miscarriages (RM). This is an observational prospective study. In total 9 subjects were recruited, 3 RIF, 3 RM, and 3 controls. Paired samples (endometrium and peripheral blood) simultaneously collected from the same subjects precisely timed on the 7th days after luteal hormone surge (LH+7). This study carried out in a reproductive medicine center of a teaching Hospital. The paired samples were extracted for total RNA. The transcriptome was determined by RNA-Seq. Differentially expressed genes were validated by quantitative real time PCR (qPCR). Among nearly 19,000 genes had sequencing readings, there were 1595 genes correlation coefficients more than 0.5. The correlation coefficients of the 9 paired samples were all over 0.64, and it seems that the correlation between blood and endometrium were higher in RIF than those in RM, with $p < 0.05$. However, among the three studied groups, RM and RIF showed distinct different gene expression patterns in endometrium, but in blood the two groups could not be separated. So far, it is still infeasible to use blood transcriptome to investigate the endometrial gene expressions.

1005F

Clinical versus research analyses of clinical genomic data: Two products of one test. *D.R. Adams[1,2], B. Pusey[2], C. Lau[2], G. Yu[2], T.C. Markello[2], C. Tifft[1,2], C. Toro[2], M. Malicdan[1,2], W.A. Gahl[1,2].* 1) NHGRI, NIH, Bethesda, MD; 2) Undiagnosed Diseases Program and Undiagnosed Diseases Network, Common Fund, NIH, Bethesda, MD.

Clinical exome sequencing has been established as a powerful and productive tool in genomic diagnostics. However, a substantial number of exome studies do not produce a definitive diagnosis. In many bioinformatics and referral centers, selected non-diagnostic cases are referred for a subsequent set of analyses, sometimes referred to as research analyses. Research analyses have not been well defined by the field and often rely on local expertise, disparate computational approaches and variant filtration strategies. The variety of approaches may be beneficial for the exploration of novel analytic techniques, but simultaneously confusing to the patient whose data is being analyzed. Furthermore, the goals of research exome analysis are diverging from those of a standard clinical analysis. Clinical analyses continue to be effectively optimized for identifying DNA sequence variants of interpretable significance. Research analyses are, in consequence, concerned with finding variants of unknown significance that nonetheless have potential value for follow up functional validation. The presence of differing goals for clinical and research analyses suggest that different strategies may be appropriate for variant reporting, sharing and annotation in each respective setting. We present: 1. The research exome analysis framework currently employed by the NIH Undiagnosed Diseases Program (UDP) as an example and starting point for discussion of possible future research analysis standards. 2. An analysis of the differences and similarities between clinical and research exome analyses as they have manifested over the last 8 years of the UDP's existence. 3. A description of the variant reporting, sharing and annotation mechanisms we have developed for research-level variants. The rapid implementation of genome-scale sequencing in the clinical environment has blurred the line between clinical and research molecular diagnostics. A clear delineation of the processes used for diagnostic and discovery uses of the technology has the potential to allow for the optimization of both processes. Furthermore, consent and return of results practices will benefit from a better understanding of the differences and similarities between these concurrently generated products of genomic sequencing.

1006W

PseudoSlayer: Clinical-grade variant identification within segmental duplications using NGS data. *D.J. Kvitek, Y. Li, S. Lin, E. Gafni.* Invitae, San Francisco, CA.

Segmental duplications (SegDups) are long DNA stretches of nearly identical sequence that occur two or more times in the genome, arising from duplication events that appear fixed in the population. SegDups complicate variant calling from short-read next-generation sequencing (NGS) data because sequence reads cannot be unambiguously aligned due to the shared sequence identity between SegDup regions. This makes clinical-grade variant calls in these regions difficult or impossible using NGS data and current variant identification approaches.   We have developed a general method for identifying SNPs, indels and CNVs within SegDups. The method consists of two steps. The first step is a bioinformatics screen using NGS data in which sequence reads derived from both the clinical gene of interest and the SegDup are analyzed for the presence of variants using a reference sequence with the gene of interest present but the SegDup(s) masked. If no variants of interest are identified in the screen, no further work is required, and the sample is negative for variants across that gene. If variants of interest are identified, the variant location is disambiguated with additional laboratory assays such as long-range PCR or MLPA, if necessary.   The PseudoSlayer method eliminates the need to perform additional laboratory assays on screen-negative samples, significantly reducing the time and cost for diagnostic testing using gene panels. We have applied this method successfully to several genes, including the Lynch Syndrome gene *PMS2* and its pseudogene *PMS2CL*, an internal 8 exon triplication of the myopathy gene *NEB* and the spinal muscular atrophy genes *SMN1/2*. We have performed an extensive clinical validation of the method for *PMS2*, achieving 100% sensitivity and specificity for SNPs, indels and deletions/duplications across a total of 295 known positive and 34,926 known reference-matching sites.   We are in the process of applying the PseudoSlayer method to other genes of clinical importance that have SegDups elsewhere in the genome. Among them are the autosomal dominant polycystic kidney disease gene *PKD1*, the Shwachman-Diamond syndrome gene *SBDS*, the incontinentia pigmenti gene *IKBKG* (*NEMO*), the Koolen-de Vries Syndrome gene *KANSL1*, and the Gaucher disease gene *GBA*.

1007T

Heterozygous deletions of *FREM1* are not associated with trigonocephaly. *A.J. Dawson[1,2,3], J. Liu[1,2,3], S. Marles[2,3], C.R. Greenberg[2,3], A. Mhanni[2,3], K. Hovanes[4].* 1) Genomics Laboratory Diagnostic Services Manitoba, Winnipeg, Manitoba, Canada; 2) Program of Genetics and Metabolism Winnipeg Regional Health Authority Winnipeg, Manitoba , Canada; 3) Department of Biochemistry and Medical Genetics University of Manitoba Winnipeg, Manitoba, Canada; 4) Combimatrix Irvine, California, USA.

The *FREM1* (*FRAS1*-related extracellular matrix 1) gene (MIM 608944) encodes an extracellular matrix protein involved in the formation and organization of basement membranes in multiple organ systems throughout development. Homozygous loss-of-function mutations in *FREM1*, mapped to 9p22.3, have been shown to cause bifid nose with or without anorectal and renal anomalies (BNAR [MIM 608980]) and Manitoba oculo-tricho-anal (MOTA [MIM 248450]) syndromes. Craniosynostosis is a common craniofacial abnormality resulting in premature fusion of calvarial sutures (coronal, sagittal, metopic and lambdoid). Causative mutations have been identified in more than 10 genes and affect each calvarial suture differently, with variant gene expression patterns in each suture. Trigonocephaly is a rare form of craniosynostosis resulting from premature closure of the metopic suture and usually occurs sporadically. Trigonocephaly type 1 (TRIGNO1 [MIM 190440]) is caused by heterozygous mutations in the *FGFR1* gene (MIM 136350). Heterozygous large deletions of 9p, spanning multiple genes including *FREM1*, have been associated with a syndromic form of trigonocephaly; however, there is variable expressivity and limited genotype-phenotype information. Heterozygous missense mutations of *FREM1* have been reported to be associated with isolated trigonocephaly, with incomplete penetrance, and thus have been designated as TRIGNO2 (MIM 614485) with dominant inheritance. However, in this study using chromosomal microarray analysis, we have identified seven patients with a 60 Kb deletion of *FREM1* spanning exons 8-23 and two patients with a 200 Kb deletion spanning exons 1-6 and including gene *LOC389705* (unknown function). None of these patients show signs of an abnormal metopic suture despite heterozygosity for *FREM1* deletions. All patients are First Nations of Cree or Ojibwa-Cree descent. Three of the seven patients have inherited the identical deletion from their phenotypically normal father. In addition, one patient was homozygous for the 60 Kb *FREM1* deletion and was diagnosed with MOTA syndrome. Our findings suggest that although homozygous deletions of *FREM1* are pathogenic, the heterozygous deletion can be considered a common variant in the Manitoba First Nations population. Therefore, the OMIM designation of dominant *FREM1* deletion mutations resulting in TRIGNO2 is premature.

1008F

Improvements in molecular inversion probe (MIP) assays to increase sensitivity for detection of copy number variants (CNVs). *R. Sapolsky, M. Chadha, O. Mizrahi Man, J. Li, A. Shukla, T. Chen, M. Shapero, J. Schmidt, E.T. Fung.* Affymetrix, part of Thermo Fisher Scientific, Santa Clara, CA.

There is great interest in improving the sensitivity of methods for the detection of CNVs, particularly for complex and/or limiting samples. Relevant situations include liquid biopsies in oncology, pre-implantation genetic diagnosis and non-invasive prenatal diagnosis, and mosaicism. When combined with microarray technology, MIP technology has been used successfully to detect clones present as low as 20% from 80 ng input DNA. We sought to determine whether aberration fraction or input mass could be improved through modifications of the assay. Using the OncoScan® assay as a starting point, we focused on the following steps for assay modification: the ratio of MIPs to genomic DNA concentration, exonuclease activity used to enrich for covalently closed, circular MIP molecules, PCR amplification, and two-color array detection methods. Genomic DNA isolated from cell lines and from clinical samples with varying levels of a spiked-in minor clone was processed through modified MIP assays and analyzed on 96-format array plates designed with high replicates of universal tag probes. Signal profile plots of A signal versus B signal were assessed to determine the quality of A/B allelic separation. Log2 ratio in regions of interest was computed and compared to corresponding log ratio in samples without copy number (CN) aberrations. Sensitivity was determined using spike-in mixtures of 95% normal and 5% aberrated regions, while specificity was determined by measuring calls in normal regions. Titration of the ratio of a 48K MIP panel to genomic DNA from 2000:1 to 51,000:1 revealed a modest increase in MIP circle formation as assessed by real time PCR. While the temperature of the anneal reaction had a demonstrable effect, anneal reaction duration did not greatly impact MIP circle formation. The combined activity of Exo I, III, and VII was optimal for increased CNV sensitivity. The introduction of a hot-start DNA polymerase showed a marked improvement in the separation of genotype clusters on profile plots as compared to conventional Taq DNA polymerase. By combining these modifications with changes to the multi-color array detection such as chemical cross-linking, we improved CN detection sensitivity from 80 ng to ~20 ng and to ~5% minor aberrant clone, with specificity and sensitivity above 90%. These assay modifications may be useful in applications such as analysis of low tumor burden FFPE samples, liquid biopsies, or other low DNA input applications.

1009W

Chromosomal Assessment by Rapid LAMP Analysis (CARLA) – A new test for chromosomal aneuploidy. *H. Shani[1], K. Barazanik[2], V. Wei[2], M. Mauro[2], L. Lodico[2], S. Klugman[1], Z. Williams[2].* 1) Reproductive and Medical Genetics. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY, USA; 2) Program for Early and Recurrent Pregnancy Loss. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY, USA.

Purpose: Rapid and point-of-care testing for genetic abnormalities has been a longstanding goal for molecular diagnostics in pre-implantation, prenatal and postnatal diagnostics. Existing methods for chromosomal assessment are time-consuming, costly and require a centralized high-complexity laboratory. Consequently, diagnosis and treatment is delayed and testing is often not an option in resource-poor settings. We aimed to develop a rapid, inexpensive test that can be performed at point of care for the detection of chromosomal aneuploidy. Methods: The new diagnostic tool, Loop-mediated isothermal amplification (LAMP), previously used for qualitative analysis of target DNA sequences was adapted to detect chromosomal aneuploidy. To our knowledge this is the first time, LAMP has been adapted for quantitative detection of human specific genomic sequences and we termed the test Chromosomal Assessment by Rapid LAMP Analysis (CARLA). CARLA was applied to genomic DNA isolated from peripheral blood samples, cell cultures, and amniotic fluid. Samples were tested using 6 primer sets for two unique single-copy target genes: the *SRY* and *RPA4* genes on chromosomes Y and X, respectively. We optimized the report assay, and used target-specific fluorescent probes that enable real-time monitoring of fluorescence increase during product amplification. Under these conditions, we were able to readily distinguish between male and female sample within 20 minutes and using as little as 1 ng of genomic DNA. By performing CARLA with serial dilutions of target DNA, we were able to quantify target DNA to as low as 3400 target copy number. Normalizing to a target sequence DNA on an autosomal chromosome (*CFTR* gene on chromosome 7) enabled diagnosis of 46XX, 46XY, 47XYY and 45X karyotypes. Summary: CARLA can provide quantitative assessment of relative copy numbers of genomic DNA targets in under 20 minutes without the need for complex laboratory equipment or training. When optimized and adapted, this assay may enable accurate detection of aneuploidy for all human chromosomes. This would enable testing for aneuploidy and CNVs in a wide range of clinical situations that would be orders of magnitude faster, easier, and less expensive to perform than our current modalities.

1010T

Conventional cytogenetics: Gold standard for mapping of large genomic imbalances on chromosome. *M. Rahman[1], N. Rao[1,2], L. Spiteri[3], T. Vo[3].* 1) Clinical Gen Ctr, Specialty Diagnostics Inc, La Mirada, CA; 2) David Geffen UCLA School of Medicine, Dept of Pathology, Los Angeles, CA 90024; 3) Ambry Genetics, 15 Argonaut, Aliso Viejo, CA 92656.

Conventional cytogenetics represents G-banded routine and or high resolution karyotyping of human chromosomes. Recently, FISH and chromosomal microarray analysis (aCGH) techniques aided in the identification of submicroscopic aberrations such as microdeletions and duplications, often undetectable by karyotype studies. We report here three cases with large genomic imbalances identified by chromosomal microarray analysis (CGH + SNP array) but the precise location of the rearrangement sites or the genomic imbalance had to be confirmed on specific chromosome bands by conventional cytogenetics. **Methodology**: DNA from blood was hybridized to a 400K oligonucleotide array, with probes at an average of 10.5 kb throughout the genome and at 5 kb on the X chromosome. Copy losses or gains are detected in comparison with a control DNA sample. Routine karyotype on G-banded cells is performed and reported. **Results:** *Case 1:* aCGH showed pathogenic GAIN of 11.201 Mb at 18p11.32p11.21, which contains 66 genes and a pathogenic LOSS of 7.152 Mb at 18q22.3q23 containing 39 genes. *Karyotype analysis revealed additional material at chromosome 18q22.3 [46,XX,add(18)(q22.3)] resulting in the LOSS of terminal 18q and confirming GAIN of whole 18p (18p11.32p11.21) at the distal end of 18q which may be a result of a meiotic recombination of a pericentric inversion in a carrier parent. Case 2:* aCGH showed pathogenic LOSS of 3.8 Mb at 14q32.32q32.33 that includes 67 genes, LOSS of 10.5 Mb at 15q11.1q13.2 with 223 genes including SNRPN and UBE3A and LOSS of 0.67 Mb at 15q13.3 with two genes, respectively. *Karyotype analysis revealed an unbalanced translocation between chromosome 14q32.3 and chromosome 15q12, resulting in the loss of distal 14q and the proximal15[45,XX,der(14) t(14;15)(q32.3;q12)], confirming the structural location of genomic imbalance on the derivative chromosome. Case 3:* aCGH showed pathogenic GAIN of 26.11 Mb that contains 190 genes at Yp11.31q11.23, most likely representing an additional whole Y chromosome. *Karyotype analysis revealed an additional Y chromosome with a pericentric inversion involving Yp and Yq [47,XY, inv(Y) (p11.3q11.23], confirming the chromosomal location of genomic imbalance.* **Conclusion:** These are few examples of the many reported in the literature that clearly support the notion that karyotyping studies are essential and complement the microarray results when large genomic imbalances are seen.

1011F

Comprehensive, high through-put workflow for automated gDNA isolation from iSWAB oral samples. *B. El Fahmawi[1], K. Durvasula[2], J. Roeder[2], T. Butts[2].* 1) Mawi DNA Technologies, Hayward, CA; 2) Omega Biotek, Norcross, GA.

High-quality DNA is a critical factor in determining success of many molecular biology applications such as next generation sequencing, qPCR, microarrays etc. Other potential applications include clinical molecular diagnostics, genetic analyses, pharmacogenomics, animal speciation studies, and forensics. Buccal swabs or saliva are the most commonly used DNA sources for these types of studies because of their non-invasiveness and ease of collection. However, these existing non-invasive technologies suffer from low genomic DNA recovery along with high bacterial contamination. Current swab-based products require manual swab removal and are not automation friendly. Mawi DNA Technologies' iSWAB collection devices addresses these issues with its innovative tube insert design that maximizes the release of cells collected on swabs into an existing proprietary selective mammalian cell lysis buffer and allows for long term, room temperature storage of the sample while preventing the release of bacterial DNA. The design is particularly attractive because it eliminates the need for swab retention and is compatible with a variety of commercially available swabs. LIMS compatible barcodes are also included on each iSWAB device for efficient sample traceability and storage purposes. Omega Bio-tek offers the Mag-Bind Blood & Tissue DNA HDQ 96 kit for rapid and reliable isolation of high-quality DNA and its usage has been automated on an open ended liquid handling platform, the Hamilton Microlab® STAR. Here we provide a comprehensive, automated work flow capable of gDNA extraction from 96 iSWAB oral samples in less than 2 hours. The purified DNA was quantified and assessed for its suitability for downstream applications such as real-time PCR. The bacterial contamination of the iSWAB samples was also estimated. Our results indicate that the DNA obtained from the iSWAB samples using Omega Bio-tek's extraction chemistry was of sufficiently high quality and suitable for a variety of downstream applications. The Omega/Hamilton protocol provides an essential framework for the qualification of DNA preparations to ensure cost-effectiveness and reproducibility at different laboratories.

Accrediting Australasia's first clinical Whole Genome Sequencing (WGS)

service. *L. Burnett[1,2,3,4], A. Borcz[2,3], M. Buckley[1,2,3,4], P. Budd[2,3], G. Chadbond[1,2,3], L. Constantinescu[2,3], J. Copty[1,2,3], M. Cowley[2,3], M. Dinger[1,2,3], L. Ewans[2,3,5], M. Gonzalez[1,2,3], T. Groza[2,3], W. Kaplan[2,3], M. Lubka-Pathak[1,2,3], B. Lundie[1,2,3], J. Mattick[3], S. Mead[1,2,3,4,5], D. Miller[6], P. Morris[2,3], M. Pinese[2,3], T. Roscioli[1,2,3,5], D. Saroufim[1,2,3], A. Statham[1,2,3], J. Stockmyer[1,2,3], K. Ying[1,2,3].* 1) Genome.One at the Garvan, Darlinghurst, NSW, Australia; 2) Kinghorn Centre for Clinical Genomics (KCCG) at the Garvan, Darlinghurst, NSW, Australia; 3) Garvan Institute of Medical Research, Darlinghurst, NSW, Australia; 4) SEALS Genetics, NSW Health Pathology Service, Randwick, NSW, Australia; 5) St Vincent's Clinical School, UNSW Australia, Darlinghurst, NSW, Australia; 6) Illumina Inc. La Jolla, San Francisco, CA.

