CDS-KB: Shared knowledge to support last-mile clinical decision support implementation for precision medicine programs. *J. Denny[1], J. Kirby[1], L. Rasmussen[2], P. Dexter[3], S. Ellis[4], A. Hartzler[5], C. Overby[6], P. Caraballo[7], M. Levy[1], P. Peissig[8], B. Phelp[1], J. Starren[2], M. Williams[9], P. Harris[1], J. Peterson[1].* 1) Vanderbilt University Medical Center, Nashville, TN; 2) Northwestern University Feinberg School of Medicine, Chicago, IL; 3) Indiana University School of Medicine, Indianapolis, IN; 4) Icahn School of Medicine at Mount Sinai, New York, NY; 5) Group Health Research Institute, Seattle, WA; 6) University of Maryland School of Medicine, Baltimore, MA; 7) Mayo Clinic, Rochester, MN; 8) Marshfield Clinic Research Foundation, Marshfield, WI; 9) Geisinger Health System, Danville, PA.

Clinical decision support (CDS) based on genomic knowledge and genomic data is vital for creating and maintaining a precision medicine program. Several genomic medicine initiatives have targeted improving standardized rule sets for CDS implementation[1,2], and while standards assist in the transportability of CDS rules and knowledge, development of CDS often requires significant local customization. CDS customization may be required to fit into existing EHR systems infrastructure, to adapt hospital specific workflows or to speak to content knowledge of the target audience. The scale and complexity of dense genomic data further highlights the difficulty in recreating a program design, CDS rule set, and EHR interfaces for health systems considering precision medicine programs[3]. In early 2015, representatives of the Electronic Medical Records and Genomics (eMERGE) and Implementing Genomics in Practice (IGNITE) Networks targeted the gap of last-mile implementation issues by developing a lightweight repository to disseminate unstructured Genomic Medicine implementation artifacts. The Clinical Decision Support KnowledgeBase (CDS-KB) hosted at cdskb.org was created to promote sharing implementation experiences at different sites. Since CDS-KB's creation, 55 artifacts have been shared from twelve institutions ranging from workflow documents, architecture diagrams, to template text. Artifacts range from CDS specific drug, gene, or disease rules to general system documents. A public webinar series is a key component of the CDS-KB "Learning" section and facilitates exchanges and discussions between implementers across institutions. A repository of implementation artifacts is a potentially valuable resource for those health systems designing and implementing a new genomic medicine program. Shared design and implementation documentation may lower the last mile implementation barriers and help increase the quality and adoption of genomic CDS. 1 Relling M, Klein T. Pharmacogenomics (PGx) decision support and return of results is an active area of genomic medicine implementation at many health care organizations and academic medical centers. The Clinical Pharmacogenetics Implementation Consortium (CPIC) has established guidelines surrounding gene-drug pairs that can and should lead to prescribing modifications based on genetic variant(s). One of the challenges in implementing PGx is extracting genomic variants and assigning haplotypes (including star-alleles) from genetic data derived from sequencing and genotyping technologies in order to apply the prescribing recommendations of CPIC guidelines. In a collaboration between the PGRN Statistical Analysis Resource (P-STAR), The Pharmacogenomics Knowledgebase (PharmGKB), the Clinical Genome Resource (ClinGen), and CPIC, we are developing a software tool to extract all variants from CPIC level-A genes with the exception of *G6PD* and *HLA*, from a genetic dataset resulting from sequencing or genotyping technologies (represented as a .vcf), interpret the variant alleles, infer diplotypes, and generate an interpretation report based on CPIC guidelines. The CPIC pipeline report can then be used to inform prescribing decisions. We assembled a focus group of thought leaders in PGx to brainstorm the issues and to design the software pipeline. We hosted a one-week Hackathon at the PharmGKB at Stanford University to bring together computer programmers with scientific curators to implement the first version of this tool. Through this process, we have uncovered many of the challenges surrounding PGx implementation. For example, the inference of diplotypes is challenging for several CPIC level-A genes. This software pipeline will be made available under the Mozilla Public License (MPL 2.0) and disseminated in Github for the scientific and clinical community to test, explore, and improve. PharmCAT will provide a solution that will enable sites implementing PGx a way to more consistently interpret genomic results and link those results to published clinical guidelines. Furthermore, we are assembling (and will be maintaining) the translation tables that underlie the tool, which will significantly reduce the effort required to implement PGx clinically and ensure more uniform interpretations of PGx knowledge. As precision medicine continues to move into clinical practice, implementation workflows for PGx, like PharmCAT, would enable standardized and consistent implementation of PGx genes.

Identifying structural variants of *CYP2D6* **with massively parallel sequencing.** *S. Lee, M.M. Wheeler, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

Cytochromes P450 (CYPs) are an important class of enzymes that metabolize thousands of endogenous and exogenous chemicals. CYP2D6, a member of the CYP family, is responsible for the activation and elimination of approximately 25% of prescription drugs, including many antidepressants, opioids, and chemotherapeutics. The abundance and efficiency of CYP2D6 enzyme varies considerably between individuals, raising the individual risk of decreased drug efficacy or increased side effects. Genotyping of the *CYP2D6* gene is performed in clinical settings to prevent adverse drug reactions. However, accurate genotyping of *CYP2D6* is challenging because it is extremely polymorphic. There are more than 100 known alleles for *CYP2D6* and these are characterized by single nucleotide variants (SNVs), insertion-deletions (indels), and complex structural variants (SVs). The SVs are facilitated by the high sequence identity between *CYP2D6* and its neighboring, non-functional paralog, *CYP2D7*. Although several methods (e.g., qPCR, FISH, and aCGH) can detect the SVs in *CYP2D6*, they are time-consuming and largely dependent on known DNA variants. With the advent of low-cost and high fidelity DNA sequencing, it is now possible to genotype *CYP2D6* in a high throughput and unbiased manner. To achieve this, we have developed a *CYP2D6* genotyping strategy that uses next generation sequencing and a customized analysis pipeline. Our analysis pipeline accounts for presence of paralog genes and computes paralog-spcific copy numbers based on the read depth. We validated the performance of this pipeline using 32 trios from the HapMap project sequenced by a targeted capture sequencing platform. Using this data set, we studied the inheritance of SVs from parent to offspring and compared these results to previous genotyping efforts that employed different analytic strategies. Within each trio, we were able to detect expected inheritance patterns of *CYP2D6* alleles. In addition, our results show high concordance between our genotype calls and those reported previously. We are currently analyzing a larger whole-genome data set to show that our method can be generalized to different types of next generation sequencing data and further validate the accuracy of this approach. Overall, our customized analysis enhances SV detection in *CYP2D6* and adds to our understanding of the genetic variation in this clinically relevant gene..

Target Gene Explorer: A durable and dynamic workbench connecting genetics and drug discovery. *M.P. Reeve[1], J. Wierzbowski[1], A. Kirby[1], S. Ripke[2,3], H. Huang[2,3], J. Heymont[1], M. Daly[2,3], J. Hutz[1].* 1) Human Biology & Data Sciences, Eisai, Andover, Ma; 2) Analytic and Translational Genetics Unit, MGH, Boston, MA; 3) Broad Institute, Cambridge, MA.

While genetic association studies have generated an avalanche of potential clues to the causal mechanisms of many human diseases, actionable therapeutic hypotheses have been slow to emerge from these studies owing to the challenges in the statistical and functional interpretation of such results. Many disparate genome browsers and databases provide access to unfiltered genome annotations and genetic results, but there is currently no way to maintain group curation of relevant information integrated with proprietary data. We introduce an electronic workbench to facilitate the comprehensive organization of results from GWAS and variant-based functional assays for the purposes of assisting therapeutic target evaluation and creation of durable institutional or public knowledgebases.   With a gene (potential drug target) as the focal point, the software identifies candidate published associations, introducing an adjudication system for relevance that allows the user to review and store an assessment of the finding. Qualitative assessments are pre-computed through heuristics designed to assess statistical robustness and variants' known or predicted functional effects on genes in the region. The process relies on LD patterns across global populations derived from reference panels and derives 'credible result sets' for association (directly presented in papers or based on LD surrounding index SNPs reported in GWAS publications).   Public resources of relevance to target evaluation (e.g., variation patterns in ExAC, expression patterns in GTEx, established links and mutations relevant to rare disease) are presented and user annotations enabled to create durable and shareable conclusions. Target-specific results from exome sequencing and functional assays – whether proprietary internal data or public findings – are captured and tracked alongside reference variation patterns in the gene. The software will prompt users when new data or publications of potential relevance to the target validity are available, and facilitate the transfer and persistence of knowledge within a large group by providing a permanent record of the adjudication of such 'clues' and allowing re-review of underlying data at a later time if needed. Implementation is such that private instances can be shared across groups or sites as needed - potential users include pharma (for tracking knowledge of targets) and disease consortiums for collating results and interpretations.

1805T

RNA sequencing analysis identifies genes involved in the genistein induced bone differentiation in mouse osteoblastic cell line MC3T3-E1. *Y.S. Cho[1], M. Kim[2], J. Lim[1], J.-H. Lee[1], K.-M. Lee[2], C.W. Nho[2].* 1) Biomedical Science, Hallym University, Chuncheon, Gangwon-do, South Korea; 2) Natural Products Research Center, KIST Gangneung Institute of Natural Products.

Genistein, structurally similar to 17β-estradiol, is a phyto-estrogen that may be beneficial for postmenopausal women as a substitute for the loss of endogenous estrogens. Although genistein is ingested in the diet and also widely consumed as dietary supplements, its underlying molecular mechanism that replaces endogenous estrogens in postmenopausal women is not fully understood. To gain insight into the effect of genistein on the bone differentiation, we tried to detect the differentially expressed genes by the treatment of genistein. To meet this objective, we conducted RNA sequencing analysis in genistein treated and untreated mouse osteoblastic cell line MC3T3-E1. After adaptor trimming and removing reads with poor quality (Q < 20), TopHat and Bowtie programs were employed to map RNA-seq reads to mouse reference genome version mm10. Genome-wide gene expression in the cells was normalized by total-count normalization (FPKM) and differentially expressed genes in genistein treated cells were identified by Cufflinks-Cuffdiff algorithm. Our analysis shows 50 up-regulated (including *CCL7*, *MMP13*, and *WISP2*) and 78 down-regulated genes (including *CAMK2B*, *CCL5*, and *CXCL9*) in genistein treated MC3T3-E1 cells (t-test p < 0.05 and 1.5-fold change). These results were validated by the real-time qPCR experiments. Pathway analysis demonstrates that these differentially expressed genes are highly involved in cytokine-cytokine receptor interaction, implying the role of genistein in this biological function.

1806F

Accounting for technical batch effects in single-cell RNA sequencing analysis. *C. Jia[1], M. Li[1], N.R. Zhang[2].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Statistics Department, the Wharton School, University of Pennsylvania, Philadelphia, PA.

Recent technological breakthroughs have made it possible to measure RNA expression at the single-cell level, thus paving the way for exploring expression heterogeneity among individual cells. Current single-cell RNA sequencing (scRNA-seq) protocols are complex and introduce technical biases that vary across cells, and can lead to severe type I error inflation without proper adjustment. Compared to bulk RNA sequencing, in scRNA-seq the reverse transcription and preamplification steps could lead to dropout events and amplification bias, the former describing the scenario in which a transcript expressed in the cell is lost during library preparation and is thus undetectable at any sequencing depth. Due to the high prevalence of dropout events and amplification bias in scRNA-seq, it's crucial to account for them in data analysis. In order to adjust for these cell-to-cell technical differences, we propose a statistical framework, TASC (Toolkit for Analysis of Single Cell RNA-seq). TASC uses an empirical Bayes approach to reliably model the cell-specific dropout rates and amplification efficiency by use of external RNA spike-ins. Subsequently, TASC incorporates the estimated technical parameters, which reflect cell-to-cell batch effects, into a hierarchical mixture model to estimate the biological variance of a gene and detect differentially expressed (DE) genes. More importantly, TASC is able to adjust for additional covariates to further eliminate confounding that originates from cell size and cell cycle differences. In our simulations based on real scRNA-seq data, TASC displays superior sensitivity and specificity in detection of DE genes. The higher sensitivity of TASC is more pronounced when fold change is moderate; for example, when fold change is 1.75, at the 0.0001 significance level, the average power of TASC is 25%, 37%, and 428% higher than DESeq2, MAST and SCDE, respectively. Moreover, TASC is robust in the presence of batch effects. In contrast, DESeq2, MAST and SCDE yield highly inflated type I error rates. In real data analyses, TASC discovers the largest number of DE genes, and its performance is consistent across various sample sizes. TASC is programmed to be highly efficient computationally, taking advantage of multithreaded parallelization. A typical run on a dataset of 100 cells and 4,000 genes takes approximately 45 minutes using 24 cores. We believe that TASC will provide a robust platform for researchers to leverage the power of scRNA-seq.

Fleximer: Accurate quantification of RNA-seq via variable length k-mers. *C. Ju, R. Li, Z. Wu, Z. Yang, W. Wang.* Computer Science, University of California, Los Angeles, Los Angeles, CA.

The advent of RNA-Sequencing (RNA-Seq) has made it possible to quantify transcript expression in a large scale simultaneously. This technology generates small fragments of each transcript sequence, known as sequencing reads. As the first step of the data analysis towards expression quantification, most of the existing methods align these reads to the reference genome or transcriptome to establish their origins. However, this read alignment process is computationally costly. Recently, a series of methods have been proposed to perform a lightweight quantification analysis in an alignment-free or pseudo-alignment manner. These methods utilize the k-mers idea, which are short consecutive sequences representing the signatures of each transcript, to estimate the relative abundance from RNA-Seq reads. Current k-mers based approaches make uses of a set of fixed size k-mers; however, the true signatures that can distinguish one transcript from another may not exist in a fixed size. In the work, we demonstrate the importance of k-mer selection in transcript abundance estimation. We propose a novel method, Fleximer, to efficiently discover and select an optimal set of k-mers with variable sizes. Using both simulated and real datasets, the preliminary results have demonstrated that Fleximer is capable to achieve higher prediction accuracy with a smaller number of k-mers. These k-mers with flexible lengths are able to cover more reads in the datasets, and thus substantially reduce the percentage errors in transcript abundance estimation.

1808T

Association between telomere length and SNP array probe intensities in a cohort of 100,000 subjects. *M. Kvale[1], K. Lapham[1], J. Lin[1], E. Blackburn[3], P. Kwok[1], C. Schaefer[2], N. Risch[1].* 1) Institute for Human Genetics, UCSF, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Salk Institute, La Jolla, CA.

The Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort contains data on telomere length and Affymetrix Axiom SNP array genotypes for each of 100,000 subjects. In a GWAS of relative telomere length and genotypes in this cohort, a large number of associations were found significant at the p<5e-8 level, and several with extreme statistical significance. To evaluate the veracity of these genetic associations, an investigation was undertaken of genotype call quality, one aspect of which was the underlying SNP array probe intensities. In a GWAS of relative telomere length with the log probe intensity contrast (log(A)-log(B)), thousands of associations significant at the p<5e-8 level were found, revealing an excess correlation of telomere length with probeset intensity beyond what would be expected from purely genetic effects. The correlation of telomere and genotype assay data beyond the putative genetic associations breaks a fundamental GWAS assumption of the independence of phenotype and genotype assays. To reduce the effects of probe intensity artifacts while maintaining genotype information, we developed a novel intra-cluster regression analysis for the GWAS analysis. By this approach, we were able to effectively eliminate the large number of artifactual GWAS associations due to probe intensity correlation that were not due to genotype, while retaining robust SNP genotype associations. This led to the elimination of 115 artifactually significant SNPs. Our final GWAS identified 25 genome-wide significant SNP association regions, 21 of which have been previously reported and 4 of which are novel.

1809F

Identification of differentially expressed genes in biased expression data based on RNA-Seq. *J. Sun[1], M. Tang[2], K. Shimizu[1], K. Kadota[1].* 1) The University of Tokyo, Tokyo, Japan; 2) Gertrude H. Sergievsky Center, Columbia University, New York, USA.

Identification of differentially expressed genes (DEGs) under different experimental conditions is one of the fundamental tasks in RNA-Seq study. The goal of DEG identification is to determine candidate genes for further analysis as well as to provide evidences to reveal biological process. edgeR and DESeq2 are two well-known software packages for DEG identification. Generally, DEG identification consists of two steps: normalization and hypothesis test, and improvement of any step leads to increase accuracy and specificity in DEG identification. We have proposed a robust normalization strategy, called DEG elimination strategy (DEGES), to improve the normalization step. Overexpressed gene in one of the compared conditions (i.e., biased expression) is known to compromise normalization. We introduced procedures to remove bad influences affected by genes with biased expression into normalization steps. Furthermore, we implemented DEGES-based normalization into TCC, an R/Bioconductor package that aims for DEG identification. According to simulation studies, we found that TCC outperformed edgeR and DESeq2 in two-condition comparison as well as ANOVA-liked multi-condition comparison. We believe that identifying of DEGs using TCC contributes higher reproducibility given that TCC provides high accuracy and specificity in DEG identification. The latest version of TCC is available on Bioconductor repository (http://www.bioconductor.org/packages/release/bioc/html/TCC.html).

1810W

DNASTAR software for accurate variant detection and interpretation using a variant annotation database. *M. Keyser[1], K. Maxfield[1], T. Schwei[1], T. Durfee[1], D. Nash[1], S. Baldwin[1], R. Nelson[1], K. Dullea[1], E. Edlund[1], A. Pollack-Berti[1], J. Stieren[1], F. Blattner[1,2,3].* 1) DNASTAR, Inc., Madison, WI; 2) University of Wisconsin, Department of Genetics, Madison, Wisconsin, USA; 3) Scarab Genomics LLC, Madison, Wisconsin, USA.

DNASTAR offers an integrated software suite for assembly and analysis of next-generation sequence data from all major sequencing platforms, supporting key workflows in a desktop computing environment. The SeqMan NGen program provides extremely accurate alignment and variant calling, while the integrated Variant Annotation Database makes interpreting the results feasible via automated import of variant annotations sourced from dbNSFP, 1000 Genomes Project and the Exome Variant Server. Here we present an example of how the software can be used to quickly identify variants in cancer causing genes from a whole exome data set. By utilizing this DNASTAR workflow, users can easily align large NGS data sets and quickly identify interesting variants using live, interactive views and comprehensive filtering tools. Alignment and analysis is scalable from individuals to large groups of individuals so that variant and gene sets of interest can be efficiently isolated and identified no matter the project size.

1811T

Models of single-sample and multisample SNP calling. *A. Pourshafeie[1], S. Shringarpure[2], C.D. Bustamante[2].* 1) Department of Physics, Stanford University, Stanford, CA; 2) Department of Biomedical Data Sciences , Stanford University, Stanford , CA.

Variant calling is an important step in the analysis of Next Generation Sequencing (NGS) data, since it affects the results of downstream analyses. Single-sample and multi-sample calling are the main methods for SNP discovery from genomes of many individuals. While single-sample calling is efficient and parallelizable, it is limited to extracting information from a genome of a single individual. Multi-sample calling was developed to address this shortcoming by sharing information across many samples. While many empirical observations of the characteristics of these callers exists, there are no models that describe the general behavior of these callers with varying coverage, sample size and minor allele frequency (MAF). We developed Bayesian models for single-sample and multi-sample SNP calling that characterizes the performance of these methods. We use our models to show the dependence of these methods on factors like coverage, sample size, and MAF. Using the SNP quality Phred score as a metric, we show that multi-sample quality score has a more direct dependence on SNP MAF than the single-sample quality score. We further explore our model using simulations and variant calls on a dataset with hundreds of individuals sequenced to 30x coverage. We compare our predictions for Phred quality score and concordance score to the real data. In particular, our model discusses the tradeoffs between coverage, number of individuals and error rates and explains the following previously reported empirical observations: 1) For low-coverage data, multi-sample calling has higher power than single-sample calling. 2) For high-coverage data, both methods have high power. 3) In large datasets, multi-sample calling has less power than single-sample calling for identifying variants with very low frequency (singletons etc.).

1812F

IOBIO Dev Kit: Resources for making genomic, real-time web applications and services. *C. Miller, A. Ward, Y. Qiao, T. DiSera, G. Marth.* Human Genetics, University of Utah, Salt Lake City, UT.

IOBIO (http://iobio.io) is an open-source web-based genomic platform enabling real-time analysis of large, remotely-stored, distributed datasets, with analysis algorithms operating as web servers on data-streams in standardized data formats. Several IOBIO apps have been previously released and can be found at http://iobio.io/applications.html. Here we introduce the IOBIO Dev Kit (https://developer.iobio.io), which provides libraries, examples, and documentation to build your own IOBIO apps and services. The dev kit consists of three main libraries: iobio.js is a client-side javascript library that streamlines creating and executing iobio commands, while hiding complicated web-socket connection code; iobio.viz is a d3-based, streaming genomic visualization library that consumes iobio data streams; and minion is a server library that wraps (with only a few lines of code) standard command line tools and converts them into iobio web services that can be mixed and matched with all other iobio web services. As an instructive example, we have rebuilt our bam.iobio.io app (http://bam.iobio.io) using dev kit components with all code found here: https://github.com/chmille4/bam.iobio.io. Using the IOBIO Dev Kit, developers will be able to create new genomic analysis apps on the web at a fraction of the time it currently takes to build desktop applications: IOBIO will be no less than an ecosystem for genomic analysis.

1813W

Bayesian nonparametric isoform discovery and quantification of many RNA-seq samples. *D. Aguiar[1], L. Cheng[2], B. Dumitrascu[3], F. Mordelet[4], B.E. Engelhardt[1,5].* 1) Department of Computer Science, Princeton University, Princeton, NJ; 2) Department of Electrical Engineering, Princeton University, Princeton, NJ; 3) Lewis Sigler Institute, Princeton University, Princeton, NJ; 4) Institute for Genome Science and Policy, Duke University, Durham, NC; 5) Center for Statistics and Machine Learning, Princeton University, Princeton, NJ.

The human genome contains approximately 22,000 protein-coding genes, each composed of exons that may be spliced in multiple ways, leading to possibly many distinct RNA *isoforms*. This *alternative splicing* encourages molecular diversity and plays an important role in disease etiology. The goal of isoform inference methods is to characterize the exon composition of isoforms for each gene across multiple samples and to quantify sample-specific proportions of each isoform using mapped RNA-seq reads. However, isoforms are difficult to characterize from short-read RNA-seq data because they are often composed of different combinations of identical exonic subsequences of transcribed DNA. Many tools exist for isoform reconstruction and quantification but they have a number of drawbacks making their application ill-equipped for multisample RNA-seq data: (1) many quantification methods assume a high-resolution isoform reference, which is unreliable, in particular, for non-model organism genomes, rare tissues, or disease samples; (2) most methods consider a single sample in isolation, ignoring the sharing of isoforms across samples; and (3) many methods make technology dependent assumptions by controlling for specific biases that do not generalize across technologies or samples. To address these drawbacks, we develop BIISQ, a **B**ayesian nonparametric method for **I**soform discovery and **I**ndividual **S**pecific **Q**uantification from RNA-seq data. BIISQ assumes neither knowledge of the existing isoforms nor sample-specific covariates, but instead postulates an infinite admixture model to probabilistically assign the aligned reads into their isoform of origin while inferring isoform compositions across samples. Joint inference across many samples enables the sharing of statistical strength to better identify low abundance isoforms and allowing each nucleotide base to have an independent frequency allows BIISQ to account for technical biases. We develop efficient posterior estimation based on stochastic variational inference that enables the discovery of novel isoforms and characterization of sample-specific and global isoform distributions quickly. We validate BIISQ using RNA-seq simulations and long sequence read technologies and demonstrate superior precision and recall compared with several existing isoform reconstruction methods. Lastly, we apply BIISQ to a large-scale RNA-seq study, GEUVADIS, for validation and to identify novel isoforms and isoforms specific to populations.

1814T

LeafCutter: Annotation-free quantification and prediction of RNA splicing. *D.A. Knowles, Y.I. Li, J.K. Pritchard.* Stanford University, Stanford, CA.

We recently developed LeafCutter to study sample and population variation in intron splicing. LeafCutter identifies variable intron splicing events from short-read RNA-seq data and finds alternative splicing events of high complexity. Instead of focusing on exon inclusion as do most splicing quantification tools, we quantified RNA splicing by modelling what is removed in each splicing event. This approach obviates the need for transcript annotations and overcomes the challenges in estimating relative isoform or exon usage in complex splicing events.Using LeafCutter, we identified over three times as many genetic variants that impact RNA splicing (i.e. splicing QTLs, or sQTLs) compared to contemporary methods. Notably, we find that sQTLs are highly enriched among variants that are also associated with diseases including multiple sclerosis.Motivated by the connection between RNA splicing and disease, we next built a machine learning model to predict the effects of genetic variants on RNA splicing from DNA sequence alone. Inspired by the process by which the core spliceosome selects introns to be excised during pre-mRNA splicing, we model intron selection dependent on the relative strength of adjacent splice sites determined by sequence features. We learn a mapping from sequence to splice-site strength in a tissue-specific manner and predict alternative intron excision in a panel of tissues from GTEx. We outperform the state-of-the-art in predicting the effect of common and rare genetic variants in individuals with matched whole genome and RNA sequencing. Our model therefore opens the door to improved personal exome and genome interpretation, in particular for rare diseases where relevant tissues are difficult to sample. .

Annotation sources database management and genome annotations software workflow in Ion Reporter. *G. Altun, Y. Lou.* Thermo Fisher Scientific, South San Francisco, CA.

Ion Reporter™ software is a cloud-based software that can analyze next generation sequencing research data on local servers as well as on the cloud. Ion Reporter software not only finds data that is statistically significant for a given experiment, it also provides metadata such as annotations. The annotation workflow of Ion Reporter software has gained immense popularity in the past two years. The reasoning behind this is because the Ion Reporter annotation pipeline is very comprehensive and consists of significant number of pre-built private and public genomic and clinical research databases. The information from these databases are processed, optimized and stored in the Ion Reporter internal database. The Ion Reporter's internal database currently stores millions of records from multiple public and private datasets. These records are searched by the software within seconds to annotate statistically significant biological data such as SNP (Single-Nucleotide Polymorphism) mutations and CNVs (Copy-Number Variations). This presentation will provide more details Ion Reporter software features and capabilities that provide biologically meaningful results and help decipher the genomic data.

1816W

Functional validation of human protein-truncating genetic variants. *I.M. Armean[1,2], K.J. Karczewski[1,2], J.L. Marshall[1,2], B.B. Cummings[1,2], E. Minikel[1,2], D. Birnbaum[1,2], P. Singh[1,2], B. Weisburd[1,2], M. Lek[1,2], M.J. Daly[1,2], A. Palotie[1,2], S. Kathiresan[2,3], D.G. MacArthur[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Center for Human Genetic Research and Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA, USA.

Knockout model organisms have been used for decades to study the function of genes. The identification of so-called "human knockouts", individuals with both copies of a gene inactivated by null mutations, in different populations across the globe offers a unique opportunity for investigating gene function. Homozygous protein-truncating variants (PTV) are typically rare but are more often observed in populations with historical bottlenecks or high levels of consanguineous mating, which skew the frequency spectrum and induce homozygosity, respectively. In addition to providing information about the function of human genes, human knockouts can provide valuable information about the potential efficacy and toxicity of therapeutic inhibition of specific biological targets. Here we outline a pipeline for the functional validation of predicted protein-truncating genetic variants using both public databases and newly generated data. We first identify human knockouts from samples including over 60,000 exomes assembled by the Exome Aggregation Consortium (ExAC). Secondly, we describe approaches to filtering candidate PTVs using both an *in silico* pipeline, LOFTEE, and publicly available RNA-seq data from over 1,000 genome-sequenced individuals. Finally, we propose an approach to direct functional validation of candidate gene-disrupting PTVs using participant cell lines or CRISPR-engineered equivalents differentiated into relevant tissues. Finally, we describe a schema for the aggregation of these variants into a database of LoF variants, dbLoF, providing a resource for pharmaceutical development, transplant biology and understanding of rare Mendelian diseases.

Simple and accurate adjustment for winner's curse. *S. Bacanu[1], T.B. Bigdeli[1], V. Vladimirov[1], A.H. Fanous[1,2], K.S. Kendler[1].* 1) VIPBG, Virginia Commonwealth University, Richmond, VA; 2) VA Medical Center, Washington, DC.

Genome-wide SNP and sequencing scans, henceforth denoted as genome scans, have discovered/will discover numerous genetic variants significantly associated with various phenotypes. However, while significant signals explain only a small fraction of the variation in most traits, variants with smaller signals in aggregate explain a much larger part. To extract the signals of all magnitudes from a genome scan, e.g. by estimating their unbiased values, our group recently proposed a very simple method for winner's curse adjustment, which we called **F**DR **I**nverse **Q**uantile **T**ransformation (FIQT). The essence of this method was to perform the multiple testing adjustment on the p-value scale (i.e. FDR) and quantile transform it on the desired scale, e.g. mean Z-score, ORs or regression coefficients. Compared to competing algorithms, FIQT was more accurate in predicting the true values of effect sizes and, for large fraction of scenarios, its prediction was sensibly better. However, the method likely did not achieve its full accuracy potential due to its treatment of individual markers as independent. To remedy this shortcoming, we extended FIQT (eFIQT) such that it now takes into account the linkage disequilibrium (LD) between adjacent markers. At the price of a reasonable increase in computational power, eFIQT offers a meaningful increase in the already class-leading accuracy of FIQT.

1818F

Clinical Interpret, an application giving improved accuracy of interpretive analysis of variant and clinical data and providing novel e-diagnostics for future and deeper understanding of disease and its application in a clinical context. *L. Bean[1], J. Shovelton[2], L. Parkes[2], G. Alexandrou[2], D. Luerrssen[2], J. Holdstock[2], K. Ghandi[1], M. Hegde[1].* 1) Human Genetics, Emory University, Decatur, GA; 2) Oxford Gene Technology, Oxfordshire, UK.

Next-generation sequencing (NGS) promises to be the lynchpin for the delivery of precision and personalised medicine. Although NGS is quickly becoming the centre- piece assay in both clinical and research settings, this technology is not able to interrogate all clinically relevant areas of the genome. Genetic data management systems do not, however, incorporate data from all biological assays mainly due to varying data formats, variability in and complexity of interpretive analysis and difficulties of data management. Our solution addresses these difficulties, and aims to increase the ease and accuracy of interpretive analysis of genomic data for further and deeper understanding of disease and the application of genomics in a clinical and research context. Clinical Interpret is a clinician-friendly GUI-driven interpretation package for whole-genome scale genetic data. To this end, Clinical Interpret has been designed to import data from any number of popular tools including molecular, biochemical and cytogenetic assays to allow the user to perform a comprehensive analysis on all genetic evidence for a given case. It provides functionality for variant annotation by attaching meaningful information to variants such as gene name, predicted effect on the protein etc. Critically, information that may be clinically relevant, such as previously reported disease association segregation data, and population data is made visible to the end-user via its intuitive user interface. The software supports commonly used and custom variant filtering workflows thereby allowing users to employ analysis algorithms that are locked to ensure all analyses are reproducible, immutable and auditable. Integration with existing databases for genetic disease is a core part of the functionality. In addition, the software provides a mechanism to flag, store and collate information in a local database. The simple preparation of reports for clinical use is another key aspect that will enhances clinical interpretation for NGS data analysis. Furthermore, with all data being stored in an easily accessible medium Clinical Interpret provides a powerful tool for clinical research activities that complement the clinical diagnostic applications. In summary, Clinical Interpret provides a bridge between the biologists running the experiements, in clinical and research setting, the bioinformaticians processing the data and the clinicians delivering a clinical interpretation.

A sequencing deliverable: Theoretical sensitivity to heterozygous SNPs. *K. Bergin, D. Benjamin, J. Bloom, M. Costello, J. Rose, C. Tolonen, Y. Farjoun.* The Broad Institute of MIT and Harvard, Cambridge, MA.

Sequencing experiments can be characterized by the quality, quantity, and uniformity of the resulting reads. However, in many experiments, the ultimate metrics of interest are the sensitivity and specificity to detect genetic variants. Here we derive and implement a theoretical measure of sensitivity to heterozygous Single Nucleotide Polymorphisms (SNPs) within a widely used software package (Picard). In particular, we estimate the probability of calling a true heterozygous site with confidence greater than a threshold. The confidence is defined as the likelihood ratio between the heterozygous model and the homozygous-reference model for the data. Our estimate is based on the distributions of read-depth and base-quality within the region of interest. This metric is shown (on over 2500 libraries) to be a good predictor of the empirical sensitivity (found by variant calling with HaplotypeCaller) for various data types and qualities on a well-characterized sample (NA12878). In practice, this metric provides a more comprehensive view of the quality of sequencing data and a more actionable deliverable than coverage and base quality on their own..

Linear mixed models for quantitative traits in health-system scale data. *M. Bilow, P. Zhou, Y.-T. Chen, J. Cong, E. Eskin.* UCLA, Los Angeles, CA.

Modern health systems and numerous national and international projects have ascertained genetic information on tens or hundreds of thousands of individuals. Linear mixed models are a standard tool for determining association between genetic data and quantitative traits; however, performing linear mixed model analysis of quantitative traits becomes computationally intractable when the number of individuals rises into the tens of thousands. The most computationally-intenstive step of performing linear mixed model analysis involves performing a singular value decomposition; this process scales quadratically with the number of individuals. This significant time complexity combined with the challenge of manipulating input data makes performing mixed-model analysis at scale very challenging. Using Apache Spark and the MLib librarires, we demonstrate a performant and easy-to-apply method capable of performing end-to-end linear mixed model analysis at scale.

1821F

Phasing whole genome sequencing data in pedigrees utilizing lineage specific alleles. *A. Blackburn, J. Blangero, H.H.H. Göring.* South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX.

Phasing genotype data is useful for enabling haplotype specific genetic analyses, identification of compound heterozygosity, improving genotype error checking, imputation of missing genotypes, and it can be used to reduce the multiple testing burden inherent to the whole genome sequencing approach by applying segment based tests. Phasing in pedigrees using whole genome sequence (WGS) data is an attractive proposition, but current methods are limited by pedigree size, by the distance of relationships, by computation time, and/or by robustness to missing individuals. Within pedigrees, alleles carried by a single founding chromosome, which we call lineage specific alleles, are highly informative for identifying DNA segments that are identical-by-descent. Here we present software designed to phase WGS genotypes for whole chromosomes within pedigrees based on this rationale. Our method is capable of phasing any size pedigree, from trios and nuclear families to large multigenerational pedigrees across a range of levels of non-sequenced individuals, using only data inherent to the pedigree dataset itself. We have compared the performance of our software to AlphaPhase and SHAPEIT (utilizing the duoHMM option) using simulated data. WGS genotypes were simulated using male X-chromosomes from the 1000 genomes project to represent chromosomes among pedigree founders and gene dropping. Our software consistently produces the lowest switch errors rates in these simulations across a variety of scenarios. The percentage of heterozygous genotypes our software phases varies based on pedigree size and the percentage of individuals that are sequenced within the pedigree, whereas SHAPEIT consistently makes a phasing call for every heterozygous genotype, albeit with a somewhat higher (though still very accurate) switch error rate. In large pedigrees, filling in the gaps of the phasing results generated by our software with the results from SHAPEIT performs better than either method alone, and should be considered the current standard bearer for phasing WGS data in pedigrees.

1822W

Findings from the Fourth Critical Assessment of Genome Interpretation (CAGI), a community experiment to evaluate phenotype prediction. *S.E. Brenner[1], R.A. Hoskins[1], J. Moult[2], CAGI Participants.* 1) University of California, Berkeley, CA; 2) IBBR, University of Maryland, Rockville, MD.

The Critical Assessment of Genome Interpretation (CAGI, 'kā-jē) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. CAGI participants are provided genetic variants and make predictions of resulting phenotype. These predictions are evaluated against experimental characterizations by independent assessors. The fourth CAGI experiment recently concluded. It included 11 challenges which reflected: non-synonymous variants and their biochemical impact measured by targeted assays; noncoding regulatory variants and their impact on gene expression; research exomes for prediction of complex traits; personal genomes and trait profiles; and clinical sequences and associated referring indications. There were notable discoveries throughout the CAGI experiment, and general themes emerged. The independent assessment found that top missense prediction methods are highly statistically significant, but individual variant accuracy is limited. Moreover, missense methods tend to correlate better with each other than with experiments (for reasons that may reflect the predictive methods and the assays themselves). Structure-based missense methods excel in a few cases, while evolutionary-based methods have more consistent performance. Bespoke approaches often enhance performance. On the clinical studies, predictors were able to identify causal variants that were overlooked by the clinical laboratory, and it appears that physicians may not always order the most relevant genetic test for their patients. The results showed that predicting complex traits from exomes is fraught. Beyond this, creating a genetic study that provides a reliable gold standard is remarkably difficult. However, there were notable improvements in the ability to match genomes to trait profiles. Results from the recent CAGI experiment will be presented, exploring these topics and discussing how the field has advanced. Clinical implications will be discussed. Complete information about CAGI may be found at https://genomeinterpretation.org.

Fast genotype phasing in very large cohort. *R.C. Brown, G. Lunter.* Wellcome Trust Centre of Human Genetics, Oxford, Oxfordshire, United Kingdom.

Title: Fast genotype phasing in very large cohorts Haplotype phasing is an essential first step in genome-wide association studies and many other genetic analyses. The Li and Stephens model accurately describes the structure of genetic data in large populations, and underpins most existing algorithms for haplotype phasing in large populations. However, the full implementation of the Li and Stephens model as an HMM scales poorly, and existing algorithm rely on clever approximations and heuristic narrowing of the search space to achieve acceptable run-times. We present a haplotype phasing method that takes advantage of a novel and fast algorithm for calculating the exact maximum likelihood solution to the Li and Stephens model over large populations that we recently introduced [ref bioRxiv]. The algorithm is built on the positional Burrows-Wheeler transform to implement efficient haplotype searching on large-scale populationd data. On simulated data, the algorithm's run-time scales linearly with the number of polymorphic sites, but is independent of the cohort size, a highly desirable characteristic for very large cohorts. We present results on an initial implementation, which has allowed experimentation of cohorts in the tens of thousands, with the method expected to scale well to even larger sizes given its desirable complexity properties. Real world haplotypes obtained from the 1000 Genomes project, combined into new individuals were used initially to test the accuracy of the method. A section of chromosome 10, subset at sites common to those on an Affymetrix snp chip were extracted for experiment. Results obtained show runtimes and switch error rates that are comparable to the popular phasing tool SHAPEIT2. We expect that our approach will give superior performance for larger cohorts because of the favourable runtime behaviour.

1824F

Conform-gt: Software for harmonizing genetic marker data in VCF files. *B.L. Browning.* Medicine, Med Genetics, University of Washington, Seattle, WA.

Many genotype data sets cannot be easily combined because the chromosome strand or the VCF reference allele differs between data sets for some markers. Naïve use of inconsistent genotype data creates errors in downstream analyses such as genotype imputation or genetic association testing. The Conform-gt program is an open source software program that automatically re-orders marker alleles and flips marker chromosome strand when necessary so that marker and genotype data in a target VCF file are consistent with a reference VCF file. The software can match reference and target markers using either chromosome position or marker identifier. Matching by marker identifier is particularly useful when reference and target data are defined with respect to different genome builds. Once markers are matched, marker alleles for each target VCF record are updated to match the reference data using information from allele labels and statistical tests of allele frequency and allele correlation. The output log file reports harmonization data for each target marker, including whether the target marker could be matched to a reference marker, whether an input target marker was defined using the same chromosome strand as the reference marker, and the information that was used to harmonize the reference and target chromosome strand. The conform-gt program is freely available for download from https://faculty.washington.edu/browning/conform-gt.html.

Predicting the translational consequences of reading-frame changes induced by stop-lost and frame-shift variants. *M. Butkiewicz, J.L. Haines, W.S. Bush.* Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Annotation and prediction of the functional consequences of DNA sequence variants is gaining importance for human genomic studies. Variants that create a "Loss-of-Function" (LOF) are of special interest given their disruptive aspect towards protein sequence, and are presumed more likely to be pathogenic. At the sequence level, LOF typically implies the insertion of a stop-codon, disruption of a splice site, or insertions/deletions (InDels) leading to a derangement of the translational reading frame. Although affected transcripts may be subject to nonsense-mediated decay (NMD), recent studies show that a substantial portion of transcripts actually evade NMD, therefore the resulting effects on protein function are unclear. Current in silico annotation approaches, such as SNPEff or the ENSEMBL Variant Effect Predictor (VEP), only report the impact of a variant in the context of altered DNA sequence; information about changes in the resulting transcript, reading frame, or translated protein product is typically not provided. To alleviate these limitations, we introduce COCOS, the Codon Consequence Scanner, a plugin for VEP that provides new information about the altered reading frame and the translated protein sequence changes resulting from LOF variants. The new amino acid sequence stemming from variants that produce an altered reading frame, such as stop-lost variants and InDels, is generated until a subsequent stop-codon is reached. We applied COCOS to data from the 1000 Genomes project (phase 3), evaluating 1,283 stop-lost single nucleotide variants and over 2.5 million small InDels. 2244 variants (4,451 transcripts) with viable translation sequence alterations were identified. While these variants were previously predicted to be LOF, approximately 36% (815) of variants exhibit a benevolent character, only introducing 10 or less altered amino acids. Conversely, approximately 13% (291) of variants introduced a protein with at least 100 altered amino acids, with 7% (21/291) of these variants located in genes classified as tolerant to variation and associated with a pathological background; e.g. SRCAP (prostate cancer), AHNAK (Systemic lupus erythematosus), and SH3PXD2A (Alzheimer's disease). In conclusion, information provided by COCOS allows for a more detailed analysis of variant consequences with respect to the sequence of gene transcripts, and thus will guide the scientific community to place these sequence alterations into their biological context.

Copy number estimation from targeted and shallow sequencing. *Z. Che, A. O'Hara, R. Keshavan, W. Sherman, V. Wasnikar, S. Shams.* BioDiscovery, Inc., El Segundo, CA.

Targeted panel sequencing has been a popular method to achieve high depth of coverage for certain regions of interest at an affordable cost compared to whole genome sequencing. Shallow whole genome sequencing, where average read-depth can be as low as 0.1x, provides a cost savings-approach for identification of large copy number variant (CNV) events; it has been utilized in various application areas, including oncology and Pre-Implantation Genomic Screening (PGS). Depending on genomic coverage (whole genome vs. whole exome vs. targeted panel) and sample type (constitutional vs cancer), different algorithmic approaches may prove to be more or less ideal for estimating copy number from next generation sequencing (NGS) results. Some approaches require matched normal samples (e.g. ngCGH) while others use the characteristics of the sample itself for normalization (e.g. Wisecondor and QDNASeq). Other methods use a pool of reference samples (e.g. Pooled Reference, xHMM, and CONFIER). Here, we introduce a new approach (dCNVSeq) that extends the Pooled Reference algorithm to function with shallow, as well as targeted, sequencing data by introducing a novel dynamic binning approach. The approach uses a Hidden Markov Model to segment the genome into areas forming the "backbone" using the off-target reads and additional areas where targeted reads are present. dCNVSeq uses coarse binning in the backbone area providing base line copy number as well as detection of large CNV events and fine binning in targeted areas to provide high resolution CNV detection in targeted regions. We present a comparison of copy number estimation results from ngCGH, QDNASeq and dCNVSeq using WES, targeted panels, and shallow sequencing data.

1827F

Accurate identification of disease-specific non-coding risk variants based on multi-omics profiles. *L. Chen[1], P. Jin[2], Z. Q[3,4].* 1) Department of Mathematics and Computer Science, Emory University, Atlanta, GA 30322, USA; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322, USA; 3) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, Atlanta, GA 30322, USA; 4) Department of Biomedical Informatics, Emory University School of Medicine, Atlanta, GA 30322, USA.

The majority of variants identified by Genome-wide association studies (GWASs) fall outside of the protein-coding regions. Understanding the cryptic link between non-coding sequence variants and pathophysiology of complex diseases is a fundamental challenge. To overcome the lack of annotations in the non-coding regions, various recent computational methods have been developed to identify non-coding risk variants using genome-wide genomic and epigenomic profiling data. A common feature of these methods is that they do not distinguish risk variants associated with different diseases. Since different biological mechanisms are believed to contribute to the etiologies of different diseases, it is desirable to characterize the impact of a non-coding variant in a disease-specific manner. In this work, we describe DIVAN, a data-driven machine learning approach that aims to identify disease-specific risk variants. Using 1,806 epigenomic profiles across cell types and factors, along with other static genomic features, we adopt a novel feature selection based ensemble-learning framework to achieve this goal. To evaluate the predictive performance, we first conduct comprehensive tests across 45 different diseases belonging to 13 different classes and compare DIVAN with multiple existing methods. We observe that the proposed method accurately discriminates (AUC from 0.65 to 0.88 with median 0.74 in cross validation) disease-specific risk variants from benign ones in non-coding regions and outperforms other competing methods. We further demonstrate DIVAN achieves better predictive performance than other competing methods in an independent testing dataset including 36 diseases. These results suggest that the DIVAN has the potential to identify novel variants in a disease-specific manner, which will be important in interpreting personal genome sequencing data. We use number of reads instead of peaks around the variants as feature in DIVAN in order to accommodate the scarcity of known risk variants for each disease. Our major finding is that, H3K9me3, a histone mark associated with repressed chromatin and depleted in most diseases, shows up as the most informative features in distinguishing risk variants from benign ones in 34 out of 45 diseases studied. Enriched in most diseases, open chromatin, defined by DNaseI and FAIRE, comes in second. Overall, histone marks contribute more to informative features than transcription factors and open chromatin in DIVAN. .

In silico variant effect prediction for whole exome analysis: Clinical caveats. *S. Chervitz, J. Anderson, D. Glazer, S. Galasinski, K.M. Chen, J. West, R. Chen.* Personalis, Inc., Menlo Park, CA.

Computational tools such as SIFT, PolyPhen and others provide in silico prediction of the pathogenicity of missense sequence variants based on sequence information. Some of these tools, such as SIFT and PolyPhen, have been in use since the early 2000's, before the completion of the human genome. Current versions of SIFT & PolyPhen2 have sensitivity ~70%, but they suffer from low specificity (~15%, Flanagan et al 2010). If ~1% of missense variants are truly damaging in a typical exome, then, given the 20% false positive rate for SIFT and PolyPhen2, such tools would incorrectly flag 19 of 20 missense variants as damaging, for a positive predictive value of only 5%. The clinical utility of these tools, given this performance is questionable at best. Efforts to improve the performance of in silico tools are on-going (Masica & Karchin 2016), but given their wide use in the clinical community, we need to recognize and understand the limitations of these pathogenicity prediction tools. Here, we assess the reliability of SIFT, PolyPhen2 and other variant effect predictions on a set of variants observed in clinical whole exome samples processed by Personalis, Inc. We examine the correlation between the damaging/tolerated calls of the tools compared to a reference set of clinical significance values assessed by genetic counselors using a variety of newer resources. We highlight the risk of misinterpretation of results from commonly used in silico tools, particularly for variants of uncertain significance (VUS), and underscore the need of the clinicians to understand the limitations of such tools when assessing variant results from whole exome analyses. The growing amount of publicly available data from individual whole exome and whole genome sequences is increasingly making the use of in silico tools obsolete for variant classification. Resources from such new data include allele frequencies in control and patient populations and case observations. Growing use of transgenic animal models as well as the improvement and wider usage of in vitro functional studies will also increase the number of useful resources available for classification. **References**: Flanagan et al. (2010). Using SIFT and PolyPhen to predict loss-of-function and gain-of-function mutations. Genet Test Mol Biomarkers 14(5):730. LocusZoom.js: Web-based plugin for interactive analysis of genome and phenome wide association studies. *C.P. Clark, M. Flickinger, R. Welch, P. VandeHaar, D. Taliun, M. Boehnke, G. Abecasis.* Biostatistics, University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have revealed hundreds of loci associated with common human genetic diseases and traits. Phenome-wide association studies (PheWAS), wherein each genetic variant is analyzed against a broad range of phenotypes, provide a different cross-sectional view over the same genotype data sets. In order to facilitate understanding these association results, data visualizations must be generated that combine association results with relevant context such as local linkage disequilibrium (LD), recombination patterns, and the positions of genes in the region. The original LocusZoom, a web-based plotting tool for fast visual display of GWAS results, targeted this problem by allowing users to upload data, specify region(s) of interest, and generate static visualizations. Since its inception in 2010 it has generated over 500,000 plots for use in presentations, publications, and other research settings. We have developed a new implementation of LocusZoom targeted at interactively visualizing both GWAS and PheWAS results: LocusZoom.js. This extensible open source JavaScript framework generates plots supporting many new features such as real time rearrangement, elastic scaling, simultaneous display of multiple analyses, dynamic inclusion and removal of analyses, and interactivity to afford deeper study (for example: conditional analysis). Plots can be generated by loci within the genome, providing panning and zooming capabilities to explore nearby loci, or plots can be generated using any other value for the domain: for example, plotting by grouped phenotypes results in a PheWAS. Publication-quality static snapshots of interactive plots can be easily exported. LocusZoom.js was designed as a general module for generating interactive visualizations of genetic data for a wide variety of use cases. It has been implemented in the Accelerating Medicines Partnership (AMP) Type 2 Diabetes Knowledge Portal for multiple phenotype analysis and PheWeb, a Michigan Genomics Initiative resource for phenome-wide association studies. Source code and user documentation can be accessed at github.com/statgen/locuszoom. Functional versions of original LocusZoom and new LocusZoom.js can both be accessed at http://locuszoom.sph.umich.edu.

mini-mitoCalc: **An ultra-fast program to estimate mitochondrial DNA copy number from whole-genome sequences.** *J. Ding[1], Y. Qian[1], C. Sidore[2], R. Nagaraja[1], F. Cucca[2], G.R. Abecasis[3], D. Schlessinger[1].* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy; 3) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

The mitochondrial cellular power plant is partially encoded in its own constituent circular genome of ~16kb. In humans, every cell has 100-10,000 copies of the mitochondrial DNA (mtDNA). The copy number is tightly regulated in various tissues, and is both a critical determinant of the level of mitochondrial function and a potential biomarker for diseases. With the collection of whole-genome sequencing data in various large-scale genetic studies, we and others have shown that the mtDNA copy number per cell can be directly estimated from whole-genome sequencing. The computation is based on the rationale that average sequencing coverage should be proportional to underlying DNA copy number for autosomal and mitochondrial DNA. Because the mitochondrial genome is comparatively quite small, most computing time is spent calculating the average autosomal DNA coverage across all ~3 billion bases. That makes investigation of the tens of thousands of samples already available in the public domain very slow. Here we present "*mini-mitoCalc*", which is >100 times faster than conventional programs including our published program "*mitoCalc*". It takes advantage of the indexing of sequencing alignment files, focusing on a selected subset of the nuclear genome to estimate autosomal DNA coverage accurately (correlation > 0.999 with the full genome estimate). Consequently, a computer cluster with 50 CPUs can now finish analyzing low-pass sequencing (a 4X average nuclear DNA coverage) of 10,000 samples in 3 hours rather than the 17 days required by the original program. As a result, analyses can be conducted efficiently to test for association of mtDNA copy number with quantitative traits or to identify any variants that regulate mtDNA copy number using large-scale consortium data.