Background: Garvan's KCCG operates the Illumina HiSeq X-Ten whole genome sequencing (WGS) system. This enables a minimum 30x coverage of the human genome. Application of WGS to clinical practice requires accreditation. Worldwide, very few WGS facilities have gained accreditation and, to our knowledge, none have achieved the international standard of ISO 15189. Aims: To describe the process used to obtain NATA/RCPA (National Association of Testing Authorities/Royal College of Pathologists of Australasia) accreditation for human clinical WGS, including certification to ISO 15189. Methods: Following WGS facility commissioning, a 12-month plan progressively upgraded infrastructure and processes to accreditation requirements. A new company ("Genome.One", a subsidiary of the Garvan) was established to ensure management control over processes involved in clinical report production. Key accreditation developments included a Quality Management System to control procedures and documents, audit and nonconforming event management, and a clinical Code of Conduct for all staff. Innovations included wikis and job ticketing systems facilitating rapid communication between expert teams. WGS-specific issues included design and execution of validation plans to meet regulatory requirements for in-house in-vitro devices (IVDs; laboratory-developed tests; LDTs) and for massively parallel sequencing; online web requesting; information systems meeting regulatory requirements and capable of integrating phenotype ontologies with genotypes; optimisation of filtering pipelines; and structured clinical reports compliant with ACMG Guidelines. Results: NATA/RCPA accreditation to ISO15189 was achieved at first application. Discussion: The initial WGS IVD detects SNVs and indels <20nt in bioinformatically-defined panels. While it can diagnose individuals, it is optimised for familial trios. The second version of our WGS clinical product will also include CNV detection at resolutions comparable to current microarray technologies. Although our IVD already outperformed Sanger sequencing during validation, we will routinely orthogonally confirm medically significant findings in the short term.

1013T

Proposal to clarify population frequency filter criterion for classifying

sequence variants as benign. *S. Harrison[1], B. Funke[1], R. Karchin[2], H. Rehm[1], M. Greenblatt[3], L. Biesecker[4], ClinGen Sequence Variant Interpretation Working Group.* 1) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Cambridge, MA; 2) Johns Hopkins University School of Medicine, Baltimore, MD; 3) University of Vermont College of Medicine, Burlington, VT; 4) National Human Genome Research Institute (NHGRI), NIH, Bethesda, MD.

In 2015, the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) published a guideline for variant interpretation that provides an evidence-based framework to classify variants. The guideline defined 28 criteria, each with an assigned code that addressed heterogeneous types of variant evidence. The committee recognized that the guideline was a starting framework that would evolve over time. ClinGen's Sequence Variant Interpretation (SVI) Working Group aims to optimize and update the ACMG/AMP guidelines for use in ongoing variant curation efforts by ClinGen-supported Expert Panels. Here we address changes to the criterion of "population allele frequency" that allows variants to be classified as benign without the presence of other supporting data. This criterion is designated as "BA1" (for Benign, stand Alone) and was intended to be a genome-wide filter such that any variant above this frequency can be dropped from further consideration of pathogenicity for a Mendelian disorder, with few clearly indicated, well-recognized exceptions. We have changed several attributes of this criterion. The new criterion is "Allele frequency is >0.05 in any general continental population dataset of at least 2,000 alleles for a gene without a gene-specific recommendation." First, we have clarified that the tested individual does not need to be matched in ethnic origin to the population dataset. Second, we have specified that the comparisons can be made to individual, continental population datasets and not necessarily to aggregate data. We have specified that these are population datasets and not controls, since in most cases phenotypes are unknown. The definition also clarifies that the comparison should be performed only on datasets of 2,000 or more alleles, instead of individuals, which is important for X and Y. We have also recognized that there may be alleles that could be pathogenic for a Mendelian disorder at a frequency >.05 and have proposed that ClinGen establish and maintain such a gene-specific exception list. Finally, this specification of the ACMG/AMP rules allows for gene-specific BA1 frequency filters that may be numerically lower than .05, based on criteria established by ClinGen Expert Panels and reviewed by the SVI. These updates to the BA1 criterion will substantially change the practices for interpreting variants and wide-ranging dissemination, discussion, and feedback is warranted.

1014F

Evaluation of the NextGENe CNV caller for use in the clinical laboratory.
T. Lewis[1], J. Durtschi[2], B. Brulotte[2], S. Dames[1], G. Pont-Kingdon[1], R. Mao[3], P. Bayrak-Toydemir[3]. 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, Utah; 2) ARUP Laboratories, Salt Lake City, Utah; 3) ARUP Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, Utah.

Statement of Purpose Using Next Generation Sequencing (NGS) data to detect exonic level deletions/duplications is very cost effective and time-saving for diagnostic laboratories, which will be replacing the traditional MLPA or array CGH. Analysis of allele frequency and read depth are the two most common methods. We used read depth data to detect copy number variation and examined the robustness of CNV Caller in the NextGENe software, version 2.4.11. Methods Used NGS read depth data was generated using a 0.5 Mb Agilent SureSelect custom target enrichment panel that captured 1193 exons from 83 genes followed by sequencing on the Illumina NextSeq platform. Samples were sequenced on Illumina NextSeq instruments. Fastq data was processed by BWA aln alignment, and Picard MarkDuplicates for duplicate removal. The average read depth of coverage was 3342. The NextGENe software utilizes the ratio of read depth of the sample to a control set then uses a Hidden Markov Model to account for dispersion (noise) and calculate copy number variations at each region. Ten samples with normal aCGH results were established as the control set. To control for gender, the 10 samples were computationally altered to represent males (single chrX) or females (2 chrX). 114 samples were compared against the gender matched controls as were seven samples known by aCGH to harbor a copy number variation. Summary of Results Using the initial data set of 114 samples, a quality control cutoff was established using the average dispersion for each sample. Of the 93 samples (81%) passing QC, thirty-nine of the samples had no calls. In the remaining 54 samples, there were 95 calls of copy number variation. 85 of the calls represented 12 regions that were called in 5 or more of the samples. These 12 regions were marked as potential false positives. A total of ten unexpected CNV calls were seen in the remaining 8 samples and need to be further evaluated. Seven known positive controls were analyzed using the NextGENe CNV caller and the appropriate gender control set. In each instance, the copy number variation was accurately identified by the software. The preliminary results indicate that the CNV Caller in the NextGENe software is robust enough to consider for use in the clinical lab. Positive results need to be confirmed by a second method but the elimination of aCGH for the majority of samples (85 of 114 samples, 75%) would be both a time and cost saving measure.

1015W

An automated approach for identification and pre-classification for clinical reporting of CNVs and SNVs.
A. O'Hara, Z. Che, V. Wasnikar, S. Shams. BioDiscovery, Inc., El Segundo, CA.

Clinical case review is focused on identification and classification of pathogenic copy number variations (CNVs) and single nucleotide sequence variants (SNVs), while excluding common benign alterations and frequently observed artifacts. Published ACMG recommendations and guidelines call for inclusion and classification of copy number variations (CNV) and sequence variants (single nucleotide variants or SNVs) into different well-defined classes (Pathogenic, Benign, VOUS, etc.) based on a series of set criteria. Variant Interpretation Assistance (VIA) is a system that uses a decision tree machine learning approach to set up rules for automatic pre-classification of CNVs and SNVs. This sophisticated tool includes pre-classification based on user specified designations (defaults include benign, likely benign, VUS, likely pathogenic, pathogenic and artifact); the VIA system then uses region specific functions, such as SIMILARITY, OVERLAP, PREVIOUS_SIMILAR_CASES, and POSITION to allow the user to set up lab specific rules. This includes the presence of genomic contents within the affected interval (intergenic v. intragenic, intronic v. exonic). For CNV, the type (e.g. gain, loss, etc.) and length of the alteration must be considered. For SNV, the type of alteration (nonsense, frameshift, insertion, deletion, etc.) must be considered. Finally, systematic evaluation requires comparison of CNV and SNV to both internal and external databases, including in-house legacy sample results and well-established databases including OMIM, DECIPHER, and ClinGen, respectively. VIA tracks results in real time from previously annotated samples to allow for interpretation of newly uploaded samples based on the evolving in-house results archive. Microarray results on mixed array platforms from normal and affected samples were tested with VIA. A set of previously reviewed samples with a mix of benign and pathogenic classified calls was imported into the system. VIA then pre-classified these same samples and the results were compared. All pre-classification results were annotated with the logic used by VIA to keep a complete audit trail of calling. This system was able to correctly identify pathogenic results for affected samples while finding benign results for normal samples. Final results were then auto-reported in ISCN nomenclature. VIA is capable of quickly and reliably classifying CNVs from microarray and includes an extensive audit trail for potential regulatory demand.

panelcn.MOPS: CNV detection in targeted panel sequencing data for diagnostic use. *G. Povysil[1], A. Tzika[2], J. Vogt[2], V. Haunschmid[1], L. Messiaen[3], K. Wimmer[2], G. Klambauer[1], S. Hochreiter[1].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria; 3) Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, Birmingham, AL.

While various copy number variation (CNV) detection methods exist for whole-genome and whole-exome sequencing data, highly accurate methods for targeted panel sequencing data that are suitable for a diagnostic setting are still missing. The challenges with analyzing this kind of data include the small size and number of target regions as well as their uneven coverage. For clinical applications a method should furthermore be able to detect both short CNVs affecting only single exons or just parts thereof as well as longer CNVs that affect multiple exons or even an entire gene. Another important issue is the risk of incidental findings. Our new method panelcn.MOPS for copy number detection extends cn.MOPS to targeted panel sequencing data. We optimized the design of the count windows, the read counting procedure, the parameters of the model and the segmentation algorithm for targeted panel sequencing. Additionally, several quality control criteria both for samples and targeted exons have been implemented to increase the confidence in called CNVs. In contrast to other CNV detection methods all targeted regions are exploited for the detection of CNVs, but only results for user-selected genes are reported to avoid the risk of incidental findings. We have tested panelcn.MOPS on simulated and real sequencing data. The real sequencing data was enriched with the TruSight cancer panel that targets 94 cancer predisposition genes including *NF*1/2, *BRCA*1/2 and *APC*. The performance of panelcn.MOPS was compared on a data set of 150 samples against several CNV detection tools including NextGENe, ExomeDepth, CoNVaDing, and VisCap. The size of the CNVs ranges from a 20bp deletion affecting only part of an exon over duplications of several exons to a 350kb deletion of an entire gene. In contrast to the other methods, panelcn.MOPS not only achieved a sensitivity of 100%, but also the highest specificity. Furthermore, we do not only provide panelcn.MOPS as an R package, but also as a standalone program with a practical graphical user interface. Therefore, panelcn.MOPS can be conveniently used by users without any programming experience. Our results show that panelcn.MOPS accurately predicts CNVs in targeted panel sequencing data. Consequently complementary biotechnologies to detect CNVs, such as MLPA, can be omitted in order to reduce time and costs.

1017F

Whole exome NGS at the Geneva Genome Clinic: A successful translation to diagnostics through a multidisciplinary team. *E. Hammar[1], S. Fokstuen[1], P. Makrythanasis[1,2], M. Guipponi[1,2], E. Ranza[1], K. Varvagiannis[1], F.A. Santoni[1,2], A. Mauron[4], S.A. Hurst[4], C. Moret[4], C. Gehrig[1], J. Bevillard[2], A. Vannier[1], S. Gimelli[1], E. Stahaki[1], A. Bottani[1], A. Paoloni-Giacobino[1], M. Lidgren[1], F. Sloan-Béna[1], L. D'Amato-Sizonenko[1], T. Nouspikel[1], J.-L. Blouin[1], S.E. Antonarakis[1,2,3].* 1) Genetic Medicine and laboratory, Univerity Hospital of Geneva (HUG), Geneva, Geneva 4, Switzerland; 2) Department of Genetic Medicine and Development, University Medical Center, Geneva 4, Switzerland,; 3) Institute of Genetics and Genomics of Geneva (iGE3), 1 rue Michel-Servet, 1211 Geneva, Switzerland; 4) Institut Ethique Histoire Humanités IEH2, University Medical Center, Geneva 4, Switzerland.

The advances of next generation sequencing (NGS) technologies enable their application in clinical care. Despite this most promising progress, there are several significant challenges for their implementation in clinical diagnostics. In Geneva, we use whole exome sequencing (WES) followed by targeted bioinformatics analysis of individual gene panels for the diagnosis of Mendelian disorders and we have created a multidisciplinary working group, the Genome Clinic Task Force which meets once a week. During these meetings, clinical cases and results are presented, the interpretation of identified variants is debated and the final laboratory reports are critically discussed. Reimbursement and ethical issues such as informed consent, disclosure of incidental findings and/or variants of unknown clinical significance (VUS) are also addressed. In Switzerland, reimbursement of diagnostic NGS tests is integrated in the public health insurance since January 2015. During the pilot year 2015 and the beginning of 2016, a total of 198 cases were analyzed. We found pathogenic variants (class 4 or 5) in 35% of patients with developmental delay, 43% of patients with cardiac diseases, 38% in patients with various neurological diseases and in 41% with various other mendelian phenotypes. The average detection rate of (likely) causative variants was 38%. The decision to report VUS was made on an individual case basis. In order to render our diagnostic use of NGS even more efficient and patient-friendly, our current aims are to 1) improve different steps of the workflow in order to accelerate the analysis process 2) continuously update the variant interpretation methods 3) continuously learn from the challenges during the genetic counseling sessions, such as the informed consent process and 4) develop and implement specific strategies for prenatal exome diagnosis and diagnostic exome analyses of trios.

1018W

Application of exome sequencing for diagnosis and research of rare Mendelian disorders - A preliminary Indian experience. *M. Hebbar[1], A. Shukla[1], J. Shah[1], S.S. Lewis[1], S.L. Bielas[2], K.M. Girisha[1].* 1) Department of Medical Genetics, Kasturba Medical College, Manipal University, Manipal, India; 2) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, USA.

   Congenital disorders with severe morbidity and mortality have an estimated global birth prevalence of 5% to 7%. The Indian population is unique in being extremely divergent and heterogeneous genetically. The burden of genetic disorders in India, though enormous, remains unknown till date. The practice of consanguineous marriages, as high as 30% in some regions, further precipitates several rare disorders in this population. The high burden of infectious and nutritional diseases and scarcity of appropriate medical care overshadows the diagnosis and care of rare Mendelian disorders. Whole exome sequencing (WES) is emerging as a powerful, easy and cost-effective tool to investigate these disorders in a middle income country like India. Here, we share our experience of utility of WES in a tertiary care centre in India. Forty six families with rare Mendelian genetic disorders underwent WES. The cohort consisted of a spectrum of pediatric neurodevelopmental disorders (34%), skeletal dysplasias (36%) and other rare disorders (30%) mainly from southern part of India. Massively parallel sequencing of whole exome was outsourced and done using the NextSeq500 Sequencer (Illumina Inc., San Diego, CA, USA) in combination with the NextSeq™ 500 High Output Kit (2x150bp). Bioinformatic and clinical data analysis was done locally. A definitive molecular aetiology could be established in 21 (46%) families. Apart from these, we also ascertained two novel genes.. Twenty one families had autosomal recessive conditions, 19 of which had homozygous variants consequent to the high degree of consanguinity in this part of the country. Pathogenic variants delineated included 12 missense, five nonsense, three splice site, three frameshift deletions and a large deletion spanning 2 exons. Molecular diagnosis could not be established in 23% families. Here we report the utility of exome sequencing in a tertiary health care hospital for the first time in India. .

1019T

Reduction in pipette tip consumable cost and waste in the molecular biology. *A. Safavi.* Grenova LLC, 483 Southlake Blvd. Richmond, VA 23236.

   As the number of samples processed in labs using high-throughput processes has increased, there has been a corresponding rise in the level of waste, such that in 2010, four million pounds of plastic pipette tips were disposed of after just one use. The TipNovus high-throughput automated pipette tip cleaning system from Grenova enables laboratories to safely reuse sanitized tips and thereby reduce cost and waste output. Purpose: To validate the Grenova TipNovus tip washing and drying system to ensure that the tips used to add DNA and/or TAQ can be used multiple times following a wash and dry cycle on the Grenova TipNovus System. Precedures - PCR plates were placed on the Hamilton STARlet and ran with water and new tips. Taq was then added by the Hamilton STARlet with new tips. This was done to give a baseline (blank) data for the tips. The plates where then loaded on the thermocyclers and once completed the plates were read. The next step was to test that the Grenova TipNovus could remove any residual DNA after washing and drying the tips. The plates with MMix were placed on the Hamilton STARlet, along with the deep well plates. The PCR set up program was selected on the Hamilton STARlet and DNA was added to the PCR plates with new tips. Taq was added by the Hamilton STARlet using new tips. Plates were sealed, shaken and placed on the thermocyclers. The tips that were re-racked back on the Grenova tip racking tray were taken off the Hamilton STARlet and placed in the Grenova TipNovus and the wash and dry cycles were ran. To test for residual carryover of DNA, the cleaned tips were used to add water in place of DNA on the Hamilton STARlet to the PCR plates containing MMix. New tips were used to add Taq to the plates on the Hamilton STARlet. Plates were sealed, shaken, and placed on the thermocyclers. This was repeated for 25 runs washing the tips each time after patient DNA was added to the plates and always using new tips to add Taq to the water and patient DNA plates. All plates were read on Synergy Plate Reader. The ability of TipNovus to sanitize tips was tested by comparison and validation studies of new and washed tips. A correlation (linear regression) was obtained to monitor reuse of the disposable tips for DNA and TAQ transfer after multiple wash cycles and the rusults concluded that the Grenova TipNovus operated in a way that will allow the use of washed and dried tips to be used multiple times in the Molecular Biology Department.

1020F

Introducing genetics training and competency assessment into day-to-day working practice. *S. Deans[1], F. Khawaja[1], J. Matindale[2], I. Bamsey[3], B. Lings[3], V. Davison[4], A. Seller[4], S. Abbs[5].* 1) UK NEQAS for Molecular Genetics, Edinburgh, United Kingdom; 2) Sheffield Childrens NHS Foundation Trust, Sheffield, United Kingdom; 3) Certus Technology, Hems Mews, Exeter, United Kingdom; 4) Health Education England, Birmingham, United Kingdom; 5) Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom.

The requirement of medical laboratories to work to International Standard ISO15189 has introduced the need to evidence the training and ongoing competency of staff at all levels for all tasks performed. The demonstration of staff to accurately follow testing protocols has been widely adopted, however the measurement of training and competency for routine genetic laboratory duties is problematic. UK National External Quality Assessment Service (NEQAS) for Molecular Genetics has developed the online Genetics Training Assessment and Competency Tool (G-TACT) in conjunction with Certus Technology, with the aim to provide continuing assessment of the ability of individuals working in laboratories to perform both routine and non-routine tasks. These currently include tasks that are undertaken by Sample Receptionists, Duty Scientists, Data Analysts, and Report Authorisers, thereby covering a range of roles within the laboratory. Examples of routine tasks being assessed include logging a sample into a LIMS, answering requests from service users, analysing and interpreting genomic data, and authorising clinical reports. Participation involves entering a virtual genetic testing laboratory and navigating between different workstations to complete tasks. For each participation, the system generates a random scenario, so no individual will complete the exact same task. The system can introduce errors or problems to expose the participant to more challenging scenarios they may encounter, e.g. handling of samples which are not fit for purpose, and analysing and reporting sub-optimal results. The system automatically assesses the participant's handling of the scenario. The modular format enables new workstations, tasks and roles to be introduced as the laboratory environment changes. A manager is assigned to each individual so a laboratory based performance review can be integrated into the appraisal system and training needs can be identified locally and in real time. Multiple assessments can be assigned throughout the year. Currently the assessments cover germline and somatic molecular testing services, and additional assessments are being developed for future, including cytogenetic services. G-TACT offers, for the first time, a consistent approach to ensure individuals at all levels across all UK genetics laboratories, and potentially worldwide, are appropriately trained and competent to perform their assigned tasks to a high quality standard.

The Exome Clinic and the role of medical genetics expertise in interpretation of whole exome sequencing results. *D. Baldridge[1], J. Heeley[1,2], M. Vineyard[1], L. Manwaring[1], T. Toler[1], E. Fassi[1], E. Fiala[1], S. Brown[3], M. Wiling[1], D.K. Grange[1], B.A. Kozel[1,4], M. Shinawi[1].* 1) Division of Genetics and Genomic Medicine, Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 2) Now at Mercy Clinic - Kids Genetics, Mercy Children's Hospital St. Louis, St. Louis, MO; 3) Department of Pathology and Immunology, Washington University School of Medicine, St Louis, MO; 4) Now at National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD.

Purpose: Evaluation of the clinician's role in optimal interpretation of clinical whole exome sequencing (WES) results and the utility of post-exome auxiliary studies and follow up clinical tests in determining the pathogenicity of genetic variants. Methods: Retrospective chart review of the first 155 patients who underwent clinical WES in our Exome Clinic and direct interaction with the ordering geneticist to evaluate the process of interpretation of results. The clinical assessment was categorized as concordant or discordant with the laboratory's classification of the sequence data to analyze how the geneticist's interpretation influenced the final diagnosis. Results: The most common primary indication was neurological problems (~66%), followed by multiple congenital anomalies (~10%). The diagnostic laboratory reported 238 genetic variants, with an average of 1.5 variants per patient and a range from 0 to 6. The overall diagnostic yield was 35% based on sequencing data. After assessment by the medical geneticist, incorporation of detailed phenotypic and molecular data, and utilization of additional diagnostic modalities, the classifications of 97 total variants were changed, altering the final diagnosis of the patient in 21 cases and increasing the final diagnostic yield to 43%. Thirty-two (48%) out of the 66 definitive cases had mutations in genes described in 2011 or later. Seven patients of our cohort were included in initial case series that described novel genetic syndromes and 23% of patients were involved in subsequent research studies directly related to their results or involved in efforts to move beyond clinical WES for diagnosis. We found a higher diagnostic yield for females, patients with a craniofacial anomaly, and patients with an abnormal head circumference. Gene Ontology analysis showed enrichment for genes involved in face morphogenesis/development and brain development. Incidental findings in 10% of our cohort patients often resulted in additional interventions in both the probands and their carrier relatives. The clinical management was directly altered due to the WES findings in 12% of definitively diagnosed cases. Conclusions: Our results emphasize the clinical utility of WES, demonstrate the significant role of the medical geneticist in the diagnostic process of patients undergoing WES, and illustrate the benefits of post-analytical diagnostic work-up in solving the "diagnostic odyssey.".

1022T

Dominant *de novo* variants in consanguineous families: Increased diagnostic yield with WES trio analysis. *A. Begtrup, L. Folk, K. Retterer, B. Friedman, J. Juusola.* GeneDx, Inc., Gaithersburg, MD.

Whole exome sequencing (WES) is a powerful tool for the diagnosis of patients with complex and poorly defined genetic disorders however this technology is more expensive with a longer turn-around-time compared to traditional single gene and gene-panel tests. Individuals with parental consanguinity are more likely to have homozygous variants, therefore one approach to minimize cost and testing time in these individuals is to limit analysis to genes within regions of homozygosity (ROH). Utilizing ROH previously identified via SNP microarray, we developed a targeted exome sequencing test that focuses WES analysis to ROH (ROH Slice). Because this approach does not require samples of parents for analysis the cost is reduced. In this study, we compared the diagnostic yield of ROH Slice to trio WES in cases with a parental kinship coefficient (KC) representing second cousins or closer (KC >0.01). Our clinical diagnostic laboratory performed ROH Slice on 165 samples with a positive rate of 19.4% (32/165), and WES on 502 consanguineous trio cases with a positive rate of 29.5% (148/502). The diagnostic yield of consanguineous WES trio cases was significantly higher than the diagnostic yield of ROH Slice (P=0.0113). Although consanguineous WES trio cases were enriched for positive homozygous variants (31.9%) compared to WES trio cases without detectable parental consanguinity (4.8%; P<0.0001), de novo variants and variants associated with autosomal dominant or X-linked inheritance also contributed heavily to the diagnostic yield in consanguineous WES trio cases. Cases with a parental kinship coefficient representing second cousins (KC ≤0.025 and >0.01) were much less likely to have homozygous positive results. In these cases, more than half of the reported positive variants were in genes with autosomal dominant inheritance (53.6%) and de novo in origin (56.6%), whereas almost one-third (31%) of positive variants were associated with autosomal recessive inheritance. Therefore, while ROH Slice for consanguineous families is a viable option when parental samples are unavailable or full WES is cost prohibitive, WES trio analysis provides a higher diagnostic yield, particularly due to the ability to detect de novo variants associated with autosomal dominant inheritance.

1023F

Comparison of the diagnostic yield and clinical indications for whole exome sequencing among adult and pediatric patients. *A. Crunk, R. Willaert, S. DeWard, K. Retterer, J. Juusola.* GeneDx, Gaithersburg, MD, USA.

The diagnostic yield for whole exome sequencing (WES) ranges from 22-28%, and is affected by clinical indication, age of the proband, and analysis of proband-only versus trio cases. The adult population presents unique diagnostic challenges both in the clinic and in the laboratory. Adults accounted for 19.8% (1874/9464) of the total WES cases completed in our laboratory by March of 2016. The most common diagnoses in adults 30 and over were fatigue (33.4%), muscle weakness (29.5%), and migraine (20.4%). In contrast, the most common diagnoses in pediatric cases, less than 18 years of age, were generalized hypotonia (34.8%), developmental delay (33.3%), and seizures (25.3%). Phenotypic features of adults 18-29 years were a blend of those seen in the other age groups. The definitive diagnostic rate of WES was 17.8% (335/1874) when the proband was over 18, significantly lower than 27.6% (2096/7590) positive rate for pediatric cases (p<0.0001). Dividing the adults further, the positive rate in adults 18-29 years was 24.3% (198/814), but decreased to 12.9% (137/1060) (p<0.0001) in probands 30 years or older. The majority (72%) of pediatric cases were submitted and analyzed as traditional trios, defined as a case including a proband and both biological parents, while only 41% of adult WES cases were trios. In contrast to the higher positive rate of WES trios (29%) compared to proband-only (21%) in the pediatric population, there was no significant difference in adults. Proband-only testing in young adults 18-29 years provided a definitive result in 24.8% compared to 25.4% (p=0.9147) with trio testing. Similarly, among adults 30 years and older, there was no significant difference in diagnostic rate when comparing proband-only cases (13.7%) to traditional trios (14.5%, p=0.7494). Our data demonstrate that adults, specifically those over 30 years of age, are undergoing WES for different clinical indications with lower detection rates than pediatric cases and may benefit less from the trio-based approach.

1024W

Integration of Exomiser into a clinical whole exome sequencing analysis bioinformatics pipeline to aid variant interpretation. *J. Ji, L. Shen, J. Buckley, M. Bootwalla, D. Ruble, J. Galler, D. Maglinte, C. Quindipan, G. Raca, S. Saitta, J. Biegel, X. Gai.* Children's Hospital Los Angeles, 4650 Sunset Blvd., Los Angeles, CA 90027.

Whole exome sequencing (WES) has shown great efficacy in diagnosing patients with suspected genetic disorders. However, the need for multiple manual data interpretation steps and limited adaptation of robust informatics tools for variant prioritization limit rapid turn-around time in a clinical setting. We implemented a semi-automated workflow that integrates a number of publicly available tools and resources including Phenotips for clinical phenotype capture using Human Phenotype Ontology (HPO) terms and Exomiser for variant prioritization (http://www.sanger.ac.uk/science/tools/exomiser). A total of 28 cases (24 singleton-WES and 4 trio-WES) were sequenced using the Agilent SureSelect Human All Exon V6 kit and the Illumina NextSeq 500 sequencing system. Twenty-six cases had known pathogenic or likely pathogenic variants; one case had a variant of unknown clinical significance; and one case was negative. We manually reviewed all rare variants in a blinded manner, facilitated by priority gene lists generated from HPO terms, and achieved 100% concordance rate with prior diagnoses. We then applied Exomiser, a tool that prioritizes genes and variants in a VCF format based upon patients' phenotypes defined in HPO terms, to identify potential disease-causing variants in the 28 cases. In 25/26 (96%) cases, Exomiser ranked the known pathogenic or likely pathogenic variants as the top candidate with high scores (>0.85). In one case, Exomiser initially ranked the known pathogenic variant in 7th place. When a more specific HPO term was added however, the ranking improved to 1st place. For the case with a variant of unknown clinical significance, Exomiser ranked it in 8th place. Exomiser and manual review results were consistent for the negative case, where Exomiser showed low scores for all candidate variants. In conclusion, we have successfully tested and implemented a phenotype-driven automated WES variant analysis pipeline in a clinical diagnostic setting. With Exomiser incorporation, automated analysis is quick, accurate, and unbiased. Our study also suggests that complete and specific clinical phenotypes are critical for phenotype-driven exome analysis.

1025T

A retrospective analysis of exome sequencing cases using the GenePool™ Genomics Platform. *A. Vladimirova[2], T. Klingler[2], R. Goold[2], E. Puffenberger[1].* 1) The Clinic for Special Children, Strasburg, PA 17579; 2) Station X, 185 Berry Street, Suite 2001, San Francisco, CA 94040.

The Clinic for Special Children (CSC) is a rural pediatric non-profit medical practice serving uninsured Amish and Mennonite (Plain) children with genetic disorders. The clinic strives to identify genetic causes of childhood disability and disease and uses modern genetic technologies to diagnose and treat patients. Whole exome sequencing (WES) and data analysis in conjunction with deep phenotyping has enabled the scientific community to achieve great success in identifying the molecular bases of disease. The CSC has used these technologies successfully as well over the past several years. The CSC employs a diagnostic pipeline for new patients that involves detailed phenotyping, targeted mutation detection, chromosomal microarray analysis, and exome sequencing in order to generate a molecular diagnosis for the patient. Due to a deep knowledge of segregating mutations in the Plain populations, nearly 50% of all new patients receive a diagnosis through targeted mutation detection while roughly 3% have diagnostic copy number changes. Of the remaining patients, our diagnostic yield for clinical exomes is approximately 49%. We present a validation study of solved WES cases from the CSC where we demonstrate the ability to efficiently identify putative causative variants in GenePool, a cloud-based genomics platform for analysis of genomics data. We utilized the built-in analytical workflows for trio analysis and the pipelines designed for population-size cohort analyses. The latter analyses compared groups of affected and unaffected individuals. We used GenePool's interactive visualization filters with the comprehensive library of annotations to quickly prioritize the list of potential causative variants to a small highly-relevant set and validated our results. GenePool allowed us to efficiently screen for pathogenic variants associated with autosomal recessive and *de novo* dominant phenotypes, as well as with more complex genetic diseases. Rapid diagnosis is crucial to optimal patient outcomes, and GenePool solves a critical part of this process by enabling the analysis and identification of a small set of putative pathogenic variants in a short time frame. In this study, we found high concordance between GenePool variant prioritization and the prior *ad hoc* manual prioritization. The study we present was conducted in specific regional founder populations, but it provides important lessons for WES studies in non-founder populations.

1026F

Overcoming the challenges of regions of high homology in the clinical genomics laboratory using short-read based next generation sequencing platforms. *D.W. Close, N.S. Reading, G. Pont-Kingdon, C.P. Vaughn, K.V. Voelkerding, A. Kumanovics.* ARUP Institute of Clinical and Experimental Pathology, Salt Lake City, UT.

Regions of homology in the genome, including pseudogenes and other segmental duplications, represent a significant percentage of the genome and lead to unique challenges for targeted genomics in molecular diagnostics. This is particularly true when using short-read based next generation sequencing (NGS) platforms. Certain genes, including *IKBKG* and *PMS2*, are frequently targeted in disease specific panels but nearly identical pseudogene DNA fragments are co-captured and cannot be differentiated from functional gene DNA using standard NGS alignment workflows. Often what is required is supplemental long-range PCR followed by gene specific Sanger sequencing; a process that leads to significant increases in costs and longer turn around times. In this work, we analyze regions of homology relevant to targeted NGS panels and present methodology for processing and analyzing NGS data in the context of segmental duplications containing pseudogenes. In one approach, we demonstrate a method where functional gene specific amplicons are introduced to extracted genomic DNA followed by standard capture and sequencing. Data is then analyzed using a modified NGS pipeline for mapping just the functional gene specific reads, thus eliminating the need to perform supplemental Sanger Sequencing. We highlight an example of this method that centers on the *IKBKG* (NEMO) gene located on the X chromosome. Variants in *IKBKG* have been reported in various forms of Primary Immunodeficiency and Ectodermal Dysplasia disorders, with a number of these variants falling within exons 5-12, a region with 99.9% identity to an inverted segmental duplication located ~36,000 bp upstream of the functional gene. We show that our amplicon spiking method leads to highly accurate sequencing specific to exons 5-12 of the functional gene, without the need for supplemental Sanger sequencing. The method can be applied to other genes with confounding homologous regions such as *PMS2*, and when combined with other methods and bioinformatics tools allow interrogation of gene regions previously inaccessible by standard short-read NGS workflows.

1027W

Development of standardized pathogen detection assays using CleanAmp™ Master Mixes. *A.P. McCaffrey, S. Shore, J.M. Henderson, G. Zon, R.I. Hogrefe.* TriLink BioTechnologies, San Diego, CA.

Acute gastroenteritis (AGE) affects over 179 million people and causes over 600,000 hospitalizations and 5000 deaths in the U.S. annually (CDC). Infectious AGE can be caused by a wide variety of different pathogens including bacteria, viruses and parasites. Rapid, definitive and economical identification of the causative AGE agent could inform medical decisions while reducing the inappropriate use of antibiotics. Standardized molecular methods and multiplexing will make pathogen identification more efficient and economical, with a huge potential global impact. The molecular diagnostics field demands assays with more speed, specificity, and sensitivity. PCR is an established and reliable technology that meets these criteria. Although there are a myriad of published protocols using PCR for detection of specific diseases there is still a lack of established and standardized assays that cover the detection of certain infections. CleanAmp™ dNTPs are a universal Hot Start technology that can be applied to many different types of PCR assays including Real-Time PCR, Multiplex PCR and RT-PCR. CleanAmp™ dNTPs are 2' deoxynucleotide triphosphates with a 3' thermolabile protecting group that prevents incorporation of the dNTPs at room temperature. As temperature is increased the protecting group begins to fall off creating a standard dNTP that can be naturally incorporated into the growing cDNA or PCR strand. CleanAmp™ dNTPs do not have a specific activation temperature but their kinetics are determined by a combination of heat, time and pH that can be optimized for each assay type. CleanAmp™ dNTPs have proved to increase amplification specificity and yield in a variety of assays. We will demonstrate the use of CleanAmp™ dNTPs in robust Multiplex Real-Time PCR and RT-PCR assays that are designed for screening and detection of pathogenic bacteria and viruses in patient stool samples. Primer sets were designed to consensus regions of several strains of each pathogen to maximize detection. Assays were optimized using positive control bacterial isolates and were then tested on DNA and RNA isolated from patient stool samples that may contain inhibitors. Using commercially available CleanAmp™ Master Mixes (CleanAmp™ 2x Multiplex Master Mix and CleanAmp™ 2x RT-PCR Master Mix) we aim to establish and standardize several assay panels for detection of the pathogens causing infectious diarrhea that will make diagnosis and treatment faster and more reliable.

1028T

Use of saliva and salivary DNA for comprehensive genotyping based on RealFast and StripAssays. *C. Oberkanins, A. Berndt, B. Hauser, H. Puehringer.* ViennaLab Diagnostics, Vienna, Austria.

Nucleic acids extracted from blood are the most common sample types used in molecular genetic diagnostics. Blood is an abundant and reliable specimen, yielding high amounts of DNA and RNA with homogenous quality. Since drawing blood is an invasive procedure, and DNA extraction is time consuming and requires special equipment, salivary DNA and saliva direct-to-PCR represent promising alternative approaches in clinical diagnostics. Saliva is considered to represent an ultra-filtrate of blood, and thus contains in abundance a huge variety of diagnostically valuable molecules. Apart from being known to contain polymerase chain reaction (PCR) inhibitors, saliva is mucous and inhomogenous and thus often difficult to handle. Moreover, its human DNA content is by far lower compared to blood. Here we examined blood-derived DNA, salivary DNA and saliva direct-to-PCR to carry out reliable genotyping based on single-plex RealFast and multi-plex StripAssays for up to 22 mutations. Our data suggest that saliva collected and stored in dedicated devices is suitable to be used for isolating ample amounts of high-quality DNA, but also for direct-to-PCR approaches towards comprehensive molecular diagnostics.

1029F

Taking another look: Results of high-resolution microarray analysis in patients with previous microarray testing. *M.R. Sdano, M.M. Martin, R.J. Vanzo, M.A. Serrano, P.A. Mowery-Rushton, E.R. Wassman.* Lineagen, Inc., Salt Lake City, UT.

Chromosomal microarray (CMA) has become the first tier test for individuals with intellectual disability (ID), developmental delay (DD), multiple congenital anomalies (MCA), and/or autism spectrum disorder (ASD). While it is well established that CMA has a higher diagnostic yield than other cytogenetic tests such as karyotype and fluorescence *in situ* hybridization (FISH), few studies have looked at the diagnostic yield between microarray platforms. The purpose of this study was to compare the results of a patient's previous microarray with the results of a newer ultra-high resolution CMA. Patient data was retrospectively collected from 7,412 patients consecutively referred for clinical microarray testing by their healthcare provider between August 2012 and May 15, 2016. CMA was performed using a commercial microarray optimized for diagnosis of ID/DD/MCA/ASD through the addition of 88,435 custom probes of relevance to these disorders to an Affymetrix array platform resulting in a 2.8M probe microarray (FirstStep$_{Dx}$ PLUS). Referral information or case medical records revealed that fourteen patients (0.02%) previously had CMA with one of a variety of lower resolution microarrays. For seven of the 14 patients with a previous microarray, new information was obtained by FirstStep$_{Dx}$ PLUS, with four of these patients receiving a new or updated genetic diagnosis. The four new diagnoses were cerebral cavernous malformation (CCM) syndrome (patient 1), KBG syndrome (patient 2), 49,XXXXY (patient 3; previously diagnosed as 47,XXY), and a mosaic 13q deletion (patient 4). Additionally, FirstStep$_{Dx}$ PLUS was able to further refine the breakpoints and gene content of previously identified deletions and duplications in three of the seven patients. This case series highlights the benefits of ultra-high resolution CMA over lower-resolution platforms since clinically relevant information was obtained in 7/14 (50%) patients. Identifying previously unreported copy number variations led to a new genetic diagnosis in four of 14 patients (28.6%), suggesting that re-analysis of patients who previously had low resolution CMAs should be considered. These new diagnoses resulted in more personalized medical management as well as new recurrence risk information for the family. When choosing a CMA platform for a patient, it is important to choose the highest resolution platform available in order to have the greatest chance to identify a genetic condition, thus impacting clinical management.

1030W

Automated evaluation of *de novo* **copy number variants from SNP array trios using pCNV.** *A.P. Wiita[1], C.A. Mather[1], J.Y. An[2], S.J. Sanders[2].* 1) Laboratory Medicine, University of California, San Francisco, San Francisco, CA; 2) Psychiatry, University of California, San Francisco, San Francisco, CA.