1831W

Combined prioritization of genetic variants using the Variant Effect Scoring Tool (VEST). *C. Douville[1], D.L. Masica[1], P.D. Stenson[2], D.N. Cooper[2], D.M. Gygax[3], R. Kim[3], M. Ryan[3], H.K. Carter[4], R. Karchin[1,5].* 1) Biomedical Engineering and Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 2) Institute of Medical Genetics, School of Medicine, Cardiff University, Heath Park, Cardiff, UK; 3) In Silico Solutions, Fairfax, VA; 4) Division of Medical Genetics, University of California, San Diego, CA; 5) Department of Oncology, Johns Hopkins University School of Medicine, Baltimore, MD.

The average genome contains tens of thousands of single nucleotide variants (SNVs) as well as hundreds of insertion/deletion (indel) variants that alter protein sequence. Computational tools for most variant types have been developed to assess their potential impact on human health. Most computational tools, however, can only prioritize one type of genetic variant. Here, we present the Variant Effect Scoring Tool (VEST) [1,2], a method that jointly prioritizes all non-silent variant types: missense, in-frame and frameshift indels, splice site, nonsense and nonstop. VEST is trained on pathogenic variants from the Human Gene Mutation Database [3] and polymorphisms from the Exome Sequencing Project [4]. It uses a mix of predictive features that are shared between variant consequence types and those that are unique to a single variant consequence type. Scores for different consequence types are integrated using characteristic analytical null distributions, so that p-values are comparable across types. To our knowledge, the only other method for joint prioritization of multiple variant consequence types is Combined Annotation Dependent Depletion (CADD) [5]. We use a hold-out validation protocol to compare VEST and CADD. For a variant set dominated by missense VEST ROC AUC=0.9 and CADD ROC AUC=0.88. For a variant set where missense and indels have equal portions VEST ROC AUC=0.91 and CADD ROC AUC=0.74. VEST 3.0 is available at http://cravat.us and https://hub.docker.com/r/karchinlab/cravat-mupit/. [1] Carter, Hannah, et al. ClinGen's gene and variant curation interface suite: Centralized and consistent evaluation of the clinical relevance of genes and variants. *S. Dwight[1], M. Wright[1], K. Dalton[1], K. Liu[1], M. Choi[1], F. Tanaka[1], J. Zhen[1], D. Azzariti[2], L. Babb[2], C. Bizon[3], M. Distefano[2], S. Harrison[2], R. Patel[4], P. Pawliczek[4], E. Rooney Riggs[5], N. Strande[6], A. Buchanan[5], R. Ghosh[4], J. Berg[6], C. Bustamante[1], C. Martin[5], A. Milosavljevic[4], S. Plon[4], H. Rehm[2], J.M. Cherry[1], the ClinGen Consortium.* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Partners HealthCare Laboratory for Molecular Medicine, Cambridge, MA; 3) Renaissance Computing Institute, University of North Carolina at Chapel Hill, NC; 4) Baylor College of Medicine, Houston, TX; 5) Geisinger Health System, Danville, PA; 6) University of North Carolina at Chapel Hill, NC.

Critical to the field of clinical genomics is an understanding of the strength of correlation between genotype and phenotype. The central mission of ClinGen (clinicalgenome.org) is to define the "clinical relevance of genes and variants for use in precision medicine and research." Inherent to this mission is the ability to access and evaluate evidence for a gene or variant's role in disease in a consistent, efficient manner. As such ClinGen is building a suite of interconnected interface tools, one for gene curation and the other for variant curation. These tools are currently accessible to ClinGen curators and are also being designed and developed for use by the broader community. The ClinGen gene and variant curation interfaces have been developed according to the following important specifications: 1) gene curation will follow the Clinical Validity Classifications framework established by ClinGen's Gene Curation Work Group while variant curation will follow the ACMG Standards and Guidelines, 2) both interfaces will centralize evidence from relevant resources in order to enable efficient, consistent curation, 3) curated evidence and evidence retrieved from external resources will be shared between the gene and variant curation tools, 4) the interfaces will be designed to guide curators through the curation process, 5) controlled vocabularies and ontologies will be used in order to promote the capture of discrete evidence, facilitate connections, and promote consistency, 8) the ClinGen Allele Registry will be used to normalize variants and provide an identifier for ClinVar submission, 7) external and curated evidence will be viewable by all curators, while curated evidence can only be edited by its creator, 8) the interfaces will support expert review of provisional classifications and interpretations through access to all evidence, 9) contextual help and documentation will be included to assist the curator within the interface, and 10) JSON-LD will be used to promote rich relationships within these data. The ClinGen gene curation interface is currently in production and actively supports ClinGen curation while an early version of the ClinGen variant curation interface is in production and undergoing rapid and iterative update cycles. The rich evidence captured by both tools exists in a structured format that allows it to be accessible on ClinGen's public portal (clinicalgenome.org).

***Ella*: Decision support and structured data in clinical variant classification.** *M. Eike, S.T. Seljebotn, E. Nafstad, T. Håndstad, H. Fontenelle, D.J. Honneffer, E. Severinsen, T. Grünfeld, D.E. Undlien.* Dept of Medical Genetics, Oslo University Hospital, Oslo, Norway.

We have made a software tool named *ella* to aid and improve the quality and reproducibility of clinical interpretations of genetic variants, a core task for genetic laboratories. Clinical classification is usually done according to procedures that detail how different types of evidence should be assessed and combined, and many have adopted the revised ACMG guidelines for variant interpretation (Richards et al., 2015). The conclusion, however, still very much depends on the experience of the interpreter and their subjective judgement. With the increased volume from high-throughput sequencing, this quickly becomes a daunting task. Moreover, the documentation often involves a high degree of unstructured data in the form of free text comments and/or literature references, which makes automated decision support and quality control difficult to achieve. In response to these challenges, we have created *ella*, a web-based software tool that guides the interpreter through a series of steps where different types of information are presented for assessment. A major step involves evaluating literature references through a dynamic questionnaire, which translates key evidence from the reference into structured data. Together with a set of configurable rules, this enables the software to automatically suggest evidence categories based on ACMG guidelines for both various types of annotation and evaluated literature, as well as a clinical classification. As a result, the reasoning behind each evaluation becomes more standardised, transparent, and reproducible, which increases trust in the classifications and facilitates their sharing and future reuse. A main goal has also been to simplify the decision making process for the user, and *ella* has been carefully designed in close collaboration with lab engineers at our department. The current version of the tool is particularly useful for large-volume sample analyses with re-occurring variants and defined phenotypes (e.g. genetic tests for inheritable cancer), but we are also working to include more open-ended setups for low-volume, less clearly defined phenotypes. *Ella* is currently being tested at our department and will be used in production later this year. This presentation will demonstrate the logic behind the software, with specific examples.

ExpressionLncr: A pipeline for leveraging latent gene expression data in lncRNA studies. *G. Ellis[1], L. Akhabir[1], C. Brown[2], D. Daley[1].* 1) Centre for Heart Lung Innovation, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

Background: Investigating the functionality of lncRNA and other RNA in regulating the genome is an active and growing area of research. Databases of non-coding RNAs such as NONCODE and LNCipedia contain 141k and 119k human annotated lncRNAs to date, respectively—necessitating informatics tools to sift through and investigate functionality en masse. A wealth of functional genomics data is already deposited in NCBI GEO but, likewise, harnessing these 70 thousand experiments on 1.8 million samples in an effective manner can be challenging for those without informatics resources. **Hypothesis:** Existing functional genomics data can be leveraged to predict functionality of lncRNAs. **Methods:** We have created a program called ExpressionLncr(na) to harness this latent information. It is a pipeline to investigate the potential expression of lncRNAs by leveraging existing NCBI GEO gene expression information. The software sources lncRNAs from lncRNA databases such as NONCODE or LNCipedia and is not restricted to lncRNAs, allowing user-specified chromosome features. Features are restricted to reference organisms with expression probe array annotation information in Ensembl. The tool computes matches for positional overlap between Ensembl expression probes and lncRNAs. Summary results from GEO DataSets relevant to these overlapping features are used to calculate presence or absence of expression at each lncRNA. Positive links between probe expression data and lncRNA position may suggest possible functionality of the lncRNA worth further investigation. ExpressionLncr is written as a collection of command-line scripts with an optional graphical interface. The software will be available in two formats, both freely available: as a set of tools for the popular Galaxy bioinformatics web platform, and as an operating system independent desktop application. Future work is planned to extend the pipeline to RNA-seq information. **Summary:** ExpressionLncr is a bioinformatics pipeline to investigate the functionality of lncRNAs and other chromosomal features by computing positional overlap between lncRNA databases and existing gene expression probe information in NCBI GEO. Exploiting this latent information should help investigators interested in non-coding RNAs in planning new studies as well as prioritising candidate non-coding RNAs for molecular biology experiments.

1835T

A framework for benchmarking aligners and variant callers. *K. Ghose[1], G. Rakocevic[3], J. Spencer[2], W. Lee[1], D. Kural[1].* 1) Seven Bridges Genomics, Cambridge, MA; 2) Seven Bridges Genomics, London, UK; 3) Seven Bridges Genomics, Belgrade, Serbia.

There is a huge abundance of tools available for almost every step in any given genomics data processing pipeline. While this proliferation of tools can be beneficial, it also poses problems for researchers trying to construct a pipeline for their data analysis. Researchers are faced with the daunting task of determining which tools are trustworthy, give good results for their domain of interest and fit their accuracy, cost and time trade offs. While developing a new breed of genomic processing pipeline (a graph reference based aligner and variant caller) Seven bridges engineers had to also develop a framework for efficiently testing and benchmarking the performance of the new pipeline, comparing performance between different pipeline versions as well as against existing genomic pipelines. The variant calling benchmarking component is compliant with the GA4GH specifications for benchmarking variant callers.The benchmarking framework enables tool developers and users to run multiple pipelines against the same simulated or standard truth data sets with various parameter combinations and receive reports at multiple levels of detail. The reports start with leaderboard summaries, that give a high level overview of the field of tools being compared, which can then be inspected at increasing levels of detail, sufficient to debug tool performance at the level of individual variant calls and read alignment.While components of the framework can be run manually and locally, it is much more convenient to use the automation component to run and manage the huge volume of benchmark reports and raw data on the Seven Bridges Cloud Computing Platform. This has the added benefit of yielding accurate estimates of pipeline run time and cost when executed on the same platform.Though the framework has been developed to benchmark alignment and variant calling pipelines, the architecture has been designed to be flexible to be able to accommodate different kinds of genomics pipelines, with appropriate plugins for data analysis and display tailored to those classes of pipelines.

1836F

Towards the internet of DNA: Large-scale multi-institutional case-solving improves the power of and access to sequence-based rare disease diagnostics. *J. Gulcher[1], Y. Meng[1], K. Meirelles[1], H. Dai[1], Q. Zhao[1], T. Yu[2], S. Ennis[3], H. Wang[4], W. Zhou[4], P. Fang[1].* 1) WuXi NextCODE, Cambridge, MA; 2) Boston Children's Hospital, Boston, MA; 3) University College Dublin, Dublin, Ireland; 4) Children's Hospital of Fudan University, Shanghai, China.

Economical, high quality exome and whole-genome sequencing provides the raw data with which to diagnose and better treat an increasing proportion of rare disease cases. The challenge is interpreting that data efficiently and effectively, leveraging the wealth of large sequence databases, reference sets, and clinical genetics expertise worldwide. Doing so will benefit patients, who are, by definition, geographically scattered from others with similar rare disorders and who have variable levels of access to clinical genomics expertise. We will present our approach to meeting the challenge of data access and expert analysis through multi-institutional case-solving. We use a computationally efficient standard data architecture (a Genomically Ordered Relational database or GORdb) to store whole-exome or whole-genome sequence data. This includes aligned reads, variant data, and phenotype data, all identity-encrypted, at two sites: on local servers in China and on a HIPAA-compliant secure cloud in the United States. These data are made accessible to multiple clinical institutions in the US (WuXi NextCODE in Cambridge and Boston Children's Hospital), Ireland (UCD), and China (Fudan Children's Hospital) using a standard, validated decision-support user interface (Clinical Sequence Analyzer, or CSA).   With the ability to query and visualize raw sequence data at a distance, clinicians, clinical geneticists and bioinformaticians in Shanghai, Dublin, and Boston can collaborate on dozens of cases per week. All can work simultaneously from the same data, harmonized with the same set of public reference data, to identify known, novel and de novo pathogenic and likely pathogenic variants; instantly visualize the aligned reads for confirmation; search sequence databases at other institutions for the same variants or other variants in the same genes; and create diagnostic reports from their consensus findings. Final reports are signed off by certified medical professionals at the patients' institutions.   All of this is done without moving the raw data itself. This makes it much easier to share data and interpretation, and in a systematic and validated manner. For diagnostics this offers a scalable way to overcome major logistical and compliance barriers to using the full power of the data and the latest knowledge. It also makes possible the linking together of large collections of sequence data for discovery.

1837W

Development of a text mining algorithm to extract socioeconomic data from electronic health records for precision medicine research. *B. Hollister[1], E. Farber-Eger[1], N. Restrepo[2,3], D. Crawford[2,3], A. Non[4], M. Aldrich[5,6].* 1) Vanderbilt Genetics Institute, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Epidemiology & Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 4) Department of Anthropology, University of California, San Diego, La Jolla, CA; 5) Department of Thoracic Surgery, Vanderbilt University Medical Center, Nashville, TN; 6) Division of Epidemiology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

Socioeconomic status (SES) is a fundamental contributor to health, particularly when analyzing racial disparities in disease. SES data are rarely included in genetic studies and translational precision medicine research, due in part to the difficulty of collecting these data when studies were not originally designed for that purpose. The emergence of large clinic-based biobanks linked to electronic health records (EHRs) provides research access to large patient populations with longitudinal phenotypic data captured in structured fields as billing codes, procedure codes, and prescriptions. SES data however, are often not explicitly recorded in structured fields, but rather recorded in the free text of clinical notes and communications. The content and completeness of these data vary widely by practitioner. To enable gene-environment studies that consider SES as an exposure, we sought to extract SES variables from racial/ethnic minority patients (n=11,197) in BioVU, the Vanderbilt University Medical Center biorepository linked to de-identified EHRs. We developed several measures of SES using information available within the de-identified EHR, including broad categories of occupation, education, insurance status, and homelessness. 200 patients were randomly selected for manual review to develop an algorithm for extracting SES information from de-identified medical records. The algorithm consists of 15 categories of information, with 830 unique search terms. An additional 50 records were then randomly selected for algorithm evaluation. These 50 records were reviewed by two independent reviewers, with Kappa statistics ranging from 0.47 for occupation to 0.92 for retirement, and percent positive agreements ranging from 80% (Medicaid) to 93.3% (retirement). The manual review results from the 50 records were then compared to the results from the algorithm, resulting in positive predictive values of 35% (education), 63.6% (retirement), 87.5% (unemployment), 81.8% (Medicaid), and 33.3% (homelessness), suggesting some categories of SES data are easier to extract than others. The SES data extraction approach developed here will enable future EHR-based genetic studies to integrate SES information into statistical analyses. Ultimately, incorporation of measures of SES into genetic studies will help elucidate the impact of the social environment on disease risk and outcomes.

1838T

Accurately detecting genome-wide changes in gene expression or epigenetic modifications with a novel and efficient permutation-based method. *W. Huang, L. Li.* Biostatistics and Computational Biology Branch, NIEHS, NIH, Research Triangle Park, NC.

Cost-effective sequencing-based assays have become dominant methods for studying gene expression and epigenetic regulations, particularly for identifying genetic/epigenetic changes responsible for phenotypic differences. There are many exists methods for analyzing these sequencing data though only a few of methods widely used mainly due to their easy-to-use. Sequencing technologies and their applications are, however, still advancing quickly. Some existing tools are no longer sufficient for new and more advanced sequencing applications. For example, many early tools, designed for data with few replicates, cannot take full advantage of sequencing data with more replicates; and some of these tools rely on some unrealistic assumptions (e.g., Poisson model). Many out-of-date methods have either an inflated false positive rate or low statistical power to identify true difference. Taking advantage of increasing number of biological replicates from more recent sequencing data, and parallel computing power from high-performance computing (HPC) clusters, we introduce a novel balanced permutation method in parallel computing to identify differentially expression or epigenetic changes from sequencing data. Our semi-parametric method uses the balanced permutation to estimate distribution under true-null model, and then uses the estimated distribution to calculate the statistical significance of observed data. Our balanced permutation method can deal with cases that the numbers of replicates between two groups are different, and can automatically switch from systemic permutations to random permutation when possible permutations is larger than a defined threshold. We did the performance evaluation of our method with both simulated and real RNA-seq data. The results showed that our method, in comparison with traditional permutation methods, not only more powerful in detecting changes, but also more efficient in computation time. Our method is implemented in R, and will be freely available to the public once it is released.

Imputing a large multiethnic cohort of 200,000 individuals: The Department of Veterans Affairs Million Veterans Program (MVP). *J. Huang[1], S. Pyarajan[1,9], H. Hunter-Zinck[1], N. Sun[6,7], Y. Shi[1], M. Li[1,8], J. Gelernter[6,7], P. Loh[10], S. Das[11], C. Pan[2,3], E. Hauser[4,5], H. Zhao[6,7], T. Assimes[2,3], P. Tsao[2,3], J. Gaziano[1,9], C. O'Donnell[1,9].* 1) VA Boston Healthcare System, Boston, MA; 2) VA Palo Alto Health Care System, Palo Alto, CA; 3) Stanford University School of Medicine, Palo Alto, CA; 4) Durham VA Medical Center, Durham, NC; 5) Duke University, Durham, NC; 6) VA Connecticut Healthcare System, West Haven, CT; 7) Yale School of Public Health, New Haven, CT; 8) University of Utah, Salt Lake City, UT; 9) Harvard Medical School, Boston, MA; 10) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 11) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Introduction Statistical inference of missing genotypes (imputation) has been critically essential for the discovery of thousands of complex trait loci in meta-analyses of genome-wide association studies (GWAS). Although imputation on sample sizes exceeding 100,000 has been reported (UK Biobank), imputation in the Million Veteran Program (MVP) is unique in at least two aspects. First, the MVP Axiom array contains ~300,000 variants with MAF <1%, a much bigger proportion than that in UK Biobank. Second, MVP participants consist of diverse ethnic ancestries (~30% samples of non-European ancestry). **Methods** We used EAGLE2 and Minimac3, while UK Biobank used SHAPEIT3 and IMPUTE3. We run pre-phasing on full chromosomes and imputation in chunks (5Mb with 250kb flanking region). We first evaluated the applicability of commonly used genotype filtering criteria (i.e., MAF>1%, Missingness <5%; HWE P>1E-09) to the MVP genotype data and designed a preferred strategy on keeping/excluding samples and variants for imputation. We then used Pseudo-GWAS approaches to design a preferred pre-phasing strategy on a large dataset with a diverse ethnical background. We compared our MVP Axiom array data with a few other commonly used arrays including Axiom UK Biobank, Illumina Ominiexpress, and Illumina Omni5. Finally, we evaluated the computational resources needed for imputing a dataset with ~200,000 samples, within a local cluster that has stringent regulations on data security. **Results and Conclusions** Using EAGLE2 and Minimac 3, we were able to complete pre-phasing and imputation in ~14 days. The imputed data is comprised of 540 chunks of 5Mb across 22 autosomes, including 49,859,576 variants for 192,538 Samples. Overall, 32,204,361 and 12,802,159 have imputation $r2 > 0.3$ and > 0.8 respectively. However, we found that the overall r2 does not correlate well with empirical r2, therefore, we recommend to calcualte r2 based on subset of samples with the same ethnical background. We found that our Axiom MVP panel has comparable performance to the Axiom UK Biobank array, measured by imputation accuracy and genomic coverage. Genotyping and imputatoin for the next ~200,000 samples are expected to complete soon, and we will present most up-to-date results.

1840W

Maximizing sensitivity using ensemble genotyping approaches for whole-genome sequencing. *K. Hwang[1], I. Lee[2], X. Liu[3], H. Li[1], D. Won[1], S. Kong[3].* 1) School of Computer Science and Engineering, Soongsil University, Seoul, South Korea; 2) Samsung Genome Institute, Samsung Medical Center, Seoul, South Korea; 3) Computational Health Informatics Program, Boston Children's Hospital, Boston, MA.

Analytical validity and reproducibility between genome analysis pipelines remain questionable. There is an immediate need for a comprehensive evaluation of genome analysis pipelines. Here we present approaches to improve sensitivity of genotype calls based on a comparative analysis of 70 pipelines (7 aligners x 10 variant callers). Using two whole-genome sequences from a European (NA12878) and an African (NA19240) descents, we highlight the sources of discordant variant calls and compare the results with high-confidence variants from the Genome in a Bottle Consortium (GIAB) and the 1000 Genomes Project (1KGP) data. Surprisingly, rare variants with potential high impacts – i.e., interesting variants potentially associated with phenotypes – were enriched with discordant results, which could result in false positives and false negatives. For NA12878, 92% of common SNVs (MAF ≥ 5%) were identified by more than 56 pipelines (80% of the 70) while only 23% of rare SNVs (MAF < 0.5%) were concordantly called. Similar tendencies were observed for NA19240 and for INDELs from both individuals. Sequence context such as repetitive sequences and frequency of INDELs were associated with discordant calls between pipelines. Interestingly, high-confidence variants were concordantly called by the 70 pipelines when focusing on disease genes with high fixation indices between EUR and AFR (96% of 344,791 NA12878 GIAB SNVs and 92% of 545,698 NA19240 1KGP SNVs). However, significant proportions of high-confidence SNVs in such disease genes (33 for NA12878 and 2,658 for NA19240) were detected by less than 20% of the pipelines, suggesting that the use of one pipeline could be suboptimal for identifying possible phenotype-associated variants for further evaluation and validation. For these SNVs, the highest sensitivity was achieved by applying eight pipelines for NA12878 and 47 pipelines for NA19240, when the order of applying pipelines was optimized by a greedy algorithm. We demonstrate that discordance, including a small set of high-confidence variants with potential disease-association, between whole-genome genotyping pipelines is affected by multiple factors such as allele frequency, repetitive sequences, and the frequency of INDELs. Moreover, the minimum number of pipelines needed for maximizing sensitivity varies by sequencing data, suggesting that caution should be exercised in the identification of variants with clinical implications in genomic sequences from minorities.

1841T

Hyperlink Management System for automated integration of biological databases by use of data IDs. *T. Imanishi.* Dept. Molecular Life Sciences, Tokai University School of Medicine, Isehara, Kanagawa, Japan.

Hyperlink Management System (**HMS**; http://biodb.jp/) is a system for automatically updating and maintaining hyperlinks among major public databases in the field of life science. Everyday, we create corresponding tables of data IDs that are used in major databases for human genes and proteins, and provide a CGI-program that returns correct and up-to-date URLs of corresponding data in many databases. By using the CGI program on this server, users can easily create hyperlinks to major databases in their own databases and homepages. Furthermore, on this web site, we provide useful tools such as "All Database Search", "ID converter system", "Downloading ID tables", and "ID Resolver". Based on HMS, we also developed and released BioDBScan, a free web-based application that alerts you when any data about genes, proteins, chemicals or drugs of your interest is newly released in world-renowned databases. As a recent advancement of HMS, we newly added several databases in the field of human proteome. We also added several databases concerning human genomic polymorphisms into HMS, and realized a comprehensive, recursive data search through a chain of hyperlinks, which can promote discoveries in the field of genome medicine. As a result, total number of databases integrated in HMS increased to 42 for human molecules, 19 for mouse molecules, and 17 for drugs and chemicals, and total number of data IDs covered exceeds 250 millions. We will continue to integrate more databases in the field of life science that are distributed in the world, and in the near future we plan to install new functions such as enrichment analysis tools.

1842F

Assessing the impact of gene ontology changes over time with GOTrack.

M. Jacobson[1,2], A.E. Sedeño-Cortés[1], P. Pavlidis[1,2]. 1) Michael Smith Laboratories, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Psychiatry, University of British Columbia, Vancouver, British Columbia, Canada.

   The Gene Ontology (GO) is widely used to annotate gene function, and is considered a gold standard for genomics data annotation and interpretation. It has become more popular to use "enrichment" analysis was a means for interpreting complex genetics findings. Given its prominence and value as a bioinformatics resource, it is important to understand how changes to GO and annotations over time impact users. While some studies of GO over time have been presented, routine assessment by end users remains challenging. Here we present GOTrack, a user-friendly web-based system for analyzing the historical stability of GO annotation data in multiple model organisms. The web site allows exploration of GO annotations at the gene and term level with multiple metrics and visualizations. Users can easily perform a "historical enrichment" analysis where over-representation analysis can be run on a gene hit list of interest using GO annotations from any era, with measurements of stability over time provided. Using the data and algorithms presented we investigate the impact of changes to GO on the stability and robustness of gene set enrichment results in a corpus of hit lists. GOTrack will help the research community assess the impact of changes to GO on their research and to focus on the most robust enrichment results.

1843W

Better interpretable models for proteomics data analysis using rule based mining.

F. Jayrannejad, T. O.F. Conrad. Department of Mathematics and Computer Science, Free University Berlin, Berlin, Berlin, Germany.

   Recent advances in -omics technology has yield in large data e.g. in the area of ms based proteomics. Due to noisy measurement and large size of this data, analyzing it has become a challenging issue. One of the main objectives in the analysis is identification of relevant patterns which can be used for classification. So, a method is required to find easily interpretable models from this data.An association rule (AR) mining algorithm mines patterns present in the data set frequently. The proposed method is to use AR mining algorithms to find appropriate classifying features. Many other techniques, e.g. machine learning methods, have been proposed to solve this problem. As mentioned before, one of the purposes of proteomics studies is to find features which can be used in diagnosis of diseases and provide an easily interpretable model. Many of the machine learning approaches e.g. neural networks do not provide easily interpretable models for the end users. On the other hand, most diseases are connected to a group of features (presence of a peak at a certain m/z value). ARs show this inter-dependency in an easily interpretable way. In addition, there are some groups of features which presence of only one of them might cause the occurrence of the phenotype. Therefore, a disjunctive AR mining algorithm, TitanicOR,is used to find this features in each class. In some cases, e.g. classifying two different types of blood cancer, there might be some features connected to a phenotype shared between two classes, here blood cancer. These features are not discriminating. In order to eliminate them, the idea of jumping emerging patterns is applied, to select the features that have a high frequency in one class and are not present in the other class at all. So, the method suggested in the current study starts with the peaks-lists from the spectras. Afterwards, the disjunctive emerging patterns will be mined using an adaptation of TitanicOR. Later, a collective likelihood based classification algorithm- PCL- will be used as classifier.Experiments of the proposed method on the real data available publicly and artificial data sets shows this method outperforms in terms of number of the features reported, reporting the inter-dependency between the features and diagnostic power of every selected feature individually, in comparison with state-of-the-arts method, SVM(liblinear) which has outperformed other classifies (Liu et. All, 2008).

1844T

Visualizing correlated causal variants. *R.D. Johnson[1], G. Kichaev[2], B. Pasaniuc[2,3,4].* 1) Dept of Mathematics, University of California, Los Angeles, Los Angeles, CA, USA; 2) Bioinformatics IDP, University of California Los Angeles, Los Angeles, CA, USA; 3) Dept of Human Genetics, Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA; 4) Dept of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA.

   Integrative methods that leverage disparate data sources have become important strategies in genetics research. For example, large-scale GWAS and functional annotation data derived from the ENCODE/Roadmap project have been successfully assembled to improve power in GWAS, fine-mapping, and eQTL studies. However, while the statistical engines that drive these methods have been well-established, principled ways of visualizing the resulting outputs is currently lacking. Here, we describe PAINTOR CAN-viz, a fine-mapping tool that visually summarizes an integrative fine-mapping experiment. The tool provides visual representation of the local correlation structure (LD), the functional annotations used, as well as association statistics and posterior probabilities for each SNP. Through PAINTER CAN-viz, we can visualize which SNPs form the credible set, which helps to identify the more significant SNPs. Additionally, the tool allows users specify smaller intervals of the genome to further examine areas of interest. Examining this output enables rapid identification of variants of interest for follow-up functional studies, providing insight into the driving mechanisms underlying a GWAS association. This command line tool is implemented in Python and we make freely available to the research community [https://github.com/ruthjohnson95/PAINTOR_CAN-vis].

1845F

PEMapper and PECaller – A more efficient whole genome sequence analysis pipeline. *H.R. Johnston, V. Patel, P. Chopra, M. Zwick, D.J. Cutler.* Department of Human Genetics, Emory University School of Medicine, Atlanta, GA.

   PEMapper and PECaller represent a marked improvement in efficiency and performance of whole genome mapping and genotype calling. PEMapper, while similar to BWA and Bowtie in approach, leverages the high-memory environment of modern computing clusters to allow the mapping processes to happen in parallel by significantly decreasing the number of read/write events to storage drives. This significantly increases the throughput of whole genome mapping by, for the first time, allowing a parallelized cluster to map multiple genomes without creating massive read/write bottlenecks in the process. PECaller represents an innovative approach to variant calling, in that it leverages both SNV and indel information simultaneously. This, paradoxically, allows PECaller to better distinguish between a true SNV and a true indel. Additionally, variant calling is done simultaneously in all samples of a given experiment. This allows PECaller to better differentiate between loci that are homozygous for the reference allele versus those that are 'missing data'. It also permits the imposition of a population genetics prior on the data as well as sophisticated models of read error. These combine to allow PECaller to better eliminate false-positives while still calling true heterozygotes effectively. This pipeline is dramatically more efficient than GATK in terms of resources used (storage space, computational time, network utilization, and efficiency in a computer clustered environment). Additionally, the data generated by PEMapper/PECaller is of the highest quality. We find that the number of false-positive variants called is likely to be less 0.1% (1 in 1000) per sample; the number of false-negative variants missed (true variants not called) is likely less than 3%, and the overall genotyping accuracy at known SNPs is somewhere between 99.7% and 99.9%, depending on the underlying accuracy of Illumina 2.5M arrays used as a comparison standard. When run on a novel experimental data set, PEMapper and PECaller perform exceptionally well. Over 400 samples were run through the pipeline, and the data quality is very high. Samples have theta between .0008 and .0009 across the board, as expected and the Ts/Tv ratio is greater than 2. Theta in the exome region is ~.00045, and the exome Ts/Tv ratio is greater than 3. Coupled with the accuracy information attained in the comparison to Illumina 2.5 array data, it is clear that this pipeline is both efficient and accurate.

1846W

High accuracy HLA alleles imputation system for Affymetrix Axiom Japonica Array™ and its application on Steven-Johnson Syndrome. *S.S. Khor[1], X.W. Zheng[2], H. Sawai[1], N. Nishida[1,3], Y. Hitomi[1], M. Ueta[4], R. Shingaki[5], S. Iwata[5], S. Kinoshita[4], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine,, University of Tokyo, Tokyo, Tokyo, Japan; 2) Department of Biostatistics, University of Washington, Seattle, WA, United States; 3) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 4) Department of Frontier Medical Science and Technology for Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 5) Toshiba Corporation, Life Science Div, Life Science Business Dept, Tokyo, Japan.

Human leukocyte antigen (HLA) or the Major histocompatibility complex (MHC) has been reported to be associated with various diseases and traits. Due to the complexity of the linkage disequilibrium (LD) structure of the MHC region, many genome-wide association studies (GWAS) failed to identify the primary causal variants or associated HLA alleles due to high cost of HLA typing. Statistically imputation of HLA alleles has becoming a routine in fine-mapping of GWAS studies. However, HLA imputations are highly dependent on the matching of HLA imputation reference and target population (eg: European reference performed poorly on Japanese GWAS). We have previously reported the reference panel for Japanese using Affymetrix 6.0, Affymetrix Axiom ASI and Ilumina HumanOmni2.5 reaching HLA imputation accuracies of 95.2-99.5% across the six HLA genes (-A, -B, -C, -DRB1, -DQB1, -DPB1). Recently, ToMMo (Tohoku Medical Megabank Organization), Toshiba healthcare together with Affymetrix Axiom® have developed Japonica Array™ specially customized for Japanese population. Japonica Array™ is shown to provide better SNP imputation performance in comparison to other commercially available genotyping platform. Based on our HLA imputation system (HIBAG), Japonica Array™ performed consistently well across the six HLA genes and performed exceptionally well in HLA-B compared with the other 3 genotyping platforms. Moreover, the Japonica Array™ could impute the risk *HLA* alleles (*HLA-A*02:06* and *HLA-B*44:03*) for cold medicine related Japanese Steven-Johnson Syndrome (SJS) with 100% accuracy in comparison with Affymetrix Axiom ASI with an accuracy of 59/59 and 28/29 in 117 patients who carry the risk *HLA* alleles respectively. Therefore, the new Japonica HLA imputation could provide a nearly 100% accuracy imputation for common alleles in comparison with other commercial genotyping platforms.

JGA: Japanese Genotype–phenotype Archive. *Y. Kodama[1], J. Mashima[1], M.T. Minowa[2], M. Kawashima[2], K. Miyazaki[2], N. Mitsuhashi[2], E. Kaminuma[1], O. Ogasawara[1], K. Okubo[1], Y. Nakamura[1], T. Takagi[1].* 1) DDBJ Center, National Institute of Genetics, Mishima, Shizuoka, Japan; 2) National Bioscience Database Center, Japan Science and Technology Agency, Tokyo, Japan.

This poster focuses on the Japanese Genotype-phenotype Archive (JGA, http://trace.ddbj.nig.ac.jp/jga) in collaboration with our partner institute, the National Bioscience Database Center (NBDC, http://humandbs.biosciencedbc.jp) of the Japan Science and Technology Agency. JGA is the Japanese counterpart of the dbGaP (database of genotypes and phenotypes) and EGA (the European Genome-phenome Archive) at NCBI and EBI, respectively, serving as one of centralized repositories providing authorized access to individual-level phenotype and genotype data. To exploit personal genomic data while respecting the privacy and informed consents of study participants, it is essential to establish a centralized repository for data management and a policy for data usage. In the US, the National Institutes of Health (NIH) have established guidelines for sharing human subject data. Likewise, NBDC in Japan established guidelines and policies for sharing human-derived data. The Data Access Committee (DAC) at NBDC reviews and makes decisions about data submission to JGA and usage requests from researchers. JGA accepts data that are de-identified by submitters. Acceptable data types include raw data from array-based and next-generation sequencing platforms, clinical images, and phenotype data associated with data samples. Processed and analyzed data such as alignments, assemblies and variations are also acceptable. Upon submission, the JGA team will archive the original data files in encrypted form in the database. Information in JGA is organized in a hierarchical JGA data model based on that of EGA. JGA assigns stable, unique identifiers prefixed by 'JGA' to studies and subsets of information from those studies. Once access has been granted by DAC, datasets with access permission can be downloaded with secure downloading software. Information about available studies (summary level data) can be accessed freely on the JGA (https://ddbj.nig.ac.jp/jga/viewer/view/studies) and NBDC websites. As of 27 May 2016, 28 studies are available at JGA. In the poster, we present contents, system and recent developments of JGA.

Reducing genotoxicity risk in gene therapy - Identification of tumor insertion sites using next gen sequencing. *H. Kuck[1], P. Westmoreland[2], V. Nadella[1], H. Zhong[1], D. McCarty[2], P. White[1].* 1) The Institute for Genomic Medicine at Nationwide Children's Hospital, Columbus, OH; 2) The Center for Gene Therapy, The Research Institute at Nationwide Children's Hospital, Columbus, OH.

Gene therapy utilizing recombinant adeno-associated virus (rAAV) vectors has been a safe and effective treatment in mouse models of human disease and in clinical applications. Although the risk is much lower for integration into chromosomal DNA, potentially promoting tumor growth, than with retroviral vectors, there have been reports of genotoxicity limited to specific vectors associated with excess hepatocellular carcinomas (HCC) in mice. In order to understand the potential mechanisms of genotoxicity and identify insertion patterns of integration events that could promote tumor formation, we identified insertion sites from tumors in tumor prone C3H/HeJ mice treated with self-complementary AAV (scAAV) vectors, either conventionally expressing a gene, or designed to promote insertional activation.   To identify insertion sites we followed Agilent's SureSelect QXT NGS target enrichment workflow to enable us to enrich genomic DNA fragments containing scAAV. Genomic DNA extracted from the tumors was fragmented, adaptor-ligated and PCR amplified. Custom SureSelect Probes of 120bp designed using Agilent's SureDesign service to target the scAAV vectors were used for library capture. The target enriched DNA library was further PCR amplified using dual indexing primers and sequenced on Hiseq 4000 using Paired end 2X 150bp chemistry. For bioinoformatic analysis of the resulting sequence data we developed a custom application to identify insertions sites. Read pairs were aligned to the mouse and vector using BWA-MEM and SAMBLASTER was used to find split and discordant reads. Potential insertion sites are identified and quantified by analyzing split and discordant read pairs that align to both mouse and vector. These sites are ranked by the strength of supporting evidence: insertion sites where multiple reads have junctions at the same location with high quality alignment to both sequences most likely identify a true insertion site. Insertion sites will be validated by PCR amplification of the identified vector-chromosome junctions and Sanger sequencing.   Our results indicate repeated patterns of vector insertions associated with specific proto-oncogenes depending on which vector was administered. This suggests new possibilities in vector design to minimize the risk of the most common proto-oncogene interactions.

1849W

Interpretable, integrative deep learning models of *in-vivo* **transcription factor binding reveal the context-specific heterogeneity of regulatory DNA.** *A. Kundaje[1,2], N. Boley[1], J. Israeli[3], A. Shrikumar[2], P. Greenside[4].* 1) Dept. of Genetics, Stanford University, Stanford, CA 94305; 2) Dept. of Computer Science, Stanford University, Stanford, CA 94305; 3) Biophysics Program, Stanford University, Stanford, CA, 94305; 4) Biomedical Informatics Program, Stanford University, Stanford, CA 94305.

We develop the first multi-task, multi-modal convolutional neural networks with biophysically motivated deep architectures that integrate both haploid or diploid raw DNA sequence and chromatin accessibility profiles (DNase-seq or ATAC-seq) to model and predict in-vivo binding sites of 100s of TFs (using ChIP-seq data from the ENCODE project) across diverse cell types with high accuracy. Our integrative models provide very significant improvements over other state-of-the-art methods including recently published deep learning TF binding models especially when evaluated in terms of precision and recall of predictions across the whole genome in cell types not used in training. Using calibrated models, we provide the largest resource of high-resolution, high-confidence predicted in-vivo TF binding profiles of 100s of TFs in 250 cell types with DNase-seq data but no TF ChIP-seq data. Next, we develop DeepLIFT (Deep Learning Importance Feature Tracker), a novel interpretation engine for extracting predictive and biological meaningful patterns from deep neural networks (DNNs) for diverse genomic data types. Since DNNs learn inherently distributed representations, we find that multiple convolutional filters often cooperatively represent distinct regulatory features such as TF binding preferences and hence caution against overinterpreting individual filters. Filter nullification and 'in-silico mutagenesis' are commonly used methods to score the relative importance of specific inputs such as individual bases in input DNA sequences. These approaches are not only computationally expensive but can often provide misleading results when the inputs contains redundant signals that potentially buffer each other. DeepLIFT is the first method that can integrate the combined effects of multiple cooperating filters and compute importance scores accounting for redundant patterns. We apply DeepLIFT on our TF binding models to obtain novel representations of TF sequence affinity models that highlight the importance of flanking nucleotide sequences; infer high resolution point binding events; discover novel regulatory sequence grammars involving homodimer and heterodimeric co-factor binding with spatial constraints; learn de-novo TF DNase footprints and unravel the heterogeneity of TF binding sites.

Giggle: A scalable and fast search engine for large-scale multi-omics data integration. *R.M. Layer, B.S. Pedersen, T.L. Di Sera, A.R. Quinlan.* University of Utah, Salt Lake City, UT.

While the analytic benefit of integrating genetic variation with functional genomic annotations is clear (see Pickrell, Am. J. Hum. Genet, 2014), our current capacity to consider these data is far outstripped by the pace at which annotations are accumulating. There are thousands of annotations for the human genome, ranging from gene annotations to deep catalogs of genetic variation. Large-scale functional studies have created an even richer resource: 1,600 annotation tracks have been produced by ENCODE, 2,800 by Roadmap Epigenomics, and 8,500 by GTEx. Leveraging this wealth of information requires a scalable mechanism to quickly identify and quantify overlaps across large and diverse sets of annotations. Existing tools such as TABIX and BEDTOOLS were designed to investigate a single annotation set, not thousands. We developed GIGGLE, a novel and highly scalable genomic interval searching strategy that indexes the genome features from many (thousands or more) different annotation files and formats. GIGGLE is based on a B+tree, where the bounds of an interval serve as keys to the path and file offset of the original record. Single-interval GIGGLE searches return a list of overlapping genomic intervals per annotation set, which on their own can be used for rapid summary and prioritization statistics. Multi-interval GIGGLE searches can also give a list of tracks ordered by an estimate of significance based on either intersection or proximity. This estimate uses a Fisher's exact test; we demonstrate that this metric is well correlated with permutation tests, yet is substantially faster. These summaries are returned nearly instantly, thereby enabling extremely fast (seconds not minutes) data exploration. A single-interval search across GTEx (31 files, 1.7M intervals) requires 0.076s (12.9X faster than TABIX, 540.8X faster than BEDTOOLS), and a search of 1597 intervals across Roadmap Epigenomics (1905 files, 55M intervals) takes a mere 0.92s (66.8X faster than TABIX, 94.3X faster than BEDTOOLS).GIGGLE (https://github.com/ryanlayer/giggle) can be used as a C API, via Python bindings, and as both a command line and web-based tool to search a curated set of published and experimental data. We present the use of GIGGLE as a large-scale public search engine with an index across major projects like ENCODE, Roadmap Epigenomics, and GTEx.

1851F

Integrative post-GWAS analysis unifies cell type-specific and phenotype-centric functional annotations and provides insights into the genetic basis of complex traits. *Q. Lu[1], R. Powles[2], U. Shaham[3], Q. Wang[2], Y. Hu[1], B. Li[1], S. Abdallah[4], D. Ou[4], C. Jin[5], Y. Lu[6], H. Zhao[1,2,7].* 1) Department of Biostatistics, Yale School of Public Health, New Haven, CT, USA; 2) Program of Computational Biology and Bioinformatics, Yale University, New Haven, CT, USA; 3) Department of Statistics, Yale University, New Haven, CT, USA; 4) Yale University School of Medicine, New Haven, CT, USA; 5) Yale College, New Haven, CT, USA; 6) Department of Immunobiology, Yale University School of Medicine, New Haven, CT, USA; 7) VA Cooperative Studies Program Coordinating Center, West Haven, CT, USA.

Many genetic variants influence complex traits through perturbing regulatory elements that are specific to disease-relevant cell types. Accurate prediction of cell type-specific functionality in the human genome is a critical step towards understanding the genetic basis of complex traits. In this project, we first predicted functional DNA elements for 127 distinct tissue and cell types through integrative analysis of various histone marks, DHSs, DNA methylation, and RNA-seq data. These integrative annotations, coupled with GWAS summary data, enabled us to stratify trait heritability by cell type. In total, we identified significantly enriched cell types for more than 40 complex diseases and traits. Compared with any individual annotation, our integrative approach substantially increased power to identify disease-relevant cell types. Our analysis highlights strong enrichment in immune cells for neurological disorders. Primary monocytes were significantly enriched for both Alzheimer's disease (AD) and Parkinson's disease (PD) signals ($P=2.3\times10^{-5}$ and 2.3×10^{-6}). Brain anterior caudate was highly significant for schizophrenia ($P=1.7\times10^{-11}$), bipolar disorder ($P=1.6\times10^{-4}$), cognitive performance ($P=8.7\times10^{-6}$), education years ($P=8.7\times10^{-10}$), and body mass index ($P=8.1\times10^{-8}$). Liver was consistently enriched for multiple lipid traits, and surprisingly, for AD ($P=4.4\times10^{-4}$) as well. Signal enrichment in liver remained significant after removal of *APOE* region, suggesting a potential role of the metabolic system in AD etiology. Finally, integrative annotations that accurately identify cell type-specific functionality, in conjunction with enrichment analysis well supported by the literature, open the door to phenotype-centric pathogenicity prediction for non-coding DNA variants. Functional variants in trait-relevant cell types should be given higher priority in their potential to influence the trait. Based on this idea, we have developed a deep learning approach to predicting trait-specific pathogenicity using cell type enrichment results. Among 7 recently validated regulatory variants for coronary artery disease, 4 ranked in the top 5% of all variants based on our integrative phenotype-centric pathogenicity prediction ($P=1.9\times10^{-4}$), while CADD identified none. Taken together, our approach unifies cell type-specific genome annotation and phenotype-centric pathogenicity prediction, and provides insights into the genetic basis of many complex diseases and traits.

1852W

The SSV evaluation system: A tool to prioritize short structural variants for studies of possible regulatory and causal variants. *M.W. Lutz[1], R. Saul[2], D.K. Burns[3], A.D. Roses[1,3], O. Chiba-Falek[1,4].* 1) Department of Neurology, Duke University School of Medicine, Durham, NC 27710; 2) Polymorphic DNA Technologies, Alameda, CA 94501; 3) Zinfandel Pharmaceuticals, Chapel Hill, NC 27517; 4) Center for Genomic and Computational Biology, Duke University Medical Center, Durham, NC 27710.

Short Structural Variants (SSVs) are short genomic variants (<50 bp) other than SNPs, and include short deletions, short insertions, insertion/deletions (In-del), mixed (cluster that contains multiple classes), multiple nucleotide polymorphism (MNP), and microsatellites or simple sequence repeats/short tandem repeats (SSRs/STRs). Recently it has been suggested that SSVs contribute to many human complex traits. However, high-throughput analysis of this class of variants presents numerous technical challenges. In order to facilitate the discovery and assessment of SSVs, we have developed a prototype bioinformatics tool, the "SSV evaluation system", which is a searchable, annotated database of SSVs in the human genome, with associated customizable scoring software that is designed to evaluate and prioritize SSVs that are most likely to have significant biological effects and impact on disease risk. The SSVs database currently contains annotations for over 7.5 million (M) SSVs including, 1.3M Simple Sequence Repeats, 2.7M insertions and 3.2M deletions. Annotation includes data describing the genomic location and type of the SSV, variability indicators, clustering index, gene context, tissue specific regulatory tracks and epigenomic signals, conservation, position within a linkage disequilibrium (LD) block, and genome-wide association studies (GWAS) signals. This new bioinformatics tool is a component in a broad strategy that we have been using to discover potentially important SSVs within candidate genomic regions that have been reported in the literature or identified in GWAS, with the goal to prioritize candidate functional/causal SSVs for in-depth analyses. The SSV evaluation system allows the investigators to focus the follow-up genotyping and sequencing efforts as well as validation and functional experiments on a relatively small list of SSVs that are more likely to be functional and causal. We have been using the SSV evaluation system to discover new candidate causal variants related to complex neurological diseases of the aging brain such as, Synucleinopathies, late-onset Alzheimer Disease (LOAD) and Amyotrophic Lateral Sclerosis (ALS). We have found the SSV evaluation system to be a powerful tool to guide genetic investigations aiming to uncover SSVs that underlie human complex diseases including idiopathic neurodegenerative disease in aging.

Optimizing pediatric health care outcomes through genomics studies and innovative infrastructure involving effective and efficient research organization/healthcare provider integration. *F. Mentch[1], H. Qiu[1], J. Connolly[1], C. Kim[1], R. Chiavacci[1], R. Pellegrino[1], L. Hermannsson[1], P.M.A. Sleiman[1,2], H. Hakonarson[1,2].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

The Center for Applied Genomics (CAG) at the Children's Hospital of Philadelphia (CHOP), founded in 2006, is one of the largest genetics/genomics research programs and has the world's largest collection of pediatric samples linked to extensive phenotype and genotype information. Being embedded in CHOP and as a member of the University of Pennsylvania research network, the CAG has access to world-class clinical and scientific expertise in a multitude of disease and research areas, recruits participants from a large and disease/condition-enriched patient population, and works with motivated families that routinely volunteer parental samples and grant recontact opportunity for deep phenotyping and access to extensive pedigree information. CAG has contributed multiple bioinformatics tools to the community, has established the Philadelphia Neurodevelopmental Cohort with a recall of nearly 10,000 previously recruited patients for extensive phenotyping in a joint CHOP/Penn effort, has contributed to enhanced sample handling technology in collaboration with industry leaders in robotics hardware, and is working with another innovative company on a methodology to overcome limitations imposed by short read DNA technology. The CAG has numerous on-going collaborations with CHOP/UPENN researchers and other national and international researchers and is actively engaged in translating our genetic discoveries to therapeutics in collaboration with four drug discovery companies. CAG is an active participant in the NHGRI sponsored Electronic Medical Records and Genomics (eMERGE) Network. We report the unique organization and infrastructure that enabled rapid investigation and novel discoveries in over 60 disease phenotypes involving more than 100,000 children yielding over 500 publications in both complex and Mendelian disease areas, and resulting in on-going clinical trials in pediatric oncology and ADHD and planned clinical trials in autism, schizophrenia and several rare disease disorders. We describe the recruiting strategies, sample preparation, tracking and management methodologies and database organization and access methods that in combination have accelerated CAG's genomics discovery activities and the translational work for new and improved diagnostics and therapies for others to follow.

1854F

JustOrthologs: A fast, accurate, and user-friendly ortholog-identification algorithm. *J.B. Miller, B.D. Pickett, P.G. Ridge.* Biology, Brigham Young University, Provo, UT.

Orthologous gene identification is fundamental to all aspects of biology. Specifically, ortholog identification between humans and other organisms can provide functional insights for genes of unknown function. Currently, most ortholog identification algorithms require all-versus-all Basic Local Alignment Search Tool (BLAST) comparisons, which are time consuming and memory intensive. We developed a novel algorithm, JustOrthologs, which exploits a previously unidentified bias in coding sequence (CDS) length. By requiring the same CDS lengths between two genes, JustOrthologs decreases ortholog identification runtime by 90%, while obtaining comparable precision and recall scores to OrthoMCL, OMA, and OrthoFinder. Using this technique, we compared 308 complete eukaryotic genomes and confirmed gene annotations for 1,447,473 genes, clustered 370,606 genes in previously unreported groups, and identified 7,182 potentially mislabeled genes across 464,982 ortholog groups.

1855W

Phasing variants of duplicated genes using whole genome sequencing data. *T. Mimori[1], N. Nariai[2], K. Kojima[1], Y. Sato[1], Y. Kawai[1], Y. Yamaguchi-Kabata[1], M. Nagasaki[1].* 1) Tohoku Medical Megabank Organaization, Tohoku University, Sendai, Miyagi, Japan; 2) University of California, San Diego.

Genomic studies based on population-scale whole-genome sequencing data has revealed the diversity and fine-scale picture of human genomes. The variation of individual genomes has been described and cataloged in form of variant types, such as SNPs, indels, short tandem repeats, inversions and copy number variations (CNVs). The genotypes and phases of these variants have been analysed for building reference panel, which has been a foundation of genetic association studies via genotype imputation. Although the diversity of duplicated genes is also an important source of phenotypic difference, variants and haplotype structures inside of duplicated genes are not fully investigated, which could be partly due to the difficulty and complexity of such analysis. We proposed a computational apporach CNValloc to reveal phase of variants inside of duplicated genes using high-throughput sequencing data of multiple individuals. In addition to performance evaluation via synthetic data, we present a utility of CNValloc for highly variated genes within and among populations such as AMY1 gene.