   Introduction: The identification of clinically relevant copy number variants (CNVs) in single nucleotide polymorphism (SNP) arrays can be complicated. While some pathogenic variants may be inherited from a carrier parent, many deleterious variants will be *de novo.* Our ability to confidently assign *de novo* status to small CNVs, however, is hampered by noise inherent to the assay and minimum size thresholds for CNV reporting. We therefore used a new computational method, pCNV, to identify and assign confidence values to *de novo* CNVs identified in parent-child trios. **Methods:** SNP arrays were performed using the Illumina CytoSNP-850K assay and initially evaluated using Illumina BlueFuse software for standard clinical reporting. The pCNV method was initially described by Sanders *et al.* (*Neuron* (2015) 87:1215). Briefly, all CNVs were predicted using existing algorithms and the specificity of de novo CNV predictions was estimated using a per CNV p-value (pCNV), based on the per SNP variability in Log R Ratio (LRR) and the number of SNPs consistent with a deletion/duplication based on B Allele Frequency (BAF). *De novo* CNV calls were compared between the pCNV and the BlueFuse outputs. **Results:** We evaluated 16 trios and one quintet. Twenty-one CNVs that met our reporting criteria were identified in the probands. Manual review of the probands and relatives revealed that five of these CNVs were *de novo*. These were confirmed by pCNV, which also reported one other, 0.94 Mb, *de novo* duplication. This duplication was confirmed on review of the BlueFuse output. **Conclusions:** The pCNV program accurately identified all reported *de novo* CNVs in our study set. This algorithm can automatically identify *de novo* CNVs from trio samples without manual review of the data, which could streamline the process of identifying and evaluating CNVs of uncertain significance. The finding of an additional, *de novo* CNV in our sample set raises consideration that pCNV could be used to detect causative CNVs that might otherwise be dismissed because they are too small to meet standard reporting criteria in the clinical laboratory. Furthermore, our study demonstrates the potential utility of performing trio SNP array analysis, analogous to routinely-performed trio whole exome sequencing, to enhance detection of *de novo* variants which may be of clinical relevance but would otherwise be ignored.

1031T

Modification of Eureka Genotyping for detection of RNA without conversion to cDNA. *J. Curry[1], P. Dickinson[2], A. Schweitzer[2].* 1) Eureka Genotyping, Affymetrix part of ThermoFisher Scientific, Hercules, CA; 2) Affymetrix part of ThermoFisher Scientific, Santa Clara, CA.

   Analysis of RNA often suffers from a bias due to its conversion to cDNA prior to analysis. We have modified the Eureka Genotyping Solution, which utilizes next generation sequencing and enables the simultaneous genotyping of hundreds of thousands of DNA samples for tens to thousands of loci, for the direct interrogation of RNA. This solution is based on ligation dependent PCR and uses interrogation site probes as well as sample index barcodes that are added during amplification. The utility is demonstrated by performing a highly multiplexed reaction that uses a commercially available RNA ligase to ligate DNA probes hybridized to RNA templates. Next generation sequenced data is created from the resulting PCR products. Each read is assigned to a sample (based on index) and to a locus. The sequence produced from left and right probe ligation is examined to determine if/what type of RNA splicing occurred by reading from the left portion into the adjoined/ligated right portion. Here we show the results of a 778-plex panel of probes designed to interrogate the RNA produced from housekeeping genes and from human gene exons selected for cancer fusion gene detection. The expected exon junctions were found in the house-keeping genes. Additional uses of Eureka Genotyping for RNA include the targeted study of expression, allele-specific expression, alternative splicing, and fusion gene detection. This direct from RNA detection is a simplified assay that also removes the RNA to cDNA conversion bias.

1032F

Phenotypes of Distinction": When and how to integrate unique phenotypic information into variant interpretation. *B. Johnson, S. Topper, S. Aradhya, A. Entezam, Y. Kobayash, K. Mitchel, C. Morgan, R. Nussbaum, J. Tahiliani, K. Nykamp.* Invitae, San Francisco, CA.

For well-described hereditary diseases with a specific phenotype, there is a relatively high prior probability that pathogenic variant(s) will be detected, if the appropriate genes have been sequenced. The presence of a unique phenotype in a patient can provide a powerful line of evidence for variant classification. We set out to establish a systematic approach for integrating unique phenotypic data into variant interpretation. In the course of sequence variant classification, the potential exists to conclude incorrectly that a novel VUS found in a patient with a disease must be causative. This incorrect conclusion arises from an overestimate of the prior probability that any variants in a patient found in a gene consistent with the patient's disorder must be causative. The likelihood that any variants detected in a gene cause disease, depends on how distinctive the phenotype of the individual is, the degree of locus heterogeneity, the fraction of locus heterogeneity that is accounted for by the genes being tested, and the prevalence of phenocopies in the population. It is also modulated by the observed genotype in the patient. The ACMG Interpretation of Sequence Variants guidelines address this subject with a single criterion: PP4, "Patient's phenotype or family history is highly specific for a disease with a single genetic etiology". We sought to clarify the usage of this rule with more detailed, gene-level guidelines. We use a point system for variant interpretation that is based on the ACMG guidelines. We defined a new set of evidence-based criteria that can be applied during variant interpretation when the following criteria are met: (1) our diagnostic yield is >75% for the gene(s) tested, (2) the clinical features described in a given patient must be so specific that they are essentially pathognomonic for the disorder, and (3) the patient's genotype must match the expected inheritance of the disease. The relative weight of the criteria is determined by the likelihood that a patient's observed genotype explains disease. As a result of these new criteria, we have been able to classify multiple rare variants as likely pathogenic or pathogenic that would have otherwise been classified as VUS by an approach that ignores phenotype. Thirteen patients have received a positive diagnosis for primary ciliary dyskinesia, L1 syndrome, and pyridoxine responsive epilepsy who would have received uncertain findings without the use of these criteria.

1033W

Signature of positive selection at the *CDK6* locus in Pima Indians of Southwest Arizona and association with type 2 diabetes. *P. Kumar, P. Piaggi, A. Nair, P. Chen, S. Kobes, R. Hanson, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ.

Polygenic diseases often disproportionately affect certain ethnic groups. In some cases, positive selection of genomic regions may have led to population-specific enrichment of risk alleles. Here, we analyze the signatures of positive selection in the Pima Indians of Arizona who suffer from a high prevalence of obesity and type 2 diabetes (T2D). SNPs detected in whole genome sequence (WGS) data in 296 Pima Indians were integrated with 1000 Genomes data. Population differentiation analysis (F_{ST}) between Pima and Caucasian (CEU) identified rs2237572 (F_{ST}; 0.8) as one of top 1% differentiated signals. The derived allele at rs2237572(C) had a higher frequency in Pima (86%) and Chinese (CHB; 80%) as compared to CEU (4%). This variant maps to the *CDK6* gene which regulates the cell cycle. Overexpression of CDK6 and cyclin D3 in β-cells results in efficient replication and proliferation; therefore, the *CDK6* locus was studied further. Summary statistics of neutrality, including nucleotide diversity and Tajima's *D* across *CDK6* showed reduced diversity and a negative *D* in Pima as compared to CEU and CHB based on coalescence analysis for different recombination events. An integrated haplotype score (iHS) analysis for extended haplotype homozygosity of *CDK6* identified a long range haplotype around rs2237571 (iHS score; -3.4471 and F_{ST}; 0.3), which shares the same linkage disequilibrium block as the high F_{ST} variant rs2237572. This extended haplotype (600 kb) contained the rs2237571 derived allele (G), suggesting positive selection in the Pima population. Genotyping of the variant rs2237571 in a population-based sample of Pima Indians showed that the derived allele (G) modestly associated with T2D (N=7,710 *P*=0.001 after genomic control, odds ratio=1.23 per copy [95% confidence interval, 1.10-1.41]; adjusted for age, sex, birth year, and first 5 principal components derived from GWAS). Among 300 normal glucose tolerant Pima Indians assessed for acute insulin response to glucose bolus, carriers of the derived allele had an impaired insulin response (P=0.0023, beta as multiplier=-0.090) even after adjustment for differences in fatness. Our results suggest an important genetic role and selection of *CDK6* gene in Pima Indians and their association with T2D and insulin secretion. Future studies to functionally characterize *CDK6* variation are planned.

1034T

The high prevalence of *UGT1A1* TA8 allele in the Tunisian population as a possible African ancestral protection factor in congenital unconjugated hyperbilirubinemia diseases. *N. Abdelmoula[1], N. Abdellaoui[1], R. Abdelhedi[1,2], N. Kharrat[2], H. Ameur[3], R. Louati[1], D. Dlansi[1], W. Aloulou[3], S. Aloulou[3], P. Lohse[4].* 1) Lab Histology, Univ Medicine, Sfax, Tunisia; 2) Lab Molecular and cellular screening process , CBS, Sfax, Tunisia; 3) Medical university, Sfax, Tunisia; 4) Dep Clinical Chemistry, Munich, Germany.

UGT1A1 which is the major UGT1 gene product is located on chromosome 2q37. Expression of UGT1A1 is, in part, controlled by a polymorphic dinucleotide repeat within the UGT1A1 promoter TATA box consisting of between 5 and 8 copies of a TA repeat, with A(TA)6TAA considered as the wild type. In the regulatory region of UGT1A1, many polymorphic variations such as the phenobarbital responsive enhancer module (PBREM) are described. The A(TA)7TAA allele has been identified as the most frequent allele in Caucasian populations whereas A(TA)8TAA allele, described for the first time by Beutler E et al. (1998) in Afro-Americans with different genotype combinations and later on detected in Sub-Saharian Africans, remains the most rare allele worldwide including in North African and Arab populations. Here we report results of a Tunisian study in which our goal was to determine, using bidirectional sequencing, the UGT1A1 gene mutations and TATA box polymorphisms in Crigler Najjar 1 and 2 patients as well as their parents and family members. Among 82 Tunisian alleles (42 subjects), A(TA)8TAA was detected 13 times (16 percent-PC-) versus A(TA)6TAA 45 times (54 PC) and A(TA)7TAA 24 times (30 PC). Genotypes were distributed as the following: TA6/6 in 5 subjects (12,2 PC), TA6/7 in 14 subjects (34,1 PC), TA7/7 in 14 subjects, TA7/8 in 3 subjects (7,3 PC) and TA8/8 in 5 patients (12,2 PC). It is the first study in which such high frequency of TA8 allele was reported particularly with but also without the association to the Tunisian CN1 mutation (UGT1A1 exon 3 mutation: c.1070A-G). TA8 subjects included 5 double homozygous CN1 cases, 2 double heterozygous parents and one TA7/8 heterozygous subject. Moreover, TA7/8 status of UGT1A1 was not associated with obvious manifestations of Gilbert trait. The same observation was done for the only Tunisian reported case of TA7/8 among the healthy cohort (n= 137) of Chaouch L et al. 2011. Additionally, CN patients with TA8/8 status seem to have better outcome with a survival rate of 10 years for 1 out of our 5 cases. We suggest that the TA8 UGT1A1 promoter polymorphism may be a prevalent allele in our Tunisian population and may be a protection factor against high bilirubin levels. This protection may be secondary to the DNA features of the ancestral African haplotype especially in the regulatory region of UGT1A1 (such as the absence of -3275T-G at PBREM which is frequently associated to TA7 allele).

1035F

Pinpointing *IVD* regulatory variants that impact leucine metabolism in a region under selection in East Asians. *E.A. Brown[1,2], R. Tewhey[1,2], J. Vitti[1,2], S. Schaffner[2], P. Sabeti[1,2].* 1) Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Broad Institute, Cambridge, MA.

Only a few genetic loci have been firmly linked to metabolic adaptations despite genome-wide selection scans indicating that infectious disease, climate, and diet have exerted strong recent (50kyr) selective pressure on human metabolism. While we previously used the Composite of Multiple Signals (CMS) test to identify and narrow in on a strong signal of positive selection at the locus of the metabolic gene isovaleryl dehydrogenase (*IVD*) in East Asian populations, neither the underlying adaptive sequences nor their phenotypic effects have been characterized. To address this, we comprehensively characterized genetic variants falling in this selection region for their ability to regulate gene expression. We chose to focus on variants overlapping the selection peak that associated with *IVD* expression and metabolites of *IVD* in the blood for two reasons: First, our broad goal was to extend selection scans to find candidates for adaptation by intersecting our CMS loci with loci that associate with gene expression because the majority of selected loci likely function through non-coding regulatory alterations. Secondly, *IVD* catalyzes digestion of leucine, an essential amino acid in the human diet with roles in muscle anabolism and insulin signaling early in development, which makes it an intriguing candidate for adaptation. Leucine is found at high concentrations in eggs and cheeses, as well as soy beans, which originally were domesticated in East Asia. Using the luciferase reporter gene assay, we identified two variants whose derived alleles increased expression of IVD and are at 80% frequency in East Asians. We confirmed these alleles endogenously regulate *IVD* using CRISPR/Cas9-based homologous replacement of alleles in the same cell lines. Additionally we dissected the sequence determinants of regulation using a multiple parallel reporter assay (MPRA) to bash the locus to identify transcription factor motifs responsible for regulatory function. Lastly, we further refined the selection signal by dating the functional alleles and analyzing selection measures across a diverse set of human populations. Detecting and exploring regulatory variants of *IVD* lays the groundwork for understanding natural variation in important human traits affected by leucine in diverse human populations. .

1036W

Natural selection at circadian clock–fasting glucose-related gene loci associated with the cryptochrome 2 and melatonin receptor 1B genes. *I. Yoshiuchi.* Dept Med, Yoshiuchi Med Diabetes Inst, Kamakura, Kanagawa, Japan.

Type 2 diabetes mellitus (T2DM) is highly heritable and shows significant variation in prevalence among populations. The circadian clock has been linked with diabetes and obesity, and short sleep is associated with risk of diabetes and obesity. According to the thrifty gene hypothesis, natural selection for diabetes and glucose-related genes is important during feast and famine because such genes control glucose levels. Human adaptations to environmental changes in food supply, lifestyle, and geography may have influenced the selection of genes associated with the metabolism of glucose, lipids, and energy. The cryptochrome 2 (*CRY2*) and melatonin receptor 1B (*MTNR1B*) genes are associated with fasting glucose, and are also related to the circadian clock . Single nucleotide polymorphisms (SNPs) in *CRY2* and *MTNR1B* have been linked with fasting glucose levels. Here, we investigated selection at circadian clock –fasting glucose-related gene loci associated with *CRY2* and *MTNR1B* . We performed a three-step method to detect selection at the *CRY2* and *MTNR1B* loci using HapMap population data. We used Wright's F-statistics as a measure of population differentiation, the long-range haplotype test to identify extended haplotypes, and the integrated haplotype score (iHS) to detect selection at *CRY2* and *MTNR1B* . We found high population differentiation between European and African populations at one *CRY2* and one *MTNR1B* fasting glucose-associated SNP using Wright's F-statistics. The iHS also showed evidence for natural selection at the *MTNR1B* locus. These findings provide evidence for natural selection at the *CRY2* and *MTNR1B* loci . Further investigation is warranted into adaptive evolution at circadian clock –fasting glucose-related gene loci.

1037T

Association between variants of melanocortin 1 receptor *(MC1R)* gene and the systemic lupus erythematosus development. *N.F. Cagnin[1], F.B. Barbosa[1], L. Marano[1], C.T. Mendes-Junior[2], E.A. Donadi[3], A.L. Simoes[1].* 1) Genetics, University of São Paulo, Ribeirão Preto, São Paulo, Brazil; 2) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Brazil; 3) Division of Clinical Immunology, Ribeirão Preto Medical School, University of São Paulo, Brazil.

Systemic lupus erythematosus (SLE [MIM: 152700]) is an autoimmune disease, which has higher incidence and prevalence in African descent people of non-tropical regions compared to European descendants and Africa inhabitants. It has been proposed that vitamin D deficiency contributes to the development of SLE, because the active vitamin form has biological functions in the immune system. The capacity to synthesis of this vitamin is lower in darkskinned individuals. They have much of melanin pigment that acts as a physical barrier to the UVB rays incidence, essential for the vitamin synthesis. The melanin synthesis is triggered by activation of melanocortin 1 receptor (MC1R) and polymorphisms in coding region of the receptor gene contributes to the determination of human skin pigmentation phenotype. Facing the possible association between *MC1R* (MIM: 155555/HGNC:6929) gene and SLE, this study aimed to investigate the association between SNPs of *MC1R* gene and the occurrence of SLE and, compare ethnic profiles of patients and control by Ancestry Informative Markers (AIMs). Using genetic sequencing, a total of 18 SNPs distributed throughout the whole coding region of *MC1R* gene was genotyped in DNA samples from 138 patients and 123 controls. Departures from Hardy-Weinberg equilibrium weren't found. Allele, genotype and haplotype frequencies were obtained and compared between patients and controls using logistic regression test, in which sex and age variants were controlled. The haplotype B1 of *MC1R* (p=0.016; OR=0.443; CI=0.219-0.855), the allele T of the 1558GT locus (p=0.012; OR=0.422; CI=0.216-0.827), that features this haplotype, and its heterozygous GT genotype (p=0.026; OR=0.434; CI=0.208-0.906) were associated with protection to SLE. Additionally, we genotyped 12 AIMs and their allelic frequencies were used to estimate ancestral composition of sample groups. The ancestral composition of patient group and control was similar: 64% and 70% European contribution, 22% and 17% of African and 14% and 13% of Amerindian, respectively, and there was no genetic difference between the groups. These results revealed that there is an association between *MC1R* gene and the SLE development.

1038F

Genetic adaptation and Neandertal admixture shaped the immune system of modern human populations. *H. Quach[1,2,3], M. Rotival[1,2,3], J. Pothlichet[1,2,3], Y.-H.E. Loh[1,2,3], M. Dannemann[4], N. Zidane[1,2,3], G. Laval[1,2,3], E. Patin[1,2,3], C. Harmant[1,2,3], M. Lopez[1,2,3,5], M. Deschamps[1,2,3,5], N. Naffakh[6], D. Duffy[7], A. Coen[8], G. Leroux-Roels[8], F. Clément[8], A. Quintana-Murci[1,2,3].* 1) Human Evolutionary Genetics, Institut Pasteur, Paris, Ile de France, France; 2) CNRS, URA3012, Paris 75015, France; 3) Center of Bioinformatics, Biostatistics and Integrative Biology, Institut Pasteur, Paris 75015, France; 4) Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig 04103, Germany; 5) Université Pierre et Marie Curie, Cellule Pasteur, Paris 75015, France; 6) Institut Pasteur, Molecular Genetics of RNA Viruses Unit, Paris 75015, France; 7) Institut Pasteur, Dendritic Cell Immunobiology Unit, Paris 75015, France; 8) Center for Vaccinology, Ghent University and University Hospital, Ghent 9000, Belgium; 9) Centre National de Génotypage, CEA, Evry 91000, France; 10) Department of Cancer Immunology, Genentech, California 94080, USA.