1856T

Sparse polygenic modeling approaches are highly effective for prioritizing causal eQTL variants. *N. Nariai[1], C. DeBoever[2], H. Li[1], K. Frazer[1,3].* 1) Institute for Genomic Medicine, University of California, San Diego, La Jolla, CA; 2) Bioinformatics and Systems Biology Program, University of California, San Diego, La Jolla, CA; 3) Department of Pediatrics, University of California, San Diego, La Jolla, CA.

   Genotyping data combined with RNA-seq data of tissue samples from many individuals can identify expression quantitative trait loci (eQTL) variants. However, there are several drawbacks with the standard single-variant association analysis used for eQTL studies: 1) combinatorial effects from multiple causal eQTL variants cannot be estimated; 2) variants that show the strongest associations are not necessarily causal, but can be just in linkage disequilibrium (LD) with the causal ones; and 3) association signals are more significant for common variants than low-frequency variants, given the same effect size. To address these issues, we assess several sparse polygenic modeling approaches for prioritizing causal eQTL variants. We evaluate Lasso, Elastic Net, and Bayesian Sparse Linear Mixed Models (BSLMM) in identifying eQTL variants utilizing simulated gene expression data but real genotype data of 503 unrelated individuals to maintain LD structure among tested variants. We find that Elastic Net and BSLMM outperform the standard single-variant association analysis in identifying more causal eQTL variants at the same false discovery rate across a range of sample sizes (100 or 503), number of causal variants (1, 5, 10, or 100) and heritability (20% or 60%). We apply BSLMM to RNA-seq data and whole-genome sequencing data of 131 iPSC lines for eQTL variant prioritization. Among the top 10,000 ranked eQTL variants, multiple variants (ranging from 2 to 29) are jointly associated with expression levels for ~ 67% of genes with one or more eQTL variants, and 13.9% of the eQTL variants are low-frequency (MAF 1-5%); whereas only 7.6% of the top eQTL variants identified by single-variant association analysis are low-frequency. To determine if the prioritized eQTL variants are likely to be causal, we calculate their enrichment in stem cell regulatory regions. We observe a higher enrichment in iPSC DNase I hypersensitive sites for eQTL variants prioritized by BSLMM, compared with those identified by single-variant association analysis. Additionally, the top ranked eQTL variants are highly enriched in H1 hESC Nanog and Oct4 binding sites, which play important roles in reprogramming and pluripotency. We show that BSLMM is highly effective for prioritizing causal eQTL variants, with the ability to jointly estimate effect sizes of multiple variants and simultaneously take LD structure into account, regardless of minor allele frequencies, even from a limited number of samples.

1857F

Benchmarking of mutation calling methods with NGS data. *M. Nomura, Genome Evaluation Group in Center for iPS Cell Research and Application, Kyoto University.* Center for iPS Cell Research and Application, Kyoto University, Kyoto, Japan.

   With genomic sequences generated by next generation sequencers, we have checked iPS cells and differentiated cells for clinical use from various points of view in genome, epigenome and transcriptome. Especially, we have been focusing on detecting genomic mutations, i.e., SNVs, Indels, CNVs and SVs, in iPS cells manufactured in the iPS cell stock project. For our purpose, mutation calling algorithms must handle the following issue that stems from unique characters of iPSC clones: iPSC clone is composed of homogeneous cells but small portions of heterogeneous cells may exist. Therefore, we pay attention to the sensitivity of algorithms but the specificity is also important to reduce false positives for validating candidates of mutations by other methods. To achieve both high sensitivity and specificity, mutation calling methods that integrate existing mutation callers known as ensemble approach, e.g., SomaticSeq[1] and MetaSV[2], have been proposed recently. Because performance of calling methods can be altered depending on sequencing conditions, e.g., read length and read depth, and because they have been usually evaluated with standard genomes such as NA12878 and cancer genomes, we have to reevaluate their performance concerning nature of our data. We have started making synthetic data sets that reflect characteristics of our data and applying existing calling methods including MuTect2[3] to the synthetic data as well as synthetic data generated in ICGC-TCGA DREAM Genome Mutation Calling Challenge[4] to evaluate their performances. In this poster, we will present our very preliminary results.   References 1. An ensemble approach to accurately detect somatic mutations using SomaticSeq, Genome Biol., 16 : 197 (2015). 2. 1858W

Interactive analytics for very large scale genomic data. *C. Pan[1,2,3], N. Deflaux[4], G. McInnes[3], M. Snyder[2,3], J. Bingham[4], S. Datta[3], P. Tsao[1,5,6].* 1) Palo Alto Veterans Institute for Research, Palo Alto, CA; 2) Department of Genetics, Stanford University, CA; 3) Stanford Center for Genomics and Personalized Medicine, Stanford University, CA; 4) Google Inc, Mountain View, CA; 5) Division of Cardiovascular Medicine, Stanford University, CA; 6) VA Palo Alto Health Care System, CA.

Large-scale genomic sequencing is now widely used to decipher questions in diverse realms such as biological function, human diseases, evolution, ecosystems, and agriculture. With the quantity and diversity these data harbor, a robust and scalable data handling and analysis solution is desired. Here we present interactive analytics using public cloud infrastructure such as Google Cloud Platform and distributed computing database Dremel, as developed according to the standards of Global Alliance for Genomics and Health, to perform complex information representation, comprehensive quality controls, and biological information retrieval in large volumes of genomic data. We demonstrate in a dataset of 500 deeply sequenced (50x) human genomes that (1) the nested and repeated features of our database schema help to preserve rich information of alignment and variant calling while achieving a near lossless compression, (2) a comprehensive set of population genomics metrics can be implemented in Dremel using query languages for monitoring sample-level and variant-level data quality, and (3) the query solutions we developed can quickly help researchers navigate the statistics of genotypes and search for biological and medical information by referencing database records. Such computing paradigms of combining public cloud and distributed computing database can provide orders of magnitude faster turnaround for common analyses, transforming long-running batch jobs submitted via a Linux shell into questions that can be asked from a web browser in seconds.

1859T

Kmer-SSR: An efficient tool for perfect SSR detection in genetic sequences. *B. Pickett, J. Miller, P. Ridge.* Department of Biology, Brigham Young University, Provo, UT.

Simple Sequence Repeats (SSRs) exhibit great inter- and intra-specific variability in the number of repeats. This attribute makes them useful markers in forensics, population genetics, and other applications. We developed a new algorithm for SSR detection that is conceptually based in k-mer decomposition. Our algorithm could be implemented as part of any tool that uses k-mer decomposition; e.g., sequence alignment tools using De Bruijn graphs. Our stand-alone Python implementation is fast, 100% accurate and complete, and provides fine-tuned user control while maintaining simplicity for the average user. Conversely, existing softwares are plagued with one or more deficiencies in these areas.

1860F

Mutation visualization on 3D protein structures in the context of known pathogenic mutations and other data. *P.M. Ponomarenko.* Bioinformatics, ICG SB RAS, Novosibirsk, Russian Federation.

   Next Generation Sequencing translates genetic information into bits of data with rapid cost decline. Doctors have access to it in a form of tables with thousands and/or millions of lines. Using databases, filters and sometimes machine learning they look for mutations that may be pathogenic to help with diagnosis. At this stage data continue to be in a form of tables with numbers and words like BRCA1, NM_007294.3:c.107C>A p.Ser36Tyr, HET, DP=15, SIFT=0, PolyPhen=1, Exon 3 out of 22, etc. This information is very useful but hard to build your intuition around and make a treatment decision even after you studied many publications about this gene. Is this mutation in exon 3 more likely to be pathogenic than in exon 4? Is position 455 of the same importance for protein function as position 460, some changes in which are known to be pathogenic? Is this particular aminoacid change can be pathogenic? There are many questions doctors and/or lab directors need to know before assigning treatment. These questions can be answered to some extent by computational algorithms like SIFT and PolyPhen scores mentioned above, but most of these algorithms rely on conservation scores and were developed for a broad range of diseases and genes. On the other hand doctors and researchers are trained to notice minor visual changes and abnormalities in patients and data like chest X-rays, CAT scans, etc. For that reason I think that visual representation of mutation on protein 3d structure with relevant data about positions of known pathogenic mutations, drug binding domains and other information may give doctors a new picture that is easy to understand and remember. To show mutations in the context of 3d structures, I created a database of homology models using ICM-Pro by Molsoft with different levels of quality for human proteins found in NCBI RefSeq when a base structure can be found in RCSB protein databank and using Blast and UniProtKB. Users can find relevant structure and pinpoint mutations of interest with single search term in HGVSp notation. Once homology model is found user can select different features for display online as 3d slides using ActiveICM like PDB structures used to build homology model, known and likely pathogenic mutations from HGMD and ClinVar as well as predicted drug binding pockets, active sites and other relevant data. These 3d slides can be downloaded in a form of icb file to share with colleagues for further research or put inside PowerPoint presentation.

1861W

Deriving genetic ancestry using deep learning on electronic health records. *K.M. Quinnies, R.S. Vanguri, N.P. Tatonetti.* Columbia University Medical Center, New York, NY.

   Genetic ancestry is a significant factor in disease risk and an essential factor for studies aiming to discover variants with clinical significance. With existing genetic data, clustering by ancestry is relatively simple and often achieved with principal components analysis (PCA). PCA reduces dimensionality while maintaining variability, making shared ancestry in complex populations easily identifiable. However, genetic data are not always readily available in clinical and research settings. On the other hand, clinical data, like those stored in electronic health records (EHR) are vast, but can be difficult to understand and do not directly capture ancestry information. We present a novel strategy to estimate genetic ancestry using deep learning on the electronic health records of 5,000 patients. Once trained, our model can then be used to predict the genetic ancestry of any patient in the EHR that meets the minimum data requirements (nearly 2 million patients in our institutional EHR). We call this inferred genetic ancestry the "clinical ancestry score." To compute this score, we begin by deriving principal components using whole exome sequencing data from the 1000 genomes project. The 1000 genomes project contains known populations which are sufficiently diverse (incl. caucasians, african americans, and multi-ethnic groups). Whole exome sequencing data from 2,700 individuals and genotyping data from 2,300 individuals which have been cross referenced with Columbia University Medical Center's Clinical Data Warehouse (CDW) is then projected onto the derived eigenvectors. We then formed a dataset of clinical variables, focusing on the most commonly collected variables (i.e. disease diagnoses, medical history, drug orders, and demographic data) and used the clinical variables to predict the two principal components which have the largest possible variance. We achieved a classification area under the receiver operator characteristic curve (AUROC) score of 0.75 (p = 0.0003). In the future, we will have a model that can be applied to the majority of patients in our EHR data (since it has been trained on commonly collected clinical variables). This model will predict the ancestry of the patient with error that can be estimated. We will be able to use this clinical ancestry score as another genetic proxy variable to select subgroups of patients with shared genetic etiologies.

1862T

A suite of programs for pre- and post-Imputation data checking. *N.W. Rayner[1,2,3], N.R. Robertson[1,2], A. Mahajan[1], M.I. McCarthy[1,4].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 3) Sanger Institute, Hinxton, Cambridge, United Kingdom; 4) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

Rigours data quality control prior to imputation is vital to ensure high quality output and although the availability of public imputation servers has greatly reduced the complexity associated with performing an imputation run, they do not remove this requirement to verify the data both prior to and post imputation. To simplify this checking we have developed two programs that check the data at both the pre- and post-imputation stages. Both are written in Perl with some additional steps in the post-imputation program in Java. At the pre-imputation stage the program compares a Plink format bim and frequency file to the selected reference panel, 1000G phase 3 and HRC r1 and r1.1 are supported. The program checks all variants in the bim file that match the reference for a wide variety of potential issues, such as differences in chromosome and position, alleles, allele frequency (AF), strand and reference allele. Summary statistics are written to a log file and for each potential issue a list of variants affected is produced. These lists are used in Plink to update issues and remove variants. This validation is quick to run (~5 minutes using HRC reference panel v1.1) and updating ensures the data submitted to the imputation servers will not be rejected and that the output is of high quality. Post-imputation, the program takes the most common output formats from the current suite of imputation programs (Minimac and IMPUTE) or servers (hosted by Oxford, University of Michigan, and Sanger) and produces a wide range of charts on information score, AF and position to visually assess the quality of the imputation run, flagging such issues as missing regions in the output, as evidenced by two or more regions of 1MB or greater without SNPs, or regions with low information score. For ease of visualisation these charts are collated into a single html file with embedded images, viewable in any current web browser. The program can also be run on multiple imputed data sets, comprising any supported imputation format, and produces an additional html summary across all. Both programs are freely available to download and have been used extensively in single cohort studies, as well as for large consortia such as DIAMANTE where >35 genome-wide data sets were prepared using our pre-imputation program and >20 were checked post-imputation. Using the post-imputation program we were able to easily identify a wide range of issues such as AF differences and missing or duplicated regions.

1863F

Asynchrony: **A framework for asynchronous software tested with bioinformatics use cases.** *N.R. Robertson[1,2], N.W. Rayner[1,2], M.I. McCarthy[1,2].* 1) Wellcome Trust Centre for Human Genetics, Nuffield Department of Medicine, University of Oxford, Oxford, OX3 7BN, UK; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Oxford, OX3 7LE, UK.

Modern computer processors are being released with an increasing number of independent cores; however standard synchronous programming techniques do not facilitate the use of more than one core. Once a program is developed it is necessary to manually parallelize the work by running multiple executions concurrently, adding burden and complexity for the end user. We have developed *Asynchrony,* an asynchronous software framework for Java, which enables the programmer to organize a program into a multitude of sub-tasks that can be executed in parallel. We have been able to evaluate and expand this framework by building a series of tools to support key bioinformatics use cases such as file processing, sorting, compression, and indexed file access. Our software is able to scale across available processors, reducing execution times and improving ease of use. By utilizing multiple cores, we can show significant performance benefits over standard compression tools such as *gzip* and *bgzip*, while closely following the performance profile of the parallelized *gzip* implementation, *pigz*. Using 8 cores, our software takes 50 seconds to gzip encode a 3 GB file of 147 million records from dbSNP; *bgzip* manages the same task in over 5 minutes. For indexed file access, we provide an alternative to the block compression index software *tabix*, a tool widely used by bioinformatics researchers to access files by genomic position. In our test dataset of 147 million records, *tabix* is able to locate 10K search terms in 5.89 seconds. While our software is targeted at a more general use case, using 8 cores it can achieve the same lookup in 4.56 seconds, a performance we hope to improve in future iterations. We have extensively tested these tools on large datasets. For the interim release of UK Biobank data (152,732 individuals, 847,441 markers) have used the toolset to transpose and compress 1.8 TB of individual-wise intensity data into 753 GB of marker-wise gzip indexed data. Intensity data can now be randomly accessed in milliseconds without laboriously parsing whole files to generate cluster plots. Our suite of tools is available for public use immediately. The framework itself will be made available in pre-release form.

Alternate-scaffold aware variant calling in whole genome sequencing.

P.N. Robinson[1,2], M. Jäger[1], M. Schubach[1], T. Zemojtel[1], K. Reinert[2]. 1) Institute for Medical Genetics, Charite-Universitätsmedizin, 13353 Berlin, Germany; 2) Institute for Bioinformatics, Freie Universität Berlin, 14195 Berlin, Germany.

The last two human genome assemblies have extended the previous "golden-path" (linear) paradigm of the human genome to a graph-based model in order to better represent regions that display too much variability in human populations to be adequately represented by a single haploid sequence. In this work, we explore challenges and opportunities presented by the new genome model for variant calling in whole-genome sequencing (WGS). We show that stretches of sequences that are largely but not entirely identical between the primary assembly and an alternate scaffold and can thereby result in multiple variant calls against regions of the primary assembly that correspond to the reference sequence of the alternate scaffolds. In WGS analysis, this results in characteristic and recognizable patterns of variant calls (termed alignable scaffold-discrepant position or ASDP). We present a heuristic algorithm that can be used to flag these ASDPs in VCF files and annotate the most likely scaffold genotype. In 121 in-house genomes, on average 51.1±3.8 of the 178 regions were found to best correspond to an alternate scaffold rather than the primary assembly sequence, and filtering these genomes with our algorithm lead to the identification of 7864 variant calls per genome as ASDPs (and thus potentially false positive calls of variants against the primary assembly), or 6.51% of all variants located in the 178 regions. We found that 376 of 791 GWAS hits located within one of the regions corresponded to ASDPs. Since the distribution of the alternate loci shows population-specific biases, this should be taken into account in future association studies. We implement our algorithm as a Java application called ASDPex, which is made available under a BSD2 license.

Hail: An open-source framework for scalable genetic data analysis.

C. Seed[1,2,3], A. Bloemendal[1,2,3], J. Bloom[1,2,3,4], J.I. Goldstein[1,2,3], T. Poterba[1,2,3], B.M. Neale[1,2,3]. 1) Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston 02114, MA, USA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 4) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA 02139, USA.

The widespread application of massively parallel sequencing for complex trait analysis offers unprecedented power to link genetics with disease risk. However, these projects pose substantial challenges of scale and complexity, making even trivial analytic tasks increasingly cumbersome. To address these challenges we are actively developing Hail, an open-source framework for scalable genetic data analysis.The foundation of Hail is infrastructure for representing and computing on genetic data. This infrastructure builds on open-source distributed computing frameworks including Hadoop and Spark. Hail achieves near-perfect scalability for many tasks and scales seamlessly to whole genome datasets of thousands of individuals. On top of this infrastructure, we have implemented a suite of standard tools and analysis modules including: data import/export, quality control (QC), analysis of population structure, and methods for performing both common and rare variant association. Simultaneously, we and other groups are using Hail to manage the engineering details of distributed computation in order to develop and deploy new methods at scale.In addition, Hail exposes a high-level domain-specific language (DSL) for manipulating genetic data and assembling pipelines. As an example, porting a rare-variant analysis from Python to Hail reduced the number of lines of code by ~10x and improved performance by ~100x. We aim to grow Hail into a scalable, reliable and expressive framework on which the genetics community develops, validates, and shares new analytic approaches on massive datasets to uncover the biology of disease.

Genotype data quality analysis at the next order of magnitude in the Department of Veterans Affairs' Million Veteran Program (MVP). *Y. Shi[1], T. Webster[2], H.S. Hunter-Zinck[1], M. Li[1,11,12], C. Dow[2], N. Sun[3,9], J. Huang[1], C. Pan[4,7], J. Gelernter[3,10], T.L. Assimes[4,7], P.S. Tsao[4,7], C.J. O'Donnell[1,6], E.R. Hauser[5,8], H. Zhao[3,9], S. Pyarajan[1,6] for MVP Genomic Working Group.* 1) VA Boston Healthcare System, Boston, MA; 2) Thermo Fisher Scientific, 3420 Central Expressway, Santa Clara, CA 95051; 3) VA Connecticut Healthcare System, West Haven, CT; 4) VA Palo Alto Health Care System, Palo Alto, CA; 5) Durham VA Medical Center, Durham, NC; 6) Harvard Medical School, Boston, MA; 7) Stanford University School of Medicine, Stanford, CA; 8) Duke University, Durham, NC; 9) Yale School of Public Health, New Haven, CT; 10) Yale School of Medicine, New Haven, CT; 11) University of Utah, Salt Lake City, UT; 12) Johns Hopkins University, Baltimore, MD.

The U.S. Department of Veterans Affairs (VA) has initiated the Million Veteran Program (MVP) to implement personalized medicine in the care of U.S. veterans. Integration of a patient's genetic information with the clinical record is an essential step in personalized medicine. Here, we describe genotypic data from the first 200,845 patients in the MVP. The MVP encompasses a biobank of samples of consented veterans as well as nationally consolidated clinical information on the same patients from the VA's electronic health record system. The first installment of data includes genotypes of 200,845 patients genotyped with a custom Affymetrix Axiom MVP_1.0 array of 668,513 genetic markers in two independent laboratories and analyzed in 45 experimental batches. The initial quality control was performed separately in each laboratory following Affymetrix Best Practices to remove low quality samples. Additional quality analysis was performed on samples that passed initial quality control and were delivered to the VA. After genotype re-calling within the VA, the call rate for samples is approximately 99%. After a stringent genotype cleaning procedure, we retain 92% of probesets and 97% of markers. Over all samples, the median fraction of missing genotype calls per sample is less than 4%. About 3% of the samples were intentional duplicates, and we conducted concordance analysis using these samples. Concordance between genotypes of intentionally duplicated samples is extremely high with nearly 100% concordance for all duplicate pairs when analyzing common markers (minor allele frequency (MAF) greater than 5%). Even for extremely low frequencies, markers with MAF of 0.005% to 0.01% are still exactly concordant for approximately 80% of duplicate pairs with at least one copy of the minor allele. We also explored population structure of the samples and found substantial diversity in genetic ancestry. Approximately 71% of our samples are of European ancestry but 18% of samples have inferred admixture with approximately 5% of the total sample with admixture from three or more continents. The completed quality control analysis of the first 200,845 samples demonstrates that the MVP is a high quality and diverse resource for researchers seeking to understand the complex interactions between genetics, the environment, and medicine.

1867W

Development of a long indel detection method using the realignment of the misaligned reads. *D. Shigemizu[1,2,5], F. Miya[1,2], A. Fujimoto[3], K.A. Borovich[2], S. Okuda[4], T. Tsunoda[1,2,5].* 1) Department of Medical Science Mathematics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 2) Laboratory for Medical Science Mathematics, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 3) Department of Drug Discovery Medicine, Graduate School of Medicine, Kyoto University, Kyoto, Japan; 4) Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan; 5) CREST, JST, Japan.

Insertions and deletions (indels) have been implicated in dozens of human diseases through radically altered gene functions by short frameshift indels as well as long indels. However, the accurate detection of these indels from next-generation sequencing data is still challenging, particularly for long indels (50bp), due to the short DNA sequencing reads. In this study, we developed a new method that detects these long indels using BWA soft-clipped fragments (unmatched fragments in partially mapped reads) and unmapped reads. We report on a comparison of our detections with those from GATK HaplotypeCaller, which was recently extended to detect long indels using *de novo* assembly, using whole exome sequencing data from a HapMap-JPT sample, NA18943. The number of long indels detected by our method and the GATK were 70 and 34, respectively, and approximately 20% of our detections (13/70) were in common with those of GATK. On the other hand, while all of the long indels in GATK were less than 121 base pairs, more than half of our detections (36/70) were longer, ranging from 121bp to 2,792bp. To show that our method is effective in longer indel detection, we further performed Sanger sequencing of 6 randomly selected indels from these 36, and all were confirmed. Though we will perform Sanger sequencing verification for all of the long indels and estimate the false positive and false negative rates of our method, we expect that this methodology will contribute to the discovery for long indels associated with human diseases in the near future.

1868T

Multi-omic data exploration using pathway and correlation analysis in Agilent's GeneSpring. *S. Shukradas[1], D. Roy Choudhury[1], B. Prasad[1], M. Rosenberg[1], D. Renu[2], P. Tata[2], A. Wandycz[1].* 1) Agilent Technologies, Santa Clara, CA; 2) Strand Life Sciences, Bangalore, India.

Scientists today face serious challenges as they try to analyze increasingly large and more complex sets of data, such as those generated by genomics, transcriptomics, proteomics, and metabolomics experiments. GeneSpring provides a platform for data analysis and integration enabling comparisons across a variety of data types allowing for identification of co-regulated genes, proteins and metabolites in an intuitive way. An integrated approach for analyzing multi-omic data can significantly alleviate bottlenecks and provide valuable information that is often missed in individual experiments. One successful method for translating diverse analytical data into biological understanding can be achieved by projecting and visualizing experimental data onto the curated biological pathways (WikiPathways/BioCyc/KEGG) or literature-derived networks. GeneSpring makes it easy to resolve nomenclature inconsistencies by providing a powerful built-in tool, Agilent BridgeDB. This resource automatically links an annotated metabolite, protein, or gene identifier in the experiment to the corresponding identifier used by the pathway database, resulting in better annotation coverage for downstream analysis. Complementing more traditional bioinformatics techniques, correlation tools and specialized visualizations allow investigators to identify co-regulated genes, metabolites, and proteins in an intuitive and easy-to-use manner. In this analysis, we demonstrate how GeneSpring can be used to study correlation of expression of transcriptomic and proteomic data to identify curated signaling pathways that might be deregulated specifically in Glioblastoma (GBM).

1869F

Comprehensive analysis of the spatial distribution of missense variants in protein structures reveals patterns predictive of pathogenicity. *R.M. Sivley[1,4], W.S. Bush[3,5], J.A. Capra[2,4].* 1) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Biological Sciences, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 5) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

The spatial distribution of genetic variation within protein structures is shaped by functional constraints and thus provides information about the importance of protein regions and the potential pathogenicity of protein alterations. We developed a statistical framework in which to model and compare spatial patterns of genetic variation across multiple distance scales. We then performed a comprehensive 3D analysis of protein-coding single-nucleotide variants (SNVs), including population-derived missense (ExAC, N=196,176) and synonymous (ExAC, N=122,963), pathogenic (ClinVar, N=4,827), and cancer (COSMIC, N=114,574) variants in 4,575 human proteins with solved structures in the Protein Data Bank. Population-derived missense and synonymous, pathogenic, and cancer variants have drastically different spatial distributions. Missense variants observed in the general population are found in nearly every protein in our dataset (N=4,523) and are typically dispersed throughout structure, while synonymous variants trend towards spatial randomness. In contrast, nearly 20% (88 of 453) of proteins with at least three pathogenic variants exhibit significant spatial clustering in 3D. This is substantially greater than the 0.3% (15 of 4,547) of proteins with significant clustering of cancer variants, in which there has been considerable recent interest. Indeed, we find that pathogenic variation is more clustered than recurrent cancer variation in two thirds (200 of 301) of proteins with sufficient occurrence of each. Motivated by the significant 3D spatial clustering of pathogenic variation and the general dispersion of putatively benign variation, we hypothesized that analysis of variants' spatial distributions could provide a new line of evidence to use in the prioritization of variants of unknown significance (VUS). We will present several examples that demonstrate the predictive performance of our approach compared to common methods for the prioritization of candidate mutations. These findings suggest that explicit modeling of the spatial distribution of protein-coding variation has great promise to complement existing strategies for VUS prioritization and pathogenicity prediction.

1870W

EGA: Towards distributed consented genetic and phenotypic data access. *J.D. Spalding[1], M. Alberich[2], J. Almeida-King[1], A. Carreño-Torres[2], P.A. Garcia[1], A. Gil[2], J. Kandasamy[1], G. Kerry[1], O.M. Llobet[2], A. Lloret-Villas[2], M. Moldes[2], A. Senf[1], S. de la Torre[2], S. Ur-Rehman[1], P. Flicek[1], A. Navarro[2,3,4], H. Parkinson[1], J. Rambla[2].* 1) European Genome-phenome Archive, European Bioinformatics Institute (EMBL-EBI), Cambridge, Cambridgeshire, CB10 1SD, UK; 2) Centre for Genomic Regulation (CRG), Dr. Aiguader 88, 08003 Barcelona, Spain and Universitat Pompeu Fabra (UPF), Barcelona, Spain; 3) Institute of Evolutionary Biology, Barcelona, Spain; 4) Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

The European Genome-phenome Archive (EGA) is a controlled-access archive, which facilitates the secure long-term storage and controlled distribution of genetic and phenotypic data, for the purpose of biomedical research. Access to data is via application, and data delivery is encrypted to protect the participants' identities. As of April 2016, the EGA stores over 3.9 petabytes of data derived from over 700,000 unique samples in over 900 studies. The EGA is developing the technology to become a distributed and federated archive. This addresses both scalability issues, where the data can be hosted close to the compute, and Ethical, Legal, Social Implications (ELSI) issues, where data cannot leave a certain jurisdiction, while facilitating data access and discovery. For data access this includes implementing and extending the Elixir Authentication and Authorisation Infrastructure (AAI) to encompass the EGA use-case for greater Levels of Assurance (LoA) (e.g. step-up authentication). Accessibility to the raw data in EGA is improved by using AES encryption technology to facilitate random-access to indexed encrypted files, and EGA is developing a FUSE layer to allow native applications to access encrypted data directly. This allows EGA data to be accessed directly from a third-party application of platform, for example Galaxy. These technologies are available as a set of Docker containers, or a pre-built virtual machine, facilitating the implementation of new EGA nodes. To improve data discoverability, EGA has implemented the v0.3 3-tier Beacon (https://www.ega-archive.org/beacon/#/), improved integration with BioSamples - a sample archive for accessioning samples and preventing duplication (https://www.ebi.ac.uk/biosamples/), and meta-data annotation of both existing and new meta-data via Zooma (http://www.ebi.ac.uk/spot/zooma/) and the Ontology Lookup Service (http://www.ebi.ac.uk/ols/index). Our collections include reference data for rare and common diseases, including data derived from the UK10K project, WTCCC, Human Induced Pluripotent Stem Cells Initiative (HipSci), RD-Connect and the International Cancer Genome Consortium (ICGC), and improved meta-data curation allows enhanced queries across these datasets. The EGA is maintained by European Bioinformatics Institute (EMBL-EBI) and the Center for Genomic regulation (CRG) and is available at http://www.ega-archive.org.

1871T

The UCSC Genome Browser: New display modes to facilitate study of clinical data. *M.L. Speir, G.P. Barber, C.M. Lee, K.R. Rosenbloom, A.S. Hinrichs, C. Tyner, L. Guruvadoo, B.T. Lee, A.S. Zweig, D. Karolchik, R.M. Kuhn, W.J. Kent.* Genomics Institute, University of California Santa Cruz, Santa Cruz, CA.

The University of California Santa Cruz (UCSC) Genome Browser (http://genome.ucsc.edu) is a free, web-based tool that allows researchers to visualize and explore large, varied data sets from a number of sources including ClinVar, OMIM, GTEx, and GENCODE. In addition to providing a large repository of browseable data, we enable users to upload and visualize their data sets alongside those we offer. The Genome Browser also provides numerous other web-based tools for exploring and analyzing these data in different ways. One of our newest visualization tools, multi-region configuration, features the ability to display multiple, sometimes distant, regions of the genome alongside one another in the same Genome Browser image. The exon-only and gene-only modes of this feature let users remove both intronic and intergenic sequence or just intergenic sequence from the display, respectively, allowing them to focus in on the coding regions of the genome. These modes are based on a pre-selected gene set determined to be appropriate for that genome. The display will react to changes and filters applied to this gene set, removing regions from the display that are no longer covered by exons or genes. Another configuration option of the multi-region feature allows for user-defined regions that are then combined into a single Genome Browser image, permitting the visualization of multiple genes, variants, or other important genomic regions. These user-defined regions are specified using a remote BED file that contains basic position information. A final multi-region configuration option enables researchers to view the sequence of an alternative locus inserted into its corresponding region in the reference genome, rather than being displayed as an isolated chromosome. While multi-region configuration adds a great deal of customization and configuration to the Genome Browser display, the current implementation has limitations that we plan to address in future releases. These improvements include allowing gene set selection for both the exon- and gene-only modes and expanding the custom region mode to support additional ways to specify regions.

1872F

SurvivalGWAS_SV: Software for the analysis of genome-wide association studies of imputed genotypes with "time-to-event" outcomes. *H. Syed, A.L. Jorgensen, A.P. Morris.* Department of Biostatistics, Block F, Waterhouse building, University of Liverpool, Liverpool, United Kingdom.

   Methodology for the analysis of genome-wide association studies (GWAS) has focused primarily on binary (case-control) phenotypes and quantitative traits. Software implementing these methods, such as PLINK and SNPTEST, can efficiently handle the scale and complexity of genetic data from GWAS, allowing for imputed genotypes at millions of single nucleotide polymorphisms (SNPs). However, the key outcome of interest in many genetic studies, particularly those in pharmacogenetics, is often "time to event" data (such as death, disease remission or occurrence of an adverse drug reaction), which cannot adequately be modelled by existing software. To address this challenge, we have developed the SurvivalGWAS_SV software implemented using C# and run on LINUX operating systems. SurvivalGWAS_SV is able to handle large scale genome-wide imputed data, modelling time to event outcomes under an additive dosage model in the number of minor alleles at a SNP. Analysis can be performed using either Cox proportional hazards or Weibull regression models, the latter capable of analysing accelerated failure time and non-proportional data. The software also allows for multiple covariates and incorporation of SNP-covariate interaction effects. Running analysis of 1.5 million SNPs across 22 chromosomes for 1000 individuals will take approximately 6 hours to complete, dependent on number of computer cores used and processor speed. In conclusion, we introduce a new console application analysis tool for GWAS with time to event outcomes. SurvivalGWAS_SV can analyse large scale GWAS datasets efficiently and effectively, without incurring memory issues. With its particular relevance to pharmacogenetic GWAS, SurvivalGWAS_SV will enable discovery of genetic biomarkers of patient response to treatment for a range of complex human diseases, ultimately allowing personalisation of therapeutic intervention.

1873W

Genetic architect: Discovering genomic structure using learned neural architectures. *S. Targ[1], L. Deming[1], N. Sauder[2], D. Almeida[2], C.J. Ye[1].* 1) UCSF Institute for Human Genetics, San Francisco, CA; 2) Enlitic, San Francisco, CA.

   Deep learning demonstrates excellent performance on tasks in computer vision, text and many other fields, but has only recently been applied to challenges in genomics. While the genetic code allows us to annotate the 5% of the genome encoding proteins, we do not have a "grammar" for decoding the rest of the non-coding sequences important for gene regulation, evolution of species and susceptibility to diseases. The design and application of neural network architectures specific to functional genomic data is a promising approach for automating the annotation of genomic information into forms that humans can grasp. We develop a broadly applicable search algorithm to discover two models, AttentionNet and PromoterNet, which combine simple and cutting-edge neural network building blocks to learn patterns in genomic data and identify the most important sequence motifs predictive of TF binding and gene expression. Our learned models contain convolutional layers, residual blocks, an LSTM recurrent layer, and an attention-based dimensionality reducing step, followed by fully connected layers. Previous deep learning approaches to genome annotation use convolutional networks, which are ideal for detecting local features. However, more closely approximating the structure of genomic information would take into account that a real genome is a sequence, not a disjointed set, of local features – an input type on which recurrent architectures generally excel. We use AttentionNet to learn general structure and sequence features from 108 K562 ENCODE ChIP-seq datasets recovering known JASPAR motifs for 42/57 tested TFs and achieving an AUC of 0.933, significantly outperforming other models. We also develop a novel benchmark regression task of predicting lineage-specific gene expression from ImmGen Consortium microarray data using input genomic sequences +/- 1kb around TSSs. Our approach, PromoterNet, obtains an average Pearson r correlation of 0.6, outperforms existing models, and identifies both conserved TSS proximal core promoter elements and lineage-specific features in genes selected for maximal variance in expression. Our results show these learned architectures are well-suited to understand the regulatory structure of multimodal genomic data including ChIP-seq, RNA-seq, ATAC-seq and DNase-seq, genomic position, and chromatin conformation and capture effects of local patterns and long-range sequential dependencies on functional genomic outcomes.

1874T

Turning *big data* **into** *small data* **through crowdsourced curation: Integrating all types of medical and scientific knowledge.** *T.D. Taylor, N. Kumar.* Laboratory for Integrated Bioinformatics, RIKEN Center for Integrative Medical Sciences, Yokohama, Kanagawa, Japan.

　Big data in the form of scientific media comes in many languages and formats: journal articles, books, images, videos, etc. Text media often includes additional embedded or associated information such as tables, figures and supplementary data. While there are many resources for browsing, searching and annotating some of this media, there is no single place to search them all at once, and generalized search engines do not allow for the comprehensive and precise searches researchers require. One could argue that any scientific media that is on the web is therefore connected, but much of it remains offline or is inaccessible and is therefore neither discoverable nor connected. To address these issues, we created **iCLiKVAL** (iclikval.riken.jp), a web-based tool that uses the power of crowdsourcing to accumulate annotation information for all scientific media found online, and potentially offline. Annotations in the form of key-relationship-value tuples (any language) added by users through a variety of methods can make vast amounts of unstructured data easier to comprehend and visualize by turning it into *small structured data*. This allows for richer data searches and discovery of novel connections by integrating all forms of scientific knowledge through common terminology. Users can create or join common interest groups to annotate related media together as a community. They can also create and edit their own controlled vocabulary lists, or import established vocabularies such as MeSH and GO terms, and then select which lists to use for auto-suggest terms in each of the form fields. Within user groups, vocabulary and bookmark lists can be shared. We also implemented a notification center, several customization options, and annotations page where users can view and edit all of their own annotations. Most of the pages, such as annotations, bookmarks, search history, reviews and vocabularies, are searchable, sortable and filterable, so users can quickly find what they need. Besides PubMed articles, we recently added annotation support for YouTube, Flickr, SoundCloud and anything with a DOI name, allowing for the inclusion of hundreds of millions of media objects. We also created a Chrome Browser extension that allows any non-password protected online media to be bookmarked and annotated (even offline), to facilitate the annotation process. The iCLiKVAL database is completely searchable, and all of the data is freely available to registered users via our API.

1875F

CRAVAT 4.2: Informatics tools for high-throughput analysis of exome variants. *C. Tokheim[1,5], C. Douville[1,5], D.L. Masica[1,5], R. Kim[2,5], R. Bhattacharya[3], N. Niknafs[1], D. Gygax[2], K. Moad[2], M. Ryan[2], R. Karchin[1,4].* 1) Department of Biomedical Engineering, Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 2) In Silico Solutions, Fairfax, VA; 3) Department of Computer Science, Institute for Computational Medicine, Johns Hopkins University, Baltimore, MD; 4) Department of Oncology, Johns Hopkins Medical Institutions, Baltimore, MD; 5) Authors contributed equally.

　Analyzing thousands or millions of exome variants causes a daunting prioritization challenge. CRAVAT is a high-throughput web-based resource for analysis of exomic variants (single base substitutions and indels). CRAVAT provides scoring, sorting, filtering, and interactive visualizations to assist with identification of important variants. Variants relevant to cancer are particularly emphasized. Variants are submitted in either the standard Variant Call Format (VCF) or a simple tab-delimited format; subsequently results are quickly emailed to users in spreadsheet and machine-friendly format. Summaries are provided on the variant- and gene-level, which include population Minor Allele Frequency (MAF), occurrence in COSMIC, mutation call quality, and frequency of gene variants. CRAVAT 4.2 is enhanced with new variant scoring, an interactive viewer, detection of variant hotspot regions, and expanded tool ecosystem. *In silico* pathogenicity scores are now provided for all non-silent mutation types in a unified statistical framework that allows one-pass sorting. The interactive viewer includes lollipop diagrams, population MAF widget, dynamic sorting and columns, integrated display of variants on protein structure, and a pathway enrichment viewer. The protein structure viewer is enhanced with a new algorithm that detects mutation hotspot regions in 31 human cancer types. Users with protected data can now use a docker version for analysis on local computers or in the cloud. The utility of CRAVAT is exhibited by a wide user base, which has submitted over 6,000 jobs annotating 355 million variants in the past year. CRAVAT provides streamlined analysis of exomic variants, using multi-faceted information for improved variant prioritization.

Homogenization of dbGaP data. *C. Tripathi, G. Ellis, L. Akhabir, D. Daley.* University of British Columbia, Vancouver, British Columbia, Canada.

   Introduction: The overarching goal of sharing data and collaborating is to decipher complex trait etiologies by genetic, epigenetic and genomic means. The database of Genotypes and Phenotypes (dbGaP) stores and distributes results of genotype-phenotype association studies. To harness the full potential of this valuable resource, integration of data from multiple studies is necessary. Studies submitted to dbGaP are from different time points and have thus used different genotyping chips and human reference genome versions (hrg). Consequentially, SNPs on these chips differ in aspects such as: number, identifiers (rs number), strand genotyped (+/-) and genomic coordinates. Such differences present challenges to data integration. To address the need to homogenize dbGaP data, we have designed a suite of web-based tools. We will demonstrate utility of the tools by taking example of one such tool: to compute overlap of SNPs between genotyping chips. The tool can be used choose the most appropriate chip for a hypothesis and to choose the custom content for chips.**Methods:** The following tools have been coded in Java to form **suite of new tools**: 1) Tool to estimate overlap of SNPs between genotyping chips 2) Tool to homogenize SNPs in studies by identifying SNPs common across all studies of interest 3) Tool that homogenizes variable names in a semi-automatic fashion.Tools already available are integrated to form **suite of existing tools**: 1) NCBI Remap tool to map coordinates of SNPs to latest version of human reference genome 2) NCBI Remap to update SNP rs numbers 3) A plink command to homogenize DNA strands to which alleles are mapped.**Results:** As an example of how the tool to compute SNP overlap works, we used it to estimate SNP overlap between the high density Illumina Genome Wide Association Studies (GWAS) Omni5 chip with the NHGRI GWAS catalog. We found that of the 4,415,047 SNPs on Omni5, the overlap with: directly genotyped SNPs of GWAS catalogue (8,696 SNPs) is 7,420; GWAS cancer (1,610 SNPs) is 1,237; GWAS cardiovascular (1,835 SNPs) is 1,276; GWAS alzheimer (313 SNPs) is 218; GWAS dementia (829 SNPs) is 550 and GWAS diabetes (807 SNPs) is 620.**Conclusion:** Our web-based tools will facilitate homogenization of dbGaP and similar data. On request, the tool to estimate SNP overlap has been distributed to Illumina and fellow research labs. On completion, all tools will be shared with collaborators and other researchers to catalyze data integration and utilization.

Automated genotypic imputation of PAGE II data using scientific workflows. *K. Vahi[1], S. Buyske[2], L. Zhou[3], T.C Matise[3], E. Deelman[1].* 1) Science Automation Technologies, USC Information Sciences Inst, Marina del Rey, CA; 2) Department of Statistics & Biostatistics, Rutgers University Hill Center, Piscataway, NJ; 3) Department of Genetics, Rutgers University Piscataway, NJ.

   The PAGE II (Population Architecture using Genomics and Epidemiology) study has genotyped 50,000 samples using MEGA, an Illumina high density consortium-built array array. PAGE is also imputing genotypes on an additional 50,000 subjects who were genotyped in 20 different GWAS studies. Imputation on a PAGE sub-study, using SHAPEIT and IMPUTE2 with the 1000 Genomes Project reference panel, has over 650 computational tasks.   Imputation can be parallelized by chromosome to reduce total processing time. Researchers often write custom batch scripts to setup complex computational pipelines. Such scripts are responsible for both making the data available to the batch jobs and the application specific logic that identifies the processing steps and pipeline structure. This approach results in complicated error recovery semantics, and often can only run on the computation resource for which it was developed. Keeping these concerns in mind, we modeled the PAGE production imputation pipeline as a computational workflow using the Pegasus Workflow Management System. Pegasus represents the application pipeline in an abstract form, agnostic of the resources available and the location of data and executables. It compiles these workflows into an executable form and discovers location of data and executables by querying catalogs. The executable workflow is executed on potentially remote and distributed resources, such as remote clusters and clouds. Pegasus has well defined error recovery semantics. Pegasus supports automatic job retries in case of job failures, workflow-level checkpointing and fallback to alternative data sources for staging data. When a fatal error is encountered, a rescue workflow containing only the remaining work is provided. Pegasus provides monitoring and debugging tools that enable users to easily identify what steps in the pipeline failed and the reason for failures.The imputation pipeline is currently in production and is setup to run on the Rutgers Genetics Cluster and has been applied to datasets from seven PAGE studies with minimal user intervention. When a new study dataset becomes available, it takes the researcher only a few minutes to launch the imputation workflow. The clean separation of application logic and underlying compute infrastructure, ensures that the workflow description generation code does not need to be altered when porting to a different computing environment such as Amazon EC2. The workflow will be shared publicly on GitHub.

1878F

Building high-quality, de novo genome assemblies by scaffolding next-generation sequencing data with BioNano's next-generation genome mapping. *J. Wang, A.W. Pang, E.T. Lam, W. Andrew, T. Ananthara- man, A. Hastie, W. Stedman, H. Sadowski, M. Saghbini, Z.Y. Zhu, M. Austin, M. Borodkin, H. Cao.* BioNano Genomics, San Diego, CA.

Combining next generation sequencing (NGS) data and next-generation mapping (NGM) data from BioNano Genomics's Irys System has recently been demonstrated as a promising workflow to produce affordable, high-qual- ity and chromosome-scale *de novo* genome assemblies.   To broaden the scope of such a hybrid-scaffolding approach to highly fragmented NGS data, we described a novel workflow that utilizes more than one nicking endonucle- ase to increase the information density of genome maps. We generated two independent sets of genome maps, each with a different nicking endonu- clease and developed a novel algorithm that uses the NGS sequences as a bridge to merge single-enzyme genome maps into combined genome maps that contain the sequence motif patterns from both nicking enzymes. Since the genome maps were generated independently they serve as orthogonal sources of evidences to detect and correct assembly errors in either sequence assemblies or genome maps. The complementarity of different data type also greatly improves the contiguity of the merged genome map while doubling the information density. This in turn allows for anchoring of shorter NGS se- quences in the final scaffold.   We benchmarked our approach by scaffolding a sequence assembly from Illumina short-read sequencing with two sets of BioNano genome maps from the human NA12878 sample. The NGS datasets were obtained from the NCBI's short read archive. It contains 630,209,622 reads with 251 bp per read and were assembled using DISCOVAR de novo. We produced a final scaffold that increased the contiguity of the sequence assembly from an N50 of 0.179 Mb to 18 Mb and anchored more than 80% of the total NGS sequences in length while reducing the number of chimeric joins – two distal regions in the genome that were erroneously joined together by assembly algorithms -- from 52 to 9. Compared to the published single-en- zyme hybrid-scaffolding approach, the wo-enzyme approach improved the scaffold contiguity by 300% while anchoring ~30% more sequence contigs, leading to the incorporation of additional 200Mb of sequence in the final scaffolds.   This new approach can greatly expands the type of NGS data that can be integrated with BioNano genome maps to produce highly accurate and contiguous assemblies for complex genomes.

1879W

Bayesian latent variable models for single-cell trajectory learning. *C. Yau, K. Campbell.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxon, United Kingdom.

The transcriptomes of single cells undergoing diverse biological processes - such as differentiation or apoptosis - display remarkable heterogeneity that is averaged over in bulk sequencing. Single-cell sequencing itself offers only a snapshot of these processes by capturing cells of variable and unknown progression through them. Consequently, one outstanding problem in sin- gle-cell genomics is to find an ordering of cells (known as their pseudotime) that best reflects their progression, for which several computational methods have been proposed. To date, the vast majority of such methods emphasise transcriptome-wide 'data-driven' approaches that assume no prior knowledge of gene dynamics along the trajectory during inference. The suitability of the inferred trajectory is typically assessed by post-hoc examination of a set of marker genes to ensure the inferred behaviour aligns with prior assumptions. Furthermore, most current methods are algorithmic and rely on heuristics as opposed to probabilistic models, which in the context of bifurcations requires the pseudotimes to be first inferred prior to the identification of any bifurcation events. Here we introduce a general probabilistic framework for single-cell trajectory learning based on Bayesian non-linear factor analysis. First, we demonstrate how such a framework may be used to integrate prior knowledge of gene behaviour in trajectory inference. By assuming a parametric form of gene expression evolution across pseudotime we can place informative priors on parameters that govern gene behaviour and remove the need for subjective post-inference checks. We demonstrate that a small panel of marker genes is often sufficient to achieve comparable results to transcriptome wide alterna- tives and that such a method can be used to recover trajectories correspond- ing to known pathways in the presence of heavily confounding effects. Our second application is to modelling bifurcations in single-cell data. By consid- ering a Bayesian mixture of factor analysers we simultaneously infer both the pseudotimes and branching behaviour of the cells, which is unique compared to existing methods. We derive a Gibbs sampler that allows for fast inference across hundreds of cells while accounting for the zero inflation that is pertinent to single-cell RNA-seq data. Notably, by using a Bayesian framework we can integrate prior knowledge of branch-specific gene behaviour allowing for robust inference on challenging datasets.

1880T

SeqArray - A storage-efficient high-performance data format for WGS variant calls. *X. Zheng[1], S. Gogarten[1], M. Lawrence[2], A. Stilp[1], D. Levine[1], B. Weir[1], C. Laurie[1].* 1) Department of Biostatistics, University of Washington at Seattle, Seattle, WA; 2) Bioinformatics and Computational Biology, Genentech, Inc., South San Francisco, CA.

Whole-genome sequencing (WGS) data is being generated at an unprecedented rate. Analysis of WGS data requires a generic and flexible data format to store the different types of DNA variation. The variant call format (VCF) is a general text-based format developed to store genotypes and annotations, however VCF files are large and data retrieval is relatively slow. Here we introduce a new binary data format implemented in the Bioconductor package "SeqArray" for storing variant calls which provides the same capabilities as VCF. SeqArray stores variant data in an array-oriented manner with multiple high compression options including the Lempel-Ziv-Markov chain algorithm (LZMA). Benchmarks using real data sets show that the file sizes for 1000 Genomes Phase 3 genotypes are 14.0G (VCF), 12.3G (BCF, binary VCF) and 2.4G (SeqArray). For an unpublished WGS study with 9K subjects and 140M variants, the VCF file size is 66.4G, BCF 50.1G and SeqArray 14.4G. Calculating allele frequencies in SeqArray is at least 2x faster compared to other tools that use VCF or BCF files. Other Bioconductor packages built on top of SeqArray provide general functionality in WGS analysis. For example, parallel implementations of relatedness and principal component analysis with SeqArray format are enabled in the package SNPRelate. This work was supported, in part, by NIH Grant GM099568. .

Utilizing allele specific expression to identify cis-regulatory variants. *J. Zou[1], S. Shifman[3], J. Sul[4], J. Ernst[1,5], E. Eskin[1,2].* 1) Department of Computer Science, University of California, Los Angeles, CA, USA; 2) Department of Human Genetics, University of California, Los Angeles, CA, USA; 3) Department of Genetics, Silberman Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel; 4) Deparment of Psychiatry and Biobehavioral Science, University of California, Los Angeles, CA, USA; 5) Deparment Biological Chemistry, University of California, Los Angeles, CA, USA.

Understanding cis-regulatory control of gene expression is crucial towards understanding complex diseases. Traditional methods for identifying sequence variants, such as the expression quantitative loci (eQTL) approach, have identified many genetic variants correlated with changes in gene expression. However, these methods use total RNA expression, which fails to account for differences between the two alleles of diploid organisms. Allele-specific analyses account for these differences and benefit from reduced environmental and trans-acting influences. We implemented a method to identify variants that best explain observed patterns of allele specific expression (ASE) across individuals. We applied this method using RNA-seq data and genotype data collected from the Genotype-Tissue Expression (GTEx) Project. Increased power from allelic discrimination in our method allows us to identify variants with high functional relevance based on gene annotation and epigenomics data.

1882W

A scalable and secure genome archiving and communication system for the clinical enterprise. *R. Swaminathan[1], Y. Huang[1], E. Yu[1], J. Fitch[2], K. Lintner[1], P. White[2,3], S. Lin[1,3].* 1) Research Information Solutions and Innovation, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 3) Department of Pediatrics, College of Medicine, The Ohio State University, Columbus, OH.

The plummeting costs and increased diagnostic yield of whole exome/genome sequencing have resulted in an increased use of this technology for clinical purposes.The resulting genomics data influx requires a novel technological approach to store the data, communicate with other Clinical Decision Support systems, interface with Health Information Exchange,and enable secondary use in research studies.The Hadoop framework has been at the forefront in dealing with "Big Data",harnessing its distributed storage and processing capabilities.The high scalability and low cost of Hadoop,along with its suite of authentication,authorization,and auditing schemes to maintain HIPAA compliance,makes it an ideal candidate for archiving large clinical genomic datasets.Similar to the Picture Archiving and Communication System (PACS) for radiology,we designed an open source Genome Archiving and Communication System (GACS) for clinical genomics that utilizes the Hadoop Filesystem (HDFS) for genomic data storage (FASTQ/BAM/VCF/GVCF);H-Base for real time querying of variants;Google Genomics compatible API for query interface;and a NIST-derived, enterprise-supported risk management framework for data security.We evaluated the performance and scalability of the GACS implementation for data ingestion and retrieval measures using both public data from the 1000 Genomes Project as well as a larger simulated dataset of 250,000 exomes.The average ingestion time was calculated as a function of the number of exomes/genomes in the database and the storage footprint,whereas retrieval is the response time as a function of the number of exomes/genomes in the database, tested for both clinical and research use cases.We also compared the performance from Hadoop with existing genomic analytical tools such as tabix(file data store) and GEMINI(relational database) to store and query genomic information,both of which are limited in their scalability.With increasing exomes within HBase,the average ingestion time for a batch of 100 exomes using the Hadoop system was approximately 3 minutes, 4 times faster than tabix.For data retrieval, although HBase outperforms tabix,the average response time for both tabix and HBase to process 100 concurrent requests is under 1 second.In summary, the reference implementation suggests the feasibility of using a highly scalable and secure archiving system for clinical genomics, which is also conducive for integrating clinical phenotypes and public genomic information.

1883T

IGLCBP - A cloud based clinical bioinformatics pipeline. *X. Liu, P. Kothi, D.C. Thach, W.S.W. Wong, S. Ravulapalli, K.B. Tokarz, S. Madhappan, A. Black, G. Eley, B.D. Solomon, R.K. Iyer, J.F. Deeken, J.E. Niederhuber.* Inova Translational Medicine Institute, Fairfax, VA.

Inova Genomics Laboratory (IGL) is a CLIA-certified clinical genomics laboratory within Inova Translation Medicine Institute that performs high-complexity molecular testing including NextGen sequencing. To meet the fast-expanding service needs we developed a flexible, scalable bioinformatics pipeline framework IGLCBP(**IGL C**linical **B**ioinformatics **P**ipeline).   IGLCBP is based on the open-source NextGen sequence analysis workflow system bcbio-nextgen (https://github.com/chapmanb/bcbio-nextgen). IGLCBP takes advantage of several built-in features from bcbio-nextgen that match well with clinical analysis's needs including a) pre-installed /configured top sequence analysis tools from the community; b) ease of benchmarking and comparing different tools; c) support of parallelization on the Amazon Web Service (AWS) cloud; d) built-in validation module against NIST's Genome in a Bottle (GIAB) genome standard for accuracy evaluation; e) support for Docker container service (www.docker.com) that makes deployment, versioning, and reproducibility all much more manageable. We further customize IGLCBP to suit our specific clinical mandates in the following areas: a) various QC report capabilities on sequencing, alignment, coverage, and variant calls; b) functions that automate the generation of comparison matrix on accuracy, and target coverage from using different variant calling workflows (e.g. GATK vs. Samtools, single caller vs. ensemble, etc.); c) data transfer functions to meet hospital's IT security and HIPPA compliance requirements; d) modules to evaluate reproducibility and reliability from sample re-sequencing; e) utilities that connect to the database backend for fast annotation and clinical interpretation.   Here we present our process to generate a production analysis pipeline for a clinical test using IGLCBP. To demonstrate the flexibility and accuracy of our system, we tested IGLCBP on a subset of clinically relevant genes enriched by Agilent's OneSeq Comprehensive Target Panel using the CEPH NA12878 sample. Results of comparing different variant discovery workflows using IGLCBP and with Agilent's own SureCall program are presented. We plan to open source IGLCBP to the clinical genomics community to make precision medicine more easily accessible in the near future.

1884F

A standard allele registry for the human genome. *S. Sherry, B. Holmes, E. Yaschenko.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

The NCBI Allele Registry addresses the problem of allele ambiguity in human genetic data. Sequence Variation objects are currently modeled as: a single identifier attached to an interval of sequence and alternative alleles; a semantic string in a recognized nomenclature system like HGVS; a structured (but possibly un-registered) row of data in a set of called human variants in VCF format; or a variant implicit in the CIGAR string of aligned next-gen sequence fragments. The lack of cardinality and precise identification of individual sequence alleles across these data sources requires each user of the data and every global repository of allele data to individually track these variants, discern equivalencies, and track or link accordingly. Given the tremendous recent growth in the size of the data sets– hundreds of millions of total genomic variants, and hundreds of thousands of them with clinical assertions – the Allele Registry was developed to provide a standardized, comprehensive set of reference-grade allelic identities that can be assigned and indexed within NCBI archives including ClinVar, dbSNP, GTR, dbGaP, and the Genotype Server. The opportunity to correctly query for alleles across resources offers important opportunities to eliminate data redundancy, join properties of alleles across resources, and present them coherently and efficiently to users as sequence annotation, population frequency estimates, phenotype associations, and clinical assertions. The reference set of allele identifiers developed by NCBI are freely available to external communities for clinical lab management, GWAS research, array development, and medical record integration.

1885W

High-throughput clinical reporting of gene panels with the Neptune Pipeline. *E. Venner[1], M. Bainbridge[1], C. Kovar[1], T. Chiang[1], S. White[1], M. Leduc[2], M. Murugan[1], W. Salerno[1], D. Muzny[1], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX;; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas.

High throughput clinical analysis of DNA capture panels demands automated processing in order to provide timely and cost-efficient reporting for patient benefit. We developed Neptune, an automated analytical pipeline to sign-out and deliver clinical reports any site ordering a test. Our process relies on a highly-scalable Data Warehouse of curated variant and gene data that feeds into an automated reporting engine. After initial processing with the Human Genome Sequencing Center's Mercury Pipeline, custom annotation software within Neptune identifies variants of putative clinical relevance for manual review and possible addition to a dynamic "VIP" database of clinically relevant variation (cSNP, SNV, indel, CNV), drawing on both public resources (ClinVar, literature review) and internal data sets. Neptune relays these variants to a manual review interface, which captures the reviewer's input and updates the VIP database accordingly. Once all variants have been categorized, Neptune extracts known pathogenic variants using the VIP set. Neptune outputs an automated clinical pre-report populated with prioritized variants (or a negative report if no relevant variants are found), descriptive text and coverage statistics produced by the HGSC's ExCiD software. The VIP database currently houses 20,872 SNPs and 3,946 indels.   Initial data intake occurs in a HIPAA compliant environment, and samples are de-identified before moving into the CLIA lab. Neptune is engineered to provide the shortest possible turn-around times while still maintaining consistency and CAP/CLIA compliance. During initial validation, 20% of samples contained at least one reportable variant while the remainder generated a negative report. Future work will move further towards fully automated approaches for use on future clinical sequencing projects.   Early application includes reporting for the National Institutes of Health eMERGE network where more than 12,500 samples and a panel of ~100 genes will be processed in less than three years.

1886T

Developing an integrative method to improve GWAS inference using enhancer annotations. *Y.H. Hsu[1,2,3], T.H. Pers[4,5], R.S. Fine[1,2,3], J.N. Hirschhorn[1,2,3].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Boston, MA; 3) Broad Institute of the MIT and Harvard, Cambridge, MA; 4) Novo Nordisk Foundation Centre for Basic Metabolic Research, University of Copenhagen, Copenhagen, Denmark; 5) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark.

Genome-wide association studies (GWAS) have identified many genetic variants associated with human traits and diseases. However, because more than 90% of GWAS variants fall in noncoding regions of the genome, it is often difficult to predict the functional effects of these variants and to uncover trait-relevant biology from GWAS results. We have previously developed a GWAS inference method, DEPICT (Data-driven Expression Prioritized Integration for Complex Traits), that combines datasets of gene expression, protein-protein interactions, mouse knockout phenotypes, and gene sets to prioritize important genes, pathways, and tissues/cell types for complex traits. In this project, we incorporated enhancer annotations from the FANTOM5 project into DEPICT to prioritize transcriptional regulators. We mapped the enhancers to downstream target genes by correlating the expression of proximal enhancer-gene pairs across cell types. We also identified upstream regulators for the enhancers by scanning their DNA sequences for transcription factor binding motifs from the Cis-BP database. We then summarized these regulatory relationships into a gene by regulator data matrix, in which each score indicates how strongly a gene is controlled by an upstream regulator. We used the gene by regulator matrix in DEPICT to prioritize regulators that are important for various traits, including height, inflammatory bowel disease, low-density lipoprotein, and schizophrenia. In some cases, we were able to further validate the prioritized regulators by showing that, in trait-associated loci, SNPs are more likely to overlap enhancers containing motifs for the prioritized regulators compared to other enhancers ($p < 0.05$). While additional work is needed to improve the gene by regulator matrix, our preliminary results indicate that integrating enhancer regulatory information into DEPICT can expand its utility for interpreting GWAS.

1887F

Using data-driven approaches to address clinical heterogeneity in complex traits. *J.B. Leader[1], A.O. Basile[2], H.L. Kirchner[1], C.B. Manney[1], A. Verma[1], M.D. Ritchie[1,2].* 1) Department of Biomedical and Translational Informa, Geisinger Health System, Danville, PA; 2) Department of Biochemistry and Molecular Biology, Center for Systems Genomics, The Pennsylvania State University, University Park, PA.

Complex diseases are often heterogeneous in nature; instead of representing a single disease, these conditions may in fact be comprised of multiple disorders, each with varying symptoms, clinical presentations, and thereby differing etiology. Trait heterogeneity is a confounding variable that has largely been overlooked in traditional genetic approaches. It complicates clinical patient diagnoses, and has been shown to decrease both the statistical power to detect associations and the risk attributed to susceptibility variants. The copious amounts of biomedical data present in the Electronic Health Record (EHR) system can be leveraged using data-driven approaches to overcome clinical heterogeneity and detect homogeneous patient subgroups. We performed *in silico* dataset evaluations to examine the performance of multiple machine learning algorithms in homogeneous data classification. The evaluated algorithms included classical clustering approaches such as hierarchical clustering and k-means analysis, random forests, and dimensionality reduction strategies such as Principal Component Analysis (PCA) and t-Distributed Stochastic Neighbor Embedding (t-SNE). Further, various proximity and similarity metrics were evaluated to account for mixed data types within the EHR, e.g. binary, continuous, ordinal, and missing variables. We demonstrate the utility of the given algorithms by using Chronic Obstructive Pulmonary Disease (COPD), a condition with known clinical heterogeneity, for our proof of concept. Approximately 49,000 patients from the Geisinger Health System MyCode® Community Health Initiative with a known COPD diagnosis were subset using spirometry data, clinical lab variables, presence/absence of co-morbidities, clinical diagnosis codes, metabolic panels, medication usage data, vitals readings, and exercise testing measures. Using COPD as our proof of concept disease model, we demonstrate that data-driven approaches can be used as a means to overcome clinical heterogeneity of disease by embracing the complexity and wealth of data within the EHR. Moreover, these methods have the potential to build more accurate predictive disease models that can aid in uncovering the genetic basis of complex traits.

1888W

A framework for the construction of information maps. *H.S. Ooi[1,2,3], J. Grove[1,2,3,4], M. Schierup[4], A. Borglum[1,2,3], M. Mattheisen[1,2,3].* 1) Department of Biomedicine, Aarhus Univeristy, Aarhus, Select a Country; 2) iPSYCH, The Lundbeck Initiative for Integrative Psychiatric Research; 3) iSEQ, Centre for Integrative Sequencing; 4) BiRC, Bioinformatics Research Centre, Aarhus University, Denmark.

Molecular networks are undoubtedly an important resource for large-scale genetics studies. However, most of the existing methods only present the users with the network, without any auxiliary information to derive context-specific sub-networks for data analysis. Here, we present a flexible framework for the construction of an information map for large-scale genetics analysis. The information map is derived from more than 60 network-related resources and cover a wide-range of data types, including protein-protein interactions, gene co-expression, tissue expression, subcellular localization, drug targets, co-participation in pathways and co-association in diseases. Our framework first integrates and evaluates a molecular interaction network using a Bayesian-based approach, which transforms the heterogeneous information into an easily interpretable model. Unlike many of the existing approaches which ignore importat aspects of the raw information, we transform the data during the integration process into pair-wise relationships that indicate co-associations between genes or proteins under a particular conditions. This auxiliary information is then combined with the scored network to form the final information map. The base network in our information map is derived from multiple experiments spanning across various conditions and tissues. However, the biological processes are likely context dependent, where biological molecules interact with each other in a time- and space-specific manner. Here we illustrate the ability of our approach to derive a brain-specific network directly from the information map, and show the benefits of using such a brain-specific network in analyzing psychiatric disorders. The disease co-association information available in the information map allowed us to perform cross-disorder analyses of five major psychiatric disorders. This comparative analysis identified biological processes that are involved in multiple disorders or in contrast play a central role in one specific disorder. We could further demonstrate the flexibility of our information map by including disease-associated loci identified by our Danish iPSYCH study by means of genome-wide association studies or whole-exome sequencing experiments.

Predicting gene regulation in diverse global populations. *A. Badalamenti, N. Jachym, A. Almatrafi, V. Saulnier, J. Ng, S. Shah, H. Wheeler.* Department of Biology and Computer Science, Loyola University Chicago, Chicago, IL.

How the genetic architectures of complex traits vary between populations is not well understood, in part due to the historical paucity of GWAS in populations of non-European ancestry. For many complex traits, gene regulation is likely to play a crucial mechanistic role given the consistent enrichment of expression quantitative trait loci among trait-associated variants. We have previously developed PrediXcan, a gene-based association method that tests the mediating effects of gene expression levels by quantifying association between genetically regulated expression levels and the phenotypic trait of interest. The goal of our research is to build and test genetic predictors of gene expression within and between global populations. Utilizing genetic and transcriptomic data from diverse populations, we have built statistical models that accurately predict gene expression using variant genotypes. Our genotype data comes from the third phase of the International HapMap project, containing approximately 1.1-1.3 million SNPs per population. We used gene expression levels measured in lymphoblastoid cell lines from a subset of these individuals from seven non-European populations [Han Chinese (CHB), Gujarati Indians (GIH), Japanese (JPT), Luhya in Kenya (LWK), Mexican (MEX), Maasai in Kenya (MKK), and Yoruba in Nigeria (YRI)]. We performed elastic net modeling with 10-fold cross-validation to select genotypes and their weights that best predict expression of each gene. As expected, predictive performance (measured by R2) across genes correlated across populations. The best predicted gene in each population was the same, HLA-DRB5, with R2 > 0.94 in each population. However, reflective of differing allele frequencies and effect sizes, the highest predictive performance correlation was found between populations from the same continent. For example, the Pearson correlation between CHB and JPT is 0.59 and between LWK and MKK is 0.51, whereas the correlation between LWK and MEX is only 0.29. We will impute genotypes in each population to potentially improve predictive power. We aim to see how these genetic predictors of expression vary between populations, as well as determine if differences in predicted expression of the same genes associate with a particular complex trait between these populations by applying our PrediXcan method. Our method advances biological knowledge of the underlying regulatory mechanisms of disease risk not assessed in GWAS alone.

1890F

SCONE: Correcting and evaluating the influence of unwanted variation on single-cell RNA-seq data. *M. Cole[1,2], D. Risso[3], A. Wagner[2,4], J. Ngai[5], E. Purdom[6], S. Dudoit[3,6], N. Yosef[2,4].* 1) Department of Physics, University of California, Berkeley, Berkeley, CA; 2) Center for Computational Biology, University of California, Berkeley, Berkeley, CA; 3) Division of Biostatistics, School of Public Health, University of California, Berkeley, Berkeley, CA; 4) Department of Electrical Engineering & Computer Science, University of California, Berkeley, Berkeley, CA; 5) Department of Molecular & Cell Biology, University of California, Berkeley, Berkeley, CA; 6) Department of Statistics, University of California, Berkeley, Berkeley, CA.

  Single-cell RNA sequencing (scRNA-Seq) technologies are opening the way for transcriptome-wide profiling across diverse and complex mammalian tissues, facilitating unbiased identification of novel cell sub-populations and their functional roles. As in other high-throughput assays, a fraction of the heterogeneity observed in scRNA-Seq data results from batch effects and other technical artifacts. In particular, single-cell protocols' reliance on miniscule amounts of starting mRNA can lead to widespread "drop-out effects," in which expressed transcripts are missed. Due to the biases inherent to this assay, data normalization is an essential step prior to any downstream analyses. However, relatively few studies have assessed the performance of common normalization methods employed by the growing scRNA-Seq community. We introduce SCONE (Single-Cell Overview of Normalized Expression), a new R package for single-cell expression data quality control (QC) and normalization; our data-driven framework uses summaries of expression data to assess the efficacy of normalization workflows. Starting from read count data, our template normalization workflow begins with an optional drop-out imputation step, followed by a choice of scaling normalization (e.g. DESeq scaling factor) and ending with a regression-based adjustment for factors of unwanted variation (e.g. RUVg normalization). We compare the performance of hundreds of normalized data matrices by dimensionality reduction, scoring clustering metrics over cell classifications (prior or *de novo*) and scoring correlation metrics over control gene sets (e.g. cell-cycle genes or "housekeeping" genes). We apply SCONE to a publicly available data set of 130 high- and low-coverage single-cell libraries obtained from 65 human neural cell lysates (Pollen et al. 2014). Our results highlight negative trade-offs between preservation of biological variance and removal of artifact and demonstrate the extent of confounding between experimental batch, biological variation, library quality, and expression estimates. Top-ranked normalization methods for low-coverage sequencing data recover the covariance structures present in matched high-coverage data, showing that SCONE properly guides the study-specific choice of normalization work-flow based on empirical evidence. We will emphasize the issues surrounding the design of scRNA-Seq experiments and highlight the utility of positive controls and QC metrics in combating unwanted variation.

SeqSQC: An R package for sample quality check with NGS data. *Q. Liu[1,2], Q. Hu[2], Q. Zhu[2].* 1) Department of Biostatistics, University at Buffalo, SUNY, Buffalo, NY; 2) Department of Biostatistics and Bioinformatics, Roswell Park Cancer Institute, Buffalo, NY.

  Objective: To identify problematic samples in next-generation sequencing (NGS) data, including samples with gender mismatch, abnormal inbreeding coefficient, cryptic relatedness, and population outlier. **Method:** SeqSQC is an R package that automates the sample quality control (QC) of large-scale NGS data. 100 independent samples and 10 family-related samples were selected from 1000 Genomes Project as benchmark to facilitate sample QC of study cohort. SeqSQC takes VCF files from whole-genome sequencing or exome sequencing data as input and stores the genotypes in GDS format to accommodate the extremely large-scale dataset with limited memory. The package generates interactive plots in each QC step as an intuitive interface for visualization. Statistical methods are implemented in the package for identifying problematic samples. **Result:** SeqSQC is capable of dealing with sequencing data from different platforms, different capture regions, and in different sample sizes. With simulation dataset and real data selected from 1000 Genomes Project, we have successfully identified all problematic samples. **Conclusion:** SeqSQC is highly efficient and flexible tool, with interactive visualization functions and statistical classification methods for sample quality investigation.

Cross-Validated BLUPs: A novel and powerful summary statistic opens new doors to multi-phenotype analyses. *J.A. Mefford[1], N. Zaitlen[2], J. Witte[1].* 1) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA; 2) Department of Medicine Lung Biology Center, UCSF San Francisco, CA.

With The Precision Medicine Initiative are emerging mega-scale genetic cohorts with rich phenotypic data collected over hundreds of thousands of individuals. Current gold standard analyses ignore the high-dimensionality of phenotypic data, and even multivariate LMMs are computationally incapable of leveraging the shared genetics between tens, let alone hundreds of phenotypes. Here we overcome this problem by introducing a novel summary statistic that is efficiently computed and securely shared without providing access to individual level genotypes. We propose to produce and release, in addition to SNP-level summary statistics, a genetic prediction of the phenotype of each individual in the study. To prevent over-fitting and provide securely shareable data, we adapt a machine learning technology to produce out-of-sample (i.e. cross-validated) predictions, which we call "cvBLUPs". Similar to SNP-level summary statistics, subject-level summary statistics open a range of new analysis possibilities. We highlight two of these here in the form of (1) the most efficient computation of genetic correlation produced to date and (2) efficient multivariate LMM association studies with up to hundreds of phenotypes analyzed jointly. We show analytically that the correlation of a pair of vectors of cvBLUPs is an efficient estimator of the genetic correlation of those phenotypes and accord well with genetic correlation estimates made using bivariate REML. Because calculation of genetic correlations by cvBLUP is essentially free after univariate analyses have been run we easily computed genetic correlations for over 300 phenotypes analysis of 4367 unrelated Finnish men. We discuss our findings including our discovery of a genetic correlation between BMI and smoking of 0.81. Unlike other summary statistics based methods cvBLUPs can be used to compute conditional or partial genetic correlations helping to unravel underlying causal relationships as opposed to just pleiotropy. We also use cvBLUPs to efficiently model polygenic effects across multiple traits with sets of cvBLUPs as fixed effects in a standard linear regression. This boosts the power of association analyses beyond what is possible with existing methods. For example, in an association analysis of BMI in the Finnish study, adjustment by the cvBLUPs for total cholesterol and smoking status each boost chi squared test statistics a further 2 percent.

Identifying multi-tissue gene expression outliers to elucidate the functional impact of rare variants. *E.K. Tsang[1,5], J.R. Davis[2,5], A. Battle[3,6], S.B. Montgomery[2,4,6].* 1) Biomedical Informatics Program, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Computer Science, Johns Hopkins University, Baltimore, MD; 4) Department of Pathology, Stanford University, Stanford, CA; 5) co-first authors; 6) co-senior authors.

Each human genome harbors more than 40,000 rare variants and over 95% are non-coding. We expect that a subset of these variants disrupt physiological processes and significantly impact cellular phenotypes such as gene expression. Typical methods for identifying common regulatory variants, like eQTL studies, lack the power to detect rare variants. However, we can investigate rare variants with large effects on gene expression through outliers—cases where an individual strongly over-expresses or under-expresses a given gene compared with the rest of the population. Our group and others have successfully used this approach in single tissues, but the impact of rare variants across tissues remains uncharacterized. Studying multiple tissues lends insight into their regulatory similarities and combining information across tissues may yield a larger, more confident set of outliers. Here, we have developed a method for identifying multi-tissue gene expression outliers that captures situations where each individual has a different subset of sampled tissues. One of our method's key features is that it directly models similarities between tissues. In contrast to methods that ignore the expression correlation between tissues, we can discover expression outliers that break the population correlation structure in addition to outliers with consistent effects across tissues. We evaluated our method on simulated data and applied it to expression data from 23 primary human tissues from approximately 330 individuals in the GTEx data set. We find that expression outliers discovered in the GTEx data are more strongly enriched for nearby rare variants than for common ones. Rare variants near outlier genes are more conserved and more often in known regulatory regions, such as promoters and splice sites, compared with variants near the same genes in non-outlier individuals. Genes with outlier expression are enriched for allele-specific expression across tissues, providing evidence that these rare variants act in *cis*. We have applied our method to multi-tissue expression data and show how it can be extended to discover outliers in multi-omics data sets. Our findings demonstrate that our method identifies multi-tissue expression outliers that help pinpoint rare variants with regulatory effects. Improved characterization of the rare variants categories with large expression effects is essential to integrating whole genome data in our understanding of health and disease.

Facilitating collaborative analysis in large-scale rare disease genomics. *E. Valkanas[1,2], B. Weisburd[1,2], L. Xu[1,2], H. Arachchi[1,2], M. Lek[1,2], T. Mullen[1,2], A. Topf[3], M. Bertoli[3], K. Johnson[3], V. Straub[3], M.J. Daly[1,2], D. MacArthur[1,2].* 1) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 3) Newcastle University John Walton Muscular Dystrophy Research Centre and MRC Centre for Neuromuscular Diseases, Institute of Genetic Medicine, Newcastle upon Tyne, UK.

One of the critical challenges in rare disease diagnosis is ensuring that data can be effectively shared between informatics groups and clinical experts. We have developed an open source web-based tool, *seqr* (https://seqr.broadinstitute.org/), that provides a centralized platform for analyzing exome and whole genome variant call sets, capturing phenotype information, and communicating progress and results. *seqr* allows users to leverage a variety of different data sources when searching for causative variants in patient and family data. In addition to allowing easy searching of patient genotype information, *seqr* also give access to reference populations, known disease associations, CNV data, and allows users to interactively view NGS read support and sequence context for variants. The platform allows the collection of structured phenotype data (Human Phenotype Ontology) through integration with PhenoTips. For unsolved cases, users have the option to search for individuals with similar phenotype and genotype profiles through the Matchmaker Exchange. Finally, the system facilitates collaboration between groups by allowing joint analyses of the same data sets, and variant-level tagging and discussion of pathogenicity by multiple users. The *seqr* platform has been applied to rare disease projects spanning 9363 exomes and 1088 whole genomes. We demonstrate the utility and usability of this platform using data from the MYOSEQ project, a collaboration between the Newcastle University John Walton Muscular Dystrophy Research Centre and the Broad Institute that has sequenced 1,000 exomes from patients with undiagnosed limb-girdle muscle weakness. Using the *seqr* platform, our analysis team, distributed across two continents, has successfully diagnosed 281 of the 725 families analyzed to date, including 14 index cases where diagnosis has altered therapeutic outcomes. A critical component of such successes is connecting with collaborators to develop new features within the platform and increase usability. As our user community grows, we plan to continue this iterative process to facilitate rare disease research.

PheWeb: A tool for interacting with and visualizing PheWAS results. *P. VandeHaar[1], C. Clark[1], E. Schmidt[1], M. Flickinger[1], L. Fritsche[2], C. Brummett[3], S. Kheterpal[3], G. Abecasis[1].* 1) Biostatistics, University of Michigan, Ann Arbor, MI.Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 2) K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health, NTNU, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Anesthesiology, University of Michigan Medical School, Ann Arbor, MI.

Phenome-Wide Association Studies (PheWAS) report the association between single genetic variants and many traits. Each trait is typically a disease state defined by a collection of ICD-9 (International Classification of Disease, 9th Edition) or ICD-10 codes. When PheWAS are combined with modern genotyping and sequencing technologies, they can result in billions of association statistics and hundreds of association signals. Translating these large result sets into new understanding of health and disease requires making the results accessible to many scientists. Here, we describe a tool that can make these very large result sets easily accessible and intuitively browseable. PheWeb enables interactive exploration of the associations between hundreds or thousands of traits and genetic variants. It can easily handle matrices summarizing association between millions of SNPs and thousands of traits, such as would be produced by running a GWAS on a modern electronic health record dataset.For each trait, the browser currently includes a Manhattan plot, a QQ plot, and a LocusZoom-like region view. For each SNP, the browser includes a PheWAS plot and a table of the most-associated traits. These plots are based on LocusZoom.js, allowing them to link to each other, zoom, and show tooltips, providing an exploratory interface.An instance of PheWeb is available at http://pheweb.sph.umich.edu to browse EHR-based association results from the Michigan Genomics Initiative. If you have association results for many phenotypes, we encourage you to use PheWeb to visualize your results to improve understanding and interpretation of signals.

Generic, protein-, and mechanism-specific computational tools for variant interpretation. *M. Vihinen, A. Niroula, S. Urolagin, J. Väliaho, H. Ali.* Lund University, Sweden.

   Next Generation Sequencing (NGS) technologies produce huge amounts of sequence information. Large genomic projects aiming at personalized medicine are underway; however, variation interpretation has been and still is a bottleneck. Due to the huge amounts of produced data, reliable and fast computational tools are needed to enhance variation interpretation and to cope with the datasets. We have developed several tools to predict the impact of variations which can be broadly grouped as generic tools to predict the tolerance of variants, locus-specific tools to predict the tolerance of variants in specific proteins, genes or domains, and mechanism-specific tools to predict the mechanism of variation effect. The generic and locus-specific tools rank and prioritize variants and the mechanism-specific tools help to interpret the mechanism of variation effect. PON-P2 is a generic tool for predicting variant pathogenicity with highest performance among related tools[1]. The method computes reliability for each variation and classifies the reliably predicted variants as pathogenic or neutral and the unreliably predicted variants as unclassified. PON-P2 is fast and it can be integrated into variation interpretation pipelines since there is a application programming interface API) available. Our locus-specific tools include PON-BTK for variants in the kinase domain of Bruton tyrosine kinase[2], PON-MMR2 for mismatch repair protein variants[3] and PON-mt-tRNA for mitochondrial tRNA variants[4]. Mechanism-specific tools include PPSC for protein stability affecting variants[5], PON-Diso for protein disorder affecting variants[6], and PON-Sol for protein solubility affecting variants[7]. All these tools are among the most reliable ones. They are freely available at http://structure.bmc.lu.se. References: 1 Niroula, A. *et al. PLoS One* **10**, e0117380, (2015). 2 Väliaho, J. *et al. Visualization and analysis of single-cell RNA-seq data by kernel-based similarity learning. *B. Wang[1], J. Zhu[2], E. Pierson[1], S. Batzoglou[1].* 1) Computer Science, Stanford University, Stanford; 2) Department of Electrical Engineering, Stanford University.

   Single-cell RNA-seq (scRNA-seq) technologies enable gene expression measurement of individual cells and allow the discovery of cell population heterogeneity. Recent advances in scRNA-seq have allowed simultaneous profiling of thousands of cells and increased the sensitivity in quantifying single-cell transcriptome landscapes of complex biological systems. However, scRNA-seq data sets are noisy with high degree of dropouts, and exhibit higher levels of diversity such as cell input heterogeneity and variation in cell cycle stages. These challenges make it difficult to define cell-to-cell similarity measures based on strict statistical assumptions that have been developed for bulk RNA-seq. Here, we propose a novel similarity-learning framework, SIMLR (single-cell interpretation via multi-kernel learning), which learns an appropriate distance metric from the data for dimension reduction, clustering and visualization. We profiled >50,000 peripheral blood mononuclear cells (PBMCs) with the ChromiumTM system from 10x Genomics, and used SIMLR to provide an unbiased classification of all major subpopulations at expected proportions. In order to evaluate the sensitivity and accuracy of SIMLR, we further analyzed individual purified populations from PBMCs and pooled the data in silico at varying proportions. In addition, we extensively evaluated SIMLR using published scRNA-seq datasets generated by several other micromanipulation and microfluidics platforms with varying sequencing depths. For all the datasets above, we first show that simple correlation-based or distance-based similarity measures are sensitive to noise, dropouts and outlier effects among the high dimensional data. In contrast, SIMLR can uncover clear similarity block structures by automatically learning appropriate cell-to-cell similarity specific to each dataset. Furthermore, we performed dimension reduction on these high dimensional datasets using the similarity learned by SIMLR, and compared it with 8 other popular alternative methods. We evaluated the effectiveness of SIMLR's dimension reduction both quantitatively and qualitatively by considering clustering accuracy and visualization. Dimension reduction performed via SIMLR yields a substantially higher clustering accuracy. When applied to visualization, we illustrate SIMLR's advantages over other methods in projecting the high dimensional data to 2-D where the different cell types are automatically projected in spatially distinct clusters. .

Scaling rare disease genomics to tens of thousands of samples. *B. Weisburd, E. Valkanas, H. Arachchi, M. Daly, M. Lek, D.G. MacArthur.* Broad Institute, Cambridge, MA.

Rapid advances in exome and whole-genome sequencing make it possible to identify the full spectrum of genetic variation in rare disease patients and family members. However, to make sense of this data, and discover the causal variants underlying rare diseases, powerful filtering and decision support tools are needed that can handle the very large data sets now being produced. We are addressing this challenge by developing seqr - an open source, interactive web-based tool that allows researchers to work together to search and annotate variant call-sets from exome and whole genome studies involving families of rare disease patients. This presentation will describe the technology stack underlying seqr, including the database, server-side and client side technologies involved, with a focus on the design choices made to facilitate the scaling of the system to tens of thousands of exome and genome samples. The need to allow interactive searching of terabytes of genomic sequencing data requires custom solutions and thoughtful design trade-offs. We will present the technical details of how seqr dealt with these challenges. Additionally this talk will describe how interactive visualization of read-level data, copy number variation, detailed phenotype data, and other relevant data types were brought together in a single user-friendly interface.

1899F

Pedigree reconstruction in the era of many thousands of samples. *A.L. Williams[1], R. O'Hern[1], J. Blangero[2].* 1) Biological Statistics & Computational Biology, Cornell University, Ithaca, NY; 2) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX.

Members of sexually reproducing species are related to each other through a pedigree in which each individual has two parents, some number of offspring, and is related to all other individuals through these first degree relationships. While numerous genetic analyses require or benefit from knowledge of pedigree relationships, this information is not always available. Moreover, when a pedigree is reported, errors in it can confound downstream analyses so the structure must be confirmed. We present Attila, a novel method for pedigree reconstruction that is accurate, efficient, and scalable to thousands of samples. The algorithm works by first estimating the probability that each pair of samples is related via three possible relationship classes: parent-offspring, full sibling, or other (2nd degree or more distant). Given these probabilities, the program constructs a pedigree as a graph with nodes representing samples and edges labeled by the relationship between each sample pair. Attila inserts edges in order of the most likely relationship, and during this process, propagates information implied by the edge using biologically-derived constraints on the relationships between any three samples. If an inserted edge leads to a constraint violation, the program reverts to the previous graph and inserts the next most likely edge until all relationships are defined. Thus the algorithm uses backtracking search to efficiently reconstruct a pedigree with high likelihood. Many pedigree reconstruction methods scale exponentially in the number of samples, whereas Attila has polynomial runtime and memory scaling, with a theoretical runtime scaling limit of $O(N^3)$, where N is the number of samples. In practice, a set of samples can be divided into subsets based on simple measures of relatedness and each of these subsets individually analyzed for pedigree structure, thus reducing runtime significantly. We ran Attila and PRIMUS on samples from a Mexican American pedigree dataset containing 257 individuals and consisting of six separate pedigrees. PRIMUS only reconstructed the smallest (21 sample) pedigree among those examined, but did not detect others and reported no errors. By contrast, Attila reconstructed all six pedigrees in only 6.6 hours. Of the >32,000 pairwise relationships in the reported data, all but four (likely misreported) were classified correctly. We are further improving Attila's efficiency and will present results from analyzing >115,000 UK Biobank samples.

1900W

Population-scale SV detection and characterization using SVTools. *H.J. Abel[1,2], D.E. Larson[1,2], C. Chiang[1,3], A. Badve[3], L. Ganel[1,3], R.M. Layer[4], A.R. Quinlan[4], I.M. Hall[1,3].* 1) McDonnell Genome Institute, Washington Univ. School of Medicine, St. Louis, MO; 2) Dept. of Genetics, Washington Univ. School of Medicine, St. Louis, MO; 3) Dept. of Medicine, Washington Univ. School of Medicine, St. Louis, MO; 4) Dept. of Human Genetics, Univ of Utah, Salt Lake City, UT.

   Structural variation (SV), including copy number variation and balanced rearrangements, comprises a large part of human genetic diversity. The contribution of SV to human disease remains unknown, however, as the full range of SV cannot be detected from the SNP microarray or exome sequencing data collected in most large-scale genetic studies to date. The current wave of population-scale whole-genome sequencing (WGS) studies (eg, CCDG, Topmed) provides unique opportunities, both for the characterization of the SV landscape in the healthy population and for investigation of the role of SV in common disease. To succeed, such endeavors will require new approaches to SV detection, as current algorithms scale to at most several hundred genomes.   We have developed svtools (https://github.com/hall-lab/svtools), a suite of python tools for SV detection and characterization, scalable to tens of thousands of genomes. The svtools pipeline is loosely modeled on the GATK 'N+1' framework: single-sample SV callsets are generated in parallel using LUMPY, whose output describes the uncertainty in breakpoint position via probability distributions. SV calls are then merged across samples, with shared evidence in breakpoint distributions combined to provide improved precision. Each sample is then genotyped and annotated with read-depth information, in parallel, at all variants in this discovery set; the resulting multi-sample VCF describes cohort-level SV with greater sensitivity and precision than the original single-sample calls.   The SVTools suite enables joint SV discovery and genotyping on population cohorts, thus promising a wealth of new genetic variation to aid in the understanding of human disease. As proof of principle, we present the results of our initial SV callset comprising more than 7000 deep WGS datasets from individuals of diverse ancestry. We observe an abundance of rare, high impact SVs that are predicted to alter gene function, including a remarkable number of balanced and/or complex rearrangements that would not be detected by traditional CNV-centric methods such as microarrays or read-depth analysis. Finally, we discuss our plans for data-sharing and the creation of an SV catalog resource to improve the understanding of the landscape of genetic variation in the healthy population. Such a resource should prove invaluable, in particular for the evaluation of 'n-of-1' type variants often encountered in clinical settings and in the study of rare disease.

1901T

A population-level structural variant catalogue to improve the recall and consistency of common structural variant calls. *M.A. Bekritsky[1], P. Krusche[1], N. Johnson[2], A. Gross[2], S. Ivakhno[1], S.J. Humphray[1], D.R. Bentley[1], M.A. Eberle[2].* 1) Illumina Cambridge Ltd., Saffron Walden, Essex, Essex, United Kingdom; 2) Illumina Inc., 5200 Illumina Way, San Diego, CA 92122, USA.

   Accurate and consistent copy number variant (CNV) and structural variant (SV) detection is an essential component of genomic research and necessary for maximizing the diagnostic yield of clinical sequencing. Yet, the quality of SV calling cannot be assessed accurately in part because there are no comprehensive benchmarking datasets for large variants. While there are high quality benchmarking databases for SNVs and indels, SV benchmarking resources are limited to either a few samples sequenced to high depth or many samples sequenced to low depth. Additionally, these resources are heavily biased towards deletions over duplications and other SVs. To improve the current benchmarking resources, we are developing a database of common SVs identified from whole-genome sequence data from over 4,000 samples sequenced to an average depth of 35x. We have developed algorithms that scan through aggregated SNV datasets to identify population signals consistent with common underlying deletions and duplications. Using this approach we identified ~13,000 strong signals based on deviations from Hardy-Weinberg equilibrium and depth correlations that were consistent with deletions and duplications. A primary differentiator of this method is that it uses population signals to identify CNVs, in contrast to traditional CNV callers, which use read depth and/ or split reads. Using the population signals as hypotheses, we have identified a high-quality subset of CNVs whose depths are strongly correlated to the genotypes of a nearby SNV. We have also de novo assembled an initial subset of over 6,000 deletions (mean size ~500bp) to breakpoint resolution and are developing variant callers that leverage population information by using graph-based methods. This approach will allow these deletions to be reliably and consistently called in future studies. For variants that are not amenable to graph-based detection methods we are using population-level depth signals so that these variants can also be called consistently and reliably. To provide a public resource underpinning this variant catalogue for further benchmarking and algorithm improvement, we are sequencing 150 Coriell samples from disparate ethnicities to high depth using 2x150bp reads generated on a HiSeqX and releasing the sequence data and variant calls on these samples. We will present the results of our analysis and ongoing additional improvements to increase the completeness of this SV resource.

1902F

SVScore: An impact prediction tool for structural variation. *L. Ganel[1,2], I.M. Hall[1,2,3].* 1) McDonnell Genome Institute, Washington University School of Medicine, St. Louis, MO, USA; 2) Department of Medicine, Washington University School of Medicine, St. Louis, MO, USA; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO, USA.

Structural variation is an important source of human genome variation that includes deletions, duplications, inversions, mobile element insertions, translocations, and complex rearrangements. Over the past several years, much progress has been made in the area of structural variant (SV) detection, and we are now able to routinely detect 5,000-10,000 SVs in a typical deeply sequenced human genome. However, predicting the functional impact of SVs discovered in whole genome sequencing (WGS) studies remains extremely challenging. Accurate SV impact prediction is especially important for WGS-based rare variant association studies, such as those undertaken by the NHGRI Centers for Common Disease Genomics, and for WGS-based studies of rare disease. Here we present SVScore, a novel computational tool for *in silico* structural variant impact prediction. SVScore leverages existing single nucleotide variant (SNV) pathogenicity scores such as CADD (Kircher et al., 2014). SVScore aggregates per-base pathogenicity scores across relevant genomic intervals for each SV in a manner that considers variant type, gene features, and uncertainty in breakpoint location. To evaluate its effectiveness in a large dataset, we used allele frequency (AF) as a proxy for pathogenicity by assuming that, due to selection, pathogenic SVs are enriched among rare variants and benign SVs are enriched among common ones. We show that the AF spectrum of SVs that received high impact scores was skewed toward lower frequencies and vice versa, suggesting that high-scoring variants are indeed under negative selection. We quantify this effect and show that the allele frequency skew of high-scoring SVs in SVScore is stronger than the skew produced by various naïve approaches that merely consider variant size or genome annotations, suggesting that SVScore is more effective in identifying deleterious SVs than existing alternative methods. We further show that SVScore identifies pathogenic SVs in both coding and noncoding regions and compare the strength of the AF skew imposed on SVs by our scoring system to that of comparable SNV methods. Finally, we demonstrate that high-scoring duplications are under surprisingly strong selection relative to high-scoring deletions, suggesting that duplications can be more deleterious than previously thought. In conclusion, SVScore provides pathogenicity prediction for SVs that is both informative and meaningful for understanding their functional role in disease.

1903W

High resolution measurement of DUF1220 domain copy number from whole genome sequence read depth. *I.E. Heft, D.P Astling, K.L. Jones, J.M. Sikela.* UC-Denver Anschutz Medical Campus, Aurora, CO.

DUF1220 protein domains show the most extreme human lineage-specific increase in copy number of any coding region in the genome. There are 302 haploid copies of DUF1220 in hg38 (~160 of which are human-specific) and the majority of these can be divided into 6 different subtypes (clades). Copy number changes of specific DUF1220 clades have been associated in a dose-dependent manner with brain size variation (both evolutionarily and within the human population), cognitive aptitude, and autism and schizophrenia severity. However, DUF1220 sequences have been difficult to measure and, as a result, have typically not been directly examined in searches for human disease genes. To address these challenges and maximize the utility of emerging whole genome sequence (WGS) datasets, we have developed a high resolution method for the measurement of DUF1220 copy number from WGS data. We have characterized the effect that various sequencing and alignment parameters have on the accuracy and precision of the method and defined the parameters that lead to optimal DUF1220 copy number measurement and resolution. We show that copy number estimates obtained using our read depth approach are highly correlated with those generated by ddPCR for three representative DUF1220 clades. By simulation, we demonstrate that our method provides sufficient resolution to analyze DUF1220 copy number variation at three levels: (1) DUF1220 clade copy number within individual genes & groups of genes (gene-specific clade groups) (2) genome wide DUF1220 clade copies and (3) gene copy number for DUF1220-encoding genes. This is the first approach that measures DUF1220 copy number with clade-specific resolution and, to our knowledge, represents the most detailed method for the copy number measurement of DUF1220-related sequences. This approach greatly enhances our ability to analyze the role that these sequences play in human variation and disease.

1904T

CoNVaDING: Single exon variation detection in targeted NGS data. *L.F. Johansson[1,2], F. van Dijk[1,2], E.N. de Boer[1], K.K. van Dijk-Bos[1], J.D.H. Jongbloed[1], A.H. van der Hout[1], R.C. Niessen[1], H. Westers[1], R.J. Sinke[1], M.A. Swertz[1,2], R.H. Sijmons[1], B. Sikkema-Raddatz[1].* 1) University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, The Netherlands; 2) University of Groningen, University Medical Center Groningen, Genomics Coordination Center, Groningen, The Netherlands.

   1. Introduction We have developed a tool for detecting single exon copy number variations (CNVs) in targeted next-generation sequencing data: CoNVaDING (Copy Number Variation Detection In Next-generation sequencing Gene panels). CoNVaDING includes a stringent quality control metric, that excludes or flags low quality exons, making the tool useful in both research and clinical diagnostics.   2. Materials & Methods The method is based upon a read depth comparison of selected target regions between a sample of interest and a set of control samples. Existing tools, such as XHMM, CoNIFER and CODEX consider all control samples equally informative even though there are sample to sample variations caused by differences in PCR and capturing efficiency. CoNVaDING, however, selects the control samples showing a coverage pattern most similar to that of the sample analysed. Data is then normalized in two different ways, using within the sample all autosomal targets or all targets within the same gene. Based on the normalized data, for each target the ratio of the normalized average read depth of the sample to that of the controls and a distribution analysis using a Z-score are calculated and a prediction is made for each target to determine whether a CNV is present or not. CoNVaDING provides for each sample quality metrics to distinguish high quality samples and targets from low quality ones.   3. Results We compared the performance of CoNVaDING with XHMM, CoNIFER and CODEX in 320 samples captured with two different targeted gene-panels (Agilent Sure Select custom design 0421101 and 0679001) containing in total 376,440 exons. For all CNV calls made by one of the first three methods MLPA was performed. CoNVaDING detected all known CNVs in high-quality targets, giving 100% sensitivity, at a 99.998% specificity for 308,574 high-quality exons.   4. Discussion CoNVaDING outperforms XHMM, CoNIFER and CODEX by exhibiting a higher sensitivity and specificity and by precisely identifying low-quality samples and regions, which have a high risk of false positive or false negative results. Since the quality control metrics show exactly which exons can be reliably analyzed and which exons are in need of an alternative analysis method, CoNVaDING can not only be applied for CNV detection in a research setting, but also in clinical diagnostics. CoNVaDING software is available under the GNU GPL open source license and can be freely downloaded from https://github.com/molgenis/CoNVaDING.

ClinVar: For researchers and medical practitioners alike. *M.J. Landrum, J.M. Lee, M. Benson, G. Brown, C. Chen, S. Chitipiralla, B. Gu, J. Hart, D. Hoffman, W. Jang, K. Katz, Z. Maddipatla, M. Ovetsky, G. Riley, A. Sethi, R. Tully, R. Villamarin, W.S. Rubinstein, D.R. Maglott.* National Center for Biotechnology Information, Bethesda, MD.

   ClinVar is a public archive of interpretations of clinical significance and functional effects of variants in any gene and for any disease. Interpretations are submitted by many sources, including research laboratories, clinical testing laboratories, locus-specific databases, expert panels, practice guidelines, as well as OMIM® and GeneReviews™. Currently ClinVar holds more than 9700 variant interpretations submitted as research results from 196 organizations. A submission may be held private until the corresponding paper is published; submitters are encouraged to start their submission to ClinVar when they start the publication process, to allow time for NCBI staff to process the data. ClinVar accessions for submissions can be provided early so that the manuscript can reference the ClinVar record. The PubMed ID for the submitter's paper may be included with the original submission or added later in an update. Submissions of a single variant interpretation are welcome, and an online submission wizard guides you through the process. A research submission may report the clinical significance of the variant, if patients were evaluated as part of clinical research. Alternatively, the functional significance of the variant may be provided if the submitter describes experimental results, such as a functional assay or an animal model. Submitters are encouraged to send updates to ClinVar when further research indicates that their classification should be changed or provides additional evidence. ClinVar can be used to inform research as well. The full dataset is available as XML for download; summary data is available as a VCF file and tab-delimited summary files. ClinVar data may be accessed programmatically with E-utils, NCBI's API for data retrieval. The data may also be viewed on the ClinVar website. The database may be searched by variant, gene symbol, disease or phenotype, PubMed ID, submitter, and more. Search results may be filtered in several ways, including allele origin, type of submission, variant type, functional consequence, and clinical significance. Each search result links to a variation page for the variant or set of variants that were interpreted. The variation page includes the aggregate clinical significance and review status based on all submissions. Details from each submission are also displayed, including each submitter, each submitted interpretation, criteria used to evaluate the variant, citations, and evidence for the interpretation.

A robust statistical approach to refine frequency thresholds for clinical variant interpretation. *N. Whiffin[1,2*], E. Minikel[3,4*], R. Walsh[1,5], A. O'Donnell-Luria[3,4], K. Karczewski[3,4], A.Y. Ing[6], B. Funke[6,7], S.A. Cook[1,2,8#], D. MacArthur[3,4#], J.S. Ware[1,2,4#].* 1) National Heart and Lung Institute, Imperial College London, London, UK; 2) MRC Clinical Sciences Centre, Imperial College London, London, UK; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 5) NIHR Royal Brompton Cardiovascular BRU, London, UK; 6) Partners HealthCare Personalized Medicine, Laboratory for Molecular Medicine, Cambridge, MA; 7) Department of Pathology, Harvard Medical School/Massachusetts General Hospital, Boston, MA; 8) National Heart Centre Singapore, Singapore.

Distinguishing pathogenic variants from benign bystanders is a principal challenge in clinical genetics. Allele frequency (AF) is a key potential discriminator, as variants found in the general population can often be excluded as causes of penetrant Mendelian disease. The Exome Aggregation Consortium (ExAC) dataset provides unprecedented power to characterise rare variants, but it is often unclear whether a variant present at very low frequency should be classified as benign, given that Mendelian diseases may also be present in the population. Consequently, there is large variation in practice, and a conservatively high threshold is often used, leading to inconclusive variant interpretation. We have developed a rigorous framework to evaluate whether an AF observed in a population is compatible with pathogenicity. This permits the safe and appropriate use of much more stringent AF thresholds. We consider disease prevalence, genetic/allelic heterogeneity and penetrance to calculate a maximum population frequency for a variant causing a given disease. We then assess the frequency of a variant in a fixed population sample, to determine whether it is compatible with disease causation. We apply this method to a range of clinically important inherited cardiac conditions, with ExAC as a population reference dataset. To evaluate our approach, we aggregated high quality reference variants from 7,855 cardiomyopathy cases classified by two clinical laboratories. Compared to a conventional 0.1% AF filter, our more stringent filter reduced the number of 'Variants of Uncertain Significance' by 10% (69 variants), while preserving 375/376 'Pathogenic' variants. The filtered 'pathogenic' variant causes a low penetrance phenocopy. To further validate our approach, we curated the 28 ClinVar 'pathogenic' variants that failed our stringent filter: none had robust evidence of disease-causation. In a clinical setting, stringent AF thresholds allow for much more confident variant interpretation: in patients with HCM the proportion of *MYBPC3* variants that are pathogenic increases from 78% at AF<0.1% to 98% at AF<0.001%. In a whole exome approach, the mean number of potential disease-causing variants for a dominant disease is reduced ~3-fold from 179 (AF<0.1%) to 67 (AF<0.001%) per exome. To facilitate variant interpretation, we have pre-computed our frequency annotations for all variants in the ExAC dataset, and are releasing these data through the ExAC website. *Contributed equally.