The immune response to stress is a highly complex phenotype. Inappropriate immune activity can increase susceptibility to infectious, inflammatory, and autoimmune diseases, the clinical manifestations of which vary considerably in humans, at both individual and population levels. Yet, the extent of population differences in immune responses, and their genetic and evolutionary determinants, remain undefined. Here, we characterized, using RNA-sequencing, the transcriptional response of primary monocytes, from 100 Africans and 100 Europeans, exposed to various bacterial and viral stimuli — ligands activating Toll-like receptors pathways (TLR1/2, TLR4 and TLR7/8) and influenza virus — and mapped expression quantitative trait loci (eQTL). We find that marked differences in immune responses exist within and between human populations, due to the contribution of multiple *cis*- and *trans*-acting regulatory variants. These include, for example, a *TLR1 trans*-regulatory hotspot associated with the expression of a large gene network of 101 genes, which decreases the expression of multiple pro-inflammatory genes in Europeans only. Furthermore, we show that natural selection has preferentially targeted loci affecting monocyte gene expression, and identify a list of immune-responsive regulatory variants that have conferred different selective advantages in African and European populations. Specifically, our analysis uncover attenuated inflammation as an evolutionarily advantageous mechanism, as attested by the cases of *TLR1*, *CCR1* and *DUSP14*. Finally, we demonstrate that admixture with Neandertals has shaped monocyte gene expression by introducing regulatory variants into European genomes that affect preferentially responses to viral challenges, and report novel cases of adaptive introgression, as highlighted by the *cis*-eQTL regulating *PNMA1* in response to influenza infection. Overall, our analyses provide a comprehensive view of the impact of population genetic differences on transcriptional responses to innate immunity activation, and highlight evolutionarily important determinants of host immune responsiveness. The regulatory variants identified in our study constitute a useful resource for evaluating the role of such variants in the molecular and cellular mechanisms underlying host immunity to infection and susceptibility to disease, at the individual and population levels.

1039W

Insights into the geographical distribution of genetic admixture of unrelated volunteer donors and recipients of stem-cell transplants. *A. Madbouly[1], K. Besse[1], Y. Wang[2], J. Byrnes[2], C. Ball[2], N. Myres[2], M. Maiers[1].* 1) Bioinformatic Research, National Marrow Donor Program, Minneapolis, MN; 2) Ancestry.com, San Francisco, CA, USA.

Genetic ancestry of self-described groups may vary across geographic locations in the US, a phenomenon documented anecdotally but not thoroughly explored in the literature. We studied the genetic ancestry of 995 HLA matched donor/recipient (DR) pairs from the Be The Match® registry with a focus on regional ancestry differences among ethnic groups. We hypothesized that, along with historical events, donor/transplant center distribution and socioeconomic factors might influence the geographical spread of some genetic admixtures. We genotyped 995 DR pairs on the Illumina OmniExpress chip with approximately 730,000 SNPs. Self-reported race and ethnicity was collected for donors at the time of registry recruitment. Recipients' race and ethnicity was recorded at the transplant hospital once at the time of diagnosis and again after transplant. The majority of the study cohort (94%) self-identified as European Caucasian (CAU). The rest identified as Hispanic (HIS) (3.5%), African-American (1%) and Asian or Pacific Islander (1.5%). Address zip code information was available for 99% of recipients but only 59% of donors. Genetic ancestry was estimated by applying the AncestryDNAÔ ethnicity estimator pipeline, which provides a vector of 26 admixtures. Some admixtures were combined for the analysis due to small counts and minimal impact such as detailed African (AFR) admixtures. We then mapped the geographical distribution of European (EUR) and non-EUR genetic admixtures for self-reported CAU and non-CAU individuals, optimizing geographical regions for subject privacy. The main self-reported race groups showed average proportions of AFR and EUR admixtures compatible with Bryc and colleagues (2015). However, our results revealed larger Amerindian admixture in self-reported HIS, especially among recipients. When stratifying regionally, systematic differences emerged in admixture distribution among similar race groups mostly interpretable by historic events. Separating donors and recipients suggested possible additional influences, such as donor and transplant center geographical spread. Importantly, we observed differences in the distribution of non-majority admixtures such as increased AFR admixture in self-reported CAU donors (but not recipients) in some southern states suggesting a possible socioeconomic link. This work has the potential of guiding stem-cell donor registry strategies on volunteer donor recruitment and donor and transplant center planning.

1040T

The MHC Diversity in Africa Project (MDAP) Pilot - 125 African high resolution HLA types from 5 populations. *M.O. Pollard[1,2], N. Park[3], C. Pomilla[1], S. Peacock[5], D. Dilernia[4], D. Gurdasani[1], M. Quail[3] on behalf of MDAP Investigators.* 1) Genetic Epidemiology, Department of Medicine, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; 2) Human Genetics Informatics, Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 3) Sequencing Research And Development, Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 4) Emory Vaccine Center, Emory University, Atlanta, GA; 5) Histocompatibility and Immunogenetics Laboratory, Cambridge University Teaching Hospitals NHS Foundation Trust, Addenbrooke's Hospital, Hills Road, Cambridge, UK.

The major histocompatibility complex (MHC), or human leukocyte antigen (HLA) in humans, is a highly diverse gene family with a key role in immune response to disease; and has been implicated in auto-immune disease, cancer, infectious disease susceptibility, and vaccine response. It has clinical importance in the field of solid organ and bone marrow transplantation, where donors and recipient matching of HLA types is key to transplanted organ outcomes. The Sanger based typing (SBT) methods currently used in clinical practice do not capture the full diversity across this region, and require specific reference sequences to deconvolute ambiguity in HLA types. However, reference databases are based largely on European populations, and the full extent of diversity in Africa remains poorly understood. Here, we present the first systematic characterisation of HLA diversity within Africa in the pilot phase of the MHC Diversity in Africa Project, together with an evaluation of methods to carry out scalable cost-effective, as well as reliable, typing of this region in African populations. To sample a geographically representative panel of African populations we obtained 125 samples, 25 each from the Zulu (South Africa), Igbo (Nigeria), Kalenjin (Kenya), Moroccan and Ashanti (Ghana) groups. For methods validation we included two controls from the International Histocompatibility Working Group (IHWG) collection with known typing information. Sanger typing and Illumina HiSeq X sequencing of these samples indicated potentially novel Class I and Class II alleles; however, we found poor correlation between HiSeq X sequencing and SBT for both classes. Long Range PCR and high resolution PacBio RS-II typing of 4 of these samples identified 7 novel Class II alleles, highlighting the high levels of diversity in these populations, and the need for long read sequencing approaches to characterise this comprehensively. We have now expanded this approach to the entire pilot set of 125 samples. We present these confirmed types and discuss a workflow for scaling this to 5000 individuals across Africa. The large number of new alleles identified in our pilot suggests the high level of African HLA diversity and the utility of high resolution methods. The MDAP project will provide a framework for accurate HLA typing, in addition to providing an invaluable resource for imputation in GWAS, boosting power to identify and resolve HLA disease associations.

1041F

Population diversity in transcriptional responses of macrophages to TLR7/8 signaling. *R. Song[1], I. Dozmorov[1], R. Levitz[2], C. Liang[1], B. Zhang[1], B. Wakeland[1], C. Arana[1], K. Viswanathan[1], J. Kahn[2], E.K. Wakeland[1].* 1) Department of immunology, UT southwestern medical center, Dallas, TX; 2) Department of Pediatrics, Division of Infectious Diseases, University of Texas Southwestern Medical Center, Dallas, TX,.

The Toll-like receptors (TLR) of the innate immune system play a key role in the recognition of pathogens and the initiation of a robust innate immune response. Although an innate immune response is essential for resistance to pathogen infection, the magnitude and qualities of innate immune responses are quite variable in the human population. Here we performed transcriptome sequencing of monocyte-derived macrophages generated from 185 healthy individuals, including 10 replicates from repeat donors, to profile gene expression patterns in responses to TLR7/8 signaling. Extensive qualitative and quantitative diversity was apparent in the response of individuals in this panel. Cluster analysis discriminated seven distinct clusters of genes expressed in response to the TLR7/8 agonist (R848) with correlated expression variations within this panel. Interestingly, the induction of cytokine and chemokine transcription varied among donors and majority of these genes have very reproducible variability of their expression in 10 replicates. In addition, it was shown that donors with high expression of cytokine and chemokine genes after R848 stimulation were also high responders to Respiratory syncytial virus infection. Furthermore, it was shown that distinct/similar time dynamics of gene expression in high and low responder in a time course of R848-induced gene expression. Especially, expression of phagocytosis genes was increased in only low responder after 12 hours of R848 stimulation. These results suggest that variations in gene expression among individuals following TLR7/8 stimulation involve coordinate variations in clusters of genes which mediate specific effector functions, suggesting that genetic polymorphisms in "master" regulators may diversify macrophage activation and function within human populations.

1042W

Prevalence of immunity-dependent disease-associated SNPs in human populations. *A. Cherednichenko[1], V. Stepanov[1,2], E. Trifonova[1,2], K. Vagaitseva[1,2], A. Bocharova[1].* 1) Research Institute of Medical Genetics, Tomsk, Russian Federation; 2) National Research Tomsk State University, Tomsk, Russian Federation.

The immune system provides protection from a wide range of pathogens. Pathogens have represented an significant selective force in the process the adaptation of human populations to changing environment. Therefore, immune system is one of the functions enriched with genes under natural selection. Here, allele frequency distributions for gene polymorphisms associated with autoimmune and allergic diseases, as well as with the regulation of cytokines levels and immunoglobulin E, were studied in 26 populations of Northern Eurasia in comparison with data in 31 populations from 1000 Genomes, HapMap, HGDP projects. The frequencies of genotypes demonstrated wide variability. The level of genetic differentiation of worldwide populations was 12.5%. It was shown that allele frequency for most SNP demonstrated significant correlation with one or more climatic and geographic parameters as well as with the incidence of parasitic diseases. Significant correlations between average expected heterozygosis in 27 loci in 57 populations and average annual level of precipitations, range of average temperatures, absolute latitude, temperature of the coldest month and filariasis were found. Population groups exhibited clustering according to their geographic location. Signals of natural selection were revealed for some genomic regions of studied polymorphic markers. The results demonstrate that genetic diversity in immune-related genes in human populations was partially shaped by adaptation to climate and/or parasitic load driven by natural selection. This work was supported by Russian Foundation for Basic Research (grant # 15-04-02442).

Evaluation of local ancestry differences in multiple sclerosis among US minority populations. *A. Beecham[1,2], L. Amezcua[3], A. Chinea[4], N. Isobe[5], P. Manrique[1], B.T. Lund[3], A. Levy[3], D. Conti[6], G. Beecham[1,2], P. De Jager[7], S. Delgado[8], J. Oksenberg[5], J. McCauley[1,2].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Department of Neurology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 4) San Juan MS Center Guaynabo, Puerto Rico, USA; 5) Department of Neurology, University of California at San Francisco, San Francisco, CA, USA; 6) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 7) Program in Translational NeuroPsychiatric Genomics, Institute for Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, MA, USA; 8) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple Sclerosis (MS) exhibits variable prevalence across populations, with European populations having a higher prevalence than either Hispanic or African. In addition to environmental influences, this observation could be partly due to a greater genetic risk in European populations. Genetic association studies in individuals of European descent have identified 110 established MS risk variants in 103 discrete loci outside of the Major Histocompatibility Complex. Our goal was both to characterize the local ancestry across these loci in genetically admixed samples from Hispanic and African American populations as well as to use local ancestry to identify novel loci which may be related to MS. Data from the Illumina ImmunoChip were available on Hispanic (190 cases and 46 controls) and African American (973 cases and 257 controls) samples. Local ancestry was computed across 125,830 variants (inclusive of 186 fine-mapping regions for both MS and non-MS loci) with RFMix, after first phasing the haplotypes using Beagle. Reference data from 1000 Genomes (400 from each of the African, Asian, and European populations) were used for both phasing and local ancestry calculation. Separately in Hispanic and African American samples, logistic regression was used to test for the association of both the number of European haplotypes and the number of Asian haplotypes observed at each position, after controlling for global European and Asian ancestry. Global ancestry was computed by averaging local ancestry estimates across ~40,000 independent variants outside of known MS loci. In both Hispanic and African American populations we find evidence ($p \le 0.01$) of European admixture difference across known MS loci between cases and controls. In African Americans, at a threshold of $p \le 0.001$, in addition to the established *CD58* locus, which was previously identified in an admixture scan of African Americans; we saw evidence for a decreased number of European haplotypes in cases at the *NOD2* locus (a well-known Crohn's disease locus; novel to MS). In Hispanics, at a threshold of $p \le 0.001$, we saw an increase of both European and Asian haplotypes at the *NXPE1* locus (an established ulcerative colitis locus; novel to MS). The increase in Asian haplotypes among cases was also observed in African Americans ($p \le 0.05$). These results highlight the value of local ancestry evaluation in admixed populations to better characterize known risk loci and to potentially identify novel MS loci.

1044F

Malaria endemicity and genetic risk of hypertension in Africans. *S.M. Raj[1], M. Hansen[2], F. Schlamp[1], J. Hirbo[2], D. Hu[2], S. Soi[2], L. Scheinfeldt[2,3], A. Ranciaro[2], S. Thompson[2], W. Beggs[2,4], C. Lambert[5], M. Ibrahim[6], T. Nyambo[7], S. Omar[8], C. Wambebe[9], D. Meskel[10], G. Belay[10], A.G. Clark[1], S. Tishkoff[2].* 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, 14853; 2) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, 19104, USA; 3) Institute for Genomics and Evolutionary Medicine, Temple University, Philadelphia, PA, 19122, USA; 4) Department of Biology, School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA, 19104, USA; 5) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, 11724, USA; 6) Department of Molecular Biology, Institute of Endemic Diseases, University of Khartoum, Khartoum, Sudan; 7) Department of Biochemistry, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania; 8) Kenya Medical Research Institute, Center for Biotechnology Research and Development, Nairobi, Kenya; 9) International Biomedical Research in Africa, Abuja, Nigeria; 10) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia.

Africans show high incidence and prevalence of the diseases malaria and hypertension. Medical and epidemiological evidence suggests that there may be etiological links between the two diseases. However, these links have not been directly tested at a genetic level. We used population genetics-based approaches to identify correlations between the two diseases in a dataset including 1 million Illumina SNP genotypes in 634 individuals belonging to 39 African populations. First, we used two methods to identify signatures of natural selection, bayenv and hapflk, flagging regions that show high population differentiation as well as correlation with environmental factors. We identified four regions, including one on chromosome 11p15 containing the genes *PPFIBP2* and *CYB5R2*, that showed both high population differentiation as well as a correlation only with malaria endemicity out of a set of twelve environmental variables. SNPs in this region were also associated with elevated blood pressure in published genome-wide association studies. Therefore, we carried out a candidate-gene based association study for SNPs in the region that show malaria-based selection signatures to identify associations with both blood pressure and malaria endemicity. We found a significantly associated SNP ($q<0.02$), with the derived allele corresponding to increased blood pressure. Correlations between SNPs associated with blood pressure and malaria endemicity suggest that genetic variants that play a role in adaptation to malaria may also play a role in risk of hypertension in individuals of recent African origin.

1045W

Genetic contributions to the MHC and LRC regions of a South African population and its effect on TB vaccine efficacy. *M. Salie, H. Schurz, P.D. van Helden, M. Moller, E.G. Hoal.* Biomedical Science, Stellenbosch University, Tygerberg, Western Cape, South Africa.

   Genes in the MHC and LRC regions play important roles in the host immune response to disease and in reproduction, two biological processes essential for the maintenance of the human population. Due to rapid evolution and balancing selection more than 7000 class-I alleles and 400 different KIR profiles have been identified. As populations from geographical regions are under different selective pressures, the frequencies of these loci are known to vary. Differences in disease susceptibility, drug-, and vaccine efficacy between individuals of different ethnicities, highlights the importance of elucidating the genetic profiles of distinct populations. The South African Coloured (SAC) population represents a population with a unique genetic composition with influences from African, Asian and European populations. The global ancestral contributions over chromosomes 6 (MHC) and 19 (LRC) were inferred in the SAC population using three software packages: ADMIXTURE, LAMP-LD and RFMix. LAMP-LD and RFMix was used to infer locus-specific ancestry of the HLA class-I and LRC region. Three reference populations were used: CEU, LWK and JU (Khoisan, Ju/'hoan from Namibia). SAC study participants were genotyped on the Affymetrix 500K Array.We noted differences in the estimated global ancestral contribution to chromosomes 6 and 19 between the different software packages. LAMP-LD inferred a greater proportion of LWK for both chromosomes (44% and 47%), whereas RFMix inferred a greater CEU contribution (34% and 36%). ADMIXTURE showed a greater contribution from the LWK for chromosome 6 (39%) but the CEU for chromosome 19 (37%). Locus-specific analysis noted a larger LWK contribution to the HLA class-I genes, LAMP-LD (>50%) and RFMix (>30%). Conversely, the CEU was noted as having a larger contribution to the LRC region, LAMP-LD (49%) and RFMix (44%). For TB vaccine efficacy we noted that the class-I alleles that bind TB vaccine epitopes Ag85B-ESAT-6, Ag85B-TB10.4 and Mtb72f occurred at low to moderate levels in the South African Black, San and mixed populations. While the SAC population may have a greater proportion of San ancestry based on genome-wide data, the MHC and LRC regions are predominantly of black African or European ancestry, dependent on the software used. Based on class-I allele distribution across SA populations, none of the vaccines currently undergoing clinical trials would be equally efficacious across all SA populations.

1046T

An introgressed Neanderthal haplotype at the alpha-defensin CNV. *X. Xu, J. Armour.* School of Life Science, University of Nottingham, Nottingham, UK.

   The human alpha defensin genes encode an important class of innate immunity effectors. Alpha defensin 1 (*DEFA1*) and 3 (*DEFA3*) are interchangeable gene variants located in a mixed multiallelic copy number variable region (CNV) on 8p23.1. Modern humans have between 3 and 16 copies of *DEFA1/DEFA3*. Recent GWAS studies of IgA nephropathy patients identified two SNPs associated with the disease in the LD block of the *DEFA1A3* CNV. To better understand the origin of modern human diversity at the DEFA1A3 CNV, a phylogenetic analysis of the telomeric and centromeric sequence flanking the CNV was carried out. We identified a putative Neanderthal introgressed haplotype in present-day European populations. Using a molecular clock approach, we found that the upper limit of divergence time between the putative introgressed haplotype and Altai Neanderthal haplotype (220,000 ybp) was more recent than the lower limit of the divergence between other human haplotypes and Neanderthal (670,000 ybp). S* statistics also showed a cluster of derived SNPs in high LD, a characteristic signature of recent introgression. The full length of the introgressed haplotype (~135 kb) was also consistent with Neanderthal introgression. We also demonstrated evidence of introgression inside the *DEFA1A3* CNV repeat. A global distribution of the introgressed haplotype showed that it was mainly distributed in Europe and Indo-European related populations, but absent from African and East Asian populations. We therefore believe this pattern to be a result of a European-specific introgression, after the divergence of Europeans and Asians. The frequency of the introgressed haplotype in European populations is 17.7%, with a higher frequency towards Western Europe. We further evaluated natural selection in this region, and found evidence of positive selection from the integrated Haplotype Score (iHS). The *DEFA1A3* and/or *DEFA5* genes are the likely target of selection. This is the first evidence of archaic introgression reported in a multiallelic copy number variable region, and the potential role of these variants in IgA nephropathy needs to be further evaluated.