Cell type-specific annotation and prioritization of regulatory variants. *M. Li[1,2], Z. Pan[2,3], J. Wu[1], P. Sham[2,3,4], J. Kocher[5], M. Li[2,3], J. Liu[1], J. Wang[5].* 1) Department of Statistics, Harvard University, Cambridge, Boston, MA 02138-2901, USA; 2) Centre for Genomic Sciences, LKS Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China; 3) Department of Psychiatry, LKS Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China; 4) State Key Laboratory in Cognitive and Brain Sciences, The University of Hong Kong, Hong Kong SAR, China; 5) Division of Biomedical Statistics and Informatics, Mayo Clinic College of Medicine, Rochester, MN 55905, USA.

Interpreting human regulatory variants in the noncoding genomic region is critical to understand the regulatory mechanisms of disease pathogenesis and promote personalized medicine. With the accumulation of functional annotation data, several computational methods have been developed to predict and prioritize noncoding regulatory variants. However, we observed significant inconsistency in the predicted results among these tools, and the strengths and weakness of each tool are not known, which will hinder the selection of functional candidates in the follow-up experimental validation. Furthermore, the predictions made by these tools are rarely based on specific cell type conditions. But the function of regulatory variants, associating with concrete chromatin signatures and other cellular environments, is usually cell type-specific. Prediction based on cell type-specific function genomic/epigenomic data can improve the chance and accuracy of causal variants discovery. Prediction algorithms that use these information to prioritize and fine-map the putative regulatory variants are in urgent demand. In this study, we first compiled an integrative database for predictions from eight latest cutting-edge algorithms on function annotation/prediction of noncoding variants. We developed a composite strategy to integrate multiple predictions and compute the composite likelihood of a given variant being causal. We found that the composite model significantly improves the prediction performance, achieving significant AUC improvement. We further summarized a set of consolidated chromatin features using cell type-specific chromatin marks for eleven uniformly processed expression quantitative trait loci (eQTLs) datasets. We developed a logit model to measure the regulatory potential for a given variant in selected conditions. Using GWAS fine-mapped SNPs and 127 recently profiled human epigenomes, we have shown that our condition-dependent prioritization can identify the ensemble effect of chromatin signals that fine-maps the causal regulatory variant in phenotypically relevant cells, rather than the previous approach of using single chromatin marks such as H3K4me3 or H3K27ac. Finally, we combined the composite model and condition-dependent model into a unified probability to measure variant regulatory potential. We demonstrated that our unified model has better performance than state-of-the-art and cell type-specific algorithms in prioritizing regulatory variants. .

1908F

A novel 2D genome segmentation method for studying epigenetic variation in many cell types. *Y. Zhang[1], L. An[2], F. Yue[3], R.C. Hardison[4].* 1) Department of Statistics, Pennsylvania State Univ, University Park, PA; 2) Bioinformatics and Genomics Program, Huck Institutes of the Life Sciences, Penn State University, University Park, PA; 3) Department. of Biochemistry and Molecular Biology, Penn State School of Medicine, Hershey, PA; 4) Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA.

A critical step for understanding the impact of genetic variation on disease is through identification of regulatory elements and understanding how they act on target genes. With thousands of whole-genome epigenetic data sets generated in hundreds of human and mouse cell types, a major challenge is to build advanced quantitative models to exploit this rich source of information for studying the roles of functional elements in disease in cell type specific context. Most existing methods are developed for studying one cell type at a time. Frequently these methods are adopted to study multiple cell types via overly simplistic strategies that are inadequate to capture the complex interrelationship between cell types. The very few methods for joint modeling of multi-cellular epigenomics cannot scale up to studying a large number of cell types. We have developed a novel and efficient method called IDEAS that can jointly analyze multiple epigenetic marks in hundreds of cell types simultaneously, and detect differential regulatory modules across both the genome and time (e.g., cell types, conditions, individuals, differentiation stages). The novelty of IDEAS lies in its integrative and dynamic combination of information from multiple cell types within a coherent probabilistic model. The inferred functional elements are therefore not only more accurate, but also coherent and comparable across cell types, which enables robust comparative analysis of differential gene regulation in a multi-cellular context. Application of IDEAS to ENCODE has demonstrated its superior power for predicting functional elements and their impacts on expression over existing algorithms. The cell type specific regions predicted by IDEAS are more significantly enriched in disease variants than those inferred from existing genome annotations. IDEAS has linear inference complexity with respect to the number of cell types, and we have used IDEAS to annotate the 127 epigenomes in Roadmap Epigenomics. A useful application of IDEAS is to leverage existing data sets in the public domain to study specific cell types of interest by individual labs, without requiring complete data generation. This will enable studying differential gene regulation in a wide range of cell types at low cost. Our improved annotation of functional elements in the genome and their cell type specificity will further help to identify and interpret non-coding variants in disease.

1909W

Incorporating variant analysis in microRNA coding genes and microRNA target sites into the standard exome analysis pipeline. *T.S. Frisby, C.C. Lau, C.J. Adams, M.J. Warburton, N.I. Balanda, B.N. Pusey, W.A. Gahl, D.R. Adams.* NHGRI-UDP, NIH, Bethesda, MD.

Exome sequencing has become a routine assessment for patients in the NIH Undiagnosed Diseases Program. To date, several hundred patients and their nuclear families have been sequenced. Our current exome analysis methods, which attempt to expand on standard-of-care clinical exome analysis, nonetheless focus largely on variants in and around the coding regions of the genome. In order to increase our success rate, as well as to elucidate novel causes of rare diseases, we are extending our analytic pipeline to incorporate an expanding set of non-coding DNA variation. One area of interest includes microRNA (miRNA) coding genes and miRNA target sites within the 3'-UTR of protein coding genes. miRNA are small, non-coding RNA that have been shown over the past decade to regulate gene expression by binding to mRNA, causing degradation and translational repression. Variants found in miRNA coding genes and target sites have also been shown to cause diseases in humans. As part of a pilot analysis, we have investigated variants within these elements by extending our exome analysis pipeline. In the 5 nuclear families that we studied, we found a range of 70 – 323 variants (mean 220, median 278) that are rare in the general population and segregated with the diseases within the families that were previously excluded from our exome analysis. By annotating the miRNA target sites using target binding prediction tools (miRanda-mirSVR, TargetScan), we were able to prioritize variants that fell into predicted or conserved miRNA target sites. We then further prioritized variants that fell within the 95th percentile of miRNA target predictions (defined as miRNA-target mRNA predicted interactions that have 50% probability of decreasing target mRNA level by 1 standard deviation, or 70% probability of decreasing target mRNA level by 0.5 standard deviation). Finally, we computed the effect of the variants to the binding prediction, as a way to prioritize variants that may be biologically and clinically significant. Further work needs to be done to validate these findings, but this represents the first step in the analysis and interpretation of variants that had been previously overlooked. This research is supported by the Intramural Research Program of the National Human Genome Research Institute and the Common Fund of the National Institutes of Health.

1910T

dbLoF: An online database of human loss-of-function variants. *P. Singh[1], D. Mohs[1,2], E. Minikel[1,2], I. Armean[1,2], K. Karczewski[1,2], S. Farhan[1,2], D.G. Macarthur[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Genetic variants predicted to cause loss-of-function (LoF) can be powerful models for the inactivation of human genes, providing insight into disease mechanisms, gene function, and the potential therapeutic relevance of possible drug targets. Here we describe dbLoF, a database designed to provide systematic information on the distribution and (inferred or observed) phenotypic impact of LoF variants in each human gene. Drawing from a collection of population sequence data, most heavily the Exome Aggregation Consortium (ExAC) data set, dbLoF provides the positional distribution of LoF variants for each gene, their aggregate frequency distribution across human populations, information about each variant, the inferred LoF constraint of each gene, and links to further variant- and gene-level resources. In addition, we are currently populating the database with curated gene-level summaries drawn from the primary disease literature as well as population databases of genotype/phenotype associations. We will describe the back and front-end architecture of dbLoF, the underlying resources used to create the database, and typical workflows for users of the resource.

1911F

An automated method to identify familial relationships in electronic health records. *F. Polubriaginof[1], K. Quinnies[1,2], R. Vanguri[1], A. Yahi[1], M. Simmerling[3,4], I. Ionita-Laza[5], H. Salmasian[3,1], S. Bakken[1,6], K. Kiryluk[7], D. Goldstein[2], D.K. Vawdrey[3,1,9], N.P. Tatonetti[1,2,7,8,9].* 1) Biomedical Informatics, Columbia University, New York, NY; 2) Institute for Genomic Medicine, Columbia University, New York, NY; 3) Value Institute, NewYork-Presbyterian Hospital, New York, NY; 4) Division of Medical Ethics, Weill-Cornell Medical Center, New York, NY; 5) Mailman School of Public Health, Columbia University, New York, NY; 6) School of Nursing, Columbia University, New York, NY; 7) Department of Medicine, Columbia University, New York, NY; 8) Department of Systems Biology, Columbia University, New York, NY; 9) Co-senior author.

Family history is a prognostic indicator of inherited disease and is critical to precision medicine. In general, heritability is defined as the variance of the trait attributable to genetic factors. Knowledge of patient's family history in conjunction with knowledge of disease heritability enables individualized disease diagnosis, treatment, and prevention. Electronic health records (EHRs) have become ubiquitous and contain vast amounts of phenotypic data. Combined with knowledge of family histories, these data could greatly impact genetic study design, recruitment, and analysis. Unfortunately, family history and familial relationship data are poorly collected in EHRs. We developed a novel method to extract familial relationships from EHRs using emergency contact information collected during hospital admissions. The method matches an emergency contact person to his or her existing medical record in our healthcare system and documents any familial relationship between the emergency contact person and the patient being admitted (e.g., child, sibling, parent). A match was established when only one medical record matched the emergency contact information. Once the family relationships were extracted, we inferred additional relationships based on the family structure. We then identified families by graphical analysis of these relationships. We repeated this analysis independently at two large academic medical centers (AMCs). Among 1.1 million patients, we identified 379,190 families spanning up to four generations (4.7 million familial relationships in total). Pedigrees included from 2 to 134 members, and 199 families with up to fourth-degree relatives (e.g., a great-great-grandchild). We evaluated inferred relationships against two reference standards, one clinical and one based on genetics. Against the clinical reference, we obtained 92.9% sensitivity with 95.7% positive predictive value (PPV) at the first AMC and 96.8% sensitivity with 98.3% PPV at the second AMC for mother/child relationships. Using the genetic relatedness of 117 individuals, we found that parent/child relationships and sibling relationships had a PPV of 98.1% and 71.4%, respectively. This novel method for identifying familial relationships using EHR data unlocks new opportunities such as disease risk prediction and heritability estimates for phenotypes that have not been previously studied.

1912W

Bioinformatics workflow for whole genome sequence linkage analysis of multiple families afflicted with rare disease of unknown heredity and penetrance. *J.L. Rodriguez-Flores[1], M.D. Ramstetter[1], M.R. Staudt[1], A. Robay[2], K.A. Fakhro[3], J.G. Mezey[1], J. Salit[1], J. Malek[2], C. Abi Khalil[2], R.G. Crystal[1]. 1) Genetic Medicine, Weill Cornell Medical College, New York, NY USA; 2) Genetic Medicine, Weill Cornell Medical College - Qatar, Doha, Qatar; 3) Translational Medicine, Sidra Medical and Research Center, Doha, Qatar.*

Linkage analysis is experiencing a renaissance thanks to the wide availability of whole genome sequencing, which enables identification of rare variants that segregate with a rare disease phenotype in one or more families. In many cases of rare disease, the inheritance mode (dominant, recessive), the region of the genome affected (autosomal, sex-linked), the number of linked variants, and the degree of penetrance is unknown. In addition, it is not known a priori if the same variant, gene, or pathway will segregate with the phenotype in every family. A bioinformatics analysis workflow that efficiently explores all potential scenarios and accounts for ancestry and relatedness is needed, and was developed and tested in this study. Ancestry-informative markers were used to infer individual ancestry, followed by mapping reads to a population-specific reference genome that incorporates major allele SNP and indel variants. Analysis of disease families using a population-specific reference genome produced a >3x increase in mapped read depth while cutting the number of linked variants for functional analysis by 44%. Variant calling using GATK best practices followed by functional annotation identified an average of 44 thousand potentially deleterious minor allele coding variants per genome. Using an analysis package written in Python, both recessive and dominant models were tested, as well as both complete and variable penetrance. This workflow identified rare potentially deleterious candidate variants that segregate with the disease phenotype. Candidate variants were filtered based on prevalence in global populations, and a set of candidate genes were identified. Gene set enrichment analysis of the linked genes identified enriched pathways relevant to the phenotype. Candidate causative potentially deleterious variants were identified, including both cases where the same variant segregates with the phenotype in all families, as well as cases where a different variant in the same gene or pathway segregates with the phenotype in each family. By calculating the degree of relatedness between families, the likelihood of all affected individuals inheriting causative variants from a common ancestor was estimated, suggesting the possibility of inheritance from a distant common ancestor. This approach is applicable to a wide spectrum of rare diseases, and identifies candidate genes missed by standard approaches.

1913T

GeneHancer: A comprehensive database of annotated human enhancers, key to interpreting intergenic regions in whole genome sequences. *D. Lancet[1], S. Fishilevich[1], Y. Golan[2], D. Dahary[2,3], M. Safran[1], R. Nudel[1], D. Cohen[1]. 1) Department of Molecular Genetics, Weizmann Institute of Science, Rehovot 7610001, Israel; 2) LifeMap Sciences Inc., Marshfield, MA 02050, USA; 3) Toldot Genetics Ltd., Hod Hasharon, Israel.*

This year, the $1,000 whole genome target became a reality, leading to an avalanche of whole genome sequencing (WGS) projects worldwide. Yet, deciphering the ensuing data poses a major challenge, necessitating significant improvements in the annotation and interpretation of intergenic variants. Enhancers are remote regulators of gene expression, whose aberrations underlie certain diseases. They are likely the most abundant functional entities in non-coding DNA, hence of great significance to WGS analyses. We present GeneHancer, a novel database of human enhancers and their inferred target genes, in the framework of GeneCards (www.genecards.org). GeneHancer computes combinatorial likelihood scores for enhancer-gene pairs, and displays charts of probable enhancers for every human gene. It thus makes it possible to map variants to enhancers, and forms a basis for their gene-phenotype interpretation. These capacities will soon be incorporated into the GeneCards Suite next generation sequencing tools, TGex and VarElect (BMC genomics, in press). GeneHancer integrates information on ~258,000 enhancer entries from three genome-wide enhancer databases. The integration includes: a) 213,000 elements from the Ensembl regulatory build, predicted based on the ENCODE and Roadmap Epigenomics projects; b) 43,000 elements from FANTOM, identified via enhancer RNA (eRNA) transcriptomics; c) 1,700 elements from the VISTA Enhancer Browser validated by transgenic mouse assays. GeneHancer thus portrays 237,000 integrated enhancers, with ~17,500 derived from more than one source. Additional scheduled integration includes DENdb predicted enhancers in cell-lines. GeneHancer subsequently links enhancers to genes, using the following methods: 1) Employing FANTOM expression correlation between eRNAs and candidate target genes; 2) Making use of GTEx expression quantitative trait loci (eQTLs), exploring genetic association between variants within enhancers and the expression of candidate target genes; 3) Seeking across-tissue expression correlation (PMID 27048349) between a transcription factor interacting with enhancers, and candidate target genes; 4) Using Hi-C chromosome conformation capture data as indications of genomic looping between a gene promoter and enhancer. The individual scores based on these four methods, along with gene-enhancer genomic distances, form the basis for GeneHancer's combinatorial likelihood scores for enhancer-gene pairs.

1914F

Expanding and improving the 1000 Genomes Project data resources in the International Genome Sample Resource (IGSR). *S. Fairley, R. Amode, P. Harrison, E. Lowy, E. Perry, I. Streeter, S. Trevanion, X. Zheng-Bradley, L. Clarke, P. Flicek.* EMBL-EBI, Hinxton, United Kingdom. CB10 1SD.

The International Genome Sample Resource (IGSR) builds on the data resources created by the 1000 Genomes Project, moving the data to GRCh38, expanding the collection to new samples and new data types, and improving the usability of the resources. Data from phase three of the 1000 Genomes Project has been mapped to GRCh38, using the alt-aware BWA alignment algorithm. These alignments provide a foundation for generating variant calls directly on GRCh38. Preliminary single-tool call sets are being generated using SAMtools, FreeBayes and GATK. Samples beyond those included in the 1000 Genomes Project have been added to IGSR. These share similarly open consent to samples from the 1000 Genomes Project. Such samples include those in the HGDP-CEPH collection and new samples from Gambian populations. It is planned to add further populations when suitable data sets are available and IGSR welcomes potential collaborators, with IGSR being able to provide support for ethical review, data coordination, data distribution, alignment and variant calling. IGSR provides links to raw data generated from the samples it contains. This includes various new data types including 10X Genomics, BioNano optical maps, PacBio data and RNA-seq. Where possible, alignments and variant calls are also made available. To facilitate finding data, a new portal has been developed. The portal gives an overview of the available data, both by project and data type, and can be used to browse collections of data, search for data on specific samples and to download files. Further improving the usability of the data, tools from the 1000 Genomes Project genome browser are being introduced in Ensembl, allowing users to work more easily with the data alongside the rich collection of data available in Ensembl. IGSR plans to continue to develop and improve the resources it hosts, with the aim of maintaining and enhancing access to openly consented genomic data, which provide a valuable resource both as a reference panel of human genetic variation and as a data set for use by the methods development community.

1915W

NGS-SwiftCluster: A parallel computational framework for large scale genetic variation analysis in cloud. *C. Xiao, S. Sherry.* NIH, Bethesda, MD.

Large scale genetic variation analysis plays an important role in elucidating the causes of various human diseases. However, the tera- and peta-byte scale footprint for sequence data imposes significant technical challenges and financial burdens for data management and analysis, including the tasks of collection, storage, transfer, sharing, and privacy protection. Cloud Computing has recently emerged as a compelling paradigm for large scale data management and big data analysis due to the availability, scalability, and cost effectiveness of computing resources across the global. It is still a huge challenge, and often big headache, for researchers to configure and set up appropriate instance clusters in a cloud for parallel computing with all the necessary software environments before a meaningful analysis tasks can be performed. Here, we provides a parallel computational framework, NGS-SwiftCluster, for the large scale genetic variation analysis using next-generation sequencing data in cloud. This framework not only includes a customized machine image with preconfigured tools and pre-selected analysis pipelines for read alignment and variant calling (https://github.com/ngs-swift/Introduction), but also enables users to launch and manage grid-engine cluster with multiple instance nodes so that the time consuming analysis can be expedited by distributing vast computing jobs into multiple nodes. Performance of this framework has been evaluated in cloud using dbGaP study phs000710.v1.p1 (http://www.ncbi. nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000710.v1.p1), and security handling in cloud environment when dealing with control-accessed sequence data has also been addressed.

1916T

Opening the door to large scale use of clinical lab measures for association testing and phenomic profiling: Sparse multivariate analyses in electronic health records reveals novel genetic variants affecting disease risk. *C.R. Bauer[1], J.M. Mahoney[2], S. Setia[1], D.R. Lavage[1,3], J. Snyder[1,3], J. Leader[1,3], H.L. Kirchner[1], S.A. Pendergrass[1].* 1) Biomedical & Translational Informatics, Geisinger Health System, Danville, PA; 2) Department of Neurological Sciences, University of Vermont College of Medicine, VT; 3) Phenomic Analytics and Clinical Data Core, Geisinger Health System, Danville, PA.

Personalized genomic medicine promises to improve medical screening, diagnosis, and treatment but this first requires construction of an accurate genotype-phenotype map. Association studies have linked many genetic variants to disease phenotypes, but most have relied upon rigorous assessment of case-control status. Electronic health records contain a wealth of quantitative clinical lab measures that can also be used for association testing. While patients generally have few specific diagnoses, many have results from dozens of different clinical assays providing an opportunity to construct high dimensional phenotypic profiles. Factor analysis and sparse discriminant analysis allow us to project this high dimensional data into a space that aligns with the etiology of disease states and the primary effects of genetic variants. We analyzed a dataset of 143 outpatient clinical lab measures across 859,010 individuals from the Geisinger Health System. By clustering measure co-occurrence and imputing missing values, we identified latent phenotypic factors in modules of clinical variables that can serve as useful physiological traits for association testing. We then used sparse linear discriminant analysis to identify the precise profiles of physiological states that are altered in individuals with specific gene variants by integrating these quantitative traits with genotypic data for 38,813 unrelated European Americans from the DiscovEHR cohort. Even for a module of four heavily studied measurements of serum lipids, we identified novel genetic associations with linear combinations of these variables that are not significant with any of the individual lipid traits. For example, SNP rs11080055 shows a relationship with increased triglycerides (b=0.022, p=4.5x10^{-3}) and HDL cholesterol (b=0.017, p=0.035) but reduced LDL cholesterol (b=-0.015, p=0.059). While none of these effects approach genome-wide significance independently for this SNP, discriminant analysis identifies that the vector of main effect is related to reduced LDL cholesterol and increased levels of all other lipid measurements (b=0.05, p=3.5x10^{-9}). Our approach demonstrates the feasibility of high-throughput analyses of quantitative clinical lab data and highlights important considerations for their use. These high-dimensional data allow us to identify novel genetic variants that impact disease risk and provides deeper insights into the structure of the genotype-phenotype map.

1917F

Exome sequencing is the most cost-effective approach for rare variant-based novel gene discovery. *L.C. Francioli[1,2], A. Manning[2], M. Lek[1,2], M.J. Daly[1,2], D.G. MacArthur[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

Although genome-wide association studies (GWAS) in complex diseases and sequencing studies in rare Mendelian disorders have been extremely successful in identifying disease loci, much of the genetic disease burden remains unexplained. Analysis of common variation generally uncovered only alleles of weak effect, reflecting negative selection on deleterious alleles. Some Mendelian studies have discovered *de novo* or very rare alleles of large effect, but these studies are too small to find modest effect contributors. Power to detect novel disease genes is a function of sample size, risk allele frequency and effect size. It is estimated that ~25k cases are needed to find associations based on rare moderate effect variant burden tests (Zuk *et al.* 2014). Here, we compare whole-genome (WGS) and whole-exome sequencing (WES) study designs for novel gene discovery. Dense SNP microarrays and imputation have provided a relatively unbiased sampling of common human genetic variation; thus GWAS results should reflect the properties of the variation underlying common diseases. Using highly confident and replicated disease-associated loci from the GWAS catalog, we show that while 87% of associated loci are non-coding, those with higher odds ratio (OR) are enriched for coding variants. Indeed, 13 of the 26 loci with OR > 2.0 are either coding or in high linkage disequilibrium (r^2 > 0.8) with a coding SNP. This enrichment is unlikely due to differences between disease as all 7 associations with OR > 2.0 are coding when restricting our analysis to diseases with >10 associated loci. Similarly, we outline a number of independent lines of evidence from rare disease studies (including low proportion of unsolved families following successful linkage analysis, and exome solve rates in multiplex recessive pedigrees) pointing to >80% of causal variants in Mendelian disease being coding. While some studies reported high yield from WGS compared to WES, we find that this difference is largely due to comparison against outdated WES technologies. These results indicate that the majority of the variation we can expect to have power to detect with large-scale sequencing will be detectable with WES. Through simulation of different cost structures and allelic architecture, we show that WES is likely to remain the optimal approach for rare variant-based gene discovery in both common and rare disease for several more years, and provide guidelines for the design of large-scale sequencing studies.

1918W

GenAMap on the web: Intuitive and scalable machine learning for structured association mapping. *B.J. Lengerich[1], H. Wang[2], M.K. Lee[3], E. Xing[2,3,4,5].* 1) Computational Biology Department, Carnegie Mellon University, Pittsburgh, PA; 2) Language Technologies Institute, Carnegie Mellon University, Pittsburgh, PA; 3) Center for Machine Learning and Health, Carnegie Mellon University, Pittsburgh, PA; 4) Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA; 5) Computer Science Department, Carnegie Mellon University, Pittsburgh, PA.

The proliferation of genomic data has increased the usefulness of complex machine learning algorithms for structured association mapping. Such methods can effectively relate genetic polymorphisms with phenotypes, but correct use requires algorithmic expertise to run code and domain expertise to analyze results. To overcome these challenges, the GenAMap software platform was developed and released in 2010. Since then, the sizes of available biological data have continued to increase exponentially. To address these challenges, GenAMap is redesigned for scalability and updated with state-of-the-art methods for efficient calculations on human genome-scale data. The user experience is overhauled as an intuitive web application with a focus on simplicity and ease of use. GenAMap is available through http://sailing. cs.cmu/main/genamap.

1919T

Bayesian multivariate analysis of large genetic studies identifies novel associations. *M.C. Turchin[1], M. Stephens[1,2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

Genome-wide association studies (GWAS) are now a common tool to identify genetic variants that affect traits of interest. To date, the NHGRI GWAS Catalog has over 24,000 SNP-phenotype associations. However, the vast majority of these GWAS are conducted in univariate frameworks, ie when genetic variants are only tested against a single phenotype one at a time. This is in contrast to multivariate frameworks where genetic variants are tested against different combinations of traits simultaneously. Under many biological scenarios, multivariate frameworks drastically increase power. Additionally, by testing combinations of traits, multivariate frameworks allow researchers to investigate a greater level of biological complexity. Despite these clear advantages, multivariate analyses are seldom conducted. Univariate GWAS already involve a large computational and statistical burden; performing an additional, exponentially greater number of tests is highly deterring. Furthermore, it is often unclear how to properly compare different multivariate models even when they can be efficiently conducted. Here, we present a framework and R package that alleviates these obstacles -- Bayesian multivariate analysis of association studies, or bmass. bmass runs using solely univariate GWAS summary statistics. bmass can quickly conduct all possible multivariate analyses for up to 8 phenotypes. And bmass provides Bayes factors for each multivariate analysis, thus allowing models to be directly compared. Running bmass on various publicly available GWAS datasets consistently show an increase in power up to 40% over univariate approaches while keeping FDRs as low as 15%. bmass identifies many new significant associations as well as the phenotypic combinations driving these associations, thus providing a novel level of biological insight. Overall, bmass is a powerful tool enabling multivariate analysis of GWAS.

1920F

Picopili: Development and evaluation of a pipeline for quality control, imputation, and genome-wide association in family-based studies with arbitrarily complex pedigrees. *R.K. Walters[1,2], S. Ripke[1,2,3], B. Neale[1,2,4], Substance Use Disorder Group of the Psychiatric Genomics Consortium.* 1) Analytic & Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Stanley Center for Psychiatric Genetics, Broad Institute of MIT and Harvard, Boston, MA; 3) Department of Psychiatry and Psychotherapy, Charité, Campus Mitte, Berlin, Germany; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Boston, MA.

   Genome-wide association studies of case/control and trio cohort samples have greatly benefitted from the development of standardized QC and analysis pipelines implementing best practices and ensuring uniform, rigorous analysis of array data to facilitate genome-wide meta-analysis. In order to extend these benefits to include family-based studies, we introduce picopili: a flexible, freely-available pipeline for QC, imputation and genome-wide analysis of cohorts with study designs ranging from sib-pairs to complex, multi-generational pedigrees.   The development of picopili gives particular focus to evaluating three areas of GWAS analyses that lack a clear consensus for best practices in family-based data. First, picopili provides a unified interface for estimating genetic relatedness under models appropriate for homogenous or admixed samples, with the optional inclusion of reference samples to specify the ancestral populations of the admixed samples. Comparison of results from the available models demonstrates the risk of substantial upward bias in kinship estimates when population structure is misspecified.   Second, picopili automates imputation of family-based samples to standardize alignment of array data to the desired imputation reference, pre-phasing of haplotypes with a pedigree-aware hidden markov model, imputation, and calling of best-guess genotypes with identification of mendelian errors. Marked increases in imputation quality are observed from this approach, with a net gain of more than 10,000 SNPs with info > 0.9 for sib-pair data compared to a case/control design, with much larger gains anticipated for larger pedigrees.   Finally, picopili enables association testing under multiple modeling frameworks, including transmission-based tests, generalized estimating equations (GEEs), and logistic mixed models. Comparison of these testing methods in simulated and real data suggests that the optimal model is highly depending on the study design, with computational advantages observed for GEEs in simple pedigrees versus markedly better statistical properties for logistic mixed models in larger, more complex pedigrees.

1921W

Incorporating 'topologically associating domain' content into pathway analyses to implicate causal genes at GWAS loci. *G.P. Way, C.S. Greene, S.F.A. Grant.* University of Pennsylvania, Philadelphia, PA.

   Genome wide association studies (GWAS) have revolutionized the field of complex disease genetics. However, GWAS only reports signals associated with a given trait and not necessarily the precise location of culprit genes. The past ten years of GWAS did not strictly represent a decade of gene target discovery; rather, it was a decade of signal discovery. Most of these association signals are found in non-coding regions and assigning the variants to causal mechanisms has proven challenging. Topologically associating domains (TADs) are cell-type independent, genomic regions that define interactome boundaries and therefore offer an opportunity to set limits to where the causal gene(s) at a given GWAS locus must reside. We calculated that the average TAD in human embryonic stem cells spans 852kb and harbors 17 genes, 1,585 repetitive elements, and 2,200 common single nucleotide polymorphisms (SNPs). We observed that protein coding genes strongly cluster near TAD boundaries (χ^2 = 1005.5, P = 1.2x10^{-220}), as do ALUs (χ^2 = 1809.3), while common SNPs are more frequent on the 5' side of TADs (χ^2 = 154.9, P = 1.4x10^{-35}). We developed 'TAD pathways' as a computational method to identify causal genes independent of nearest gene biases. We performed a Gene Ontology (GO) process analysis over TADs and treated all genes equally in TADs that harbor a GWAS signal. This revealed disease-associated GO processes and suggested causal genes. We applied our pipeline, which can withstand content that is predominantly presumably non-causal, to bone mineral density (BMD) and type 2 diabetes (T2D) GWAS catalogs, identifying, respectively, 'Skeletal System Development' (Benjamini Hochberg adjusted P = 1.02x10^{-5}) and 'Insulin Secretion' (BH adjusted P = 1.8x10^{-2}) as the top ranked pathways. In many cases the nearest genes to the given sentinel SNP were not implicated. For example, *ERC1* is closest to a BMD signal on chromosome 12, but our approach implicates *WNT5B* as the most likely causal gene. Likewise, and as a further example, *KCNK16* is closest to a T2D signal on 6p21, but our approach implicates *GLP1R*. While these have clear biological support for the 'correct' gene, we also identify genes in situations where no obvious gene resides within the TAD; for instance *DEAF1* at the '*BET1L*' BMD locus. In conclusion, our computational method can leverage TADs in order to infer causal genes at GWAS signals.

1922T

Phased human genome assemblies with single-molecule real-time sequencing. *C. Chin[1], F. Sedlazeck[2], G. Concepcion[1], P. Peluso[1], D. Rank[1], M. Schatz[2].* 1) Pacific Biosciences, Menlo Park, CA; 2) Department of Computer Science, Johns Hopkins University, Baltimore, MD.

   In recent years, human genomic research has focused on comparing short-read data sets to a single human reference genome. However, it is becoming increasingly clear that significant structural variations present in individual human genomes are missed or ignored by this approach. Additionally, remapping short-read data limits the phasing of variation among individual chromosomes. This reduces the newly sequenced genome to a table of single nucleotide polymorphisms (SNPs) with little to no information as to the co-linearity (phasing) of these variants, resulting in a "mosaic" reference representing neither of the parental chromosomes. The variation between the homologous chromosomes is lost in this representation, including allelic variations, structural variations, or even genes present in only one chromosome, leading to lost information regarding allelic-specific gene expression and function. To address these limitations, we have made significant progress integrating haplotype information directly into genome assembly process with long reads. The FALCON-Unzip algorithm leverages a string graph assembly approach to facilitate identification and separation of heterozygosity during the assembly process to produce a highly contiguous assembly with phased haplotypes representing the genome in its diploid state. The outputs of the assembler are pairs of sequences (haplotigs) containing the allelic differences, including SNPs and structural variations, present in the two sets of chromosomes.   The development and testing of our de-novo diploid assembler was facilitated and carefully validated using inbred reference model organisms and F1 progeny, which allowed us to ascertain the accuracy and concordance of haplotigs relative to the two inbred parental assemblies. Examination of the results confirmed that our haplotype-resolved assemblies are "Gold Level" reference genomes having a quality similar to that of Sanger-sequencing, BAC-based assembly approaches.   We further sequenced and assembled two well-characterized human samples into their respective phased diploid genomes with gap-free contig N50 sizes greater than 23 Mb and haplotig N50 sizes greater than 380 kb. Results of these assemblies and a comparison between the haplotype sets are presented.

1923F

Beacon Network: A system for global genomic data sharing. *M. Cupak[1], M. Fiume[1], V. Rockai[1], S. Keenan[2,3], D. Lloyd[4], P. Goodhand[3].* 1) DNAstack, Toronto, Ontario, Canada; 2) EMBL-European Bioinformatics Institute, Hinxton, United Kingdom; 3) The Global Alliance for Genomics and Health, Toronto, Ontario, Canada; 4) Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

   Large volumes of genomic data have and will be collected to realize new discoveries and applications in medicine. No single institution has enough resources to process these vast quantities of information, which is why it is necessary to develop standards for interoperability and sharing across a federated network of genomic data resources. The development of standard protocols for genomic data discovery and exchange will open the Internet of Genomics and increase the collective power of genomics datasets being collected worldwide to resolve the causes of genetic diseases and accelerate the implementation of precision medicine. The Global Alliance for Genomics and Health (GA4GH) is a coalition of hundreds of organizations from around the world who work together to develop regulatory, ethical, and technical standards for genomics-derived advancements in human health. The Beacon Project is a GA4GH initiative that is writing an open technical specification for genetic variation discovery and sharing. It also develops regulatory, ethics, and security guidance and tools to ensure proportionate safeguards for distribution of data through the protocol according to the GA4GH-developed Framework for Responsible Sharing of Genomic and Health-Related Data. We introduce the Beacon Network, a global directory and search engine for Beacons. The system serves as a powerful, convenient, and interactive genomic data distribution channel through which users can determine the existence of alleles of interest and be directed to host organizations who have observed them. It enables global discovery of genetic data from patients, population cohorts, curated databases, and the scientific literature, federated across a large and growing network of shared genetic datasets. With tens of organizations and hundreds of datasets having joined the system, the Beacon Network is one of the largest aggregators of human genomic variation in the world.

1924W

The spectrum of loss of function tolerance in the human genome. *K.J. Karczewski[1,2], K.E. Samocha[1,2], M. Lek[1,2], D. Birnbaum[1,2], I. Armean[1,2], P. Singh[1,2], P. Natarajan[1,2], V. Narasimhan[3], A. Palotie[1,2], D. van Heel[4], R. Trembath[4], R. Durbin[3], S. Kathiresan[1,2], M.J. Daly[1,2], D.G. MacArthur[1,2], Exome Aggregation Consortium.* 1) MGH/Broad Institute, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Wellcome Trust Sanger Institute, Hinxton, UK; 4) Queen Mary University of London, London, UK.

Loss-of-function (LoF) variants, which are predicted to severely disrupt the function of protein-coding genes, are found in every individual; however, there is a broad range of effects of these variants. Most LoF variants are benign, while some may even confer beneficial phenotypes: for instance, LoF variants in *PCSK9* have been causally linked to low LDL cholesterol levels, leading to the development of PCSK9 as a therapeutic target for cardiovascular disease. On the other end of the spectrum, some genes are essential, and thus, LoF variants can never be observed in living humans in the homozygous (or even heterozygous) state. Understanding exactly where each human gene lies along the spectrum between these extremes is important for prioritizing variants both as candidate disease genes and for the development of inhibitory therapeutics.   In order to define the spectrum of LoF variants across humans, we have developed an enhanced version of our prior LoF constraint model [Samocha et al., 2014], to incorporate a range of filters to remove common annotation errors as well as accommodating transcript-specific annotations. We apply this model to variants identified from over 100,000 exomes from the Exome Aggregation Consortium (ExAC) to identify genes with severe LoF depletion. In addition, we characterize LoFs present in this dataset and in other large datasets from collaborative efforts (including deeply phenotyped samples from Finnish national biobanks as well as over 1,000 parentally-related individuals from the UK) in order to identify a set of genes at the other end of the spectrum where homozygous LoF is consistent with survival into adulthood.   We correlate this spectrum with similar frameworks derived from mouse models and cellular assays. Additionally, we investigate how the network and expression properties of genes vary depending on their location on this spectrum. With these data, we can begin to characterize genes on the spectrum of LoF mutational tolerance across all human genes.

1925T

Grouped variable selection methods for microbiome compositional data. *A. Plantinga[1], M.C. Wu[1,2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA.

Community-level and species-level analysis of microbiome sequencing data have revealed relationships between shifts in microbiome composition and a wide range of diseases and conditions. However, community level analysis does not allow identification of specific taxa that are associated with the outcome, whereas conventional species-level analyses may have low power due to multiple testing. Variable selection methods for high-dimensional compositional covariates, such as microbiome data, avoid the multiple testing problem while still allowing estimation of the effects of specific taxa. We propose an L2 penalized log-contrast model for estimating taxon-level regression coefficients and selecting groups of taxa (e.g., genera or families) that are associated with an outcome of interest. Compositional and subcompositional coherence of the regression model are enforced using a set of linear constraints on the coefficients. Simulation results show that this method correctly selects groups of taxa that are associated with the outcome. We apply the proposed method to an upper-respiratory-tract microbiome dataset comparing microbiome composition between adult smokers and non-smokers.

1926F

Navigating GRCh38 at NCBI. *V.A. Schneider, V. Ananiev, W.R. Anderson, N. Bouk, H.C. Chen, C. Clausen, M. DiCuccio, P. Kitts, A. Kuznetsov, P. Meric, T. Murphy, K. Pruitt, T. Rezaie-Jami, E. Weitz, the Genome Reference Consortium.* IEB, NIH/NCBI, Bethesda, MD.

   NCBI is a member of the Genome Reference Consortium (GRC), the group responsible for updates and improvements to the human reference genome assembly. Since the release of GRCh38 in December 2013, the GRC has also released more than 70 patches to this assembly. These fix assembly errors and introduce new sequence representations for variant or complex genomic regions not sufficiently represented in the haploid chromosome assemblies or current suite of alternate loci scaffolds, all without changing assembly coordinates. We will present examples of recent patches, including those of clinical importance. We will also discuss how the GRC is using new assemblies and genome maps to identify sequences missing from the reference and genomic regions that are candidates for improvement or variant representation. NCBI provides several tools that enable users to navigate GRCh38 and its patch updates along a variety of axes. Among these, the Genome Data Viewer (GDV), a new addition to the suite of NCBI browsers, supplies a graphical view of the assembly accessible from a variety of NCBI resources, such as Gene, Assembly and GEO. The displays in this browser are augmented with data tracks relevant to the referring resource and provide expanded access to the wealth of assembly annotations available at NCBI. Track Sets and Collections in GDV and other viewer instances at NCBI further enable users to quickly reconfigure and share browser displays. In addition, users can upload their own data in a variety of formats to GDV for visualization. We will present the features of GDV, including a demonstration of how it provides access to the patches and alternate loci. We will also discuss recent improvements to the NCBI Remapping Service, a tool that transitions user data between different assemblies and also supports mapping between reference assembly chromosome sequences and alternate loci and patch scaffolds. We will illustrate how the assembly-assembly alignments that underlie the service, along with its intrinsic support for the reference assembly structure, provide a highly accurate remapping of data associated with complex assembly updates or genomic regions. These, and other NCBI resources, facilitate the navigation of GRCh38 needed for scientific discovery.

1927W

Modeling the effects of linkage disequilibrium and allele specific expression on genotype/phenotype relations. *J. Dannemiller.* Rice University, Houston, TX.

   Allele Specific Expression (ASE) is thought to result from the effects of one or more regulatory variants in *cis* with specific alleles in the protein-coding region of a gene. Protein-coding variants (e.g., SNPs) of a gene can directly alter a phenotype downstream from and dependent on that gene. What impact might ASE have on such phenotypes by the mechanism of altering the expression *levels* of the protein-coding variants? *Purpose:* To model the effects of ASE on the hypothetical phenotypes produced by a single bi-allelic protein-coding SNP one of whose two alleles produced a protein assumed to be 25% more biologically active than the protein produced by the other allele. *Methods:* Analytic expressions were derived for estimating the mean effects at equilibrium of ASE on the Percentage of (phenotypic) Variance Explained (PVE) by the three genotypes of the protein-coding SNP in a sample of 600 hypothetical subjects. The modeling was done using a simple, linear regulatory-SNP—protein-coding-SNP system with either perfect linkage disequilibrium (LD) or perfect linkage equilibrium between the two bi-allelic loci. The phenotype depended both on the number of protein molecules of each type as well as on their relative biological activities perturbed by additional pathway noise with controlled variance. ASE was modeled using an empirical distribution of expression ratios for the gene *TGFBR1* shown in Valle et al. (2008). Minor allele frequency was set at 0.5 or 0.2 both for the regulatory and the protein-coding SNPs. *Results:* Several clear trends were evident across the different conditions: 1) The degree of LD has a very large impact on PVE, 2) ASE reduces PVE negibly when LD is 0, but substantially when LD is perfect, and 3) The phases of the alleles at the two loci can exert a large effect when LD is perfect; if the mean transcription rate in the ASE distribution is near the ratio of the biological activities of the two proteins as it was here, larger phenotypes ascribed to the more biologically active protein can be completely offset by the ASE up-regulation of the less biologically active protein molecules. This leads to apparent PVE values near 0. *Conclusions:* Allele specific expression as modeled using a single bi-allelic regulatory SNP can have a substantial range of effects on the phenotypic variance explained by the genotypes of a single, hypothetical bi-allelic protein-coding SNP. The impact of ASE is more evident when linkage disequilibrium is high.

1928T

Association analysis as a service. *J. LeFaive, E.M. Schmidt, S. Lee, P. VandeHaar, H.M. Kang, G. Abecasis.* Biostatistics, University of Michigan School of Public Health, Ann Arbor, MI.

   We have designed a web-based interface where genomic researchers can carry out large scale association analysis combining phenotypes and genetic data on tens of thousands of individuals and hundreds of millions of genetic variants. Our tool allows researchers to focus on results interpretation by automating the process of running complex software pipelines and managing compute cluster infrastructure. With our platform, a large set of genotypes is prepared for analysis and stored in a cloud environment. Users can then request analysis of specific phenotypes and covariates to be queued and processed in parallel across multiple machines. The results are then tracked and summarized and can be explored through interactive plots, tables and downloads. The current version provides built-in analyses using EPACTS (http://genome.sph.umich.edu/wiki/EPACTS), including Wald, Firth and SKAT-O tests. Future versions will allow further customization of analysis options. Our tool is designed to facilitate trackable, reproducible research and dynamically allocate compute servers on virtual hosting services in a provider-agnostic manner. As genomic data increases in size, the complexity of analyzing this data in a timely fashion follows suit. Our goal is to simplify this process in an effort to streamline research.

1929F

HapRFN: A deep learning method to identify short IBD segments. *S. Hochreiter[1], D.-A. Clevert[2], G. Povysil[1].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Bayer Pharma AG, Berlin, Germany.

   For whole genome sequencing data HapFABIA was shown to be superior in detecting short IBD (identical by descent) segments that are tagged by rare variants. Nevertheless, HapFABIA still has several problems: (1) To decide whether individuals possess an IBD segment is often difficult because of the soft bicluster membership supplied by HapFABIA. (2) HapFABIA can only extract 10-30 IBD segments at once and therefore needs to perform multiple iterations. However, the IBD segments identified in different iterations may not be decorrelated, thus they may be redundant and overlapping or even split into smaller segments. (3) Very large data sets are time intensive. We recently introduced Rectified Factor Networks (RFNs) as an unsupervised deep learning approach. Each code unit of the RFN represents a bicluster and therefore an IBD segments, where samples for which the code unit is active share the bicluster (IBD segment) and features (SNVs) that have activating weights to the code unit tag the IBD segment. HapRFN overcomes the problems of HapFABIA. (1) RFNs provide sparser codes via their rectified linear units that immediately supply bicluster memberships as factors being different from zero. (2) RFNs can learn thousands of factors and therefore many IBD segments simultaneously. Therefore, all IBD segments are mutually decorrelated, thus are not redundant and do not overlap. (3) RFNs allow for much faster processing of very large data sets using techniques from deep learning like efficient matrix multiplications and implementations of networks on graphical processing units (GPUs). As a result HapRFN makes it possible to process very large data sets and to determine the size and number of IBD segments more precisely. With HapRFN we are able to accurately detect familial relationships, populations of origin, or interbreeding with ancient genomes in data sets with thousands of individuals. Furthermore, finding disease associations via IBD mapping becomes more reliable which might be the key to uncover unknown hereditary causes of multifactorial diseases.

1930W

Improving power of association tests using genotypes imputed from different reference panels. *W. Zhou[1], M.B. Elvestad[2], K. Hveem[3,4], J. Chen[5], C.J. Willer[1,5,6], G.R. Abecasis[7], H.M. Kang[7].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) K.G. Jebsen Center for Genetic Epidemiology, Department of Public Health, NTNU, Norwegian University of Science and Technology, Trondheim, Norway; 3) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, 7600 Levanger, Norway; 4) Department of Medicine, Levanger Hospital, Nord-Trøndelag Health Trust, 7600 Levanger, Norway; 5) Department of Internal Medicine, Division of Cardiology, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America; 6) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America; 7) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, Michigan, 48109, United States of America.

Genotype imputation allows variants that are not directly genotyped to be studied without other costs than computation. Improved genetic similarity between the reference and target samples increases the accuracy of imputation. The imputation accuracy also increases as the reference panels contain more individuals, especially for lower-frequency variants. When both a smaller ethnically-matched reference panel and a large cosmopolitan reference panel are available, it is unclear what is the optimal strategy to perform imputation-based association studies from these panels. Here, we systematically evaluated and compared genotype imputation based on three reference panels and we compared different approaches to incorporate multiple versions of imputed genotypes in the association tests. First, we genotyped 9,265 individuals from the population-based Nord Trøndelag Health Study (the HUNT study) for 350,270 polymorphic autosomal variants using an Exome array with GWAS tagging markers. Next, we whole-genome sequenced (WGS) 2,201 individuals from the same study matched for ancestry (mean depth 5x) for our reference panel. Then we imputed variants from our HUNT WGS reference panel as our ethnically matched panel, the Haplotype Reference Consortium (HRC) release 1 containing 32,488 individuals and 1000 Genomes Phase 3. We observed that imputation from the HRC resulted in most extremely rare variants (MAF < 0.05%) compared to the other two panels. Imputation from the HUNT WGS uncovered more variants with low frequency (0.05-1%) than HRC and 1000G. For variants with MAF >= 0.5%, the HRC and HUNT WGS panels showed comparable imputation accuracy, even though the sample size of the HUNT WGS is 16 times smaller than the HRC. The HUNT WGS panel added 4.5 million variants that could not be successfully imputed from the other two panels. Our findings have demonstrated the benefits of uncovering variants with low frequency (0.05-1%) by using ancestry-matched reference panels. In addition, simulations showed that using genotypes with the lowest association p value (best p-value method) results in higher power for association tests than keeping only one variant per panel with highest imputation quality metrics (best r2 method), even after adjusting for the additional variants tested, particularly for less frequent variants. For lower frequency variants, best-r2 method often retains variants with much less significant p-values due to imprecise estimate of imputation qualities.

1931T

Leveraging deep genealogical structure to estimate the phenotypic contribution of rare variants. *P. Palamara[1,2], J. Terhorst[3], Y. Song[3,4], A. Price[1,2].* 1) Harvard School of Public Health; 2) Broad Institute of MIT and Harvard; 3) University of California, Berkeley; 4) University of Pennsylvania.

The phenotypic impact of rare and low-frequency variants is poorly understood. Whole-genome sequencing studies offer one route to analyzing this class of variation, but sample sizes are currently too small to draw conclusions about the genetic architecture of a trait. Here, we develop a new method to study the phenotypic effect of rare variants using SNP array data, which is available in large sample size for many traits. Our approach is to first estimate the deep genealogical history for all pairs of individuals in a sample, and then use this information as a proxy for their sequence-level genetic relatedness to infer narrow sense heritability. To reconstruct deep genealogical relationships, we estimate the time to most recent common ancestor (TMRCA) of all pairs of individuals using a coalescent hidden Markov model (HMM) whose states represent TMRCAs along the genome. This type of model has been used in population genetic studies to infer historical effective population sizes from whole-genome sequence data (Li and Durbin, Nature 2011). To enable inferring TMRCAs using array data, we leverage a recently developed approach (Terhorst, Kamm, Song, under review) that enables incorporating site frequency spectrum information from a large panel of individuals into the HMM. We correct for biases due to SNP ascertainment on arrays, comparing the observed and expected allele frequency spectra for a given demographic model. To achieve scalability to large samples, we develop computational speed-ups that enable estimating pairwise TMRCA probabilities in time that is linear in the number of genotyped SNPs and the number of TMRCA states in the HMM. In coalescent simulations of a synthetic chromosome 1 using available models of European demographic history, we attained a squared correlation of 0.92 across pairs of individuals between the true average TMRCAs and the estimates obtained by our coalescent HMM method using array data. Using the reconstructed average TMRCAs for all pairs of individuals, we can infer the sharing of sequence-level genetic variants that arose at different time strata, including recent and rare alleles, which are generally not genotyped using array platforms. We use this information to estimate the phenotypic contribution of causal alleles of different ages, via variance components analysis. We test our approach using extensive simulations, and apply it to analyze the genetic architecture of 11 phenotypes in the UK Biobank data set (N=150k).

1932F

Systematic estimation of the environmental contribution to disease using the electronic health records. *R.S. Vanguri[1], F. Polubriaginof[1], K. Quinnies[1,6], A. Yahi[1], M. Simmerling[7,2], I. Ionita-Laza[3], H. Salmasian[7,1], S. Bakken[1,4], K. Kiryluk[5], D. Goldstein[6], D.K. Vawdrey[7,1], N.P. Tatonetti[1,5,6,8].* 1) Department of Biomedical Informatics, Columbia University, New York, NY; 2) Division of Medical Ethics, Weill-Cornell Medical Center, New York, NY; 3) Mailman School of Public Health, Columbia University, New York, NY; 4) School of Nursing, Columbia University, New York, NY; 5) Department of Medicine, Columbia University, New York, NY; 6) Institute for Genomic Medicine, Columbia University, New York, NY; 7) Value Institute, NewYork-Presbyterian Hospital, New York, NY; 8) Department of Systems Biology, Columbia University, New York, NY.

Accurate estimates of the effect of shared environment on disease is critical to understanding disease heritability. However, environmental factors are difficult to quantify and few datasets exist to derive their effects directly. Electronic health records passively collect a wide range of phenotypic data on millions of individuals who are actively seeking health care. Within these data are many related individuals and families. These relationships can be used to estimate the relative effects of shared environment on the incidence of disease. Through an analysis of the clinical records of 9 million patients at two large independent medical centers we identified 4.7 million familial relationships, from siblings to great-grandparents and great-grandchildren. We used these relationships to estimate the relative effect of shared environment over 900 diseases. This is done by leveraging two properties of heritability and shared environment. The first is that the heritability of a disease is a biological property and not affected by the familial relation. The second is that the shared environment between familial relationships is independent of the disease being studied. By minimizing a likelihood using these assumptions it is possible to isolate the component of observed heritability due to shared environment and calculate heritability more likely due to genetic factors. The diversity and size of the EHR, spanning thousands of clinical phenotypes and many degrees of relationships, allows for a novel method for estimating the effect of shared environment on diseases. Consequently, a measurement of shared environment allows for more accurate estimates of heritability across a broad range of phenotypes derived purely from EHR. .