1047F

Characterization of *OCA2* gene diversity: Genetic variation and association with skin, hair and eye pigmentation in an admixed Brazilian population. *G. Debortoli[1], L. Marcorin[2], M.L.G. Oliveira[1], A.L.E. Pereira[2], N.C.A. Fracasso[1], J.D. Massaro[3], A.L. Simoes[1], E.A. Donadi[3], E.C. Castelli[4], C.T. Mendes-Junior[2].* 1) Departamento de Genética, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 2) Departamento de Química, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, SP, Brazil; 3) Departamento de Clínica Médica, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 4) Departamento de Patologia, Universidade Estadual Paulista (FMB-UNESP), Botucatu, SP, Brazil.

The *Oculocutaneous Albinism II* (*OCA2*) gene is located in chromosome region 15q11 and has been shown to be involved in normal variation of skin, eye and hair pigmentation. Notwithstanding, the diversity of *OCA2* gene region has not been studied so far and with the extent proposed by this study in an admixed population, as the Brazilian. Thus, to verify if other variation sites across the *OCA2* gene may be associated with human pigmentation, libraries of all the coding exons, intronic boundaries and regulatory regions were analyzed by next-generation sequencing in a Brazilian admixed population sample. Sample was composed of 339 unrelated individuals from São Paulo State, which were stratified according to eye, hair and skin pigmentation. DNA libraries were prepared using Haloplex Target Enrichment System (Agilent Technologies) and sequenced in MiSeq platform (Illumina). CutAdapt, BWA and GATK packages were used for trimming adapter sequences, alignment and genotype calling, respectively. CADD and SNVrap applications were used to annotate the variations effects on the gene sequences. A total of 143 variation sites were identified. Eighteen of these (with 3 of them being novel) presented strong association with at least one pigmentation feature. When subdividing the variation sites associated with pigmentation traits in upstream and promoter region, 5'UTR, coding region (plus intronic boundaries), and 3'UTR, there were identified 5 variations located near or in the promoter region, 2 in the 5'UTR region, 11 in coding regions (2 in exons and 9 in intronic boundaries), and none in the 3'UTR. Associations found relate mostly to dark skin, both light and dark hair and blue eyes. Some findings corroborates with other literature studies such as rs7497270*T allele being associated with dark phenotypes (black hair in our study, p = 0.0045; OR = 19.78), while some associations linked to different traits in other studies were also found (rs7495174*G associated with red-hair - p = 0.0063; OR = 64.47). Among the 3 novel variation sites reported here, one located in chr15:28,347,113 was associated with dark skin (p = 0.0279; OR = 25.45). In addition, an association that was not previously reported was found between rs200081580*G and blue eyes (p = 0.0116; OR = 42.60). These findings emphasize *OCA2* has an important role in human hair, eye and skin pigmentation. FINANCIAL SUPPORT: FAPESP (Grant 2013/15447-0) and CNPq/Brazil (Grant 448242/2014-1 and Fellowship 309572/2014-2).

1048W

Prevalent homozygous *TGM1* mutation in lamellar ichthyosis patients from consanguineous marriages originating from a clustered population in Northern Malaysia. *Z.A.D. Pramono[1], G.K Oh[1], U. Surana[2], W.C. Tan[3], K.F. Leong[4].* 1) Department of Research, National Skin Centre, Singapore, Singapore; 2) A*STAR Intitute of Cellular and Molecular Biology, Singapore; 3) Department of Dermatology, Hospital Sultanah Bahiyah, Alor Setar, Kedah, Malaysia; 4) Institute of Pediatry, General Hospital, Kuala Lumpur, Malaysia.

Autosomal recessive congenital ichthyosis (ARCI) is heterogeneous group of ichthyosis with 9 causative genes have to date been identified. Large part of ARCI is formed by lamellar ichthyosis that (LI) that mainly is caused by mutations in *TGM1*. We performed genetic analyses for 4 patients with LI from 3 families whereby all are consanguineous marriage originating from the same district in North Malaysia. Mutation analyses were performed by PCR and direct sequencing. Possible large deletions were examined by qPCR. We detected homozygous mutation g1166a (Arg389His) in the TGM1 gene in all 4 patients. None of the patients showed large deletions in the *TGM1* gene by qPCR. The Arg389His has previously been reported in LI patients from the US and Japan. The mutation in the highly conserved residue located in the center of the core domain of TGase 1 peptide, close to the active sites, has been predicted to lead to serious loss of TGase activity. This is the first report on the detection of a homozygous *TGM1* mutation among LI patients from consanguineous marriages in a clustered population in Malaysia. The result of this study highlights the need of public education on the risk of consanguineous marriages. Further study may reveal the prevalence of this mutation in the same ethnicity nationwide as well as the region.

1049T

MITF and ASIP genetic variation and associations with skin, hair and eye pigmentation in an admixed Brazilian population. *C. Mendes-Junior[1], A.L.E. Pereira[1], G. Debortoli[2], M.L.G. Oliveira[2], N.C.A. Fracasso[2], J.D. Massaro[3], A.L. Simoes[2], E.A. Donadi[3], E.C. Castelli[4], L. Marcorin[1].* 1) Departamento de Química, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, SP, Brazil; 2) Departamento de Genética, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 3) Departamento de Clínica Médica, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 4) Departamento de Patologia, Universidade Estadual Paulista (FMB-UNESP), Botucatu, SP, Brazil.

Microphthalmia associated transcription factor, MITF, and *Agouti signaling protein, ASIP*, are genes involved in the melanin synthesis pathway. *MITF* is known for its regulatory role in many processes like expression of *TYR, TYRP1* and *DCT*, which are directly involved in melanin synthesis in melanosomes. *MITF* expression can be regulated by *MC1R* interaction with α-MSH, stimulating *MITF* expression, or with *ASIP,* as an α-MSH antagonist, preventing *MITF* expression. Although *ASIP*'s rs6058017 have been associated with darker skin and eye phenotypes in Caucasian populations, there aren't known association studies linking *MITF* diversity and pigmentation traits. This study aimed to find genetic variation in *MITF* and *ASIP* associated with pigmentation traits in a Brazilian admixed population sample ($n = 340$) from the state of São Paulo. Samples were stratified regarding eye, hair and skin color and presence of freckles and premature hair greying. Libraries were prepared using Haloplex Target Enrichment System (Agilent Technologies) for MiSeq Illumina sequencing platform. Adapter trimming, alignment and genotype calling were done using cutadapt, BWA and GATK, respectively. Haplotypes and missing alleles were inferred computationally using PHASE, however, the known phase between variable sites (obtained with GATK) was considered. There were found 177 variation sites in the promoter, intronic, regulatory UTRs and coding regions in both genes (55 in *ASIP* and 122 in *MITF*). For *ASIP*, 17 variations (3 novel) are strongly correlated mostly with dark skin, light hair and blue eyes, and corroborates the previous findings regarding *ASIP*'s rs6058017 association with darker skin ($p=0.0001$; OR=10.89), eye ($p=6.02 \times 10^{-6}$; OR=13.81) and hair ($p=0.0011$; OR=20.63). The strongest correlations found were *ASIP* intronic rs7710617 with type VI skin color (Fitzpatrick) ($p=1.19 \times 10^{-9}$ and OR=330.52). For *MITF*, 19 variations (4 novel) are strongly correlated with dark brown eyes, either the most dark or the most light skin and hair colors and the presence of freckles. Besides singletons, the strongest correlations were found for rs74845300 and rs80232752, which are in perfect linkage disequilibrium within *MITF* upstream regulatory region and associated with black hair ($p=0.0002$ and OR=41.10). These results emphasize the role played by *ASIP* and *MITF* variations in human pigmentation. FINANCIAL SUPPORT: FAPESP (Grant 2013/154470) and CNPq/Brazil (Grant 448242/2014-1 and Fellowship 309572/2014 -2).

Evolution of the 'fused' gene family repeated region across primates. *V. Romero[1], I. Inoue[1], H. Nakaoka[1], K. Hosomichi[2].* 1) Human Genetics, National Institute of Genetics-Japan , Mishima, Shizuoka, Japan; 2) Department of Bioinformatics and Genomics, Kanazawa University, Kanazawa, Japan.

The Epidermal Differentiation Complex (EDC) on chromosome 1 is a dense cluster of genes expressed during the late differentiation of the epidermis and is responsible for maintaining hydration and structure of the skin. The cluster organization of this complex might suggest adaptation during evolution and is strongly associated with a variety of skin disorders. EDC includes the CE precursor family, S100A family and the 'fused' gene family. The 'fused' genes members are: cornulin, filaggrin, filaggrin-2, hornerin, repetin and trichohyalin. These genes have a similar organization showing an initial S100 domain followed by a tandem repeat region and a C-terminal domain. In this study, we focus on the repeat region of each gene and the evolution pathway among primates with short divergence time to fully understand any recent repeat variation. We demonstrated that each member of the 'fused' genes undergo different selective pressure, which suggests a complex model for the adaptive evolution of the EDC. Our results showed that the filaggrin repeat regions within these specific genes have the highest nucleotide diversity between them. The phylogenetic analyses across primates suggest that recent independent duplication events created the repeat sequences of filaggrin in macaque and orangutan, and trichohyalin in marmoset, which are the only ones with phenotype variation related to copy number variation. The comparisons of the repeat sequences detected the signatures of positive selections on filaggrin, filaggrin2, hornerin and repetin within a species and specific codons and branches across species. We suggest that repeat variation across species may be a consequence of non-random events accompanied by species-specific adaptive traits.

1051W

Mutational analysis of causative genes for autosomal recessive spinoc-erebellar degeneration (AR-SCD) to delineate molecular epidemiology of early-onset SCD. *Y. Hama, M. Kanai, Y. Aoshima, Y. Mukai, S. Watanabe, M. Murata, Y. Takahashi.* National Center Hospital, National Center of Neurology and Psychiatry, Kodaira, Japan.

Background: Spinocerebellar degeneration (SCD) is a group of disorders characterized by progressive ataxia caused by dysfunction and atrophy of cerebellum or its afferent or efferent projections. Hereditary SCD is genetically heterogeneous, composed of autosomal dominant (AD), autosomal recessive (AR) or X-linked SCD with more than 50 causative genes. To establish efficient diagnostic algorithms for early-onset SCD excluding AD-SCD, it is imperative to elucidate the molecular epidemiology in these disorders. Purpose: To elucidate the molecular epidemiology of early onset SCD excluding AD-SCD by the mutational analysis of causative genes for AR-SCD. Methods: Subjects with the age of onset under age 40 who were diagnosed as SCD excluding SCA1, SCA2, SCA3/MJD, SCA6, SCA8, SCA12, SCA17, SCA31, DRPLA, ataxia oculomotor apraxia type 2 (AOA2) or ataxia with vitamin E deficiency (AVED) were enrolled in this study. DNA samples obtained with informed consent were subjected to the mutational analysis of the whole exons of *APTX*, *SACS* and *SPG7* employing direct nucleotide sequencing method. This study was approved by the Institutional Review Board of National Center of Neurology and Psychiatry. Results: Among 191 patients with the diagnosis of SCD registered in our cohort, 36 patients consisting of 24 males and 12 females fulfilled the enrollment criteria. The mean age of onset was 10 years old (ranges: 0 - 39). In this cohort, 36 variants were identified. Among them, we identified novel compound heterozygous frameshift variants in *SACS*, which were considered as pathogenic mutations. The patient was thirty five years old female with slowly progressive gait disturbance and dysarthria complicated with cognitive impairment and deafness. Her brain T2-MRI showed low intensity lesions in pons and high intensity lesions in the outer edge of thalamus. All her clinical presentation, neurological findings, and MRI were characteristic of ARSACS. No pathogenic mutations were identified in *APTX* or *SPG7*. Conclusion: This study revealed that *AOA1*, *AR-SACS*, or *SPG7* is not a frequent cause in the early-onset SCD in the Japanese population. Considering the substantial genetic heterogeneity of AR-SCD, exome-first approach would be efficient for genetic diagnosis of early-onset SCD.

Admixture mapping of established HLA and non-HLA multiple sclerosis risk variants in 24,786 individuals shows evidence for European origin in Hispanics. *C. Chi[1,2], X. Shao[1], B. Rhead[1,2], E. Gonzalez[3], J.B. Smith[3], C. Schaefer[4], L.F. Barcellos[1,2], A.M. Langer-Gould[3,5].* 1) Genetic Epidemiology and Genomics Laboratory, UC Berkeley, Berkeley, CA; 2) Computational Biology Graduate Group, UC Berkeley, Berkeley, CA; 3) Kaiser Permanente Southern California, Department of Research & Evaluation; 4) Kaiser Permanente Division of Research, Oakland, CA; 5) Southern California Permanente Medical Group, Los Angeles Medical Center, Neurology Department.

Multiple Sclerosis (MS [MIM 126200]) is a demyelinating autoimmune disease with both genetic and environmental risk factors. MS genetic risk variants are hypothesized to originate in Europeans, but it is unclear whether risk variants exist in other ancestral populations, as previous studies have focused primarily on White populations. In this study, we performed admixture mapping in a diverse group of African American, Hispanic, and non-Hispanic White individuals (2,153 MS cases, 22,633 controls) from Northern and Southern California for whom we have whole genome data and race-ethnicity data through self-report. Preliminary estimates from fastStructure show evidence for case-control differences in global European ancestry proportions in Hispanics. However, ancestry estimates were similar between cases and controls in non-Hispanic White and African-American populations. In Hispanics, an average of 54% and 52% European ancestry was observed from fastStructure in cases and controls, respectively. Local ancestry estimation using LAMP show this global difference was reflected by ancestry estimates for 110 non-HLA MS risk variants established through recent GWAS. Local ancestry for each risk variant was considered together and individually. The local European ancestry proportion between Hispanic cases and controls for the top 20 risk variants had an average difference of 3.09%, most of which revealed greater European ancestry in cases. In contrast, the average difference in all non-Hispanic Whites for the top 20 MS risk variants was only -0.045%. Greater European ancestry was not observed in African-American cases nor controls for the majority of MS risk variants. Local ancestry estimates were also derived for the major histocompatibility complex (MHC) region overall and separately in class I, II and III regions. A similar trend in Hispanics was most notably observed in the MHC class I region, with an average of 47% and 44% European ancestry in cases and controls, respectively. The result that Hispanics exhibit greater European ancestry in cases versus controls supports the hypothesis that MS risk variants are primarily of European origin. However, the absence of this difference in African Americans suggests the possibility of undiscovered MS risk variants in other ancestral populations. Further work is underway to fully characterize the ancestral contributions of each candidate region, and to identify new risk variants through whole genome admixture mapping.

Language impairment in ASD and schizophrenia resulting from opposite failed domestication itineraries of the human brain. *A. Benítez-Burraco[1], E. Murphy[2], W. Lattanzi[3].* 1) Philology, University of Huelva, Huelva, Spain; 2) Division of Psychology and Language Sciences, University College London, London, United Kingdom; 3) Institute of Anatomy and Cell Biology, Università Cattolica del Sacro Cuore, Rome, Italy.

Schizophrenia (SZ) and autism spectrum disorders (ASD) are pervasive, highly prevalent neurodevelopmental disorders entailing social and cognitive deficits, including marked language deficits. Numerous genes have been associated with both conditions, but it is not clear how language deficits arise from gene mutation or gene dysregulation. In this study we have adopted an evo-devo approach to address this issue. On the devo side, we will build on the hypothesis that SZ and ASD represent opposite poles within a developmental continuum of human cognition, also encompassing the normal faculty of language. On the evo side, we have built on the hypothesis that the emergence of a modern faculty of language was brought about by changes in the human brain/skull, but also by the self-domestication of the human species. We show that people with ASD exhibit less marked domesticated traits at the morphological, physiological, and behavioural levels, whereas people with SZ show more marked domesticated traits. We also show that many candidates for both conditions are represented among the genes known to be involved in the "domestication syndrome" (the constellation of traits exhibited by domesticated mammals, which seemingly results from the hypofunction of the neural crest), and among the set of genes involved in language function that interact with them. We have performed comparative *in silico* analysis of genome-wide brain expression datasets, from humans and chimps. This allowed us to demonstrate that several of these genes exhibit altered expression in the brains of ASD and SZ patients. Interestingly, some candidates for domestication and language-readiness exhibited similar expression trends between ASD patients and chimps, while opposite trends between SZ patients and chimps, in brain areas involved in language processing. We conclude that ASD and SZ (and specifically, language deficits in each condition) may represent abnormal ontogenetic itineraries for the human faculty of language, resulting in part from opposite changes in genes important for the "domestication syndrome" and, ultimately, from the normal functioning of the neural crest.

Polygenic adaptation and how it may explain the 'evolutionary paradox'. *P.F. O'Reilly, E. Vassos, J. Maxwell, C.M. Lewis.* MRC SGDP Centre, King's College London, London, United Kingdom.

Tests for detecting natural selection in the human genome have typically focused on identifying signatures of selection at individual loci. This implicitly assumes alleles of sufficiently large phenotypic effect to leave a discernible trace in contemporary genetic data. However, GWAS have demonstrated that most human phenotypes are governed by many hundreds or even thousands of variants of tiny effect. Therefore, the mark left on the genome by selection will often be polygenic and too subtle to detect at any one locus. Using the latest publicly available GWAS we demonstrate that the risk allele frequencies for numerous diseases and psychiatric disorders are systematically lower than expected by chance, while other traits associated with increased fecundity, such as height, have systematically higher than expected frequency. Next we investigate how risk alleles for psychiatric disorders associated with particularly low fecundity may be maintained in the population (the 'evolutionary paradox'). Using polygenic risk scores and UK Biobank data, we show that having an increasing genetic load for disorders such as schizophrenia and autism is in fact beneficial for a number of behavioural traits, such as cognitive ability, risk taking and well-being - until an extreme genetic load is reached, which produces negative outcomes. Thus whether an allele is beneficial or deleterious is dependent on the overall genetic load relating to a phenotype in the individual, rather than being a fixed feature of the allele.

Association of sleep disorders with neuropeptide receptor genes polymorphism in male population in Russia/Siberia. *V. Gafarov, E. Gromova, M. Voevoda, I. Gagulin, V. Maximov, A. Gafarova, D. Panov.* FSBI Institute of Internal and Preventive Medicine, NOVOSIBIRSK, NOVOSIBIRSK, Russian Federation.

Objective: To study the association gene of candidate NPSR1 rs324981 with sleep disorders in the open population of men 45-64 years of Novosibirsk. Methods: The study of the association candidate gene polymorphisms with sleep disorders was carried out during the examination of a random representative sample of men 45-69 years (n = 1770). The response rate was 61%. The median age is 56.5 year. Every 12 subject was selected for genotyping (n = 147). To assess the level of sleep was used a questionnaire which was filled with self-test. Statistical analysis was performed using SPSS-11.5. Results: The level of sleep disorders in the male population of 45-64 years was 79.9%. The frequency of homozygous C / C genotype of neuropeptide S (gene NPSR1 rs324981) was 19.4%, T / T genotype occurs in 27.8%, C / T genotype - 52.8%. Men dominated the T allele of -54.2%, and the C allele - 45.8% growth trend Fnd dissatisfaction with the quality of their sleep among men. Men T- allele carriers, most evaluated their sleep as "satisfactory" in 69% of cases, ($\chi2$ = 15,713 df = 8, p <0.05). Conclusion Association found men carrier T - allele of neuropeptide S (gene NPSR1 rs324981), a sleep disorder. Supported by Grant of Russian Foundation for Humanities No14-06-00227/a.

Assessing population genetic evidence of selection across neuropsychiatric phenotypes. *E.R. Beiter[1], E.A. Khramtsova[2], C. Simonti[3], S. Dalvie[4], C. Van Der Merwe[4], D. Stein[4], J.A. Capra[3], J. Knowles[5], L. Davis[6], B. Stranger[2].* 1) Washington University, Saint Louis, MO; 2) Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, IL; 3) Vanderbilt Genetics Institute; Department of Biological Sciences, Vanderbilt University, Nashville, TN; 4) Department of Psychiatry, Faculty of Health Sciences, University of Cape Town; 5) Department of Psychiatry and The Behavioral Sciences, Univesity of Southern California; 6) Vanderbilt Genetics Institute; Department of Medicine, Division of Genetic Medicine, Vanderbilt University Medical Center, Nashville, TN.

Variation in neuropsychiatric traits is present across diverse human populations, has persisted across recorded history, and has a genetic basis primarily accounted for by common (minor allele frequency > 5%) single nucleotide polymorphisms (SNPs). Given recent observations that polygenic risk for neuropsychiatric phenotypes is correlated to many non-neuropsychiatric complex traits (Bulik-Sullivan et al., 2015), and that SNPs with high minor allele frequency (MAF) contribute disproportionately to some neuropsychiatric phenotypes (Davis et al., 2013), we were interested in systematically characterizing signatures of positive selection across nine neuropsychiatric traits. We performed a multi-level analysis using genome-wide association study summary statistics provided by the Psychiatric Genomics Consortium to detect evidence of 1) extreme integrated haplotype scores (iHS > 2.0) demonstrating recent strong positive selection (i.e., hard sweeps), 2) population differentiation (F_{ST} > 0.3), 3) polygenic selection, and 4) enrichment of trait-associated alleles in regions intolerant to Neanderthal introgression (S-score < 5%), among SNPs nominally associated with each trait (p < 5.0 x 10[-3]). For each set of trait-associated SNPs, we used SNP-SNAP tool to generate 500 sets of null SNPs matched on minor allele frequency (MAF), distance to nearest gene, and gene density, then compared the proportion of trait-associated SNPs with extreme iHS, F_{ST} and S-scores to their respective matched null distributions. Consistent with expectations for polygenic phenotypes, no trait displayed significant enrichment of population differentiated SNPs or strong recent positive selection. However, we did identify enrichment of risk alleles for schizophrenia (p < 0.002) within regions of the genome intolerant to Neanderthal introgression. Finally, a recently published method (Berg and Coop, 2014) for detecting polygenic selection was also applied to each phenotype. The polygenic adaptation approach detects coordinated and systematic shifts in MAF of trait-associated SNPs while accounting for genetic drift measured across 52 populations. Taken together, our results suggest that individual common risk alleles for neuropsychiatric phenotypes are unlikely to have been the targets of strong recent positive selection (i.e., hard sweeps).

1057W

An investigation of the evolution and worldwide distribution of the READ1 element in *DCDC2* **and its contribution to language development.** *M.M.C. DeMille[1], J.C Frijters[2], K. Tang[4], C. Geissler[4], N.R Powers[1], B.M. Bowen[3], A.K. Adams[3], D.T. Truong[1], J.R. Gruen[1,3].* 1) Department of Pediatrics, Yale University School of Medicine, New Haven, CT; 2) Child and Youth Studies, Brock University, St. Catharines, ON, Canada; 3) Department of Genetics, Yale University School of Medicine, New Haven, CT; 4) Department of Linguistics, Yale University, New Haven, CT.

The DYX2 locus (6p21.3), containing dyslexia candidate genes *DCDC2* and *KIAA0319*, is the most replicated locus for reading disability (RD) and language impairment (LI) worldwide. READ1, located in intron 2 of *DCDC2*, is a multi-unit transcriptional control element with approximately 40 known alleles. Previous research has shown that repeat unit (RU) length groupings of alleles of READ1 (RU1-1 and RU2-long) are associated with RD. We have also demonstrated epistasis between READ1 alleles and a RD risk haplotype spanning *KIAA0319*. Furthermore, an *in vitro* reporter gene assay demonstrated that READ1 alleles alter expression from the *DCDC2* promoter and chromatin conformation capture indicates that READ1 interacts physically with a region upstream to the *KIAA0319* promoter *in vivo*, suggesting regulation of *KIAA0319* expression as the mechanism of epistasis between READ1 and *KIAA0319*. Taken together, READ1 in *DCDC2* and *KIAA0319* are strongly implicated in RD, with functional studies elucidating a potential molecular mechanism in its etiology. We have investigated the evolution and worldwide distribution of the READ1 element, with an eye toward language development. While *DCDC2* was identified as a RD gene, it may also influence normal variation in language. First, we estimated the mutational history of the READ1 element by examining primate and archaic hominin sequences. We found that the duplication of RU1 occurred after the split between chimps and humans. Additionally, we found that RU2 did not have greater than 4 repeats until after that split. We also examined the worldwide distribution of READ1 alleles in 58 populations among five different continental groups and discovered correlations between the allele frequencies of READ1 and several attributes of the languages used in a given culture: phoneme number (RU1-1, $p = .006$), consonants (RU1-1, $p = .0151$ and RU2-short, $p = .0179$), tones (RU1-1, $p =.0084$), and ratio of consonants to vowels (RU1-1, $p = .0091$; RU2-long, $p = .0056$; rs9461045T, $p = .0104$). We also showed a significant interaction between the SNP rs9461045 (a SNP in the *KIAA0319* risk haplotype) and READ1 alleles in this correlation. The higher the proportion of RU2-long in the population, the stronger the negative relationship between the derived allele T of SNP rs9461045 and the number of consonants in a population. We hypothesize that alleles of READ1 may have influenced the type of written and spoken language developed by a given culture.

Doubts and wavering in mitochondrial DNA forensics: While interpreting length heteroplasmy conundrum of various Sindhi and Baluchi ethnic groups of Pakistan. *S. Bhatti[1], M. Aslamkhan[2], S. Abbas[3], M. Attimonelli[4], H.K. Aydin[5], E.M.S. de Souza[6].* 1) Department of Human genetic and Molecular biology, University of Health Sciences, Lahore, Punjab, Pakistan; 2) Department of Human Genetics and Molecular biology, University of Health Sciences Lahore-54600, Pakistan; 3) Institute of Molecular Biology and Biotechnology, University of Lahore-54600, Pakistan; 4) Department of Biosciences, Biotechnologies and Biopharmaceutics, University of Bari, Bari, Italy; 5) Department of Medical Biochemistry, Ege University School of Medicine, Bornova Izmir, Turkey; 6) Instituto Nacional de Pesquisa, Manaus Programa de Pós Graduação em Genética, Conservação e Biologia Evolutiva. Instituto Nacional de Pesquisas da Amazônia Av. André Araújo, 2936, Aleixo, Manaus, AM 69060-001, Brazil.

The insight heterodox genetics of mtDNA provides new perspectives at the level of human mitochondrial control region heteroplasmy, which is significant in evolutionary as well as forensic interpretation. The main goal of this study is to interrogate the recurrence and resolve the ambiguity of blurry spectrum of heteroplasmy in the human mtDNA control region of 50 Baluchi and 116 Sindhi unrelated individuals. Sanger sequencing was used classically, which was further investigated by minisequencing. Only 20% Baluchi and 25.8% Sindhi were homoplasmic, whereas rest of 80 % Baluchi and 74.1% Sindhi showed at least one heteroplasmy within the specimen. In total 166 individuals have length heteroplasmy (LH) found to be at position 16189, 303-315, 568-573, and 514-524, whilst point mutation heteroplasmy (PMH) was detected at position 73, 16093, 16189 and 16234 respectively. Overall LH was observed albeit high frequency in Sindhi ethnic group (82%) rather than Baluchi's (37%), whereas PMH accumulation relatively more (24%) in Baluchi ethnic groups followed by low percentage (11.2%) observed in Sindhi ethnic groups. The obtained results underline the necessity that growing knowledge of heteroplasmy, helps to develop a consciences in the forensic community that heteroplasmy plays a pivotal role in the forensic interpretation on a regular basis and knowledge of its biological underpinnings has a vital niche in the forensic sciences. Limited studies has focused on heteroplasmy, yet scientific attention should be given, in order to determine its magnitude in different ethnic boundaries. **Key words:** Mitochondrial DNA heteroplasmy, Control region, Sanger sequencing, Baluchistan, Sindh, Pakistan.

p.P347Q Rhodopsin mutation is a recurrent founder allele in Brazilian individuals with autosomal dominant retinitis pigmentosa. *E.M. Jones[1,2], F.B.O. Porto[3,4], Z. Soens[1,2], R.T. Simoes[5], Y. Li[1,2], R. Chen[1,2,6,7,8].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) INRET - Clínica e Centro de Pesquisa, Belo Horizonte, Minas Gerais, Brazil; 4) Departamento de Retina e Vítreo, Centro Oftalmológico de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; 5) Instituto de Ensino e Pesquisa da Santa Casa de Belo Horizonte, Belo Horizonte, Minas Gerais, Brazil; 6) Structural and Computational Biology and Molecular Biophysics Graduate Program, Baylor College of Medicine, Houston, TX; 7) The Verna and Marrs Mclean Department of Molecular Biology, Baylor College of Medicine, Houston, TX; 8) Program in Developmental Biology, Baylor College of Medicine, Houston, TX.

   PURPOSE: The p.P347Q *RHO* mutation is responsible for almost 30% of the autosomal dominant Retinitis Pigmentosa (adRP) in Minas Gerais (MG) – Brazil. The purpose of this study was to describe: the segregation of the p.P347Q *RHO* mutation in 6 unrelated families from the small isolated city of Tabuleiro-MG; the haplotype reconstruction; and the clinical characteristics of the p.P347Q allele. **METHODS:** Visual acuity, retinography, autofluorescense and OCT were performed on 23 patients, and full-field ERG on 6 patients. Blood samples were collected on 23 patients (17 affected and 6 non-affected, ranging from 2 to 61 years old). Three probands were sequenced using a targeted capture panel including 224 known retinal disease genes. Next-generation sequencing (NGS) data was then aligned, processed and filtered against control datasets using an in-house custom pipeline. Identification of p.P347Q from NGS data in each of the unrelated probands was validated through Sanger sequencing. DNA samples of the probands' parents and additional unrelated individuals linked to Tabuleiro were then collected and Sanger sequenced for the presence of p.P347Q. Informative captured SNPs were used to infer haplotypes across each of these individuals. **RESULTS:** A C to A transversion at position 1040 (p.P347Q) of the cDNA has been identified in all 12 RP individuals currently sequenced for the variant. All individuals with this mutation had early-onset night blindness and substantial visual field losses as teenagers. All patients who underwent full field ERG testing demonstrated non-recordable ERGs. Autofluorescence retinography showed maculopathy and a hipoautofluorescent ring around the optic disc in all patients. Lastly, on the basis of conserved haplotypes linked to this pathogenic variant, we propose that p.P347Q spread through a cohort of geographically isolated families by a preceding founder effect. **CONCLUSIONS:** The p.P347Q allele represents a founder mutation causing a rapidly progressive form of adRP in our distinct population. The identification of this founder effect and subsequent mutation may greatly simplify the molecular diagnosis of relevant disease in this population with important implications for the speed and cost-efficiency of diagnostic screening and prognostic counseling.

1060W

***RUNX2* and skull evolution: Insights from ancient DNA and gene expression in calvarial sutures of nonsyndromic cranisynostosis patients.** *W. Lattanzi[1], L. Di Pietro[1], M. Barba[1], P. Frassanito[2], M. Baranzini[1], L. Massimi[2], G. Tamburrini[2], A. Benítez-Burraco[3].* 1) Institute of Anatomy and Cell Biology, Università Cattolica del Sacro Cuore, Rome, Italy; 2) Institute of Neurosurgery, Università Cattolica del Sacro Cuore, Rome, Italy; 3) Department of Spanish Philology and its Didactics, Universidad de Huelva, Spain.

   The concerted skull-brain evolution occurred through a modification in the rate and timing of neurocranium ossification, specifically in the frontal region, with delayed ossification of the metopic suture being a key feature. The *RUNX2* gene, encoding a master transcription factor and downstream effector of most signaling pathways orchestrating craniofacial development, played a key role in this process. Signs of positive selection in the modern human variant of the gene have been demonstrated, by deciphering ancient hominin genomes*;* also, human and primate RUNX2 proteins show significant aminoacid changes. In humans, *RUNX2* mutations are responsible for craniofacial phenotypes including metopic synostosis. The aim of this study is to assess whether *RUNX2* functional status changed during evolution, as being involved in site-specific suture patterning that modified skull shape over time. Bioinformatic tools were used to align and compare the *RUNX2* gene in Neanderthal, Denisovan and modern humans (AMH), and map all the sequence changes that have occurred during recent evolution. The functional effect of the detected changes, with regard to alternative isoforms' transcription and gene expression regulation, was predicted *in silico*. Thereafter, *RUNX2* isoform-specific expression was analyzed in suture specimens collected from nonsyndromic craniosynostosis patients. We identified > 570 fixed changes within noncoding regions of the *RUNX2* gene, including nucleotide substitutions, indels, and annotated human SNPs; these were mostly overlapping in AMH-versus Neanderthal and Denisovan genes. Selected changes mapped within the two promoters of the gene, although they apparently do not affect isoforms' expression, based on *in silico* prediction. In addition, changes in the 3'UTR were detected that were putatively able to affect miRNA binding. Additionally, we found that the expression of *RUNX2* isoforms increased in fused coronal, lambdoid and metopic, but not sagittal, sutures compared with site-matched unfused sutures. Interestingly, by comparing suture sites, we detected an isoform-specific decrease of *RUNX2* expression in metopic versus other suture sites. These results allowed confirming a specific role of *RUNX2* in determining the changes in skull morphogenesis during AMH evolution. This should reasonably affect also brain and cognitive abilities, given that *RUNX2* is functionally related to genes important for brain development and cognitive function, including language.

1061T

Genes that are routinely subject to inactivation and genes that routinely escape inactivation are highly expressed, and are candidates in Turner syndrome phenotype. *S. Brotman[1], M. Wilson Sayres[1,2].* 1) School of Life Sciences, Arizona State University, Tempe, AZ; 2) Center for Evolution and Medicine, The Biodesign Institute, Tempe, AZ.

Individuals with Turner syndrome (45,X) exhibit wide variation in phenotypes. Differential dosage of genes on the X chromosome likely contributes to this phenotypic variation due to the partial or complete loss of one X chromosome in individuals with Turner syndrome. The process of X-inactivation silences expression of genes on all X chromosomes in excess of one. However, approximately 15% of the genes located on the silenced X chromosome(s) escape inactivation. This allows individuals with a typical (46,XX) karyotype to have expression of two copies of a gene, whereas individuals with Turner syndrome will only have expression from one copy, making the subset of escaping genes likely candidates for affecting the phenotype of people with Turner syndrome. In this study, we use an evolutionary approach to identify candidate genes that may contribute to the variation in phenotype among individuals with Turner syndrome. We confirm previous results that methylation pattern differs between genes with different inactivation statuses, in individuals with two X chromosomes, but not in individuals with Turner syndrome. We then jointly analyze estimates of variable X-inactivation status across multiple 46,XX individuals alongside patterns of gene expression on the X chromosome across five tissues in ten species. Our results suggest that genes that are subject to inactivation in all individuals and genes that escape inactivation in all individuals show high levels of expression (whereas genes that are heterogeneously inactivated across individuals are typically lowly expressed). This is consistent with selection acting on these two classes of dosage sensitive genes on the X chromosome. We expect variation in these genes to affect phenotype when the dosage is altered from normal levels.

1062F

Medical Genome Reference Bank – A comprehensive and integrated genome/phenome resource generated from a disease deplete, elderly population. *M.E Dinger[1], A. Stone[1], W. Kaplan[1], P. Lacaze[2], R.L. Woods[2], J.J. McNeil[2], S. Redman[3], B. Armstrong[3], D.M. Thomas[1].* 1) Garvan Institute, Sydney, NSW, Australia; 2) Monash University, Melbourne, VIC, Australia; 3) Sax Institute, Sydney, NSW, Australia.

The Medical Genome Reference Bank (MGRB) will house whole genome sequencing (WGS) data and rich phenotypic information from 4,000 healthy Australians over 70 years of age. The reference bank will act as a powerful filter to distinguish between causal and passenger genetic variation, and will be a resource to maximise the efficiency of disease-specific genomic analyses in both the research and clinical setting. MGRB participants, consented through contributing studies, 45 and Up (Sax Institute, Sydney), and the ASPirin in Reducing Events in the Elderly (ASPREE) clinical trial (Monash University, Melbourne), are free from cardiovascular disease, degenerative neurological disorders and of a history of a cancer. WGS is performed on the Illumina HiSeq X-Ten platform at the Garvan Institute of Medical Research (Sydney, Australia) under clinically accredited conditions (ISO 15189). Data is aligned and variant files are generated using best practice (GATK, BWA) pipelines to make results interoperable with other cohorts. Joint-called variants are loaded into an analytical framework (developed in partnership with Genome England) to enable the interrogation of genomic variants together with advanced filters based on clinical traits and genomic annotations. Curated data will be openly accessible to the international research community through an MGRB website. Preliminary features will include a data Beacon, extensive variant annotation, complex population-based clustering queries, visualisation of variant data (e.g. genome viewer/ gene networks) and analysis tools for assessing the genetic burden of individual variants and variant subsets. While basic demographic and phenotypic information will be incorporated into the MGRB data portal, researchers are invited to apply for access to comprehensive genotypic and clinical information to support high-level integrative analysis. The MGRB data portal is scheduled for launch in late 2016, providing researchers access to data from 1,500 individuals in the first instance; increasing to 4,000 individuals throughout 2017.

1063W

CGHD: A database with a user-friendly interface for genome-wide association study by whole-genome sequencing and genome-wide genotyping microarray of the Taiwanese population. *W. Fan[1], S. Su[1,2], C. Wang[2,3], W. Chung[1,2,3,4].* 1) Whole-Genome Research Core Laboratory of Human Diseases, Chang Gung Memorial Hospital, Keelung, Taiwan; 2) Chang Gung Immunology Consortium, Chang Gung Memorial Hospital and Chang Gung University, Taoyuan, Taiwan; 3) Department of Dermatology, Drug Hypersensitivity Clinical and Research Center, Chang Gung Memorial Hospital, Taipei, Linko and Keelung, Taiwan; 4) School of Medicine, College of Medicine, Chang Gung University, Taoyuan, Taiwan.

The Chang Gung Memorial Hospital reported the construction of a Taiwanese population reference database (CGHD; Chang Gung Human Database) including 250 whole-genome sequencing and 756 genome-wide genotyping microarray of healthy Taiwanese individuals. Here we identify through this high-coverage sequencing (31.7-fold on average), 15.7 million single-nucleotide variants (SNVs) and 2.6 small insertions and deletions (small Indels, size ≤ 50 base pairs). We also catalogued structural variants (SVs), including 1.4 million insertions and deletions, and 6,962 copy-number variants (CNVs). The CGHD was effective for imputing genotypes of the Taiwanese population genome wide. These data demonstrate the value of high-coverage sequencing for constructing population-specific variant panels and for identifying causal rare variants of complex human disease phenotypes in genetic association studies, such as phenytoin-related severe cutaneous adverse reactions. In addition, we build a webserver with a user-friendly interface for searching and analyzing variant with the information of gene structures, CGHD, 1000g, Ex6500, ploy-phen2 and so on. The availability of such in-house database will form a solid foundation for optimizing the quality of genomic research and test conducted in Taiwan.