1933W

VCFped: Identification of small pedigree structures in multisample variant call files. *M. Vigeland.* Dept Medical Genetics, Oslo University Hospital, Oslo, Norway.

We introduce a program, VCFped, which uses forced allele sharing to identify small pedigree structures (e.g. trios and quartets) in multisample VCF files. Correct relationships are crucial for successful analysis of family-based sequencing, e.g. detection of *de novo* variants in trios. Unfortunately, traditional methods for relatedness inference are not easily adaptable to sequencing data, which typically violate the assumptions of independent markers, accurate allele frequencies, and non-censored data. Our program sidesteps all of these problems by exploiting forced allele sharing between closely related individuals. In particular, the algorithm does not depend on allele frequencies or other variant annotations, allowing VCFped to be run as a quality control step before embarking on annotation and downstream analysis. Sequencing and genotyping errors are reduced using an automatically optimized filter based on the available quality metrics from the variant caller. VCFped is implemented as part of the pipeline for diagnostic trio analysis in the Department of Medical Genetics of Oslo University Hospital. In this study we tested VCFped in a range of family-based sequencing projects, including data from whole-genome sequencing, exome sequencing and smaller panels like TruSight One. We show that the VCFped algorithm is highly robust against low sequencing coverage, poor variant quality and inbreeding.

1934T

A versatile simulator for simulating and characterizing third-generation sequencing technologies. *B. Lau[1], M. Mohiyuddin[1], J.C. Mu[1], L.T. Fang[1], N. Bani Asadi[1], C. Dallett[2], H.Y.K. Lam[1].* 1) Roche Sequencing, Belmont, CA 94002; 2) Roche Sequencing, Pleasanton, CA 94588.

Third-generation sequencing (TGS) technology has demonstrated long read length and reduced sequencing bias. Such improvements enhance genome assembly, structural variant detection, haplotype phasing, and repeat resolution. The development, deployment and adoption of TGS can be accelerated by proof-of-concept bioinformatic analysis using simulated data; however, the sequencing characteristics and data formats of TGS have been rapidly changing, hampering the realism and versatility of simulators and bioinformatic tools when applied to different use cases. We present a simulator for profiling and simulating TGS single-molecule technologies. The software is highly adaptive, able to characterize varying sequencing characteristics and to perform I/O with different file formats. We use the software to profile CHM1 hydatidiform mole data sequenced using the P5 and P6 chemistries from Pacific Biosciences (PacBio). The software manages to distinguish the sequencing characteristics of the two chemistries. Such characteristics are automatically stored in numerical models, according to which simulation is performed. Moreover, the software can output the simulated reads in various formats, such as FASTQ, H5, and the latest PacBio BAM. This feature enables downstream analysis of a wide range of tools: PBHoney/Freebayes/Vardict, which require the widely used FASTQ, as well as PacBio's Quiver/CCS2, which require unconventional quality scores in H5/BAM from the primary analysis. The simulator is seamlessly integrated into the VarSim framework, allowing us to demonstrate unbiased comparisons among various variant callers applied to TGS data. The software enables researchers to characterize TGS sequencing technologies and to design experiments accordingly. Bioinformaticians can use simulation to tune against bias in sequencing data. Sequencing and primary-analysis developers can also use the software to predict the performance of downstream analyses.

1935F

RVS: An R package to integrate next generation sequencing (NGS) data across cohorts for association analysis. *J. Gong[1], Z. Baskurt[1], A. Derkach[2], A. Pesevski[1], L.J. Strug[1,3,4].* 1) Program in Genetics and Genome Biology, the Hospital for Sick Children, Toronto, ON, Canada; 2) Biostatistics Branch, National Cancer Institute, Rockville, MD, USA; 3) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Ontario, Canada; 4) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

A growing number of cohorts are undergoing whole genome sequencing using next-generation sequence (NGS) technologies. Integrating NGS data across patient and/or control cohorts for association analysis is challenging. Different studies may use different sequencing platforms and parameters (eg. read depth), and alignment and variant calling algorithms, that can result in spurious findings unless statistical methodology implemented explicitly accounts for these differences. In Derkach *et al.* (2014) we developed a workflow to conduct case-control association analysis for common and rare variants with 'out-of-study' controls when aligned reads in BAM format are available. The proposed method, the robust variance score (RVS), eliminates read depth bias, controls type I error and has comparable power to studies when the true genotypes are known. Here we develop a user-friendly R package to make the RVS accessible, and extend its utility to the integration of NGS data for a variety of study designs. The '*RVS*' R package consists of three modules: (1) common and rare variant association analysis using RVS, (2) conventional association using variant calls, and (3) a simulation module. Module 1 takes a multi-sample variant call format file (VCF, for example, from Genome Analysis Tool Kit (GATK, DePristo *et al*, Nat Genet, 2011)) created from all samples to be analyzed as input, obtains the genotype probabilities for the reported variants, and uses them in the RVS statistic for association analysis. Module 2 uses a conventional score test to for association with variant calls rather than probabilities, for comparison; this module uses the plink (Purcell *et al*, AJHG, 2007) format file as input. Module 3 simulates sequence data for different read depths and error rates. Sample data with examples are provided for each module. The RVS package includes extensions beyond what was described in Derkach *et al* (2014), to analysis with multiple control samples, and for integrating NGS data across consortia for analysis of quantitative traits. The RVS package has been tested using simulated data, data downloaded from 1000 genomes project website (http://www.1000genomes.org) and NGS data from our studies of childhood-onset epilepsy. The package is available at www.tcag.ca. When used with algorithms such as GATK, RVS will provide a useful tool to help researchers identify loci associated with disease while protecting from confounding due to differences in NGS study designs.

1936W

A novel phenotype permutation method to optimize threshold selection in Random Forests. *E.R. Holzinger[1], S. Szymcak[2], J. Malley[3], A. Dasgupta[4], Q. Li[1], J.E. Bailey-Wilson[1].* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland, USA; 2) Institute of Medical Informatics and Statistics, University of Kiel, Kiel, Germany; 3) Center for Information Technology, National Institutes of Health, Bethesda, Maryland, USA; 4) Clinical Trials and Outcomes Branch, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, Maryland, USA.

Standard analysis methods for genome wide association studies (GWAS) are not robust to complex disease models, such as interactions between variables with small main effects. These effects very likely contribute to the genetic etiology of complex human traits. Machine learning methods that are capable of identifying interactions, such as Random Forests (RF), are an alternative analysis approach. One currently unresolved problem with RF or any other machine learning scheme is that there is no standardized method of selecting a threshold that identifies the correct variables while filtering out false positives. The optimal threshold is highly dependent on the underlying genetic model, which is typically unknown in biological data.   To address the long-standing threshold problem, we have developed an RF-based variable selection method called r2VIM. Among other novel features, this method incorporates a permutation scheme to optimize threshold selection. Briefly, we permute the phenotype and run r2VIM on the permuted data. This provides us with a null distribution of importance scores while maintaining the relationships between the predictor variables. A threshold is then selected based on the false positive rate in the permuted data. This threshold is then applied to the non-permuted r2VIM analysis. We refer to this permutation scheme as "phenoPerm." Our results show that phenoPerm provides an ideal balance between power and false positive selection when compared to other selection methods across different complex genetic risk models, including gene-gene interactions, both with and without main effects. We also assess the relationship between the false positive rate in the permuted data to the false positive rate and power in the non-permuted data, and show how it can be used as a guide to perform threshold selection according to individual analysis requirements.

1937T

Improved correction for tissue heterogeneity in DNA methylation data. *E. Rahmani[1], N. Zaitlen[2], Y. Baran[1], C. Eng[2], D. Hu[2], J. Galanter[2,3], S. Oh[2], E.G. Burchard[2,3], E. Eskin[4,5], J. Zou[6], E. Helperin[1,7,8].* 1) Blavatnik School of Computer Science, Tel-Aviv University, Tel Aviv, Israel; 2) Department of Medicine, University of California San Francisco, San Francisco, California; 3) Department of Bioengineering and Therapeutic Science, University of California San Francisco, San Francisco, California; 4) Department of Computer Science, University of California, Los Angeles, California; 5) Department of Human Genetics, University of California, Los Angeles, California; 6) Microsoft Research New England, Cambridge, Massachusetts; 7) International Computer Science Institute, Berkeley, California; 8) The Department of Molecular Microbiology and Biotechnology, Tel-Aviv University, Tel Aviv, Israel.

Mounting evidence for the role of DNA methylation in various cellular processes and its correlation with disease and environmental factors have led to an increasing interest in Epigenome-Wide Association Studies (EWAS). In a standard EWAS of primary tissue (e.g. whole blood), methylation data represent the epigenetic states of a heterogeneous mixture of cell types. Since different cell types are highly variable in their methylation profiles, correlation between the cell type composition and the outcome of interest leads to spurious associations. In principle, false discoveries due to tissue heterogeneity can be addressed by adding the cell proportions as covariates. However, cell-type compositions are typically hard to measure in practice, and therefore the problem of tissue heterogeneity is believed by many within the epigenomics research community to be amongst the foremost challenges faced by genome-wide epigenetic studies. Although computational methods for estimating cell compositions have been proposed, these rely on scarce reference data of whole-genome methylation levels from sorted cells. Such reference datasets do not exist for most tissues and may not represent well the epigenetic state of individuals with different methylation altering factors such as age and sex. Moreover, accounting only for a preselected set of estimated cell types may still result in false discoveries in EWAS if the outcome of interest is correlated with cell types that were not estimated. We developed a new unsupervised method for reconstructing sparse low rank signal in data, and demonstrated its use and benefits in accounting for the cell composition confounder in methylation data. Using real datasets including measured cell counts and simulated data we showed that our highly efficient method, ReFACTor, increases the correlation with the cell composition and as a result substantially reduces the number of false positives and improves power in EWAS compared with existing methods. ReFACTor does not require reference data; therefore it can be applied to any tissue. We also demonstrate that ReFACTor can be further used for detecting more low rank structures in methylation data such as population structure, thus leading to a more comprehensive understanding of the underlying model of genome-wide epigenetic states. Corresponding software is available from http://www.cs.tau.ac.il/~heran/cozygene/software/refactor.html.

1938F

Efficient user-friendly toolset for the analysis of high-throughput DNA-methylation data. *R. Yedidim[1], E. Rahmani[1], L. Shenhav[3], R. Schweiger[1], O. Weissbrod[2], N. Zaitlen[1], E. Halperin[1].* 1) Blavatnik School of Computer Science, Tel-Aviv University, Tel Aviv, Israel;; 2) Computer Science Department, Technion – Israel Institute of Technology, Haifa; 3) Department of Statistics, Tel Aviv University, Tel Aviv, Israel.

 Recently introduced high-throughput technologies for probing DNA methylation states have resulted in a rapidly increasing number of phenotype-methylation associations as well as mounting evidence for the importance of methylation in disease and complex cellular processes. In particular, Epigenome-Wide Association Studies (EWAS) have become a compelling and successful study design. The exponential growth in both data collection (50% of the methylation data currently in GEO were collected since 2014) and related research (66% of the papers including the terms "DNA methylation" and "epigenome-wide" were published since 2014) demonstrate the mounting interest in EWAS. As with other highthroughput biological data, appropriate EWAS analysis requires development of tailor-made methods and tools to address the unique properties of methylation data. Although there is a growing repertoire of available tools, most of these require programming proficiency in order to perform an end-to-end data analysis. User-friendly software, which does not require any programming proficiency and can be easily accessed by more researchers, will substantially benefit the epigenetics community. We developed a highly efficient command-line toolset for the analysis of DNA methylation data and conducting EWAS, analogous to the widely used toolset PLINK for GWAS. Some of the features of the toolset include a range of statistical tests for detecting differentially methylated sites, state-of-the-art methods to account for tissue heterogeneity and confounders including ReFACTor, principal component analysis, and linear mixed models, cell type composition estimation, a method for methylation imputation and ancestry estimation from methylation. In addition, the software provides an easy to use data management tools, and it automatically generates publication-quality figures. The software is highly efficient – we demonstrate how a small-scale EWAS can be performed in minutes using just a few simple commands, and large-scale EWAS with hundreds or thousands of individuals can be performed in less than an hour.

1939W

A novel, widely-applicable method for detecting long-term balancing selection. *K.M. Siewert[1], B.F. Voight[2,3].* 1) Genomics and Computational Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia PA; 2) Department of Systems Pharmacology and Translational Therapeutics, Perelman School of Medicine, University of Pennsylvania, PA; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, PA.

 Balancing selection preserves two or more alleles at a locus over long evolutionary time periods. This type of selection is known to play a role in human evolution, a classic example being the Hemoglobin Beta locus, which maintains alleles that protect against malaria, but cause sickle-cell anemia. Owing to large-scale genomic data sets, discovery and characterization of loci subject to balancing selection has become an active area of investigation. Our goal is to quantify the number of sites and determine which genes are subject to selection in a wide-range of species. To achieve this aim, we require a test that is powerful, robust to assumptions about demographic history that are difficult to model with certainty, not reliant on outgroup sequences, and is computationally efficient so as to quickly scan entire genomes. We are developing an algorithmic approach that utilizes the signature of allelic class build-up, in which neutral variants accumulate at the same frequency as the balanced allele they are linked to. Preliminary results from simulations demonstrate that our method performs comparably to more computationally intensive methods, despite our statistic not requiring knowledge of complex demographic parameters or outgroup sequences. This indicates our method is applicable in a wide range of species where this information is not known. We will next apply our method to population genomics data from humans and drosophila to detect loci under selection..

1940T

New features improve user experience of Analyst Portal-A distributed real-time data query system. *H. Qiu[1], F. Mentch[1], L. Hermannsson[1], H. Hakonarson[1,2].* 1) Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

   Analyst Portal is the distributed and integrative data query system developed in-house where users, through web interface, perform complex queries on numerous modalities including but not limited to Electronic Medical Records (EMR), laboratory workflow information, genotyping and next generation sequencing data. Instead of involving a centralized data warehouse to store data from various sources, Analyst Portal uses distributed database query facility to query different source databases on the fly. Since production 6 years ago, Analyst portal has helped researchers search and access the data needed for hypothesis generation and making new discoveries.Based on past user activities, one of the most frequent search is selection of a cohort meeting certain criteria. In the past, Analyst portal used html form based approach in combination with intermediary patient list uploading. Although easier for implementation, it did not score well in terms of flexibility and it was not user friendly. We have developed a new AJAX based, more user friendly cohort selector that allows users to drag-and-drop search terms and build more complex ad-hoc queries that performs well in real-world scenarios.Encouraged by the early benefits seen in the past year from indexing raw SNP calls from different SNP arrays, we extend the same Word Aligned Hybrid (WAH) bitmap indexing to imputed genotypes and SNP calls from NGS sequencing data, making SNP-aware searches more unified and informational.Here we first review the architecture, implementation, lessons learned and user activity patterns of the Analyst Portal, and then present two new features: 1) drag-and-drop enabled query builder for improved cohort selection; 2) unified genotype call indexing, both of which are uniquely enabling for genotype-phenotype queries and association studies.

1941F

Interactive search over massive whole genome repository. *A. Telenti[1,2], V. Lavrenko[2], I. Bartha[2], A. Bernal[2], C. Chang[2], P. Garst[2], A. Harley[2], B. Hicks[2], E. Kostem[2], L. Pierce[2], J. Piper[2], S. Ramakrishnan[2], N. Shah[2], H. Tang[2], W.-Y. Yang[2], J.C. Venter[1,2], F. Och[2].* 1) J. Craig Venter Institute, La Jolla, CA; 2) Human Longevity Inc., San Diego, CA.

   Background. Interacting with thousands of genomes is a significant challenge: both computationally and in seamless integration with phenotype records, knowledge sources and quality metrics. Existing solutions for genomic data management do not scale to a large number of whole genomes. We developed a search engine that that enables access to genomic, phenotypic and annotation data with a high-level of interactivity and flexibility. **Materials and Methods.** We introduce innovative elements into every traditional component of a genomic search engine. The retrieval engine seamlessly integrates free-text keywords and specialized constructs, such as cohort definitions, variant effects, score/frequency filters, gene/chromosome queries and disease panels. The engine is designed to be highly-responsive and responds to almost all queries in under 500 milliseconds. The index makes use of a unified data structure to represent all the underlying information: individual genomes, phenotypes, natural-language and structured annotations. The index supports incremental updates: a whole-genome VCF can be added in 6 seconds and be fully-searchable. The engine supports multiple ranking mechanisms, including rule-based formulas, and a learning-to-rank algorithms. **Results.** We have indexed 11,981 genomes (30x coverage) comprising 217 millions of distinct variants (98% outside the exome). We indexed 1.16 million records from databases such as ClinVar, HGMD and CPDB, providing annotations for 263,305 variants, 58,143 genes and 3816 pathways. The index also contains 10,861 fully-searchable phenotype records. The engine allows individual or collective VCF calls and annotation with multiple annotation sources. Features include visualization of variants on 3D protein structures, a professional curation tool, support for crowd contributions, and interactive access to genomic read alignment for assessing variant call quality. Many analytic operations are supported: genetic association, trios, pathways, somatic oncology, and the definition of gene and variant panels for automated calls. **Conclusions.** We present a novel tool for extremely efficient and interactive access of genomic, knowledge and phenotypic data. It allows real-time free text or structured queries covering the main information needs in genome interpretation.

1942W

Population genotyping from low-coverage sequencing data using a reference panel. *L. Huang[1], P. Danecek[2], S. Batzoglou[1].* 1) Stanford University, Stanford, CA; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

In the past years, several large-scale whole-genome sequencing projects are completed, such as the 1000 Genomes Project, the UK10K Cohorts Project. These projects provide high-quality haplotypes and/or genotypes of a considerably large number of whole genomes. Besides its value in the original projects, this resource has the potential to benefit the quality of genotype calling from low-coverage sequencing data in future sequencing projects, because these existing genotype calls effectively captures the linkage disequilibrium structures of cohorts. Here we present reference-based Reveel (or Ref-Reveel in short), a novel method for population genotyping. Ref-Reveel is designed based on Reveel, our first generation of population genotyper, which has been demonstrated to be an effective tool. Ref-Reveel incorporates reference genotypes from completed projects to boost the genotyping quality of new data sets while maintaining high computational efficiency.   We demonstrate that using a reference panel substantially improves genotyping accuracy through extensive experiments on the whole genome. We also compare the performance of using three reference panels when we call genotypes of 99 CEU samples from the 1000 Genomes Project: (i) the genotypes of 3,781 UK10K samples provided by the UK10K Consortium, (ii) the Reveel-called genotypes of the UK10K samples, and (iii) the integrated call set of 2,535 samples from the 1000 Genomes Project Phase 3. We show reference panel (ii) outperforms the other panels. Critical characteristics of reference panels are then discussed based on our observations: reference panel size, ancestry of samples, genotype quality, and completeness of variants. In our experiment, the quality of two UK10K reference panels are evaluated by using the genotypes called from the high read-depth exome sequencing of the TwinsUK cohort were used as a truth set. Finally, we demonstrate the effectiveness of Ref-Reveel on an even more challenging population genotyping problem: to call genotypes of a small data set with merely ten samples from unknown populations. A public available reference panel, the 1000 Genomes Project Phase 3, is used in this experiment.

1943T

Automated, scalable quality control of heterogeneous exome sequence data. *R. Koesterer, M. von Grothuss, J. Flannick on behalf of the GoT2D, T2D-GENES, SIGMA, LuCAMP, and ESP consortia.* Medical and Population Genetics, Broad Institute, Cambridge, MA.

In the coming years, hundreds of thousands of samples will be sequenced to identify associations between genetic variation and complex phenotypes. To avoid false-positive findings but maintain power, stringent quality control (QC) procedures must be applied to these data. Current QC approaches require the direct attention of analysts, presenting scaling challenges to millions of samples.We developed a novel approach for sample QC, combining control for ancestry and other confounders with automated outlier detection. Our approach (a) projects genotypes onto principal components (PCs) of known reference populations; (b) computes a battery of metrics assessing sequence quality; (c) normalizes metrics according to ancestry and other confounders such as sequencing platform; (d) performs PCA on the normalized metrics to identify independent measures of sample quality; and (e) uses Gaussian Mixture Modeling to identify outliers according to both the individual metrics as well as their PCs. We evaluated our method relative to previously published manual approaches using 18 sample metrics computed across 12 ancestry groups from 26,171 exomes. Sample quality was evaluated based on the transition-transversion ratio (TITV) of singleton variants unique to samples that passed QC (QC+) relative to those that failed (QC-).We identified 336 QC-samples, within which singleton variants had a TITV ratio of 1.75 compared to a ratio of 2.66 for QC+ samples (p=1.63e-129), suggesting QC- samples as significantly enriched for sequencing artifacts. Among them, 210 problematic samples with a singleton TITV ratio of 1.81 (p=2.8e-76) were not identified by the current gold standard approach.Samples substantially skewed on any of the metrics, including low call rate, high number of alternate alleles, and fraction of alternate reads at heterozygous sites (allele balance), were enriched for sequencing artifacts. Metrics based on lower frequency variants were more effective than comparable metrics based on common variants. PCA of normalized metrics identified six additional outliers with a mean singleton TITV ratio of 2 (p=6.8e-3), suggesting samples skewed across multiple metrics are also enriched for sequencing artifacts.These results demonstrate that not only can automatic, scalable QC approaches be developed for heterogeneous exome sequencing data, but their performance can meet or exceed that of current gold standard approaches.

1944F

New RAREMETAL: An efficient and flexible tool for meta-analysis. *S. Chen[1,2], J. Yang[1], D. Liu[3], S. Feng[4], G. Abecasis[1]. 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Bioinformatics, University of Michigan, Ann Arbor MI; 3) Division of Biostatistics and Bioinformatics, Department of Public Health Sciences, Penn State College of Medicine, Hershey, PA; 4) Hitachi America Big Data Lab, Santa Clara, CA.*

Meta-analysis plays a critical role in large-scale genetic association studies. It provides researchers a convenient computational tool for achieving large sample sizes. Here, we report on several useful improvements to our RAREMETAL software for rare-variant meta-analysis. Specifically, we have: (1) updated score statistics for meta-analysis so that they specifically account for varying case-control ratios among the studies being analyzed, resulting in substantial power gains; (2) improved meta-analysis methods for dichotomous traits by allowing for logistic regression models in the analysis of component studies; (3) optimized workflows for large-scale datasets to enable analyses that include 10s of millions of variants across 100,000s individuals; (4) added SKAT-O and additional weighting schemes for gene-based rare variant association tests. We hope our new RAREMETAL software will continue to be a useful tool to facilitate the discovery of disease-associated genes in large studies.

1945W

Discovery and meta-analyses of trans-eQTLs from cross-tissue gene expression data using approaches that increase statistical power. *B. Jo[1], Y. He[2], I. McDowell[3], A. He[2], A. Battle[2], B. Engelhardt[4], The GTEx Consortium. 1) Department of Quantitative and Computational Biology, Princeton University, Princeton, NJ; 2) Department of Computer Science, Johns Hopkins University, Baltimore, MD; 3) Program in Computational Biology and Bioinformatics, Duke University, Durham, NC; 4) Department of Computer Science and Center for Statistics and Machine Learning, Princeton University, Princeton, NJ.*

Expression quantitative trait locus (eQTL) studies seek to identify the genetic loci that regulate gene expression levels, helping to characterize the role that non-coding genetic variants play in the regulation of complex traits. As RNA sequencing (RNA-seq) experiments have advanced to the degree that we are able to obtain multi-tissue expression profiles per individual in a robust manner, so has our ability to understand context-specific roles that genetic variants play in expression profiles. In particular, the NIH Common Fund's Genotype-Tissue Expression (GTEx) project provides a rich collection of RNA-seq experiments that span 449 individuals over 44 different tissue types. This study expands upon the previous cis-expression QTL (eQTL) discoveries in GTEx by establishing strong evidence for trans-, or distal, eQTLs. Prior eQTL studies mainly focus on cis-eQTLs, as trans-eQTLs are difficult to detect because of the high multiple hypothesis testing burden, and do not often replicate because of smaller effect sizes and greater levels of tissue- and sex-specificity relative to cis-eQTLs. In this work, we describe 44 trans-eQTLs identified in the GTEx v6 data using standard association testing in each tissue. Then, we demonstrate improvements in these results by using various approaches that seek to increase power in trans-eQTL detection, including making use of known cis-eQTLs to reduce the number of SNPs tested, and leveraging known genetic networks and trait-associated genetic variants from GWAS studies. We also apply Meta-Tissue, a linear mixed model approach to meta-analysis, for identifying putative trans-eQTLs that are shared across tissues, improving power and providing estimates of tissue-specificity. We validate our trans-eQTLs using replication in other large-scale eQTL studies (DGN, MUTHER, and GEUVADIS), functional analysis in enrichment of regulatory regions, and comparisons to effect-size confidence intervals established via Kallisto, a fast expression quantification method with bootstrapping.

1946T

ASElux: An ultra-fast and accurate allelic read aligner. *Z. Miao[1,2], A. Ko[1,3], M. Alvarez[1], M. Laakso[4], P. Pajukanta[1,2,3].* 1) Department of Human Genetics, UCLA, Los Angeles, Los Angeles, CA; 2) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, CA; 3) Molecular Biology Institute at UCLA, Los Angeles, CA; 4) University of Eastern Finland, Kuopio, Finland.

A large proportion of genes display allele specific expression (ASE). Accurate assessment of ASE can help elucidate biological mechanisms related to disease via imprinted genes or cis-regulation of expression. Since reads from the alternative allele are more likely to be falsely mapped, mapping bias remains a major obstacle in analyzing allelic expression. Previous studies have used simulation to mark the potentially biased alignment regions, however, as ~30% of SNPs are identified as biased SNPs, a large number of SNP sites are excluded from the downstream analysis and the remaining SNPs still display some degree of mapping bias. Other methods such as SNP-o-matic and GSNAP integrate the SNP information with the reference genome to perform a SNP-tolerant alignment. However, both SNP-o-matic and GSNAP are relatively slow, making them less ideal for the analysis of large data sets. To perform a fast and accurate alignment for ASE analysis, we developed a new method, ASElux that focuses on a SNP-tolerant alignment of allele-specific reads. Since the allele-specific reads comprise only ~10% of the RNA-seq data, we save a significant amount of time by ignoring the non-allele specific reads during the alignment. With ASElux, we use personal SNP information to generate all possible allele-specific reads, followed by their direct counting during the alignment. This design makes ASElux 75 times faster than GSNAP (440 queries/s) and ~2 times faster than STAR (14,286 queries/s) and HISAT2 (16,666 queries/s). We also tested the accuracy of ASElux along with other tools both on simulated RNA-seq data and 20 adipose RNA-seq samples from the METSIM study. Using GSNAP as the golden standard, ASElux shows a significantly smaller ($p<2.2\times10^{-16}$) reference bias than STAR and HISAT2. In identifying ASE SNPs, ASElux also displays a better concordance with GSNAP than STAR and HISAT2. We further built a modified version of ASElux for aligning DNA-seq data and tested it with other tools in a simulated ChIP-seq data set. ASElux shows a top speed and accuracy when compared with GSNAP and Bowtie. A total of 99.7% of SNPs aligned by ASElux showed no bias, exceeding the performance of GSNAP (88.5%) and Bowtie (87.5%). Taken together, ASElux provides a great accuracy and ultra-high speed for allele-specific read alignment, making it a powerful new tool for large scale allele-specific analysis of not only gene expression but also transcription factor and histone modification data.

1947F

Genomewide allele-specific expression (ASE) analysis of RNA sequencing and exome array data in the COPDGene Study. *M.M. Parker[1], R.P. Chase[1], A. Lamb[1], B.D. Hobbs[1,2], M.H. Cho[1,2], E.K. Silverman[1,2], C.P. Hersh[1,2], P.J. Castaldi[1,3].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 3) Division of General Internal Medicine and Primary Care, Brigham and Women's Hospital, Boston, Massachusetts, USA.

Background: Allele-specific expression (ASE) analysis quantifies the variation in gene expression observed between the two haplotypes of an individual and can be used in analysis of cis regulatory variant effects, nonsense-mediated decay and imprinting. **Methods:** To assess genomewide ASE, we combined Illumina exome array and whole-blood RNA sequencing data from 127 individuals in the COPDGene study. For subjects passing standard quality control, allelic counts at heterozygous sites were quantified using GATK's ASEReadCounter. To minimize allelic mapping bias, we excluded non-uniquely mapping reads, reads with a mapping quality < 10 and variant sites shown in simulation to change the allelic ratio > 5%. To define significant ASE, we performed binomial tests across all heterozygous sites with a minimum of 10 reads with the null value equal to the mean reference ratio. Variant sites were annotated with gene name and functional consequence using GENCODE v19. **Results:** A total of 131,740 heterozygous sites were tested for ASE (median coverage = 24x, IQR coverage = 30). The mean reference ratio over all sites was 0.53, indicating residual allelic mapping bias, which was strongest for low depth sites (reference ratio at 10-20x coverage = 0.534 vs. reference ratio at > 100x coverage = 0.523, p-value difference in mean < 1 $\times10^{-6}$). At an FDR of 5%, 4,623 sites (in 1,358 unique genes) showed significant ASE, with 972 sites showing complete ASE. The majority (70.84%) of the 4,623 sites showed ASE in > 1 subject (range = 2-67 subjects), and there were 563 genes with >1 instance of significant ASE. Stopgain/stoploss variants were significantly more likely to show allelic imbalance as compared to nonsynonymous or synonymous (p-value < 6x10^{-10}, proportion of stop variants with ASE = 0.18, proportion of synonymous = 0.047, proportion of nonsynonymous = 0.037). To assess if ASE effects were consistent across individuals, we subset heterozygous sites to those covered at > 40x and observed in > 10 individuals (n=482). We identified examples of both: 1) sites with ubiquitous ASE (n=8, max number subjects with ASE =51), and 2) sites with ASE in only a subset of individuals (n=474, mean proportion with ASE = 0.13). **Conclusions:** Our findings from ASE analysis in 127 subjects from the COPDGene study: 1) document extensive evidence of ASE in whole blood; 2) confirm enrichment of ASE in stop variants; and 3) provide evidence for both ubiquitous and person-specific ASE.

1948W

Seqant 2.0: Whole-genome variant annotation in the Amazon cloud. *A. Kotlar[1], M. Zwick[1], D. Cutler[1], T. Wingo[2].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Neurology and Human Genetics, Emory University, Atlanta GA.

As the cost of sequencing drops, whole genome and whole-exome experiments are increasingly common in labs with a diversity of computational experience. In these environments there is a need for cross-platform, easy-to-use computer programs that identify and analyze alleles relevant to researchers' phenotypes of interest. SeqAnt 2.0 is the first web-based program of this kind, called a variant annotator, that is backed by the Amazon AWS cloud. It runs on any modern browser without the need for plugins, and is capable of analyzing more than 1.5 million variants per minute for experiments in excess of 40 gigabytes in size. Its web interface is a JavaScript single-page application (SPA) that renders at 60 frames per second, achieving the simplicity and fluidity of offline applications. It features a minimalist interface that walks researchers through three simple submission steps. Once submitted, jobs are analyzed by a Perl multi-threaded annotator running in Amazon's data centers, which sends real-time progress updates with only 2 bytes overhead. Once completed, results are visualized in the browser using WebGL and JavaScript. Users can filter their results in the browser or download the full experiment for offline analysis. Furthermore, users are given accounts through which they can store their analytic steps and results in a HIPAA-compliant data center, which removes the need to worry about hard drive space limitations. SeqAnt currently serves *Homo sapiens*, *Mus musculus*, and *Drosophila melanogaster* annotations, and can be extended to support any additional eukaryotic model organisms. In conclusion, Seqant 2.0 is the first web-based variant annotator that leverages the Amazon cloud computing platform. It runs on any modern browser and on any recent computer or mobile device. Its performance and simplicity enables researchers with even limited computational experience to rapidly analyze alleles found in their whole genome and whole-exome experiments.

1949T

Decoupling pervasive transcription and real transcription reveals transposable element activity during the development of the human brain. *F. Navarro, M. Gerstein.* MB&B, Yale University, New Haven, CT.

Transposable elements (TE) constitute approximately half of the human genome. Despite the difficulties created by their highly repetitive nature, there is building evidence that transposable sequences play a significant role in the genome biology influencing gene regulation and creating variability across individuals and species. TEs show somatic activity in pathogenic and healthy cells. Among other tissues, the human brain is thought to harbor somatic transposable element somatic. Due to their high copy number and broad distribution across the genome, assessing transposable elements expression is specially affected by RNA fragments originating from pervasive transcription. We developed a new approach that deconvolutes pervasive transcription signal from real transcription and estimates TE subfamily expression level. We used RNA-seq experiments from ENCODE, BrainSpan, GTex and PsychENCODE to evaluate the activity pattern of LINE1s, SVAs and HERVs in 16 regions of the human brain across 12 developmental stages and different conditions. We observe that the majority of the reads mapped to transposable elements are due to pervasive transcription and removing this signal results in recent, and potentially active, TE subfamilies being transcribed in the human brain. Using ENCODE data, we find that pervasive transcription signal is generated in nuclear transcripts while the cytoplasm contains real transcription of L1Hs. Moreover, we found that specific brain regions harbor higher activity of L1HS and LTRs and no activity of SVAs. All together our results demonstrate that different but mostly recent TEs are active during the whole development of the human brain and might impact tissue biology.

1950F

FusorSV: A unified knowledge based framework for comprehensive Structural Variant discovery. *T. Becker[1,2], J. Leone[1], Q. Zhu[1], E. Cerveira[1], M. Romanovitch[1], C. Zhang[1], D. Shin[1,2], C. Lee[1], A. Malhotra[1].* 1) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 2) Computer Science and Engineering, University of Connecticut, Storrs, CT.

Calling Structural Variants (SV) comprehensively and with high accuracy remains a challenge. Phase 3 of the 1000 Genomes SV project made 68,818 calls from nine different algorithms and integrated them into a single call set across 2,504 individuals from 26 human populations. Methods have since been developed that combine multiple algorithms under consensus or by counting the supporting reads for each algorithm to obtain a higher quality SV call set than any single algorithm on its own. However, the existing methods do not utilize discriminating SV features or prior SV information from projects such as the 1000 Genomes.We present a state of the art data fusion method driven by SV features and prior SV knowledge to produce a comprehensive and unified call set from an arbitrary number of SV callers. The method characterizes all possible input combinations using prior SV information as a true call set for each feature and then leverages that information in the discovery step to produce an accurate genotyped result. Each output SV region is annotated with a confidence measure from the model, information about the contributing input calls and when available, the aligned targeted assembly. We tested the approach on deletion, duplication and inversion SV call types by constructing a fusion model using ten of the most popular SV callers (including some ensemble callers) with the 1000 genomes Phase 3 data set that comprises 27 PCR-Free samples each with 250bp pair-end reads at 50X coverage. Using SV type and SV length as the discriminating features, fusorSV outperformed existing algorithms based on a 3-fold cross validation with 1000 permutations. We also performed (1) in silico validation by targeted breakpoint assembly of the calls and (2) experimental validations on a randomly selected subset of novel (not present in 1000 genomes Phase 3) deletions, duplications and inversion calls.

1951W

Analytical approaches for sequence variant interpretation in clinical exome analysis. *D.J. Corsmeier[1], G.E. Herman[2,4], R.E. Pyatt[1,3], J. Gastier-Foster[1,3,4], C. Astbury[1,3].* 1) Department of Pathology and Laboratory Medicine, Nationwide Children's Hospital; 2) Center for Molecular and Human Genetics, The Research Institute at Nationwide Children's Hospital; 3) Department of Pathology, The Ohio State University College of Medicine; 4) Department of Pediatrics, The Ohio State University College of Medicine.

With the rapid adoption of whole exome sequencing into clinical practice, the volume of genomic sequence variants that must be analyzed and interpreted accurately is growing exponentially. The 2015 ACMG Guidelines are an invaluable resource for a systematic approach to the interpretation of these variants. The 28 basic evidence classifiers give specific criteria by which to approach the classification and prioritization of genomic variation. While nearly all of the 12 classifiers supporting benign interpretation and the 16 that may support calling a pathogenic finding are based on objective information, approximately half of them require more than a cursory manual effort to evaluate. We demonstrate that by performing some preliminary bioinformatic analysis, in particular the mining of databases that include known variant pathogenicity information such as ClinVar and HGMD, we can eliminate much of this manual effort. For instance, in the case of the very strong evidence of pathogenicity predicted by a null variant for a disease in which loss of function is a known mechanism (PVS1), we have precompiled a list of all known genes associated with such diseases, making retrieval trivial. Evaluation of a given variant then becomes a matter of simply inspecting the variant type (e.g., nonsense, frameshift) to determine whether the associated predicted gene product would be null. With the more complex classifiers, we utilize more involved computational methods. For example, we have compiled lists of repeat regions to facilitate evaluation of the criteria assessing in-frame indels (BP3). We have also analyzed the variant databases to establish reasonable thresholds, omitted from the Guidelines, to assess rates of pathogenic and benign variation (PP2, PM1). Through this type of preprocessing, we effectively minimize the manual effort necessary to evaluate sequence variants on the basis of the evidence criteria. Through use of a more automated approach, variant interpretation can be performed more accurately, efficiently, and with less human error and subjectivity. This is a necessary requirement with the rapid growth of clinical exome sequencing. Our goal is to minimize manual effort in the evaluation of pathogenicity evidence. This will facilitate sequence variant interpretation and demonstrate how the variant interpretation process might be further standardized in the application of the ACMG Guidelines in clinical exome analysis and interpretation.

1952T

Comparison of variant analysis pipelines for genetic diagnosis of undiagnosed diseases. *A. Dries[1,2], J. Kohler[1,2], D. Waggott[1,2], P. Batra[1,2], C. Prybol[1], E. Fernandez[1,2], D. Zastrow[1,2], D. Fish[3], M. Grove[2,3], P. Zornio[1,2], U.D.N. Members[4], E. Ashley[1,2,8], P. Fisher[5], J. Bernstein[6], J. Merker[7], M. Wheeler[1,2].* 1) Stanford Center for Undiagnosed Diseases, Stanford, California; 2) Division of Cardiovascular Medicine, Stanford University, Stanford, California; 3) Stanford Center for Genomics and Personalized Medicine, Stanford, California; 4) Undiagnosed Diseases Network, National Institutes of Health, Bethesda, Maryland; 5) Department of Neurology, Stanford University, Stanford, California; 6) Department of Pediatrics, Stanford University, Stanford, California; 7) Department of Pathology, Stanford University, Stanford, California; 8) Department of Genetics, Stanford University, Stanford, California.

For participants evaluated by the Undiagnosed Diseases Network (UDN), novel strategies analyzing genetic data are needed in the search for a genetic diagnosis. While clinical exome and genome laboratories are necessarily limited in the curation of novel genes and variants potentially causative of disease, the clinical sites of the UDN have methods to identify clinically relevant variants in rare undiagnosed diseases.   At the Center for Undiagnosed Diseases at Stanford (CUD), patients undergo whole exome or whole genome sequencing through the UDN sequencing cores. Samples are run with family member DNA in a trio or quad. In addition to a clinical report, cores return raw sequencing data to UDN clinical sites for genetic analysis and curation. The analysis team uses two parallel pipelines to identify variants of interest: Ingenuity Variant Analysis, a commercial phenotype driven tool that uses customizable filters to refine variants; and sequence to medical phenotypes (STMP), a bespoke and customizable curation pipeline that prioritizes variants using multiple levels of evidence integrating a broad array of metadata. STMP Tier 0 and Tier 1 variants are manually curated and represent rare ClinVar pathogenic or likely pathogenic variants and rare loss of function variants, respectively. Variants in tiers 2 through 4 are analyzed through a phenotype-driven approach. Variants from each pipeline are assessed by a standardized process of manual curation. In five exome cases using four trio analyses and one quad analysis, Ingenuity filters narrowed an average of 312,347 variants per proband to 115 variants moved to manual curation. Average outputs per filter showed: call quality – 181322; allele frequency – 28047; variant type – 1057; phenotype-driven gene list – 372; and inheritance pattern – 38. For the same cases, STMP analysis averaged 3 Tier 0 and 74 Tier 1 variants.   Clinical reports from the sequencing cores have revealed 4 pathogenic variants returned to 2 UDN patients. In 11 total cases, the CUD manual curation has resulted in 13 candidate variants being sent for further evaluation by the UDN Model Organism Screening Core (9), by functional or splicing assays (2) or by a novel mosaic pipeline (2). In its first 6 months, the CUD curation pipeline has resulted in 4 presumptive diagnoses. The CUD sequencing pipelines for genetic analysis are valuable for identifying potential genetic diagnoses in patients with rare and undiagnosed disease.   .

1953F

Scaling variant calling to hundreds of thousands of samples with GATK. *L.D. Gauthier[1], D. Benjamin[1], K. Bergin[1], J.M. Bloom[1], Y. Farjoun[1], M. Fleharty[1], S. Lee[1], M. Lek[1,2], H. Li[1], V. Ruano-Rubio[1], T. Sato[1], M. Shand[1], E. Banks[1], D. MacArthur[1,2].* 1) The Broad Institute of Harvard and MIT, Cambridge, MA; 2) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA.

The modern age of high-throughput sequencing has enabled sequencing studies of unprecedented numbers of samples. Whether designed to increase power in GWAS studies or establish allele frequencies in healthy populations, these projects require careful control of batch effects that can arise from non-uniform bioinformatic processing. GATK's joint calling workflow is one approach to achieving that necessary consistency of variant calling and filtration. Joint calling further benefits studies of any design by producing genotype and confidence information for every sample at every genomic position called in any sample, clearly differentiating between lack of coverage and lack of alternate reads. While the runtimes of other variant callers scale exponentially with the number of samples, the modern HaplotypeCaller algorithm in GATK enables a more efficient linear runtime increase. This implementation underlies the Exome Aggregation Consortium releases, with the most recent exceeding 100,000 samples. Using a 50/50 mixture of two deeply characterized haploid cell line samples as our control data set, we performed variant calling and filtration on cohorts of increasing size from a few dozen samples to over 100,000. We are able to show that variant calling accuracy improves as cohort size is increased up to a few hundred samples. As cohort sizes reach thousands, tens of thousands or even hundreds of thousands of samples, variant calling accuracy is preserved for both SNPs and INDELs over the samples in the intersection of those call-sets. Furthermore, we found that sensitivity to singleton variants in the well-characterized sample is preserved as additional samples are added to the cohort. These results can be used to inform approaches for variant calling in large sequencing studies and particularly highlight the need to call all samples together in order to minimize batch effects and harmonize variant representation. Based on our results, in order to achieve maximum variant calling accuracy for smaller cohorts while minimizing bioinformatic runtime, we recommend joint calling with a panel of reference samples such that the total cohort size exceeds 200.

1954W

SCOTCH: A novel method to detect insertions and deletions from next-generation DNA sequencing data. *R.L. Goldfeder[1], E.A. Ashley[2].* 1) Biomedical Informatics, Stanford University, Stanford, CA; 2) Department of Medicine, Stanford University, Stanford, CA.

Clinical-grade genome sequencing and interpretation requires accurate and complete genotype calls for all interrogated positions. While single nucleotide variant detection is highly accurate and consistent, these variants explain only a small fraction of disease risk. Other types of variation that disrupt the open reading frame, such as insertions and deletions (INDELs), have systematically been shown to have dramatic effects on phenotype. However, current methods have low sensitivity for larger INDELs (>= five bases), primarily due to challenges surrounding aligning sequence reads that span complex loci. We present SCOTCH, a novel INDEL detection method that leverages signatures of poor read alignment, through machine learning approaches, to accurately identify INDELs from next-generation DNA sequencing data. Using biologically realistic simulated genomes and sequence reads with technologically representative error profiles (generated by ART), we evaluate SCOTCH and several currently available INDEL callers. We show that SCOTCH outperforms current methods, particularly for larger INDELs and INDELs within repetitive or low complexity regions. Finally, we demonstrate the clinical utility of SCOTCH through the identification of a large number of high quality novel INDELs within patients enrolled in the Stanford Clinical Genome Service and Stanford Undiagnosed Disease Network. This method will enable researchers and clinicians to more accurately identify INDELs associated with previously unexplained genetic conditions.

1955T

A random forest model for identifying LCL-derived mutations enabling the use of LCL DNA in rare de novo variant studies. *D. Kashef-Haghighi[1,4], L. Perez-Cano[2,4], E. K. Ruzzo[2,4], J.Y. Jung[1], L.K. Wang[2], S. Sharma[1], M. Duda[1], G. M. McInnes[1], J. K. Lowe[2], D. H. Geschwind[2], D. P. Wall[1,3].* 1) Division of Systems Medicine, Department of Pediatrics, Stanford University, Stanford, California, USA; 2) Center for Neurobehavioral Genetics and Center for Autism Research and Treatment, Semel Institute, David Geffen School of Medicine, University of California, Los Angeles, California, USA; 3) Departments of Psychiatry and Biomedical Data Science, Stanford University, Stanford, California, USA; 4) These authors contributed equally to this work.

With recent technical advancements, next-generation sequencing has become a powerful and cost-effective tool for the discovery of rare disease-causing variants. But often times the difficulty of obtaining sufficient amounts of DNA for library preparation and validation limits the scope of such studies. Lymphoblastoid cell lines (LCL) have been introduced as renewable sources of DNA to be used in human molecular studies. These immortalized cell lines are developed by infecting the peripheral blood lymphocytes from a donor using Epstein Barr virus (EBV). Although the ease of their generation and cultivation combined with the resulting unlimited DNA supply from the donor renders LCLs suitable for next-generation sequencing, their genomic instability poses a new challenge for the analysis of the resulting data. During prolonged culture, LCL cells accumulate new genetic changes that can appear as *de novo* mutations when sequence reads from parents and the offspring are compared. These LCL-specific genetic mutations are not easily distinguishable from true *de novo* variants and will confound the downstream analysis of genotype-phenotype association. As a result, *de novo* variants are often excluded from analysis in LCL studies unless they can be experimentally validated in the matched whole-blood DNA, which is expensive and not always feasible. In this work, we present a novel machine learning approach for distinguishing true *de novo* variants from LCL-specific genetic aberrations or other sources of artifacts such as sequencing and mapping errors. As part of the Hartwell Autism Research and Technology Initiative (iHART), we generated high coverage (~30x) whole-genome sequence data for 75 pairs of LCL monozygotic (MZ) twins that we have used to train our model. For the training, *de novo* mutations identified in both MZ twins were considered as true events, whereas discrepant calls were assumed to be either LCL or sequencing artifacts. Additionally, we also sequenced the whole-genome of 19 pairs of matched whole blood and LCL samples to serve as an independent test set for the evaluation of our final model. We have used a diverse collection of features including various variant and genome properties, and also annotations from the "Genome in a Bottle" project to train a random forest model achieving an area under the ROC curve of 0.96. We anticipate that this work will open up a practical avenue for utilizing LCL-derived DNA to identify rare genetic variants.

1956F

Normalizing genetic variation data from more than 100,000 human samples. *G. Saunders, C.Y. Gonzalez, J. Kandasamy, J.M. Mut, P. Arce, T. Smith, D. Spalding, H. Parkinson.* Variation Archives, European Molecular Biology Laboratory, European Bioinformatics Institute, Cambridge, United Kingdom.

A number of high-profile human genetic variation datasets are publically available e.g. 1000 Genomes, ExAC, deCODE and UK10K. However, these datasets are often prepared using independent methodologies or processing pipelines and can be accessed using only custom websites or FTP servers. We present the European Variation Archive (EVA) that acquires, normalizes and re-annotates variation data from the large datasets described above and datasets that are submitted directly to us. As the EVA variant collection includes all dbSNP variants and also consumes data from a number of other sources (e.g. ClinVar) our resource represents the largest collection of open-access genetic variation data available, worldwide. In total the EVA contains data from 57 studies, describing ca.154 million unique variants from more than 100,000 human samples. Access to these data is possible via the EVA website (www.ebi.ac.uk/eva) or API (http://www.ebi.ac.uk/eva/?API), where we offer the ability to search and/or download at the database, study or custom query level. The ability to download custom datasets is the single most powerful aspect of the EVA as this allows any user the ability to easily generate a single dataset, in a number of different file formats, which best addresses their research question (e.g. 'all missense variants within the BRCA2 gene with an allele frequency greater than 0.2'). From a technical perspective, our systems are based in modern and widely used technologies and all source code is completely open-access. Variation data are stored in a NoSQL distributed database and shared via a REST web services API, including a layer compatible with the Global Alliance for Genomics Health (GA4GH) API specification. Additionally, the website that consumes and displays these APIs has been developed using HTML5 and the ExtJS 6 framework for JavaScript. We shall also describe how our efforts are aligned with other initiatives such as Ensembl (http://www.ensembl.org/) and Open Targets (previously known as the Centre for Therapeutic Target Validation; https://www.opentargets.org/) and how the EVA serves as the data source for these resources thus providing examples of our long-term strategic plan where the EVA functions as a central genetic variation warehouse for the human genetics community.

1957W

Integrated transcriptome and methylome analyses identify novel genes involved in progression of non-alcoholic fatty liver disease (NAFLD) among Indians. *A. Chatterjee[1], K. Das[2], A. Basu[1], P. Singh[2], B. Dey[3], S. Roychowdhury[3], P. Pandit[3], B. Bhattacharya[3], N.P. Bhattacharyya[3], P.P. Majumder[1], A. Chowdhury[2,3], P. Basu[1,3].* 1) National Institue of Biomedical Genomics, Kalyani, West Bengal, India; 2) SDLD, IPGMER and SSKM Hospital, Kolkata, West Bengal, India; 3) Biomedical Genomics Centre, Kolkata, West Bengal, India.

Non-alcoholic Fatty Liver Disease (NAFLD), characterized by deposition of fat in liver, is a burgeoning health problem worldwide. Epidemiological studies suggest the prevalence of NAFLD in India is highly variable and ranges between 17% to 32%. The initial stage is Simple Steatosis (SS), characterized by the deposition of triglycerides (TG) in hepatocytes. SS is asymptomatic and selectively progresses to Nonalcoholic Steatohepatitis (NASH), characterized by the presence of hepatocyte injury and inflammation. NASH, in turn, is highly susceptible to end-stage liver disease. The molecular mechanisms underlying the heterogeneous outcomes of NAFLD remain vastly unclear. In this study, we aimed to identify the difference in transcriptome between the mild and advanced stages of NAFLD spectrum and its associated changes in DNA methylome. Whole transcriptome and DNA methylome data were generated on 25 mild and 20 advanced NAFLD liver biopsy tissue samples. 28 Differentially Expressed Genes (DEGs) were observed between the mild and advanced NAFLD. Among them, the most enriched pathway was found to be PI3-AKT-p70S6K pathway, which is involved in normal insulin functioning and its impairment cause insulin resistance. We also observed increased expression of fatty acid binding proteins (FABP4, FABP5, and FABP5L2) among advanced NAFLD, suggesting increased hepatic FFA uptake. Among the other DEGs, we observed upregulation of genes involved in protein synthesis regulation (ERAL1, RBM4B), cell cycle regulation (PRAP1, ZFP36), cellular structural integrity maintenance (KRT8, ITFG2, ATP6V1F) and response to oxidative stress and apoptosis (TMEM214, URM1), which provides evidence of deregulation in these pathways quite early in the disease spectrum. We also observed subtle differential methylation between the study groups. Significant negative correlation between promoter methylation and gene expression was observed for ATP6V1F and PRAP1.

1958T

Moving beyond GWAS: Characterizing the function of pubertal timing genes in early vertebrate development. *J.T Leinonen[1], Y.C Chen[2], H. Koivula[2], P. Panula[2], E. Widén[1].* 1) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 2) Neuroscience Center and Institute of Biomedicine, Anatomy, University of Helsinki, Finland.

Puberty represents a crucial developmental stage, the timing of which varies considerably between individuals. Genome-wide association studies have identified several genetic loci associating with pubertal timing. Some of these loci implicate evolutionarily conserved genes which are expressed already during the embryonic stages. Normal puberty requires appropriate fetal development, including the formation of the hypothalamus and gonadotrophin releasing neurons. Therefore, we hypothesized that some of the pubertal timing loci may interfere with these early developmental processes. Using zebrafish as a model, we aim to study the function of selected pubertal timing-associated genes including *lin28b,* establishing the spatio-temporal gene expression patterns in embryos, and assessing the impact of their downregulation and upregulation. We model gene downregulation using morpholino-antisense and CRISPR-Cas9 technologies, and upregulation by synthetic mRNA injections. The specificity of the morpholino-induced phenotypes is verified by mRNA-rescue. We assess the potential impacts on fish morphology and RNA expression both in embryos and adult fish. While the expression of *lin28b* in wild type fish is spatially unrestricted during the first 24 hours, and subsequently restricted to organ primordia including regions of the brain, our results suggest that transient alteration of *lin28b* expression in embryogenesis leads to profound alterations in fish development. Both mRNA-injections and morpholino-induced downregulation result in dose-dependent lethality and malformations visible already during 24hpf. However, our data based on non-lethal doses of morpholinos suggest that *lin28b* may also have a specific impact on genes regulating hypothalamic functions. Whereas the injection of non-lethal doses of *lin28b* morpholino had no effect on *gnrh3*–expression at the larval stages, *lin28b*-morphants showed reduced expression of *kiss2* in qPCR analysis (p<0.05). Moreover, our preliminary data show that fish injected with a dose of *lin28b* mRNA causing no discernible phenotypic effects in the embryos had significantly greater body length as adults compared to controls (p<0.005). These results suggest that even transient dysregulation of a puberty-associated gene during the embryogenesis may result in sustained alterations in growth during later development. We currently seek to assess how permanent *lin28b* knock-out based on our CRISPR-Cas9 model may impact on development and growth.

1959F

Epigenome-wide DNA methylation and non-alcoholic fatty liver disease in adolescence. *P.E. Melton[1], K.A. Lillycrop[2,3], K.M. Godfrey[3,4], D. Anderson[5], G.C. Burdge[6], M.S. Kobor[7], T.A. Mori[8], L.J. Beilin[8], J.M. Craig[9], J.K. Olynyk[10], J.D. Holbrook[11], C.E. Pennell[12], W.H. Oddy[13], E.K. Moses[1], L.A. Adams[8], R.C. Huang[8].* 1) The Curtin UWA Centre for Genetic Origins of Health and Disease, Faculty of Health Sciences, Curtin University and Faculty of Medicine, Dentistry & Health Sciences, The University of Western Australia; 2) Centre for Biological Sciences, Faculty of Natural and Environmental Sciences, University of Southampton, Southampton, UK; 3) NIHR Southampton Biomedical Research Centre, University of Southampton and University Hospital Southampton NHS Foundation Trust, Southampton, UK; 4) MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton, UK; 5) Telethon Kids Institute, University of Western Australia, Perth, Australia; 6) Academic Unit of Human Health and Development, University of Southampton; 7) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, Department of Medical Genetics, University of British Columbia , Vancouver, BC, Canada; 8) School of Medicine and Pharmacology, University of Western Australia Perth, Australia; 9) Environmental and Genetic Epidemiology, Murdoch Childrens Research Institute, Melbourne Australia; 10) Translational Medicine Head of Gastroenterology & Hepatology, Fiona Stanley and Fremantle Hospitals Western Australia; 11) Singapore Institute for Clinical Sciences (SICS), Agency for Science Technology and Research (A*STAR), Singapore; 12) School of Women's and Infant Health, University of Western Australia, Perth, Australia; 13) Menzies Institute for Medical Research, University of Tasmania, Hobart, Australia.

Non-alcoholic fatty liver disease (NAFLD) is closely linked to adiposity and insulin resistance. NAFLD itself is increasingly recognized as causing a substantial global health burden. Epigenetic modifiers are known to be involved in biological pathways involving lipid metabolism, insulin resistance, oxidative stress, and inflammation, which can induce hepatic fat accumulation and NAFLD. To investigate the association between DNA methylation and NAFLD in adolescence, we used the Illumina 450K Bead Chip to perform an epigenome-wide association study (EWAS) on DNA extracted from peripheral blood collected at age 17 years in 852 Western Australia Pregnancy Cohort (RAINE) participants. NAFLD was assessed using ultrasound as a quantitative trait with Hamaguchi's steatosis score, ranging from 0 (no NAFLD) to 6 (moderate to severe NAFLD), combined with daily alcohol consumption <10g for females and <20g for males. The association of NAFLD with genome-wide BMIQ (Beta Mixture Quantile dilation) normalized CpG probes was tested using linear mixed effects models for quantitative trait values and penalized logistic regression for binary values. Covariates included age, sex, ancestry principal components from GWAS and batch effects; independent models adjusting for either measured white cell count or estimated Houseman cell counts (CD8T, CD4T, NK, B cells, monocytes, granulocytes). Using a conservative Bonferroni correction (p=1.00E-07) for multiple testing we identified a genome-wide significant DNA methylation CpG probe for quantitative NAFLD (cg10144473, p=8.94E-09) located in a CpG island near the gene, *SLC2A1*. Genetic variants in this *SLC2A1* have previously been associated with NAFLD, and decreased expression of this gene has been shown in NAFLD liver biopsies. In addition, in vitro down regulation of siRNA *SLC2A1* using THEL2 cells has been shown to promote lipid accumulation and increased oxidative injury. Our most significant signal for NAFLD as a binary trait was in the gene *MTA3* (cg02679503, p=1.81E-07) that plays a role in maintenance of normal epithelial architecture but has not been previously associated with NAFLD. To our knowledge this represents the first EWAS for NAFLD in an adolescent cohort. We identify plausible known and novel candidate disease markers providing additional insight into the pathogenesis of NAFLD. .

1960W

Pro-inflammatory cytokines modulate the transcriptomic landscape of long non-coding RNAs in human islets of Langerhans. *S. Kaur[1], A.H. Mirza[1,2], J. Juan-Mateu[3], D.L. Eizirik[3], F. Pociot[1,2].* 1) Department of Pediatrics, Copenhagen Diabetes Research Center (CPH-DIRECT), Herlev University Hospital, Herlev Ringvej 75, Herlev DK-2730, Denmark; 2) Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen DK-1165, Denmark; 3) Center for Diabetes Research, Medical Faculty, Universite Libre de Bruxelles (ULB), Brussels, Belgium.

The pro-inflammatory cytokines released by the infiltrating immune cells in islets of Langerhans modulate the islet gene expression programming, resulting in destruction of insulin-producing β-cells and contributing to type 1 diabetes (T1D). Modulation of the expression of both protein-coding and non-coding RNAs (ncRNAs) contributes to this process. Recent studies have shown a pivotal role for long non-coding RNAs (lncRNAs) in various biological processes, including regulation of cell cycle and immune-mediated processes. Recently, the human islet transcriptome has been profiled using deep sequencing approaches. However, most of these studies have only focused on the protein-coding and small ncRNAs such as miRNAs facet of the islet transcriptome. We have presently used paired-end RNA sequencing to survey the transcriptomic landscape of ncRNAs in human islets from five donors under control conditions and following exposure to the pro-inflammatory cytokines IL-1β and IFN-γ. A total of 1,864 ncRNA genes and 12,194 protein coding genes were expressed in human islets (FPKM >1). Differential expression analysis comparing control vs cytokine exposed samples identified ~1,200 differentially expressed ncRNA genes, including lncRNAs and potential novel miRNAs (logFC ≥ 1.2, pval < 0.05). The expression of ncRNAs modulated by the pro-inflammatory cytokines suggests that they might be involved in regulating β-cell function. The precise molecular mechanisms through which these ncRNAs exert their function are presently under study in relevant cellular and sub-clinical models.

1961T

Novel and replicated DNA methylation loci associated with Type 2 Diabetes among sub-Saharan Africans – The RODAM Study. *K.A.C. Meeks[1], P. Henneman[2], A. Venema[2], A. Adeyemo[3], C. Agyemang[1].* 1) Department of Public Health, Academic Medical Center - University of Amsterdam, Amsterdam, The Netherlands; 2) Department of Clinical Genetics, Academic Medical Center - University of Amsterdam, Amsterdam, The Netherlands; 3) Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda MD, The United States.

Introduction: Several Epigenome Wide Association Studies (EWAS) have found significant DNA methylation at several loci associated with type 2 diabetes (T2D), including *ABCG1*, *SOCS3* and *TXNIP*. However, data are lacking on DNA methylation in relation to T2D among sub-Saharan African populations. We therefore aimed to identify DNA methylation loci that are significantly associated with T2D among Ghanaians. **Methods**: The participants consisted of 713 Ghanaians (256 with T2D, 457 controls) from the RODAM (Research on Obesity and Diabetes among African Migrants) Study. The Illumina 450k DNA-methylation array was used to profile methylation on whole blood samples. Association analysis was performed for T2D and adjusted for age, sex, blood cell composition and technical covariates. Body mass index (BMI) was added to the model in order to find T2D associated loci independent of BMI. A replication analysis was done for previously reported loci identified through a systematic literature search for EWAS or methylation studies for T2D. **Results**: The mean fasting glucose was 9.1 mmol/L for T2D cases and 5.0 mmol/L for controls. After Bonferroni adjustment five 450k probes (*cg19693031*, *cg04816311*, *cg00574958*, *cg03078690*, *cg07988171*) were significantly associated with T2D ($p < 5 \times 10^{-7} \sim q < 0.05$). The major hit on the *TXNIP* gene ($p = 2.6 \times 10^{-19}$) showed hypo methylation in T2D cases compared to controls and is located on chromosome 1 in a 3'UTR open sea region. Three out of five hits, located on genes *TXNIP*, *C7orf50* and *TPM4*, remained significant after adjustment for BMI. In replication analysis adjusted for BMI, 15 significant loci were found. The probes on *TXNIP* and *C7orf50* were again identified as the 2 major hits. *TXNIP* is involved in beta-cell biology and known to be in the T2D pathway. *C7orf50* has been previously associated with T2D in Mexican-Americans and Europeans. **Conclusions**: Our study has identified DNA methylation loci associated with T2D in sub-Saharan Africans, including some that have been reported in other populations. These results provide insight into the epigenetic loci and pathways that underly the risk of T2D in sub-Saharan Africans.

1962F

Epigenetic signature of impaired fasting glucose in the Old Order Amish. *M. Montasser, J. O'Connell, Y. Cheng.* Division of Endocrinology, Diabetes and Nutrition, and Program for Personalized and Genomic Medicine, University of Maryland School of Medicine.

Type 2 diabetes mellitus (T2D) is a common chronic disease with serious health consequences and substantial economic impact. Lifestyle changes can significantly alter the course of the disease if detected at an early stage. Beside genetics and environmental factors, epigenetic changes may also play a role in T2D development and progression. Recent studies found a strong association between DNA methylation and several T2D related traits. Also, different methylation sites were detected between T2D cases and healthy controls. These results suggest a DNA methylation signature may serve as a biomarker for early detection of increase T2D risk. The few studies examining the association between DNA methylation level and T2D are mostly cross sectional designs, thus cannot discriminate between changes in methylation that predate the illness and to those caused by it. To overcome this limitation we used a longitudinal study design to identify differentially methylated sites between 24 normoglycemic Old Order Amish (OOA) individuals who later developed impaired fasting glucose (IFG) (cases), and 24 OOA individuals who remained normoglycemic after an average follow up of 10 years (controls). Cases and controls were matched on age, sex, BMI, and baseline fasting glucose. Genome-wide DNA methylation profiling for the baseline whole blood was performed using the Illumina Human Methylation 450 bead chip. Out of 274,088 successfully tested probes, we identified 17,702 probes with p-value < 0.05 which is significantly higher than that expected by chance alone ($p=2.2E-16$, X^2 test). While no probe reached genome wide significance of 1.8E-7, we identified 34 probes with suggestive p-values <1.0E-4, 23 of which are located inside genes. Identified genes include *BTC* that plays a role in pancreatic cell proliferation and insulin secretion and *ITGA1*, a known bone mineral density (BMD) gene that was recently found to be associated also with T2D and related traits, providing a possible explanation of the link between T2D and BMD, as well as *RPTOR* and *TSC2* both are part of insulin signaling pathway. Out of 1,828 probes that were identified and replicated in previous studies, 1,219 were tested in our study and 80 of them had a p-value <0.05. If replicated, these results can shed light on the initiation of IFG and help to identify high risk individuals for early intervention.

1963W

Maternal diabetes results in aberrant buccal cell DNA methylation in infants with complex malformations. *K.V. Schulze[1], A. Bhatt[2], M.S. Azamian[1], N. Sundgren[2], G. Zapata[2], P. Hernandez[2], K. Fox[4], J.R. Kaiser[2,4], J.W. Belmont[1,2,3,5], N.A. Hanchard[1,3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) USDA/ARS/Children's Nutrition Research Center, Houston, TX; 4) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 5) Illumina, Inc., San Diego, CA.

   Uncontrolled maternal diabetes is a well-known teratogen, which causes a wide and highly variable spectrum of clinical phenotypes in offspring, including congenital malformations that can often mimic other genetic syndromes. Yet, the teratogenic mechanism of maternal diabetes remains largely elusive. In the absence of known genetic and alternative environmental causes, the diagnosis "infant of a diabetic mother" (IDM) has thus become one of exclusion. As a mediator between environment and gene expression, DNA methylation is a strong candidate for involvement in the teratogenicity of maternal diabetes. We analyzed IDM methylomes to investigate whether differences in CpG methylation could serve as biomarkers for the diabetic exposure. In order to identify large effects of maternal diabetes, buccal epithelial cells were collected within ten days of birth from infants diagnosed with diabetic embryopathy (n=7). DNA methylation profiles of these newborns were compared to those of healthy infants born to healthy mothers (n=6) using targeted enrichment methylation sequencing (CpGiant, Roche Nimblegen). Differentially methylated CpG sites (MethylKit, p<0.001, ≥10X coverage, with ≤10/1,000 better random permutations) were binned into regions, if they shared the same direction of effect and were within 1kb of adjacent sites. This resulted in 244 differentially methylated regions (DMRs) with ≥3 high-confidence sites showing a difference of ≥10% methylation, and ≥1 significantly differentially methylated CpG identified with a secondary method (MethylSig, p<0.05). Sixty-nine percent of DMRs overlapped known RefSeq genes, some of which have been associated with syndromes that coincide with the phenotypic spectrum of diabetic embryopathy. The majority of DMRs (87%) were hypomethylated and resulted in highly methylated sites transitioning to sites of intermediate methylation. Principal component analysis of all CpG sites within DMRs revealed a clear separation of diabetic embryopathy IDMs and controls, in addition to a split of the former from phenotypically less severe (n=9) and unaffected IDMs (n=6). Our findings demonstrate the added resolution and potential utility of methylation sequencing in a clinical context, imply that there may be large effects of maternal diabetes on offspring DNA methylation in buccal cells, and suggest the potential to use methylation profiles to distinguish the most severe infant phenotypes of maternal diabetes.

1964T

Adipose tissue DNA methylome changes in development of new onset diabetes after kidney transplantation. *Z. Sun[1], S. Baheti[1], Y. Zhang[1,2], P. Singh[3], J. Evans[1], M.D. Jensen[4], V.K. Somers[3], J.P. Kocher[1], H. Chakkera[5].* 1) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN, USA; 2) Department of Biostatistics and Computational Biology, University of Rochester, Rochester, NY, USA; 3) Department of Cardiovascular Diseases, Mayo Clinic, Rochester, MN, USA; 4) Division of Endocrinology, Mayo Clinic, Rochester, MN, USA; 5) Divisions of Nephrology & Hypertension, Mayo Clinic, Arizona, AZ, USA.

  Background. New onset diabetes after transplant (NODAT) is a complication that occurs in 25-30% of kidney transplant recipients in the first post-transplant year and reduces recipients' survival. The pathophysiology of NODAT is not well understood, but like type 2 diabetes mellitus (T2DM) it may be related to the insulin resistance and genetic and environment factors play a significant role. Epigenetic modifications such as DNA methylation are known to contribute to insulin resistance. The aim of this study was to investigate the role of DNA methylation changes in development of NODAT. **Materials and Methods.** Renal transplantation patients who developed NODAT and did not (control) were selected and matched on age, sex, BMI and other clinical characteristics. The DNA of fresh frozen adipose tissues was extracted for Reduced Representation of Bisulfite sequencing (RRBS). The genome-wide epigenome changes were compared between the NODAT and the control patients. Differentially methylated CpGs (DMCs) and differentially methylated regions (DMRs) were detected by beta binomial model and reginal summation. The involved genes were pursued for their functional relevance. They were also compared with known T2DM associated genes from GWAS studies. Single nucleotide polymorphisms (SNP) were detected from the RRBS data simultaneously and their potential association with NODAT was studied. **Results.** Compared to the control patients, the adipose tissue from NODAT patients had noticeable reduced DNA methylation in almost all the genomic regions except CpG islands (CGIs). DMC analysis showed 78,740 differentially methylated CpGs with p value < 0.05 and methylation difference >10%, among which 41,023 were hypo- and 37,717 hyper-methylated. Similar to overall methylation, these DMCs tended to be more hypermethylated in CGIs but hypo in other genomic regions. DMR analysis revealed 540 DMRs with 390 associated genes. These genes were significantly enriched in certain pathways known to be associated with insulin resistance. Furthermore, 5 of the DMR genes are known genes associated with the risk of T2DM development. Ten genes whose SNPs were associated with NODAT were also among the T2DM genes. Some SNPs were associated with DNA methylation. **Conclusions.** Genome-wide DNA methylation sequencing of adipose tissue revealed the role and loci of DNA methylation in the development of NODAT.

1965F

Insights into type 2 diabetes predisposition through transcriptomic characterization of 427 human pancreatic islet preparations. *M. van de Bunt[1,2], A. Viñuela[3,4,5], N. Oskolkov[6], P.E. MacDonald[7], M.L. Stitzel[8], S.C.J. Parker[9,10], InsPIRE Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, United Kingdom; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Swiss Institute of Bioinformatics, Geneva, Switzerland; 5) Institute of Genetics and Genomics in Geneva, University of Geneva, Geneva, Switzerland; 6) Department of Clinical Sciences, CRC, Lund University, Malmö, Sweden; 7) Alberta Diabetes Institute, University of Alberta, Edmonton, Canada; 8) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 9) Department of Human Genetics, Medical School, University of Michigan, Ann Arbor, MI, USA; 10) Department of Computational Medicine and Bioinformatics, Medical School, University of Michigan, Ann Arbor, MI, USA.

Genetic and physiological data support a central role for human pancreatic islet dysfunction in type 2 diabetes (T2D) pathogenesis. Genome-wide association studies have implicated numerous non-coding variants with T2D-risk, but the genes through which these variants act remain poorly characterized. To identify effector transcripts at association loci for T2D, we performed RNA-sequencing and genotyping in human islets from 427 cadaveric donors. Through exon-level eQTL mapping we identified variants significantly affecting expression levels in *cis* at 6039 genes (FDR<1%, 35.0% of total expressed genes). Conditional analysis identified an additional 1705 significant secondary eQTL signals at 1288 genes. Each gene was assigned an islet-specificity score by comparing its expression in islets against that in 16 other tissues. Using islet regulatory state information, we found that eQTLs for islet-specific genes were enriched in stretch enhancers. The enrichment was even stronger for secondary eQTLs compared to primary, suggesting the genetic regulatory architecture of cell specificity is encoded in distal stretch enhancers. Integrating islet eQTL data with genetic information on 82 known T2D-associated loci identified 11 genes where a significant (q<0.01) primary or secondary islet *cis*-eQTL was in strong linkage disequilibrium (r^2>0.9) with the T2D index variant. At one such locus, near *DGKB*, two independent T2D association signals are both linked to independent and directionally consistent *cis*-eQTLs for *DGKB*. Diacylglycerol kinase - *DGKB* encodes the beta isotype - metabolises the secondary messenger diacylglycerol, which plays an important role in insulin secretion. This makes *DGKB* a strong candidate gene for mediating the T2D association. To assess tissue-specificity of the overlap between eQTLs and T2D association signals, we called exon *cis*-eQTLs in 38 tissues in the GTEx v6 data using our pipeline. Given the smaller sample sizes (n=81-361), the number of significant primary eQTLs per GTEx tissue (n=209-3976) was lower than in the islet data. Across all non-islet tissues, 6 genes were linked to T2D associated loci, one of which (*AP3S2*) was also identified in islets. This means islet eQTLs are significantly enriched for overlap with T2D association signals (3.9-fold, p=6.8x10^{-3}) compared to all other GTEx tissues. Our results demonstrate the power of transcriptomic analysis in disease-appropriate tissues to deliver molecular insights in T2D pathophysiology.

1966W

Epigenome-wide association study (EWAS) in metabolic syndrome and its components. *M.L. Nuotio[1,2], N. Pervjakova[1,3], V. Salomaa[2], K. Kristiansson[1,2], M. Perola[1,2,3].* 1) University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare (THL), Helsinki, Finland; 3) University of Tartu, Tartu, Estonia.

Background: Metabolic syndrome (MetS) is a controversial entity, which encompasses a cluster of risk factors that have been found to significantly increase the risk of cardiovascular disease and type 2 diabetes mellitus. Genetic and metabolomic studies about the metabolic syndrome have so far produced rather modest biological information about this condition, suggesting that biological processes behind the entity are very complex and not easily interpreted. Studying epigenetic differences between individuals with metabolic syndrome and their healthy counterparts, as well as the epigenetic differences in each component of metabolic syndrome separately, can shed additional light on the complex genetic and epigenetic processes underlying the phenotype and give a needed push for the challenging research on cardiovascular disease and type 2 diabetes mellitus. **Methods:** We have tested the association between the level of methylation in CpG methylation sites across the genome and MetS status in individuals defined as cases or controls for metabolic syndrome with epigenome-wide linear regression where the M-value is corrected for age, sex, smoking and alcohol use. The association between the level of methylation in CpG methylation sites and the individual components of metabolic syndrome has been tested similarly. This study includes eligible individuals from Finnish FINRISK survey conducted in 2007 (Dietary, Lifestyle, and Genetic determinants of Obesity and Metabolic syndrome, DILGOM, study collected as an extension to the FINRISK 2007 survey) forming a total sample size of 517 individuals from whom the whole-blood DNA Illumina Infinium HumanMethylation450 BeadChip methylation data is available. **Results:** When comparing MetS cases and controls, various hyper- and hypomethylated CpG methylation sites were found across the genome. The strongest site reached the significance level of P=5.1x10^{-8} for association. Significant associations were also observed with glucose and lipid traits. **Conclusions:** In our study setting, various CpG methylation sites across the genome show altered levels of methylation. Given the challenging nature of epigenetic studies, further research is needed to interpret the biological implication of the findings. We believe however, that these results potentially point out novel functional sites across the genome that associate with biological processes underlying metabolic syndrome as an entity as well as related pathologies.

1967T

Gene-by-environment interactions in diet-induced epigenetic profiles.

C.R. Edillor[1], Y. Blum[2], B.W. Parks[1,2,4], L.D. Orozco[5], M. Pellegrini[3], A.J. Lusis[1,2,4]. 1) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Department of Medicine, Cardiology Division at the University of California Los Angeles, Los Angeles, CA; 3) Department of Molecular, Cell and Developmental Biology, University of California Los Angeles, Los Angeles, CA; 4) Department of Microbiology, Immunology & Molecular Genetics, University of California Los Angeles, Los Angeles, CA; 5) Department of Bioinformatics, Genentech Inc., South San Francisco, CA.

This study examines gene-environment interactions in obesity through the lens of epigenetics. Gene-environment interactions measure the effect of an individual's genotype in response to extrinsic variables such as diet. These interactions contribute to the heritability of complex phenotypes by capturing the effect of environmental modulation on underlying genetics. Gene-environment interactions are difficult to detect in human genetic studies due to variability in the environment of different individuals. The Hybrid Mouse Diversity Panel (HMDP) leverages natural genomic variation between different inbred mouse strains to isolate regions associated with complex phenotypes, while controlling for environment. To interrogate gene-environment interactions in diet-induced obesity, strains from the HMDP consumed a calorie-rich, high-fat, high-sucrose diet for 8 weeks. Clinical traits related to metabolism and adiposity were measured, and relevant tissues sampled for genomic analysis. While the inter-strain variability of obesity phenotypes is in part explained by nucleotide variation, epigenetic differences as a function of environment and genetics provide further insight into the genomic etiology of obesity and metabolic disease. This study uses reduced-representation bisulfite sequencing to examine global DNA methylation patterns in whole livers of 40 HMDP strains fed obesogenic (32% kcal fat) or chow (6% kcal fat) diets. Many biological processes regulating metabolism and adiposity occur in the liver. We identified variably methylated sites between strains and diets, suggesting diverse networks of epigenetic regulation following dietary perturbation. We are able to identify regions that vary in methylation as a response only to environment/diet; those that vary as a function of genetic background; and those whose response to diet depends on the genotype, indicating gene by environment effects. Overlapping these data with previously published expression and chromatin data in genetically diverse strains provides a multifactorial snapshot of metabolic disease etiology. In summary, this study identifies hepatic epigenetic mechanisms involved in genotype-environment interactions of diet-induced obesity.

1968F

Mechanistic and functional properties of the *KLF14 trans*-eQTL network associated to risk of type 2 diabetes.

J.S. El-Sayed Moustafa[1], J. Fernandez[2], M. Civelek[3], C. Glastonbury[1], M. Todorcevic[4], A. Mahajan[2], M. Horikoshi[2], A. Nag[1], I. Yet[1], M. Simon[5], G. Thorleifsson[6], U. Thorsteinsdottir[6,7], K. Stefansson[6,7], J. Bell[1], A.L. Gloyn[2,4], R. Cox[5], A. Lusis[8], F. Karpe[4], M. McCarthy[2,4], K. Small[1]. 1) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Department of Biomedical Engineering, University of Virginia, Charlottesville, VA; 4) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, UK; 5) MRC Harwell, Oxford, UK; 6) deCODE genetics/Amgen, Reykjavik, Iceland; 7) Faculty of Medicine, University of Iceland, 101 Reykjavik, Iceland; 8) School of Medicine, University of California, Los Angeles, CA.

Variants upstream of the transcription factor *KLF14* are associated with type 2 diabetes (T2D) and HDL cholesterol via adipose-specific *cis*-regulation of *KLF14* expression ($P=8.70\times10^{-37}$) and resultant *trans*-regulation of 385 genes. The *KLF14 trans*-network is remarkable both for its size and reproducibility, replicating in three independent adipose expression datasets ($N_{total}=2,826$), and thus provides a powerful model to investigate mechanisms of *trans*-regulation in humans and its role in disease pathogenesis. Mediation analysis supports a causal role for *KLF14* expression in *trans*-gene regulation. The dominant *trans*-regulatory mechanism appears to be direct interaction of KLF14 with *trans*-gene *cis*-regulatory elements; upstream regions of the *trans*-genes are enriched for KLF14 binding motifs (NES=4.17) and direct binding of KLF14 in Chip-Seq data ($P=2.0\times10^{-4}$). *Trans*-genes bearing KLF14 motifs are enriched for activity during adipocyte differentiation ($Q=3.85\times10^{-8}$), consistent with a proposed role for *KLF14* in progression through adipogenesis. A sub-network of 18 genes enriched for binding motifs of SREBF1, itself a *KLF14 trans*-gene, but not KLF14 (NES=4.22) were enriched for lipid metabolism pathways ($Q=3.24\times10^{-7}$) and may mediate the lipid GWAS phenotypes. The *KLF14 trans*-eSNP is also an adipose *trans*-meQTL; the *KLF14 trans*-network is enriched for *trans*-regulation of methylation levels by the *KLF14* eSNP ($N=542; P\leq2.2\times10^{-16}$). Consistent with the known function of *KLF14* as both a transcriptional activator and repressor, the *trans*-eQTL includes both positive and negative effects, however the *trans*-meQTL is biased towards negative effects, consistent with increased KLF14 occupancy. We find a direct link between a subset of *KLF14 trans*-genes and T2D: *cis*-eQTL variants at three *trans*-genes (*STARD10*, *c6orf57* and *CDK2AP1*) were coincident with genome-wide significant T2D variants; signals in some instances attributed to different genes. This suggests both *cis* and *trans* regulation of these genes can impact risk of T2D. Within the *KLF14* network, we also observe evidence of gene-gene interactions between the *KLF14 trans*-eSNP and *cis*-eQTL variants of the *KLF14 trans*-genes, and replicate four GxG *cis-trans* effects in an independent dataset ($N=770$). Results of in-depth exploration of functionality and regulatory mechanisms of the *KLF14 trans*-network thus provide a potential mechanistic basis for *KLF14 trans*-regulation of gene expression mediating its role in T2D pathogenesis.

1969W

variancePartition: Interpreting drivers of variation in complex gene expression studies. *G.E. Hoffman, E.E. Schadt.* Department of Genetics and Genomic Sciences, Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY.

As large-scale studies of gene expression with multiple sources of biological and technical variation become widely adopted, characterizing these drivers of variation becomes essential to understanding disease biology and regulatory genetics. We describe a statistical and visualization framework, variancePartition, to prioritize drivers of variation based on a genome-wide summary, and identify genes that deviate from the genome-wide trend. Using a linear mixed model, variancePartition quantifies variation in each expression trait attributable to differences in disease status, sex, cell or tissue type, ancestry, genetic background, experimental stimulus, or technical variables. Analysis of large-scale transcriptome profiling datasets illustrates that variancePartition recovers striking patterns of biological and technical variation that are reproducible across multiple datasets. Our open source software, variancePartition, enables rapid interpretation of complex gene expression studies as well as other high-throughput genomics assays. variancePartition is available on Bioconductor: http://bioconductor.org/packages/variancePartition.

1970T

An epigenome wide association study of BMI percentile in a family cohort with children and adolescents identified novel epigenetic loci influencing metabolic syndrome. *Y. Zhang[1,2], D. Cerjak[1,2], J.W. Kent Jr.[3], R. James[1,2], J. Blangero[4], M.A. Carless[3], O. Ali.[5].* 1) Medicine, Medical College of Wisconsin, Milwaukee, WI; 2) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 3) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX; 5) Pediatrics, Medical College of Wisconsin, Milwaukee, WI.

Background: Epigenetic mechanisms mediate the interaction between gene and environment and may play an important role in the obesity epidemic. Metabolic Syndrome (MetS), a clinical comorbidity of obesity, affects 30% of American population with a clustering of cardiovascular risk factors. Epigenetic mechanisms underlying MetS are largely unknown. *Methodology:* We conducted a comprehensive epigenetic study in which we assessed the relationship of DNA methylation in peripheral blood mononuclear cells (PBMCs) with body mass index percentile (BMI%), a clinical index for obesity in children and adults, at 485,000 CpG sites across the genome in multi-generational families of Northern European ancestry (8-90 years of age) using a discovery cohort (192 individuals) and a validation cohort (1,052 individuals). We also assessed gene expression at the most significant epigenetic site in a subset of the validation cohort consisting of 330 subjects. *Results:* After Bonferroni-correction ($p_{\alpha=0.05}$=1.31 x 10^{-7}) for genome-wide significance, we identified three loci, cg18181703 (*Suppressor of Cytokine signaling 3, SOCS3*), cg04502490 (*Zinc Finger Protein 771, ZNF771*) and cg02988947 (*LIM domain containing 2, LIMD2*) where methylation status was associated with BMI%, a clinical index for obesity in children and adults. These sites were also associated with multiple MetS traits including central obesity, fat depots, insulin responsiveness and plasma lipids. The *SOCS3* methylation locus was also associated with the clinical definition of MetS. In the validation cohort, *SOCS3* methylation status was found to be inversely associated with BMI percentile (p=1.75 x 10^{-6}), waist to height ratio (p=4.18 x 10^{-7}), triglycerides (p=4.01 x 10^{-4}) and MetS (p=4.01 x 10^{-7}) and positively with HDL-cholesterol (p=4.57 x 10^{-8}). Functional analysis in a sub cohort (333 individuals) demonstrated *SOCS3* methylation and gene expression in the PBMCs were inversely correlated (p=2.93 x 10^{-4}) and expression of *SOCS3* was positively correlated with status of MetS (p=0.012). *Conclusion:* We conclude that epigenetic modulation of *SOCS3*, a cytokine signaling regulator gene involved in leptin and insulin signaling, may play an important role in etiology of MetS and DNA methylation of this gene may have diagnostic, prognostic and therapeutic significance.

1971F

Identification of cis-eQTLs for co-expressed genes associated with body mass index. *E. Kim[1], M. Alvarez[1], K. Mohlke[2], M. Laasko[3], P. Pajukanta[1,4,5].* 1) Dept. of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Dept. of Genetics, University of North Carolina, Chapel Hill, NC; 3) University of Eastern Finland, Kuopio, Finland; 4) Bioinformatics Interdepartmental Program, University of California Los Angeles, Los Angeles, CA; 5) Molecular Biology Institute, University of California Los Angeles, Los Angeles, CA.

Obesity affects one third of adults in the U.S., and is known to increase the risk of metabolic syndrome, heart disease, stroke, and diabetes. Complex diseases can be attributed to complex gene regulation and expression, which in turn is determined by expression quantitative trait loci (eQTLs). We hypothesized that sets of co-expressed genes in adipose tissue can influence development of obesity. To elucidate the expression patterns that contribute to obesity, we obtained RNA-sequence data from subcutaneous adipose samples as well as imputed genotypes and phenotype data from the Finnish METSIM (n=793) and GTEx (n=283) cohorts. We conducted weighted gene co-expression network analysis (WGCNA) on each cohort to obtain co-expression modules correlated with body-mass index (BMI). We performed eQTL analysis on the imputed genotype data (MAF>5%) from each cohort with Matrix-eQTL to discover cis-eQTLs in the co-expressed gene modules. We found significant co-expression modules for BMI (adjusted P=0.00063) in METSIM that are highly preserved between populations: 578 out of 720 genes in the METSIM network modules for BMI were found in GTEx modules for BMI, indicating that these genes may play an integral role in regulating BMI across populations. Among the shared cis-eQTL SNPs ($\leq$1 Mb, FDR <5%) that affect the same gene in the same direction in both populations, we observed 6,440 cis-eQTLs (on average 55 SNPs/gene) associated with 118 of the 578 genes (20%) from the BMI-correlated modules. The large number of variants reflects the tight linkage disequilibrium among the imputed SNPs in some regions. Functional pathway analysis of the 118 shared cis-regulated genes and the 578 overlapping genes in the BMI-modules showed significant KEGG pathways (adjusted P<0.05) using the Webgestalt server. The KEGG pathways for the 118 genes included salivary secretion and carbohydrate digestion and absorption, and for the 578 genes, multiple inflammatory pathways, supporting the claim that the co-expression of these genes serves a functional purpose in regulating BMI. In conclusion, we identified a set of co-expressed BMI genes with shared cis-eQTL regulators across populations.

1972W

Landscape of obesity pathophysiology across 44 human tissues: Evidence for disease-relevance and causality through transcriptome sequencing. *T. Tukiainen[1,2], T. Pers[2], F. Aguet[2], P. Chen[1], P. Luukkonen[3], A. Rissanen[4], C. Lindgren[5], K. Ardlie[2], K. Pietiläinen[4], S. Ripatti[1,6,7].* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Minerva Foundation Institute for Medical Research, Helsinki, Finland; 4) Obesity Research Unit, Research Programs Unit, University of Helsinki, Helsinki, Finland; 5) The Big Data Institute, Li Ka Shing Centre for Health Information and Discovery, University of Oxford, Oxford, UK; 6) Department of Public Health, Faculty of Medicine, University of Helsinki, Finland; 7) Wellcome Trust Sanger Institute, Hinxton, UK.

Obesity is a world-wide epidemic with severe and diverse health consequences. To elaborate the mechanisms linking obesity to its many sequelae, we investigated the association of body mass index (BMI), a common measure for adiposity, with gene expression (GE) assessed via RNA-sequencing in 44 tissue types in 450 genotyped donors from the Genotype-Tissue Expression (GTEx) project. Together these tissues cover the majority of human body systems, thus providing an unprecedented opportunity to understand the obesity pathophysiology. We find BMI-GE-associations in several tissues (FDR<5%), including adipose and liver, but also skin and lung tissues. The BMI-associated genes are only partly shared between tissues (estimate for sharing, mean π_1=21%) indicating tissue-dependent processes. Gene set enrichment analyses further reveal the plethora of BMI-related alterations across human tissues: Besides replicating previously documented active inflammation and reduced mitochondrial function in adipose tissue ($P_{perm.}$<0.005), we, for instance, find that increased BMI associates with decreased sensory perception in skin ($P_{perm.}$=0.004) and with reduced male germ cell number in testis ($P_{perm.}$=0.034). Our analyses also reveal tissue-tissue interplay. E.g. most processes shared between adipose tissue and adrenal gland have an opposing direction of effect, suggesting possible compensatory mechanisms between these two endocrine tissues. Pointing to potential disease-relevance of these BMI-associations, we observe that genes implicated in genome-wide association studies (GWAS) are enriched among the genes highlighted in the BMI-GE analysis. E.g. GE-alterations in adipose tissue significantly overlap with GWAS loci for several autoimmune traits, including celiac disease and multiple sclerosis ($P_{perm.}$=0.001), underscoring the presence of inflammation in obesity and supporting epidemiological observations of suggested link between obesity and immune system function. To disentangle whether BMI is mediating these GE-changes or vice versa, we utilize Mendelian randomization, and find evidence for BMI causally driving several of the observed GE-changes (e.g. $P_{perm.}$<0.0001 in adipose tissue). In summary, these results highlight how widespread and diverse obesity-associated changes are in the human body. The new affected pathways and causal links identified provide potential avenues for the prevention and treatment of obesity complications.

1973T

Cardiometabolic GWAS variants colocalize with subcutaneous adipose tissue splice eQTLs (sQTLs). *C.K. Raulerson[1], Y. Wu[1], A. Ko[2], M. Alvarez[2], T.S. Furey[1,3], M. Laakso[4], P. Pajukanta[2,5], K. Molhke[1].* 1) Department of Genetics, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 3) Department of Biology, University of North Carolina, Chapel Hill, NC; 4) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 5) Molecular Biology Institute at UCLA, Los Angeles, CA.

Cardiovascular and metabolic diseases lead to substantial public health burden and increased mortality rates in the US and worldwide. Genome-wide association studies (GWAS) have identified >200 loci for cardiometabolic traits such as type 2 diabetes (T2D), LDL and HDL cholesterol levels, triglyceride levels, body fat distribution and adiposity traits. However, the variants, genes, and mechanisms that underlie these signals are not well understood. Expression of different isoforms, as identified by RNA-sequencing reads spanning splice junctions, may contribute to the mechanisms of these GWAS signals. To investigate genetic variants that influence the expression of different splice junctions, called splice-expression quantitative trait loci (sQTLs), we used genotypes and subcutaneous adipose tissue RNA-seq data (50-bp paired-end, avg. ~45M reads) from 792 Finns from the METabolic Syndrome in Men (METSIM) cohort. We first aligned these samples to the hg19 reference, using STAR-2pass, and implemented the newly-described LeafCutter algorithm to identify both novel and known splice junctions (n=313,192) expressed in our dataset. We quantile-normalized these splice junctions, adjusted for batch and RIN value, and performed association tests between splice junctions and 8.9 M genetic variants (MAF>0.01) using Matrix-eQTL. We identified 105,055 splice junctions with at least 1 sQTL at a chromosomal FDR<1%. Among these, we focused on sQTL variants in LD with a set of 1,231 cardiometabolic GWAS loci from the NHGRI-EBI GWAS catalog. We identified 87 sQTL variants at 72 genes for which the sQTL variant is in LD $r^2>=0.8$ with the lead GWAS variant. For example, at the T2D locus *POU5F1-TCF19*, we identified an intronic SNP (rs3094226) associated with two known splice junctions of the *CCHCR1* gene (best p=9x10^{-11}), which act in the same direction. This result suggests a potential role in T2D risk for *CCHCR1,* which encodes coiled-coil alpha-helical rod protein 1. We further identify 22 sQTLs for genes without a reported gene-level eQTL in adipose, suggesting that splicing may contribute to the mechanisms. At 31 GWAS loci, only one splice junction has an sQTL; among these, 24 tag a unique isoform and 7 tag a splice junction shared among isoforms, which may represent the aggregate gene. Taken together, these results suggest that sQTL analysis of RNA-seq data can aid with the interpretation of target genes and mechanisms at GWAS loci.

1974F

Transcriptomic profiles of liver biopsies from obese individuals reveal 15 genes for fatty liver. *A. Ko[1,2], D. Kaminska[3], E. Nikkola[1], M. Laakso[4], J. Pihlajamäki[3,5], P. Pajukanta[1,2,6].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Molecular Biology Institute at UCLA, Los Angeles, CA; 3) Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland; 4) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 5) Clinical Nutrition and Obesity Center, Kuopio University Hospital, Kuopio, Finland; 6) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, CA.

Obesity is a serious health problem, predisposing to cardiometabolic disorders and leading to non-alcoholic fatty liver disease (NAFLD) that may escalate to nonalcoholic steatohepatitis (NASH), cirrhosis, and cancer. However, not all extreme obese individuals exhibit NAFLD, suggesting genetic predisposition. To identify regulatory variants and genes affecting liver health, we genotyped 265 obese individuals (mean body mass index (BMI)=43.07) that underwent bariatric surgery and RNA-sequenced their liver biopsy samples. To estimate liver health, we performed a non-linear PCA on five different liver traits (inflammation, steatosis, fibrosis, liver cell degeneration, and clinical diagnosis) and used the first component as a meta-liver trait. By Weighted Co-expression Network Analysis, we identified 7 co-expressed gene modules associated with the meta-liver trait (P<0.0021) (referred as NAFLD-modules). The NAFLD-modules are enriched for natural killer cell mediated cytotoxicity (adjusted P=6.33x10^{-16}) and metabolic KEGG pathways (adjusted P=0.006). Differential expression (DE) between healthy liver (n=175) and NASH (n=43) based on clinical diagnosis revealed a significant upregulation of central metabolic functions in healthy liver, whereas in NASH, upregulation of autoimmune and cytotoxicity pathways prevails. NAFLD-modules are significantly enriched for DE genes vs. non-NAFLD modules (51.38% vs. 18.43%, P<0.0001), indicating a coordinated shift in transcriptional regulation between healthy liver and NASH. Finally, we carried out *cis*-eQTL (≤1MB) mapping (n=265) and identified 3,987 independent loci (R^2<0.1) regulating 3,128 genes. We compared the *cis* eQTL effect sizes in obese liver to non-obese liver from GTEx (n=96 subjects, mean BMI=26.7) and found 210 SNPs, differentially regulating 197 genes (adjusted P<0.05, Z-score), which are enriched for drug metabolism and metabolic pathways (adjusted P<0.05). Fifteen DE genes in 4 NAFLD-modules are also under this differential *cis*-eQTL effect, including *MTHFD1* (lead eQTL rs2987965), a key liver enzyme of folic acid metabolism, and *NR3C2* (lead eQTL rs6970169), a nuclear receptor associated with adverse cardiovascular outcomes. Overall, we discovered tight liver transcriptional control perturbed by NASH, and 15 genes that reside in key co-expressed gene networks associated with liver health and are distinctly *cis*-regulated in obese liver as well as differentially expressed between healthy liver and NASH.

1975W

RNA-sequencing reveals multiple sclerosis patients share similar pathways to Sjögren's syndrome anti-Ro negative patients. *I. Adrianto[1], J.A. Ice[1], A. Rasmussen[1], C.G. Montgomery[1], R.H. Scofield[1,2,3,4], G. Pardo[1], K.L. Sivils[1,2], R.C. Axtell[1], C.J. Lessard[1,2].* 1) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Department of Medicine, College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 4) Medical Service, Department of Veterans Affairs Medical Center, Oklahoma City, OK.

   Multiple sclerosis (MS) is an inflammatory and degenerative disorder of the central nervous system characterized by damage to the myelin sheath. Sjögren's syndrome (SS) is an autoimmune disease characterized by autoantibodies to Ro and/or La proteins and lymphocytic infiltration into exocrine glands. Even though MS and SS have different clinical manifestations, genetic studies have suggested that the underlying etiology is common in both diseases. We used RNA-seq to compare the expression of protein-coding and non-coding transcripts in 15 MS patients to SS anti-Ro positive (n=27) and SS anti-Ro negative (n=30) patients as well as 27 healthy controls. Whole blood RNA samples were isolated using the NuGEN Encore kit. Sequencing was performed using the Illumina HiSeq 2000. Raw FASTQ files were aligned to the human genome using Tophat. The read counts per transcript were generated using easyRNASeq in R. Differentially expressed (DE) transcripts were determined using DESeq with a false discovery rate adjusted P-value (P_{adj}) of 0.05 and a fold change (FC) of >2 or <0.5. Among the 2203 DE protein-coding regions, GRIN3B was the most DE transcript in the MS case-control analysis (P_{adj}=7.40x10^{-32}, FC=4.30). Of the 1849 DE non-protein coding transcripts, we observed DE of a long non-coding RNA (lncRNA) at 5p15.1 (P_{adj}=2.57x10^{-22}, FC=0.29). The biological relevance of these transcripts to MS is unclear. Relevant pathways from MS DE transcripts included synaptic transmission, nervous system development, and cell differentiation among others similar to those of SS anti-Ro negative patients. Using DE transcripts relevant to distinguish two groups of SS patients, we also found MS patients clustered together with SS anti-Ro negative patients in the principal component analysis plot. In addition, we observed the expression of interferon-inducible genes and the B-cell cytokine, APRIL, were significantly higher in SS anti-Ro positive patients compared to MS patients and to healthy controls. Our analysis shows that RNA profiles of MS patients are more similar to SS anti-Ro negative patients than the SS anti-Ro positive patients. This suggests that MS treatments may be beneficial for SS anti-Ro negative patients. Furthermore, these data have identified several putative DE in both coding and lncRNA regions in SS and MS. Further comparisons of different MS and SS subtypes are needed to confirm and expand these findings.

1976T

Single cell expression quantitative trait loci (eQTL) analysis of established systemic lupus erythematosus (SLE)-risk loci in lupus patient monocytes. *Y. Ghodke-Puranik[1], Z. Jin[1], W. Fan[1], M. Jensen[1], J. Dorschner[1], D. Vsetecka[1], S. Amin[2], A. Makol[2], F. Ernste[2], T. Osborn[2], K. Moder[2], V. Chowdhary[2], T. Niewold[1].* 1) Dept of Immunology and Division of Rheumatology, Mayo Clinic, Rochester, MN; 2) Division of Rheumatology, Mayo Clinic, Rochester, MN.

  Purpose: While most of the confirmed SLE-risk loci are in or near genes with immune system function, a major unanswered question is how these loci influence diverse immune cell subsets. In this study we performed a single cell eQTL analysis in human monocytes to determine impact of some well-established SLE-risk loci in single human monocytes.**Methods:** CD14++CD16-classical monocytes (CL) and CD14dimCD16+ non classical (NCL) monocytes from SLE patients were purified by magnetic separation. The Fluidigm C1 System was used for single cell capture and target gene pre-amplification and equal numbers of classical and non-classical monocytes were studied. Real time PCR was used to quantify expression of 90 monocyte-related genes, and the same SLE patients were genotyped for 7 SLE-risk SNPs to enable eQTL analysis. Non-parametric analyses were used with the single cell data in CL and NCL populations separately. **Results:** We observed a large number of significant eQTL associations that surpassed the 5% FDR, supporting the idea that single cell gene expression data allows for robust eQTL discovery. The SLE-associated SNPs demonstrated more eQTLs in NCLs as compared to CLs (p=2.5x10^{-8}). For a given SNP, the eQTL associated transcripts differed between cell types (p<0.001 for all 7 SNPs for discordance), suggesting that the same SNP resulted in different cellular events between the two monocyte subsets. When comparing eQTL lists between the different SLE-associated SNPs, there was a greater degree of sharing observed in NCLs as compared to CLs. Loci which shared a significant proportion of eQTL associations with each other in NCLs included TNFAIP3, IRF5, IRF7, PTPN22, and SPP1. In CLs, TNFAIP3 shared a large number of eQTLs with SPP1 and ITGAM, although SPP1 and ITGAM showed more limited overlap with each other. Thus, SLE-associated risk loci exert coordinated effects on gene expression within individual human monocytes, and the risk loci interact in different ways in different cell types.**Conclusion:** This study emphasizes the strength of single cell gene expression strategy for eQTL discovery. Our study revealed striking differences in the occurrence and interaction between of SLE risk associated eQTLs within different but closely related cell types. This suggests pleiotropic effects from each locus across various immune cell types, and a high degree of complexity when considering how these loci impact the immune system. .

1977F

Stimulating human CD4+ memory T cells uncovers cell state-dependent allelic expression enriched in risk genes for rheumatoid arthritis. *M. Gutierrez-Arcelus[1,2], S. Hannes[1,2], N. Teslovich[1,2], H.J. Westra[1,2], K. Slowikowski[1,2], D.A. Rao[3], J. Ermann[3], M.B. Brenner[3], S. Raychaudhuri[1,2,4].* 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Smith Building, 1 Jimmy Fund Way, Boston, MA 02115, USA; 4) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

A major challenge in autoimmune disease genetics is elucidating how genetic risk factors affect gene regulation in the specific cell-types and physiological states most relevant for each disease. Since allele specific expression is largely driven by genetic regulatory variation in *cis* (Buil *et al.* 2015), it is a powerful approach to study regulatory effects in multiple cellular states without the need of a very large sample size. Here we have analyzed the effects of genetic variation on gene regulation in varying cell states of CD4+ memory T-cells, a relevant cell-type for rheumatoid arthritis (RA) (Hu *et al*, 2011). As a pilot, we isolated CD3+ CD4+ CD45RO+ T-cells by negative selection with magnetic beads from the peripheral blood of a single healthy individual. We stimulated these cells with anti-CD3/CD28 beads and performed RNA-seq at 0, 4, 8, 12, 24 and 72 hours following stimulation. We then called heterozygous variants from RNA-seq data and measured allelic expression. We performed logistic regression to identify sites with significant allelic expression changes over time. In this high-resolution time course experiment, out of 3,578 tested heterozygous sites, we found 17 SNPs (FDR < 10%) with cell-state dependent allelic effects, overlapping 13 protein-coding genes. These effects reflect the activation or inactivation of genetic regulatory effects upon stimulation. We found a 2-fold enrichment of low P-values for SNPs in RA risk genes. We have now optimized the experimental set up to process 1M CD4+ memory T cells per time point coming from 80-100 mls of blood, and multiple genotyped individuals at a time. We are currently evaluating technical variation and we are in the process of expanding the experiment to 20 densely genotyped individuals. This will allow us to characterize disease-associated pathways affected by genetic regulatory variation at multiple stages during T-cell activation.