1064T

Testing differential genetic flow across Sinai and Bab-el-Mandeb. *D. Platt[1], L. Parida[1], S. Basu[2], P. Zalloua[3,4].* 1) IBM T. J. Watson Research Center, Yorktown Hgts, NY; 2) Department of Mathematics, Purdue University, West Lafayette, IN; 3) Lebanese American University, School of Medicine, Beirut 1102 2801, Lebanon; 4) Harvard School of Public Health, Boston, MA, USA.

It has been established that SNP evidence suggests that the dominant out-of-Africa movement occurred across the Sinai rather than Bab-el-Mandeb, even though recombination event data suggests stronger admixture across Bab-el-Mandeb. Subsequent gene flow could have occurred at either or both, especially as trade routes opened up carrying spices, silk, and incense, along with water-borne commerce on the Red Sea, which supported rich trading empires in Djibouti and Yemen. These activities make the region an excellent testing ground to identify broader-based genetic lineages between populations. PCA extracts correlated structure in data allowing for identification of a small number of dimensions that capture most of the detail of Euclidean distances. If those are genetic distances, marking populations differentiated by accumulated mutations in isolation, then a large portion of evolutionary history can be identified in a small number of components. However, PCA is insensitive to structure on the thin axes, e.g. smaller numbers of alleles that emerged recently that distinguish genetically similar populations. Fisher's linear discriminant with Rao's extension provide a way to identify differentiation along those thin axes, as well as p-values via random permutations in a general ANOVA decomposition framework. Such frameworks include nested hierarchic structures, such as AMOVA. We applied multiple modes of analysis using 1087 samples from SW Asia and Africa. For simple one-way ANOVA decomposition, we show that Linear Discriminant Analysis (LDA) yields stronger differentiation compared to chance via random permutations of assignments) for regional coarser grained groups rather than finer grained national groups. Further we show much more homogeneity across the Sinai (more homogenous than chance, p-value = 0.0302) rather than Bab-el-Mandeb (less homogenous than by chance, p-value=$6.29 \cdot 10^{-24}$), contrasting the Saudi Peninsula with the connecting African regions. We report and contrast these results with other ANOVA decompositions on LDA, on computational homology, and with Patterson et al's f3 and f4 statistic results. Our data supports the conclusion that the dominant genetic flow occurred over Sinai, with subsequent admixture primarily by that route.

1065F

ACTN3 R577X and ACE I/D gene variants influence performance in elite sprinters: A multi-cohort study. *I.D. Papadimitriou[1], A. Lucia[2], Y.P. Pitsiladis[3], V.P. Pushkarev[4], D.A. Dyatlov[5], E.F. Orekhov[5], G.G. Artioli[6], J.P.L.F. Guilherme[6], A.H. Lancha Jr[6], V. Ginevičienė[7], P. Cieszczyk[8], A.M. Karlowska[8], M. Sawczuk[8], C.A. Muniesa[9], A. Kouvatsi[10], M. Massidda[11], C.M. Calò[11], F. Garton[15], P.J. Houweling[15], G. Wang[3], K. Austin[3], A.M. Druzhevskaya[12], I.V. Astratenkova[13], I.I Ahmetov[14], D.J. Bishop[1], K.N. North[15], N. Eynon[1].* 1) Institute of Sport, Exercise and Active Living (ISEAL), Victoria University, Victoria 8001, Australia; 2) Universidad Europea and Research Institute Hospital 12 de Octubre, Madrid, Spain; 3) FIMS Reference Collaborating Centre of Sports Medicine for Anti-Doping Research, University of Brighton, Brighton, UK; 4) Clinical Physiology Laboratory, Urals Research Centre for Radiation Medicine, Chelyabinsk, Russia; 5) Ural State University of Physical Culture, Chelyabinsk, Russia; 6) School of Physical Education and Sport, University of Sao Paulo, Sao Paulo, Brazil; 7) Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania; 8) Department of Physical Culture and Health Promotion, University of Szczecin, Szczecin, Poland; 9) Faculty of Physical Activity, Universidad Europea de Madrid, Alcobendas, Spain; 10) Department of Genetics, Development and Molecular Biology, Aristotle University of Thessaloniki, Thessaloniki, Greece; 11) Department of Life and Environmental Sciences, University of Cagliari, Cagliari, Italy; 12) Sports Genetics Laboratory, St Petersburg Research Institute of Physical Culture, St. Petersburg, Russia; 13) Department of Physiology, St Petersburg State University, St. Petersburg, Russia; 14) Sport Technology Research Centre, Volga Region State Academy of Physical Culture, Sport and Tourism, Kazan, Russia; 15) Murdoch Childrens Research Institute, Melbourne, Australia.

To date, studies investigating the association between ACTN3 R577X and ACE I/D gene variants and elite sprint/power performance have been limited by small cohorts from mixed sport disciplines, without quantitative measures of performance. To examine the association between these variants and sprint time in elite athletes we collected a total of 555 best personal 100-, 200-, and 400-m times of 346 elite sprinters in a large cohort of elite Caucasian or African origin sprinters from 10 different countries. Sprinters were genotyped for ACTN3 R577X and ACE ID variants. On average, male Caucasian sprinters with the ACTN3 577RR or the ACE DD genotype had faster best 200-m sprint time than their 577XX (21.19 ± 0.53 s vs. 21.86 ± 0.54 s, p=0.016) and ACE II (21.33 ± 0.56 vs. 21.93 ± 0.67 sec, p=0.004) counterparts and only one case of ACE II, and no cases of ACTN3 577XX, had a faster 200-m time than the 2012 London Olympics qualifying (vs. 12 qualified sprinters with 577RR or 577RX genotype). Caucasian sprinters with the ACE DD genotype had faster best 400-m sprint time than their ACE II counterparts (46.94 ± 1.19 s vs. 48.50 ± 1.07 s, p=0.003). Using genetic models we found that the ACTN3 577R allele and ACE D allele dominant model account for 0.92 % and 1.48 % of sprint time variance, respectively. Despite sprint performance relying on many gene variants and environment, the % sprint time variance explained by ACE and ACTN3 is substantial at the elite level and might be the difference between a world record and only making the final.

Blood nitric oxide regulation and genetic adaptation of Tibetans to high altitude hypoxia. *Y. He[1,4], C. Cui[2], X. Qi[1], W. Ouzhuluobu[2], Y. Peng[1], H. Zhang[1], Y. He[1,4], W. Yangla[2], W. Dejiquzong[2], W. Baimakangzhuo[2], W. Duojizhuoma[2], Y. Pang[2], W. Cirenyangji[2], W. Baimayangji[2], W. Gonggalanzi[2], C. Bai[2], W. Bianba[2], T. Wu[3], B. Su[1,2].* 1) State Key Laboratory of Genetic Resources and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming 650223, China; 2) High Altitude Medical Research Center, School of Medicine, Tibetan University, Lhasa 850000, China; 3) National Key Laboratory of High Altitude Medicine, High Altitude Medical Research Institute, Xining 810012, China; 4) Kunming College of Life Science, University of Chinese Academy of Sciences, Beijing 100101, China.

Tibetans are indigenous highlanders who are well adapted to high-altitude hypoxic conditions. As an important vasodilator, nitric oxide(;NO);has been highlighted in previous studies with a potential role in hypoxic adaptation of Tibetans. It was shown that highlander Tibetans exhibited greatly elevated levels of circulating NO products when compared to lowlanders. However, the observed higher blood NO concentration of high-altitude Tibetans could be caused merely by altitude difference because the previous report did not test NO levels in lowlanders living at high altitude. In this study, using ozone-based chemiluminescence, we measured blood NO concentration of 1,581 individuals, including 335 Han and 520 Tibetans living in Lhasa (elevation: 3,680m), 507 Tibetans living at 4,700m and 219 Tibetans living at 5,370m. We found that consistent with previous report, high-altitude Tibetans have a higher NO level compared to lowlanders (OR=1.87, p=0.0025). But surprisingly, Han residents in Lhasa exhibited a significantly higher NO level than Lhasa Tibetans (OR=2.35, p<0.0001). At higher altitudes (4,700m and 5,370m), the NO levels of Tibetans are lower than the level in Lhasa (p<0.0001). These data suggest that the elevation of blood NO level at high altitude is not specific to Tibetans. Rather, Tibetans showed a blunted response to NO elevation under hypoxia. We propose that similar with the regulation of hemoglobin, the regulation of blood NO plays a role in both acclimatization of lowlanders and genetic adaptation of Tibetans to high altitude hypoxia.

1067T

Geographic and historic changes in runs of homozygosity among more than 1,000,000 individuals sheds light into the recent demographic history of US population. *A. Kermany, C. Ball, J. Byrnes, P. Carbonetto, K. Chahine, R. Curtis, E. Elyashiv, J. Granka, H. Guturu, E. Han, E. Hong, N. Myres, K. Noto, K. Rand, Y. Wang.* Ancestry.com DNA, LLC, San Francisco, CA.

Runs of Homozygosity (ROH) are indicators of segments of chromosomes identical by descent between parental haplotypes. Distribution of such runs along the chromosome contains information regarding the demographic history of the population under study, in particular it reveals trends in consanguinity. In this study, we analyze the distribution of runs of homozygosity – chromosomal locations, number of runs and lengths of runs - as well as estimated inbreeding coefficient (F) among more than 1,000,000 consented AncestryDNA customers. We report on observed variations in distribution of ROH based on geographic origins - inferred from the available pedigree data - admixture proportions as well as birth year cohort. In particular, we present our results on variations in the distribution of ROH within 19 communities within the US population - identified based on analysing a network of genetic matches in the database - and investigate differences in patterns of ROH between each group and comment on the inferred demographic history within each group.

1068F

Nanopore sequencing reveals evolution of poxvirus genome structure driven by conflict with human defense mechanisms. *T. Sasani, K. Cone, R. Layer, N. Elde, A. Quinlan.* Department of Human Genetics, University of Utah, Salt Lake City, UT.

Viruses are locked in conflict with host organisms and rapidly adapt to combat antiviral host responses. To prevent viral propagation, human immune defense pathways involve a number of host proteins that work in concert. However, the Vaccinia (VACV) genome encodes two host-range factors, E3L and K3L, that each disrupt key host defenses. In the absence of E3L, VACV has been shown to rapidly adapt by duplicating K3L in tandem arrays, which confers a significant increase in fitness (Elde et al. 2012). Additionally, the appearance of an H47R mutation in a single copy of the K3L gene confers a fitness benefit comparable to duplication of wild-type K3L.The precise nature and composition of these duplications has proven difficult to characterize, primarily due to the fact that short-read sequencing technologies are unable to sequence through arrays of K3L duplications (measuring ~500 bp per copy). In this study, we utilized Oxford Nanopore (ONT) long-read sequencing technology to characterize VACV populations (lacking the E3L gene) that survived selective pressure during successive passages in HeLa cells. Using this approach, we detected individual viral genomes harboring up to 24 tandem copies of K3L, and find that the distribution of K3L copy number in VACV populations is highly heterogeneous. Also, by analyzing individual reads that contain K3L duplications, we determined that the H47R mutation is not uniformly present or absent in tandem arrays of K3L. Rather, we find that the mutation is lost and gained in subsequent duplications, perhaps due to recombination between viral genomes. For the first time, using ONT sequencing, we have uncovered the interplay between allelic diversity and structural variation during viral evolution.Accurate representation of variation in structurally unstable genomic regions is critical to understanding the genetic basis of human disease. For example, structurally labile chromosomal regions (e.g., 17p12) yield complex rearrangements driven by non-allelic homologous recombination and underlie developmental disorders. Highly variable repeat expansions within *C9ORF72* are also implicated in amyotrophic lateral sclerosis (ALS), but are effectively impossible to characterize with short read sequencing technologies. Therefore, inspired by our success in VACV, we will present new approaches for applying long-read ONT sequencing to the characterization of complex structural variation (SV) in the human genome.

1069W

Whole genome sequencing in a large pediatric African American sample. *P. Sleiman[1,2], L. Tian[1], D. Li[1], X. Chiang[1], H. Hakonarson[1,2].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

African Americans have been underrepresented in genetic research, a trend that has continued with the advent of NGS. Samples classed as African/African American make up 8.5% of the ExAC database despite harboring more variation than other populations. We have generated deep whole genome sequencing data on 900 pediatric samples including 532 children of African American ancestry representing one of the largest pediatric and African American whole genome datasets generated to date. Electronic medical record-derived deep phenotyping data is available on all participants, however, the primary aim of this work was not disease association, but rather a population genetic overview. All samples were sequenced to a depth of ~30X using a PCR free library prep on an Illumina HiSeq. FASTQ reads were aligned to the human genome reference (GRCh37) using BWA (version 0.7.12). The resulting BAM files were position sorted and duplicate reads marked by sambamba and samblaster. For SNP calling, we found a combination of FreeBayes, GATK HaplotypeCaller, and GATK UnifiedGenotyper yields the most sensitive integrated callset. For short insertions and deletions, a combination of FreeBayes, GATK HaplotypeCaller, and Platypus produced the best genotype callset. LUMPY and DELLY2 were used to call structural variants. ANNOVAR, SnpEff, and Variant Effect Predictor (VEP) were used in the pipeline to annotate and classify the effects of SNPs, short insertions and deletions, CNVs and SVs, using both Ensembl and RefSeq transcript sets. We present an overview of the 900 genomes, including the distribution and burden of rare variants in African Americans (AA) compared with the European ancestry (CEU) samples in our cohort, and with the variation and frequencies previously reported in ExAC, the distribution of rare variation in functional and coding sequence between AA and CEU, the distribution of structural variation and CNVs. We present an overview of non coding variation under negative selection in AAs by analyzing site frequency spectra in ENCODE elements, as well as structural and non coding variants under positive selection. Finally, we take advantage of deep sequence coverage on the Y and mitochondrial chromosomes to construct a detailed phylogeny of the AA individuals in the study. .

Y-chromosomal sequencing and screening reveal both stability and migrations in North Eurasian populations. *O. Balanovsky[1,2], V. Zaporozhchenko[2,1], A. Agdzhoyan[1,2], I. Alborova[5], M. Kuznetsova[2], V. Urasin[3], M. Zhabagin[4], M. Chukhryaeva[2,1], Kh. Mustafin[5], C. Tyler-Smith[6], E. Balanovska[2].* 1) Vavilov Institute of General Genetics, Moscow, Russian Federation; 2) Research Centre for Medical Genetics, Moscow, Russia; 3) YFull service, Moscow, Russia; 4) National Laboratory Astana, Nazarbayev University, Astana, Republic of Kazakhstan; 5) Moscow Institute of Physics and Technology (State University), Moscow, Russia; 6) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom.

Y-chromosomal markers exhibit the highest interpopulation diversity in the genome and thus form one of the most informative tools for tracing population history. However, their information value depends on discovering SNPs which subdivide haplogroups with broad geographic distribution into branches revealing fine population structure. Progress in such discoveries has recently moved from a slow linear phase to a rapid exponential phase due to NGS. We applied this approach to the Y-chromosomal pool of North Eurasian populations and concentrated on haplogroups C, G1, G2, N1b, N1c, and R1b. We sequenced 181 Y-chromosomes (capturing 11 Mb from each sample), developed the *NGSConv* software for calling Y-chromosomal SNPs, and identified roughly 2,500 SNPs, most of which were new. Then we constructed phylogenetic trees and dated dozens of their branches using our estimates of the mutation rate. The last – but not the least – step included screening branch-defining SNPs in the entire Biobank of indigenous North Eurasian populations (led by prof. Elena Balanovska), which includes 26,000 samples from 260 populations. This screening resulted in frequency distribution maps of 29 branches of haplogroups R1b and C, thus increasing the phylogenetic resolution by an order of magnitude compared to the two initial haplogroups. For haplogroup R1b, we identified a previously unstudied "eastern" branch, R1b-GG400, found in East Europeans and West Asians and forming a brother clade to the "western" branch R1b-L51 found in West Europeans. The ancient samples from the Yamnaya archaeological culture are located on this eastern branch, showing that the paternal descendants of the Yamnaya population – in contrast to the published autosomal findings - still live in the Pontic steppe and were not an important source of paternal lineages in present-day West Europeans. For haplogroup C-M217 - the predominant paternal component in Central Asians - we found signals of simultaneous expansion in two independent branches. Both expansion times and gene geographic maps of the expanded lineages indicated the emergence of the Mongol Empire as the likely trigger. We conclude that simply discovering new SNP is not enough, but in combination with screening for the branch-defining SNPs in large biobanks of indigenous populations, it allows comprehensive reconstruction of male population history. The study was supported by the Russian Science Foundation grant 14-14-00827 to OB. .

The borrowed fitness: Adaptation of modern Eurasians through archaic hominin introgression. *Y. Hu, Q. Ding, L. Jin.* Department of Human Genetics and Anthropology, Fudan University, Shanghai, China.

The standing or *de novo* mutations are considered as the primary source of genetic variations for adaptation especially to a changed environment. Ancestors of modern Eurasians, after their exodus from Africa continent, had to face the challenges of new environment and their fates were largely dictated by the genetic variations that they carried until they encountered the residents in Eurasia continent such as Neanderthal and Denisovan. The signatures of positive selection to the introgressed fragments of Neanderthal found in all sampled modern Eurasians suggest that such introgressions may have contributed to the adaptation of modern human in Eurasia, referred to as the borrowed fitness. In the Eurasian samples of 1000 Genomes Project, the contribution of Neanderthal introgressions to modern human was estimated at about 1% across the genome. High frequency (>30%) of Neanderthal alleles was found in genes related to inflammatory response, epigenetic modification, spermatogenesis, neuron development, etc. In particular, Neanderthal introgression in *HYAL2* and *MC1R*, two genes related to response to sunlight, may have helped adaptation of East Asians in local sunlight. In addition to Eurasians, we found that 78 Denisovan introgressions in Papuans and aboriginal Australians were under positive selection, involving genes related to evolutionarily important functions, such as fertilization, cold acclimation, brain development, immunity, etc. Denisovan introgressions also introduced at least 121 missense alleles into Papuans, which are also located in evolutionarily important genes involved in female pregnancy, visual and smell perception, wound healing, and metabolism. These findings suggested that introgressions of archaic hominins may have substantially facilitated adaptions of modern humans to the new environments. Thus, in addition to mutations, borrowing adaptive variations (i.e. borrowed fitness) from archaic hominin who had already adapted to Eurasia environment served as a supplementary and efficient mechanism to the adaptation for newcomers. .

1072W

The genetic origin of Tibetans and Sherpas of China as revealed by 15 autosomal STRs. *L.L Kang[1,2,3], L.F. Ma[1,2,3], Y.D Zhao[1,2,3], Y. Zhang[1,2,3], Z.Y. Zhang[1,2,3], N. He[1,2,3], Y. Zhang[1,2,3], L.J Liu[1,2,3].* 1) School of Medicine, Xizang Minzu University, Xianyang,Shaanxi, Shaanxi, China; 2) Key Laboratory for Molecular Genetic Mechanisms and Intervention Research on High Altitude Disease of Tibet Autonomous Region;;; 3) Key Laboratory of High Altitude Environment and Gene Related to Disease of Tibet Ministry of Education, School of Medicine, Xizang Minzu University, #6 East Wenhui Road, Xianyang 712082, Shaanxi, China.