1978W

Polygenic burdens on cell-specific cytokine pathways are the risk of rheumatoid arthritis. *K. Ishigaki[1,2], Y. Kochi[1], A. Suzuki[1], Y. Okada[6], Y. Momozawa[3], Y. Kamatani[2], R. Yamada[5], K. Fujio[4], M. Kubo[3], K. Yamamoto[1,4].* 1) Laboratory for Autoimmune Diseases, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 2) Laboratory for Statistical Analysis, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 3) Laboratory for Genotyping Development, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 4) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Japan; 5) Statistical Genetics, Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 6) Department of Statistical Genetics, Osaka University Graduate School of Medicine, Osaka, Japan.

The mechanisms underlying genetic components of complex diseases are still not well-elucidated and becoming the major target of genetic research in the post-GWAS era. Comprehensive characterization of human genome by ENCODE Project demonstrated that GWAS-identified risk alleles are enriched within cell-specific regulatory regions. Although many eQTL studies have been conducted, majority of them utilized unfractionated peripheral blood or a few cell populations from European descents. The functional variation of immune cell subsets and the complexity of population specific haplotype structure prompted us to design cell-type specific eQTL study using Asian samples. We collected peripheral blood from 105 Japanese healthy volunteers and further sorted them into five major immune cell subsets (CD4+ T cells, CD8+ T cells, B cells, NK cells and monocytes). We quantified gene expressions and splice isoforms by RNA-sequencing and tested its association with neighboring common variants. We identified 8,204 genes with significant cis-eQTL effect and 2,226 genes with significant splicing-QTL effect at least in one subset (q-value < 0.05). Given that dysregulated transcriptome caused by multiple risk alleles is probably the major drivers of immune related complex diseases, the analysis which directly examines the causal abnormality in the transcriptome should be a more straightforward approach to detect fundamental mechanism of diseases than GWAS that targets the genome. Furthermore, this approach has potential to expand the analysis from individual genes into activity of relevant pathways. Based on such motivation, we developed a three-step analytical pipeline comprising i) prediction of individual gene expression using our eQTL database, ii) gene-level association study and iii) prediction of causal pathway activity. By applying our pipeline to two independent Japanese rheumatoid arthritis GWAS datasets (2303 cases versus 3380 controls and 2342 cases versus 5017 controls), we identified multiple candidates of cell-specific causal genes (8 novel genes with Bonferroni significance) and causal cytokine pathways (upregulation of TNF in CD4+ T cells and other 8 cytokines). Our approach is an efficient way to understand the biological mechanisms of genetic contributions on complex diseases.

1979T

DNA methyltransferase 1 inhibitor 5-aza-2'-deoxycytidine modifies gene expression profiles at the asthma-associated *ZPBP2-ORMDL3-GSDMA* region in human airway epithelial cells. *S. Moussette[1], A. Al Tuwaijri[2], H.-R. Kohan-Ghadr[1], R. Farias[3], J. Bérubé[3], S. Rousseau[3], A.K. Naumova[1,2,4].* 1) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) The Meakins-Christie Laboratories at the Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 4) Department of Obstetrics and Gynecology, McGill University, Montreal, Quebec, Canada.

Chromosomal region 17q12-q21 is associated with asthma and harbors regulatory polymorphisms that influence expression levels of three genes: *zona pellucida* binding protein 2 (*ZPBP2)*, gasdermin B (*GSDMB)* and ORMDL sphingolipid biosynthesis regulator 3 (*ORMDL3*). The 17q12-q21 genotype and asthma also influence promoter methylation levels of *ZPBP2* and gasdermin A (*GSDMA*). DNA methylation differences between asthmatic and non-asthmatic subjects are very small, which raises the question of whether such small changes in methylation levels are sufficient to cause significant effect on gene expression. Therefore, the functional significance of inter-individual variation in methylation levels in this region had to be established. To clarify the role of DNA methylation in the genetic control of gene expression in the 17q12-q21 asthma-associated region, we examined the impact of DNA methyltransferase 1 inhibitor 5-aza-2'-deoxycytidine (5-aza-dC) on DNA methylation of regulatory elements and gene expression in the human airway epithelium cell line NuLi-1. NuLi-1 cells were treated with 0.5 μM 5-aza-dC for 24h and harvested after 7 days in culture for DNA and RNA extraction. Expression levels of 5 genes, IKAROS family zinc finger 3 (Aiolos) (*IKZF3*), *ZPBP2*, *GSDMB*, *ORMDL3* and *GSDMA* residing in the asthma-associated region, were determined using quantitative RT-PCR. Allelic expression was characterized using RT-PCR followed by Sanger sequencing. Promoter DNA methylation was assessed using the sodium bisulfite sequencing assay. 5-aza-dC treatment reduced promoter methylation levels (11% to 30%) and upregulated *ZPBP2* (19-fold)*, GSDMB* (4-fold) and *GSDMA* (5.7-fold) expression. Therefore, our data show that moderate reduction in promoter methylation results in dramatic upregulation of gene expression. Analysis of allelic expression showed no change in allelic ratios of *IKZF3*, *GSDMB* and *GSDMA*; however allelic expression of *ZPBP2* and *ORMDL3* was modified. We conclude that modest changes in promoter methylation levels may have a significant impact on RNA levels. Furthermore, allelic expression of *ZPBP2* and *ORMDL3* depends on DNA methylation, whereas allelic expression of *IKZF3*, *GSDMB* and *GSDMA* does not.

1980F

Novel statistical and experimental approaches for quantifying the X chromosome inactivation landscape using RNA-seq data. *D. Liu[1], L. Carrel[2].* 1) Department of Public Health Sciences, Penn State University, Hershey, PA; 2) Department of Biochemistry and Molecular Biology, Penn State University, Hershey, PA.

X chromosome inactivation (XCI) is a cellular mechanism which randomly silences one female chromosome in each cell (i.e. the inactive X chromosome - Xi) and only express alleles on the active X (Xa) for most genes. However, a subset of genes is known to escape XCI, and expressed from both alleles. It is well known that XCI escape is variable across different individuals and may be genetically regulated. A key step to understand XCI regulation is to quantify the XCI status. Direct assignement of the Xa or Xi is complicated by the mosaic nature of XCI. In order to properly analyze broadly available RNA-seq dataset, we developed a novel empirical Bayes method to infer the XCI status. The method first calculates the XCI skewness using a training set of 177 genes known to be inactivated, and compares the genic allelic expression with the estimated skewness. Genes that have different allelic imbalance from the skewness are likely to escape XCI. In order to improve power, we also borrow strength across samples by assuming realistic parametric distribution on the read depths and allelic expression levels and estimate the posterior probability for each gene to escape XCI using a new approximate empirical Bayes method. Applying these methods, we analyzed the female samples from GEUVADIS. After rigorous quality control and the correction of reference bias, 670 genes are informative for allelic inference and contain at least 1 heterozygous SNPs. We identified 375 genes to be X inactivated, while 207 genes are classified as variable escape genes and bi-allelically expressed in >15% of the samples. We validated our approaches using multiple lines of evidence. First, pseudo-autosomal (PAR) genes are expected to escape XCI and importantly 10 of 11 PAR genes were correctly classified. Next, we also observe high concordance between escape genes identified by our method and by male/female differential expression. 72% of genes identified with significant Xi expression levels are replicated by differential expression analysis. Finally, to confirm or refine estimates of XCI skewing and inference of XCI escape in mosaic LCLs, we selected a mosaic LCL and isolated single-cell derived lines with complete non-random XCI of the maternal or paternal Xi. In these lines, the number of reads that over one X directly reflects XCI escape without the need to infer XCI skewing. The analysis of the experimental data is on-going, and will be used to confirm our findings and methods.

1981W

Regulatory fine mapping resolves shared and distinct associations to multiple diseases in the same locus. *P. Shooshtari[1,2], C. Cotsapas[1,2,3].* 1) Department of Neurology, Yale University, New Haven, CT; 2) Medical and Population Genetics and Stanley Center for Psychiatric Research, Broad Institute of MIT-Harvard, Cambridge, MA; 3) Department of Genetics, Yale University, New Haven, CT.

Genome-wide association studies (GWAS) have identified hundreds of loci mediating risk to autoimmune and inflammatory diseases (AID). These diseases are co-morbid, and many risk loci harbor associations to multiple AID. However, causal variant identification is confounded by linkage disequilibrium (LD), so it remains difficult to conclude that these associations represent true pleiotropic effects. As most GWAS associations are driven by alterations to gene regulation, we still lack systematic approaches to identify pathogenic genes. To address this problem, we have developed a systematic approach to identify regulatory regions mediating

risk in associated loci. We first fine-map each association to identify credible interval (CI) variants likely to be causal, then overlay these on to regulatory regions identified by DNase I hypersensitivity (DHS) in the Roadmap Epigenomics Project to calculate the posterior probability of a DHS mediating risk. We depart from standard practice by first clustering DHS peaks across 56 replicated tissues, and identifying clusters of DHS peaks that statistically replicate across samples. We then correlate the accessibility of these peaks in each tissue to expression levels of nearby genes. By combining the correlation between DHS and gene expression and the posterior probability of a DHS mediating risk, we calculate a posterior probability of association for each gene in the region. We use this method to dissect 24 loci with strong evidence that risk of at least two AID diseases is mediated by DHS. Within these loci, we found that the most highly associated SNPs are often different between disease associations, but our model identifies the same genes as causal (Fisher's exact test p=0.014). One striking example is the BACH2 locus on chromosome 6q15, where our analysis prioritizes MDN1 for autoimmune thyroid disease, multiple sclerosis, type 1 diabetes, and possibly for celiac disease, but a distinct effect on MAP3K7 for IBD, despite the strongest associations being present in an intron of the BACH2 gene. Thus, our approach can overcome the lack of resolution inherent in genetic mapping to resolve shared associations across traits by considering the likely functional effects in a locus.

1982T

Insights into differentiation and diseases of blood cells from (epi)genomics. *R.C. Hardison[1], Y. Zhang[1], C.A. Keller[1], B. Giardine[1], L. An[2], F. Yue[2], E. Hueston[3], D. Bodine[3].* 1) Departments of Biochemistry and Molecular Biology and of Statistics, Pennsylvania State University, University Park, PA; 2) Department of Biochemistry and Molecular Biology, Pennsylvania State University, Hershey, PA; 3) Genetics and Molecular Biology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Statement of purpose: Differentiation of multipotent stem and progenitor cells into mature cells of different lineages proceeds by the precisely regulated expression of distinct cohorts of genes defining each cell type. Genetic variants in the DNA sequences that regulate gene expression (cis-regulatory modules or CRMs), such as enhancers and promoters, are strongly associated with complex traits including disease susceptibility. Thus it is important to identify CRMs reliably and connect variants in them to phenotypic effects. **Methods used:** We have generated genome-wide datasets for transcriptomes (RNA-seq) and the regulatory landscape (chromatin accessibility revealed by ATAC-seq) for mouse primary hematopoietic stem and multilineage progenitor cells. These features plus specific transcription factor (TF) binding and histone modifications were determined in mature cells and informative cell lines. All these data plus complementary data from other laboratories and consortia (including chromatin interaction frequencies) are being integrated using formal statistical modeling. One approach identifies chromatin states in two dimensions, along chromosomes and across cell types, using our new Integrative and Discriminative Epigenome Annotation System (IDEAS). This method substantially improves the identification of cell type-specific changes in inferred regulatory activity. **Summary of results:** Further analysis of the primary and integrated data gives new insights into relationships among cell types, global predictions of common and cell type-specific CRMs, prediction of gene targets for regulation, and identification of groups of transcription factors acting at a common site. Two examples of insights gleaned are described here. (1) We find limited changes in the regulatory landscape among stem and progenitor cells, whereas the landscape and transcriptional profile changes dramatically in the erythroid lineage, perhaps during commitment. Megakaryocytes are surprisingly close to multilineage progenitor cells. (2) Experimental tests of CRMs predicted by different criteria emphasize the importance of binding by key transcription factors or co-activators, whereas more general features such as histone modification profiles and chromatin accessibility give more false positives. Ongoing work aims to define quantitative, multi-CRM models for regulation that apply globally.

1983F

Non-coding sequence variants within cell type restricted DNA hypomethylated regions are significantly associated with tissue specific phenotypes. *E. Hodges[1], R.T. Levinson[1], D.C. Rinker[1], B. Chen[1], D.C. Samuels[1], A.D. Smith[2], J.A. Capra[1].* 1) Vanderbilt Genetics Institute, Vanderbilt University School of Medicine, Nashville, TN; 2) Molecular and Computational Biology section, Division of Biological Sciences, University of Southern California, Los Angeles, CA.

The use of functional genomic data is crucial to drawing biological links between non-coding sequence variants identified in Genome-wide association studies (GWAS) and their associated phenotypic states. In particular, the disruption of gene regulatory sequences has been experimentally shown to contribute to the mis-expression of genes in certain cellular contexts, implying that SNPs located around gene regulatory elements become functionally relevant within a limited cell-type context. However, these expression changes can be subtle and are often subject to developmental timelines, making the links between sequence disruption and phenotype difficult to detect. We have shown that patterns of non-coding DNA methylation, and specifically discrete regions of hypomethylation, distinguish the identities of different cell-types. Moreover, comparative profiling of intergenic and intronic hypomethylation (iHMRs) may be used not only to index putative enhancer elements, but, unlike DNase hypersensitivity and other measures of chromatin state, may also reveal the most functionally restricted subset of enhancers for the cell type in question. We hypothesized that SNPs within these regions are more likely to exhibit non-pleiotropic links to phenotype, compared to SNPs in iHMRs broadly shared among tissues. As proof of concept, we performed comparative genome-wide methylation profiling to identify a highly specific set of iHMRs in primary human lymphocytes, and intersected these regions with the NHGRI catalogue of GWAS SNPs. Among all HMRs identified, the lymphocyte specific iHMRs were highly enriched for GWAS SNPs (1-Binomial Dist., 0.0006) and were associated with immunological and inflammatory disorders. We then rationalized that SNPs located in lymphocyte iHMRs were more likely to reveal associations with immunological phenotypes than other traits. Thus, taking the inverse approach to GWAS, we performed Phenome-wide association studies (PheWAS) for all genotyped SNPs proximal to lymphocyte iHMRs, and used aggregated ICD9 codes from the electronic medical record to approximate phenotypes for ~5500 individuals. Our approach revealed numerous novel, high ranking SNPs (p-value <0.0005) associated with immune-related phenotypes, including lymphocytic neoplasms and deficiencies in humoral immunity. We demonstrate the power of combining PheWAS with epigenetic information to detect biological links between non-coding SNPs and their associated phenotypes.

1984W

Insights into DNA methylation changes in placental tissue and cells during chorioamnionitis. *C.R. Konwar[1,2], M.E. Price[1,2], M. Penaherrera[1,2], A. Beristain[2,3], W.P. Robinson[1,2,3].* 1) Dept. of Medical Genetics, University of British Columbia, Vancouver, British Columbia , Canada; 2) Child and Family Research Institute, British Columbia, Vancouver; 3) Dept. of Obstetrics and Gynecology, University of British Columbia, Vancouver BC.

Introduction: One of the major causes of spontaneous preterm birth is inflammation of the placenta and associated membranes, known as chorioamnionitis (CA). Identification of DNA methylation (DNAm) signatures in the placenta that reflect in utero conditions may provide candidate markers for earlier diagnosis of inflammation. Inflammation in the placenta is associated with an increase in placental-specific macrophages, Hofbauer cells (HCs). DNAm signatures differ strikingly between different cell lineages and can change with i) gestational age and ii) placental pathology. We proposed that increases in HC number might be detectable in placentas affected by CA by measuring placental DNAm. Methods: Pooled placental samples (chorionic villi) isolated from multiple biopsies taken from the fetal side of the placenta from 12 CA cases and 12 preterm births without other pathology (controls) were run on the Illumina HumanMethylation450 BeadChip array (450K array). Additionally, HC cells isolated from 5 independent term samples were profiled using the 450k array. Results: We identified 18 differentially methylated sites associated with CA status based on i) statistical significance (False Discovery Rate, <5%); and ii) biological significance (magnitude of methylation difference, Δβ>0.1). The majority of these sites were associated with immune-system genes including *Orosomucoid 1* which is known to increase in response to infection. When HCs were compared to chorionic villi we identified 10,739 differentially methylated sites. Three of the 18 CA-associated sites were also differentially methylated in the same direction in this chorionic villi to HC comparison. Additionally, reference-free cell type correction algorithm, an R package tool, identified 7 of 18 CA-associated sites as cell type-associated DNAm signatures. Conclusion: DNAm profiling can be useful to understand the aetiology of placental inflammation. CA-associated placentas showed altered DNAm signatures which are not observed in the absence of inflammation. These changes are consistent with changes in innate immune function and may reflect both increased numbers of immune cells as well as altered function.

1985T

Application of chromatin profiling by ATAC-seq to understand the functional genomic landscape of psoriasis. *A. Lledo Lara[1], A. Sanniti[1], I. Pulyakhina[1], M.H. Al-Mossawi[2], D. Gutowska-Owsiak[3], P. Bowness[2], A. Berlanga-Taylor[1,4], G. Ogg[3], J.C Knight[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) The Botnar Research Centre, NDORMS, University of Oxford, Oxford, United Kingdom; 3) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom; 4) St Marys' Hospital, Imperial College London, London, United Kingdom.

Psoriasis is a chronic inflammatory skin disease which may be associated with chronic arthritis manifesting as psoriatic arthritis (PsA). Both are complex diseases with strong heritability and genetic association, notably involving HLA-C*06:02. Genome-wide association studies (GWAS) have also identified more than 40 additional loci, the majority involving non-coding regulatory variants. Understanding the functional role and impact of these variants in disease aetiology still remains challenging, requiring application of bioinformatics and experimental approaches in a disease setting and cell-specific relevant context to resolve functional causal variants. We have applied transposase-accessible chromatin (ATAC-seq) profiling to keratinocyte-enriched cell populations obtained from epidermal sheets of uninvolved and lesional psoriatic skin biopsies. ATAC-seq results show nucleosomal periodicity in fragment size distribution and enrichment in overlap with DNase-I hypersensitivity ENCODE data from primary cultured keratinocytes relative to other cell types. However, we find high background limiting further application of this approach in this setting despite optimisation. We are now extending the approach to generate complementary ATAC-seq data for different immune cell types (including CD14+ monocytes, CD4+, CD8+ and CD19+) derived from synovial fluid and/or peripheral blood of psoriasis vulgaris and PsA patients. We conclude that the low sensitivity of ATAC-seq in skin currently impairs the use of the data for comparison of regulatory landscapes across lesional skin and different immune cell types. Integration of chromatin and transcriptional profiles generated in primary immune cells will be potentially informative in revealing cell and context specific differences in the regulatory landscape and it may help to prioritise GWAS variants associated with disease. Overall, this novel approach could contribute to better understand the mechanisms of action of non-coding variants in a disease and cell specific manner.

1986F

***In utero* tobacco smoke exposures and DNA methylation in a study of asthma in Latino children.** *A.M. Neophytou[1], S.S. Oh[2], D. Hu[2], C. Eng[2], S. Huntsman[2], F. Lurmann[3], L.N. Borell[4], S. Sen[5], H.J. Farber[6], K. Meade[7], P.C. Avila[8], D. Serebrisky[9], W. Rodriguez-Cintron[10], R. Kumar[11,12], J.R. Rodriguez-Santana[13], J.R. Balmes[1,2], E.A. Eisen[1], E.G. Maternal tobacco smoking during pregnancy has been linked to several health problems in children, including asthma. Minority children are not only disproportionately affected by asthma, but are also more likely to be exposed to asthma risk factors such as *in utero* tobacco smoke exposures. We investigated the relationship between self-reported maternal smoking during pregnancy (*in utero* smoking) and DNA methylation at 26 specific CpG sites previously linked to *in utero* tobacco smoke exposures, and further examined the association between methylation at these sites and asthma status in a sub-sample of 573 Latino children from the Genes-environments & Admixture in Latino Americans study (GALA II). We assessed associations between percent methylation and self-reported exposures in linear regression models adjusted for age, sex, ethnicity, recruitment region and cell-type heterogeneity, and used logistic regression models to examine associations between asthma status and methylation adjusting for the same covariates. The relative methylation difference between exposed and unexposed at 25 out of 26 CpGs was in the same direction as previously reported, and was statistically significant at 14 of the CpG sites. Methylation was associated with asthma status for six CpGs; five of the six sites were also a subset of the 14 sites where self-reported maternal smoking was found to be a significant predictor. The largest magnitude association was within the *EXT1* gene, which encodes a protein found in the Golgi apparatus. A 1% increase in methylation at a CpG site within this gene corresponded to an 18% reduced odds for asthma in our population (odds ratio = 0.82, 95% confidence interval: 0.75– 0.90). Methylation of another gene involved in the regulation of detoxification of compounds found in tobacco smoke, *AHRR,* had three different locations within the gene that were also associated with asthma status in our study population. A 1% increase in methylation at any of these three *AHRR* CpG sites corresponded to an approximate 10% reduced odds for asthma. The above results were similar in a sensitivity analysis adjusting for global genetic ancestry. Our results suggest that DNA methylation is likely an important mechanism for the adverse effects of *in utero* tobacco smoke exposures on asthma.

1987W

Epigenetic regulation of innate immune responses. *A. Pacis[1,2], L. Tailleux[3], F. Mailhot-Léonard[1,2], V. Yotova[1], A. Dumaine[1], J.C. Grenier[1], L.B. Barreiro[1,4].* 1) CHU Sainte-Justine Research Center, Department of Genetics, Montreal, Quebec, Canada; 2) Université de Montréal, Department of Biochemistry, Montreal, Quebec, Canada; 3) Institut Pasteur, Mycobacterial Genetics Unit, Paris, France; 4) Université de Montréal, Department of Pediatrics, Montreal, Quebec, Canada.

The first immune mechanisms recruited to defend against invading pathogens are those associated with innate immune cells, such as dendritic cells (DCs) or macrophages. Once they sense an intruder, these cells rapidly induce sophisticated transcriptional programs, which are regulated through a series of epigenetic changes related to histone modifications. Yet, we still know remarkably little about other epigenetic mechanisms, notably DNA methylation, in controlling transcriptional responses to infection. This is due to the belief that methylation marks are highly stable, and unlikely to respond to environmental perturbations on a short time scale. Recently, previous work from our laboratory, has shown that DNA methylation patterns can rapidly and actively change (in contrast to passive changes during cell replication) in response to infection and, are strongly associated with differentially expressed genes induced by infection. However, it still remains unclear whether changes in methylation are a cause or consequence of changes in gene expression during infection. Here, we used a combination of genomic and statistical approaches to study the causal relationship between dynamic changes in DNA methylation and changes in gene expression, during infection. Specifically, we infected DCs with a pathogenic strain of Mycobacterium tuberculosis (MTB), the causative agent of tuberculosis (TB) in humans, at different time-points (2, 18, 24, 48 and 72 hours). Following infection, we collected DNA methylation data across thousands of target regions, in non-infected and MTB-infected DCs, using capture-based bisulfite sequencing. In parallel, we collected RNA sequencing data to be able to characterize genome-wide patterns in gene expression. We observe that changes in gene expression tend to occur *prior* to detectable changes in DNA methylation. Moreover, we observe that loss of methylation in a handful of CpG sites remain stable even if expression of the associated gene reverts back to basal state. This work will yield unprecedented insights on the role of active changes in DNA methylation in the control of transcriptional responses to infection and ultimately, may lead to the implementation of novel preventive strategies against infectious diseases and other immune-related disorders.

1988T

Defining the cell specific transcriptional and regulatory landscape in patients with ankylosing spondylitis. *A. Sanniti[1], I. Pulyakhina[1], A. Lledó Lara[1], K. Plant[1], G. Scozzafava[1], K. Doig[2], J. O'Donoghue[2], P. Bowness[2], J. Knight[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Botnar Research Centre, NDORMS, University of Oxford, United Kingdom.

Ankylosing Spondylitis (AS) is an inflammatory disease with high genetic heritability, the strongest genetic association being with HLA-B27. Genome Wide Association Studies have now identified at least 43 independent associations throughout the genome, but the understanding of how these associations relate to genes involved in disease aetiology are currently largely undetermined. We have begun to answer this question by recruiting AS patients through the GENExpressID study (Genetics of Gene Expression in Immune-related Diseases) for RNA-seq and ATAC-seq (Assay for Transposase-Accessible Chromatin with high-throughput sequencing) analysis. We present data for 10 AS patients and controls, sequenced for mRNA and miRNA in up to 6 immune cell types. This data defines transcriptional activity in CD14+ monocytes, CD4+, CD8+, CD19+, CD16+ and NK cells, the role of which in AS remains unresolved. We integrate this transcriptomics data with chromatin profiling for AS patients, defining the disease specific regulatory landscape compared to healthy matched controls demonstrating the effects before and after starting biologic therapy. This integrated approach will aid in prioritising variants associated with disease, and advance our understanding of the underlying mechanisms of action.

1989F

Converging disease genes in ICF syndrome: *ZBTB24* **controls expression of** *CDCA7* **in mammals.** *S.M. van der Maarel[1], H. Wu[1], P.E. Thijssen[1], E. de Klerk[1], K.K.D. Vonk[1], J. Wang[1,2], B. den Hamer[1], C. Aytekin[3], L. Daxinger[1].* 1) Human Genetics; S4-P, Leiden University Medical Center, Leiden, Netherlands; 2) Institutes of Biology and Medical Sciences, Soochow University, Suzhou 215123, China; 3) Department of Pediatric Immunology, Dr Sami Ulus Maternity and Children's Research and Educational Hospital, Ankara, Turkey.

For genetically heterogeneous diseases a better understanding of how the underlying gene defects are functionally interconnected will be important for dissecting disease etiology. The Immunodeficiency, Centromeric instability, and Facial anomalies (ICF; OMIM 242860/614069) syndrome is an autosomal recessive disorder characterized by immunodeficiency, developmental delay and facial anomalies. Based on the underlying genetic defects, ICF syndrome can be divided into at least five different clinically indistinguishable subgroups (ICF1, ICF2, ICF3, ICF4 and ICFX). About half of the ICF patients carry mutations in the *de novo* DNA methyltransferase 3B gene (*DNMT3B*), which is referred to as ICF1. ICF2 patients carry mutations in the zinc-finger- and BTB domain containing 24 gene *ZBTB24* and account for ~30% of the ICF cases. We have recently shown that mutations in cell division cycle associated 7, *CDCA7*, and helicase, lymphoid-specific, *HELLS/LSH*, are causative for the ICF3 and ICF4 subtypes respectively, and together with few unexplained cases (ICFX) account for the remaining ICF cases. While DNMT3B and HELLS are cooperatively necessary for establishment of DNA methylation during early embryogenesis, the functional connectivity between the remaining ICF genes remains unknown. We generated a Zbtb24 BTB domain deletion mouse and found that loss of functional Zbtb24 leads to early embryonic lethality. Transcriptome analysis identified *Cdca7* as the top down-regulated gene in *Zbtb24* homozygous mutant mESCs, which can be restored by ectopic ZBTB24 expression. We further demonstrate enrichment of ZBTB24 at the *CDCA7* promoter suggesting that ZBTB24 can function as a transcription factor directly controlling *Cdca7* expression. Finally, we show that this regulation is conserved between species and that *CDCA7* levels are reduced in patients carrying *ZBTB24* nonsense mutations. Together, our findings demonstrate convergence of the two ICF genes *ZBTB24* and *CDCA7* at the level of transcription. We suggest that ICF1 and ICF4 might represent disorders of a failure in DNA methylation establishment, while ICF2 and ICF3 might be caused by a failure in DNA methylation maintenance.

1990W

Discovery of gene-networks governed by two Ikaros transcription factors highlight their function as master regulators of lymphocyte homeostasis, and suggest a pivotal role in SLE pathology. *C. Odhams[1], A. Cortini[1], L. Chen[1], A.L. Roberts[1], D.L. Morris[1], T.J. Vyse[1,2], D.S. Cunninghame Graham[1,2].* 1) Division of Genetics and Molecular Medicine, King's College London, London, UK; 2) Division of Immunology, Infection and Inflammatory Disease, King's College London, UK.

Recent genome-wide association and ensuing functional studies document three Ikaros family transcription factors (TFs) (*IKZF1*, Ikaros; *IKZF2*, Helios; *IKZF3*, Aiolos) as susceptibility genes in Systemic Lupus Erythematous (SLE) a complex autoimmune disease with undefined aetiology. Expression quantitative trait loci (eQTL) analysis show that SLE-associated variants disrupt transcription of these genes in *cis*, and it is postulated that this may be a pathogenic mechanism as the encoded proteins act as master controllers of gene expression throughout lymphocyte development and signalling. In order to understand more fully the underlying biology of the Ikaros TFs and elucidate their regulatory networks, we performed, to ENCODE quality standards, ChIP-Seq of Helios and Aiolos in lymphoblastoid cell lines (GM12878). We integrated genome-wide binding positions with RNA-Seq expression data derived from independent siRNA mediated knockdown of the two genes to predict whether binding of each factor had either an activating or repressing gene expression activity at each direct or indirect target. For Helios and Aiolos respectively, we defined 3,736 and 7,067 significant peaks (*IDR*<0.02), and 249 and 557 differentially expressed genes (*FDR*<0.01) from knock-down relative to control. Coupling gene-network analysis showed significant enrichment of direct target genes in autoimmune relevant pathways such as TLR signaling (*P*=4.5E[-10]) and FcγR mediated phagocytosis (*P*=4.9E[-10]). Isolation of discrete pathways verified the importance of Helios and Aiolos as master regulators in lymphocytes. In particular, we observed that knock-down of Aiolos increased expression of *BTK* (Bruton tyrosine kinase), a known SLE susceptibility gene involved in pro-inflammatory cytokine production through TLR9 signaling, and antibody maturation in B-cells. Using our Aiolos ChIP-Seq data, we identified a binding site in the *IBTK* promoter the natural inhibitor of *BTK*, suggesting decreased expression of *IKZF3* diminishes cellular *IBTK* which leads to aberrant TLR9 and B-cell receptor signaling. By mimicking the functional effect of SLE-associated variants through gene knockdown of *IKZF2* and *IKZF3* coupled with ChIP-Seq/RNA-Seq, we have identified the target genes and regulatory networks governed by these TFs in lymphoblastoid cells. The biological significance of these data will be the subject of targeted follow-up studies as potential markers of therapeutic intervention.

1991T

Identification of sex-biased expression and expression quantitative trait loci (eQTLs) in innate and adaptive immunity. *M. Oliva[1,2], C. Czysz[1,2], B.E. Stranger[1,2].* 1) The University of Chicago, Institute for Genomics and Systems Biology, Chicago, IL; 2) The University of Chicago, Department of Medicine, Section of Genetic Medicine, Chicago, IL.

Human males and females exhibit sexual dimorphism in a wide range of phenotypes. Several diseases display sex biases in prevalence, clinical features and prognosis, e.g. autoimmune diseases are more common in females and infectious diseases in males. Moreover, disease-related phenotypes behave in a sex-dependent manner. Herein, we characterize the influence of sex in determining inter-individual transcriptional variation in cells representing the adaptive and innate branches of the immune system in cohorts of different ancestry. We aim to: a) identify genes and regulatory networks differentially expressed (DE) between sexes, b) identify and characterize sexually dimorphic expression quantitative trait loci (eQTLs), c) pinpoint differences in sex-biased eQTL profiles between autosomal and sex chromosomes and d) determine the variation of sex biases across immune cell types and their contribution to disease. We have analyzed genotype and gene expression data from naïve T lymphocytes and monocytes in healthy Caucasian-American, Asian-American and African-American populations (Immune Variation project, Raj et al. 2014), to discover genes and pathways regulated differently between healthy males and females. We identified 6% and 7% genes that exhibit significant (FDR<5%) sex-biased expression in naïve T-cells and monocytes, respectively. Sex-biased gene sets are enriched in X-linked genes (F-test p<2×10-16) and also in pathways related to apoptosis, immunity, infectious and autoimmune diseases. Several immune pathways mediated by hormones (e.g. prolactin) exhibit sex bias, highlighting how sex-specific hormone profiles explain differences between male and female immunity. Next, to identify genetic variation that regulates gene expression differently between sexes, for each cell type and population we have modeled transcript abundance as a function of sex, genotype and the interaction of both, testing for significance of the latter as sex-biased eQTLs. To increase the statistical power of the association analysis, we meta-analyzed populations for each cell type. We are characterizing: a) whether genes that are DE between sexes demonstrate sex biases in the genetic basis of their regulation and b) differences in sex-biased regulation profiles between sex and autosomal chromosomes. We observe a strong X chromosome enrichment for sex-biased regulation. Finally, we are exploring the contribution of sex-biased eQTLs to disease through integration with GWAS results.

1992F

Hierarchical relationships among susceptibility genes, transcription factors and differentially expressed genes for systemic lupus erythematosus and signaling modules revealed by a systems approach. *T.Y. Wang, Y.F. Wang, Y. Zhang, J.J. Shen, M. Guo, J. Yang, Y. Lau, W. Yang.* Department of Paediatrics and Adolescent Medicine, The University of Hong Kong, Hong Kong SAR, China.

Systemic lupus erythematosus (SLE) is a prototype autoimmune disease with complex pathogenesis and manifestations. Recent advancement in genome-wide association studies (GWAS) has markedly improved our understanding of the genetic basis of SLE, but the details of the disease mechanisms remain elusive. An increasing amount of evidence supports the important role of gene expression in the etiology of the disease. Understanding the functional relationship between genetic findings and gene expression changes may help us better fathom the complicated disease mechanisms. Making use of public data from NCBI Gene Expression Omnibus (GEO) on a number of different studies on SLE expression profiles, we have identified 440 differentially expressed genes (DEGs) in three different cell types through gene expression meta-analysis, which is so far the most comprehensive analysis of gene expression in SLE. Functional analysis of these genes showed that up-regulated genes were mainly involved in immune and inflammatory responses, type I interferon-mediated signaling and responses to viral infection. Through integrative analyses of state-of-the-art, high-throughput biomedical data, such as expression quantitative trait loci (eQTLs), transcription factor binding sites(TFBS), and protein-protein interactions(PPIs), we identified a hierarchical regulatory system, consisting of disease-associated genes (DAGs) in the top layer, involved TFs in the middle layer and DEGs in the bottom layer. Furthermore, modularization analysis found pathways such as cell cycle regulation, apoptosis and mRNA surveillance are closely implicated in SLE pathogenesis. Our results provided a general framework to bridge GWAS findings and gene expression changes, and expanded our understanding of gene expression regulation and its roles in SLE pathogenesis.

1993W

SNPs in *NRM* and *GPANK1* miRNA target regions are associated with risk of pediatric-onset multiple sclerosis. *L.F. Barcellos[1], B. Rhead[1,2], X. Xhao[1], H. Quach[1], D. Quach[1], R. Ness[12], M. Candee[13], L. Krupp[14], M. Gorman[15], L. Benson[15], T. Chitnis[16], S. Mar[17], I. Kahn[18], C. Casper[19], S. Roastadt[19], J. Rose[19], C. Schaefer[20], E. Waubant[4].* 1) Genetic Epidemiology and Genomics Laboratory, UC Berkeley, Berkeley, CA; 2) Computational Biology Graduate Group, UC Berkeley, Berkeley, CA; 3) School of Optometry, UC Berkeley, Berkeley, CA; 4) Department of Neurology, University of California, San Francisco; 5) Children's Hospital of Philadelphia, Philadelphia, PA; 6) Texas Children's Hospital, Houston, TX; 7) University of Colorado School of Medicine, Aurora, CO; 8) University of Texas Southwestern, Dallas, TX; 9) SUNY Buffalo, Buffalo, NY; 10) Loma Linda University, Loma Linda, CA; 11) Mayo Clinic, Rochester, MN; 12) University of Alabama at Birmingham, Birmingham, AL; 13) University of Utah, Salt Lake City, UT; 14) SUNY Stony Brook, Stony Brook, NY; 15) Boston Children's Hospital, Boston, MA; 16) Brigham and Women's Hospital, Boston, MA; 17) Washington University St. Louis, St. Louis, MO; 18) Children's National Medical Center, Washington, DC; 19) Network of Pediatric Multiple Sclerosis Centers Data Coordinating and Analysis Center, University of Utah, Salt Lake City, UT; 20) Kaiser Permanente Division of Research, Oakland, CA.

Multiple sclerosis (MS [MIM 126200]) is a disabling chronic autoimmune disease that affects the central nervous system, with onset occurring in children in as high as 10% of cases ('pediatric-onset MS'). Epigenetic influences are strongly implicated in MS pathogenesis, including the contribution of micro (mi) RNAs, which are small non-coding RNAs that can alter gene expression. Further, genetic polymorphisms (SNPs) can affect miRNA functions in different ways depending on where they are located. These miRNA-related SNPs (miR-SNPs) can impact miRNA expression levels or influence the miRNA-target interaction. Resulting gene dysregulation may affect both susceptibility and phenotype. We investigated the role of miRNAs in ~36,000 controls drawn from UCSF and the Kaiser Permanente Northern California (KPNC) membership and 700 pediatric-onset MS cases recruited through the U.S. Pediatric MS Network, UCSF, and the KPNC MS Research Program. We tested 144 SNPs in regions encoding miRNAs (from the mirBase v21 database) and 28,764 SNPs in the 3' UTRs of target genes (from the MirSNP and polymiRTS 3.0 databases) for association with pediatric-onset MS in White, non-Hispanic cases (N=394) and controls (N=10,875). No SNPs in regions encoding miRNAs were associated. SNPs in miRNA target genes were tested in two separate models: the first for 28,473 SNPs outside of the major histocompatibility complex (MHC), adjusted for genetic ancestry, and the second for 291 SNPs within the MHC, adjusted for genetic ancestry and *HLA-DRB1*15:01*, the strongest genetic risk factor for MS. Two target genes in the MHC were significantly associated with pediatric-onset MS after correcting for multiple tests: *NRM* in the MHC I region on ch. 6p21 (OR=2.7, 95% CI 1.8-4.2, p=3.1e-06) and *GPANK1* in the MHC III region on ch. 6p21 (OR=2.2, 95% CI 1.4-3.3, p=3.4e-04). In addition to miR-SNP analysis, we examined expression levels of miRNAs in four sorted peripheral immune cell types from 8 treatment-naive MS female cases and 8 controls matched on age and race/ethnicity. Expression of 1,979 miRNAs was measured using the mirBase 19 multispecies microRNA microarray (Microarrays INC; Huntsville, AL). Notably, one miRNA, miR-4668, demonstrated the highest fold-change (3.7) in cases compared to controls in CD4+ T cells. CD4+ T cells are strongly implicated in MS. Our results provide the first evidence for miRNA regulation in pediatric-onset MS.

1994T

Genetic variants underlying histone modifications explain a large fraction of autoimmune disease heritability. *B. van de Geijn[1], H. Finucane[1], S. Gazal[1], A. Gusev[1], X. Liu[1], Y. Reshef[1], A. Price[1,2,3].* 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA.

Chromatin state, marked by histone modifications, is an important driver of gene regulation. However, the genetic control of histone modifications is not well understood. We partitioned the local heritability (+/- 10kb from peak) of several histone modifications, including H3K27ac, H3K4me3 and H3K4me1, by extending stratified LD score regression to jointly analyze a large number of histone modification phenotypes, using data previously collected in 65 Yoruba lymphoblastoid cell lines (LCLs). We find the most striking enrichment for heritability in the overlap of H3K27ac and DNase sensitivity peaks, where 1.6% of the SNPs in the genome explain 52% of histone modification SNP-heritability across 136,264 H3K27ac peaks (33x enrichment, P = 2.1 x 10^{-23}). These likely represent active regulatory regions, as marked by H3K27ac, which are bound by transcriptional machinery, leading to DNase sensitivity.   We investigated whether these enrichments for histone modification heritability extend to complex traits by applying stratified LD score regression to GWAS summary statistics for 15 diseases (average N=30,789). The overlaps of H3K27ac and DNase sensitivity peaks were highly enriched for autoimmune diseases where LCLs are expected to be relevant, including celiac disease, Crohn's disease, lupus, and rheumatoid arthritis (1.6% of SNPs explain 33% of SNP-heritability on average; 21x enrichment, P = 1.3 x 10^{-8}). These enrichments were even larger than those for coding or conserved regions, making them vital for unraveling the causes of these diseases. We observed no significant enrichment for this annotation in non-autoimmune diseases, likely due to LCLs being the incorrect cell type for diseases that are not linked to the immune system. We go on to use histone modification heritability explained in LCLs, where most types of data are available, to prioritize combinations of functional data for use in cell types where only a subset have been collected. Finally, we use these combinations to test a wide range of cell type specific annotations for enrichment of disease heritability.

1995F

miRNA expression in patients with HIV/AIDS with antiretroviral resistance to Tenofovir/Emtricitabine/Efavirenz. *J. Marquez-Pedroza[1,2,6], J. Cárdenas-Bedoya[2,3], C. Morán-Moguel[3], M.    Background: The micro-RNAs (miRNAs) are a class of small non-coding RNA that modulates gene expression post-transcriptionally by any of the heretofore, known mechanisms: mRNA destabilization or translational repression. MiRNAs have been proposed as therapy for the treatment of diseases in which the expression of proteins plays a key role in sustaining and disease progression, as in the case of HIV-1 and to the which it is directed the action of some antiretrovirals. The failure of antiretroviral therapy affects control of HIV infection, this is secondary to the administration of antiretrovirals and HIV resistance primary or transmitted in patients who had never received antiretroviral therapy (treatment-naïve). The success of the highly active antiretroviral therapy (HAART) with TDF/FTC/EFV in HIV patients could be related to an expression of miRNAs when compared with HIV-1 patients with and without resistance to HAART. The aim of this study was to compare the expression of miRNAs in HIV/AIDS resistance or not to the scheme TDF/FTC/EFV. **Methods:** A cross-sectional study was made using 13 medical records and 13 plasma samples from Northwestern Mexican patients with HIV/AIDS. They were involved in three groups: antiretroviral resistance to TDF/FTC/EFV (5); antiretroviral without resistance (5); and healthy subjets without HIV-1 infection as control (3). RNA viral was used to genotyping antiretroviral resistance test, with Stanford University criteria. To obtain miRNAs from plasma, first total RNA was extracted, the cDNA synthesis was performed, and the expression of 84 miRNAs detectable and differentially expressed in plasma in each subjects. The Human Serum and Plasma miScript miRNA PCR Array Qiagen® was used. The stably expressed normalization candidates for the evaluation by qRT-PCR were hsa-miR-106b-5p, hsa-miR-17-5p, hsa-miR-18a-5p, hsa-miR-148-3p and was made using a synthetic spike-in control. Student's t-test was used to examine differential expression of miRNAs between groups. **Results:** The analysis of MiRNAs expression in HIV infected treated patients with resistance versus non-resistance shown that miRNAs hsa-miR-15b-5p, hsa-miR-126-3p, hsa-miR-20a-5p, hsa-miR-26a -5p and hsa-miR-16-5p were differentially expressed (p < 0.05). **Conclusion:** miRNA should be considered in future studies as potential biomarkers of resistance to HAART. .

miRNA and mRNA profiling during disease development in an animal model of multiple sclerosis. *S.G. Gregory[1,2], S.K. Siecinski[1], C.C. Zhao[1], W.R. Morgenlander[1], D. Corcoran[3], L. Kwee[1], S. Arvai[1].* 1) Medicine, Duke Molecular Physiology Institute, Durham, NC; 2) David H Murdock Research Institute, Kannapolis, NC, USA; 3) Center for Genomic and Computational Biology, Duke University Medical Center, Durham, NC, USA.

   Purpose: Multiple sclerosis (MS) affects ~400,000 individuals in the U.S. and 2.5 million worldwide. MS is triggered by autoimmune dysfunction that causes demyelination and neuronal damage. Here, we describe the use of a mouse model of MS, experimental autoimmune encephalomyelitis (EAE), to profile microRNA (miR) and messenger RNA (mRNA) expression during EAE development. **Methods:** EAE was induced in C57BL/6J wt mice and severity quantified according to clinical scores (CS) of caudal to rostral paralysis. miR/mRNA from whole blood were profiled at increasing CS from baseline, 0.5-1.5, 2-2.5, 3-3.5. miRNAs were profiled using 50bp single end sequencing, processed using Bowtie alignment to GRCm38, and quantified after log2 transformation. cRNA libraries were hybridized to Agilent Mouse GE v2 arrays with GeneSpring used to normalize data and calculate differential expression. ANOVA was used to identify differentially expressed miR and mRNA across all clinical scores, and a moderated t-statistic in *limma* was used to identify expression changes between groups. **Results:** mir-149-5p (FDR p-val 0.002), which is down regulated by IFN-β therapy and CD8+ T-cells of MS patients and modulated by TNFα in macrophages, was upregulated as each time point. KEGG identified differentiation of miRs between early and late EAE with key MS pathways (Wnt, TGF-Beta, axon guidance) emerging as EAE progressed. mRNA analysis identified cytokine regulation, immune and defense responses as significant, with cellular and tissue components showing a gradual transition into neuronal and myelination associated genes. Analysis of mRNA between baseline and 0.5-1.5 identified connective tissue breakdown of the blood brain barrier, inflammatory/immune response. Multiple MS GWAS study genes were differentially expressed, including IKZF3, which is implicated in lymphocyte development and T-cell mediated apoptosis. Interestingly, the LXR/RXR pathway activation was significant, the importance being the recent association of LXR (NR1H3) with PP-MS. Correlation analysis at the same time points identified differential expression of 9 miRs and 14 validated mRNA targets implicated cytotoxic T-cell mediated apoptosis pathways, with 9 known miRNAs dysregulated in EAE. **Conclusions:** Our analysis identified novel quantitative changes in miR/RNA expression in etiologically relevant pathways throughout the course of EAE and describe a dynamic interrelationship of miR/mRNA expression in a model of MS.

Characterizing regulatory variation and asthma-associated SNPs in memory Th2 cells. *G. McVicker[1], J. Zapardiel[2], J. Cayford[2], B. White[2], G. Seumois[2], P. Vijayanand[2], B. Peters[2].* 1) Salk Institute for Biological Studies, La Jolla, CA; 2) La Jolla Institute for Allergy and Immunology, La Jolla, CA.

Genome-wide association studies (GWAS) have identified thousands of single nucleotide polymorphisms (SNPs) that are associated with autoimmune and inflammatory diseases. Since most of these GWAS hits lie outside of protein coding regions of the genome, they are often assumed to affect gene regulation in disease-relevant cell types. However, the mechanisms and cell types through which these SNPs act is typically unclear. We conducted a study to examine the role of regulatory genetic variation in memory T cells of the Th2 subset, which are known to be involved in autoimmune responses such as allergy and asthma. We genotyped 76 donors, and performed RNA-seq and H3K27ac ChIP-seq on Th2 memory T cells obtained from these individuals. We identified a total of 751 gene expression quantitative trait loci (eQTLs), several of which are also GWAS hits for asthma. A subset of these hits overlap with H3K27ac peaks that have an allele-specific bias toward one allele. For these GWAS hits, the eQTLs implicate specific genes and the H3K27ac peaks suggest specific enhancer sequences that are likely to be affected by the causal SNP. In summary we provide the first catalog of functional regulatory variation in Th2 memory T cells and identify enhancers that are likely to play a functional role in asthma.

1998F

Allele-dependent binding of a viral protein to autoimmune disease-associated genetic variants. *M. Weirauch[1,6], D. Miller[1], L. Kottyan[1], I. Ibarra[1], S. Syed[2], X. Chen[1], E. Zoller[1], A. Lynch[1], C. Schroeder[1], J. Lee[1], A. Magnussen[1], A. Yang[3], T. Hughes[3], J. Park[4], C. Vinson[2], J. Harley[1,5].* 1) Center for Autoimmune Genomics (CAGE), Cincinnati Children's Hospital, Cincinnati, OH; 2) Center for Cancer Research, National Cancer Instititue, Bethesda, MD; 3) Department of Molecular Genetics, University of Toronto, Canada; 4) Divisions of Urology and Developmental Biology, Cincinnati Children's Hospital, Cincinnati, OH; 5) US Department of Veterans Affairs Medical Center, Cincinnati, OH; 6) Divisions of Biomedical Informatics and Developmental Biology, Cincinnati Children's Hospital, Cincinnati, OH.

Risk factors are known for many diseases, but the etiologies of most autoimmune diseases remain unknown and are idiopathic. Pathogenesis of disease likely involves complex interplay between genetic and environmental risk factors. Specifically, Epstein Barr virus (EBV) has suggestive associations with many autoimmune diseases, and EBV infection is nearly ubiquitous in adults. The molecular mechanisms underlying these associations, however, remain unclear. We tested the hypothesis that some autoimmune variants might act by altering the binding of the EBV-encoded transcription factor ZTA, consequently resulting in downstream changes in gene expression. To this end, we comprehensively characterized the DNA binding of ZTA to both methylated and unmethylated DNA sequences using protein binding microarrays (PBMs). Based on these data, we identified plausible causal variants for multiple sclerosis (MS), systemic lupus erythematosus (SLE), and juvenile idiopathic arthritic (JIA) predicted to alter ZTA binding. From among these, we identified variants located within likely regulatory regions in EBV-infected B cells using publically available functional genomic datasets. We screened these candidate variants using electrophoretic mobility shift assays (EMSAs) to identify general differential binding of nuclear factors, and validated differential ZTA binding using EMSA-supershift and DNA Affinity Precipitation Assays coupled with Western blots (DAPA-Westerns). These experiments revealed three genetic variants, associated with MS, SLE, and JIA, respectively, exhibiting stronger ZTA binding to the risk allele. We provide data showing that each of these variants is associated with genotype-dependent expression in EBV-transformed B cell lines. Using luciferase reporter assays, we further demonstrate that the autoimmune risk alleles result in greater promoter activity. Collectively, these data demonstrate for the first time that differential binding of a viral protein to a disease-associated genetic variant can result in altered levels of host gene expression in ways that are predicted to influence autoimmune disease risk of MS, SLE, and JIA. Since ZTA is a viral protein, and is expressed throughout human life subsequent to EBV infection, but only in virus infected cells, these results offer a potential therapeutic target for multiple autoimmune diseases.

Bloom's syndrome study by RNA-seq. *M.M. Montenegro[1], D.A.M. Silvestre[2], A. Rangel[3], G.M. Novo-Filho[1], E.A. Zanardo[1], A.T. Dias[1], A.M. Nascimento[1], T.V.M.M. Costa[1], F. Madia[1], Y. Gasparini[1], C.A. Kim[4], L.D. Kulikowski[1].* 1) Department of Pathology, Cytogenomic Laboratory, FMUSP, Sao Paulo, Brazil; 2) Department of Bioinformatics Interunit, Mathematic Institute of São Paulo University, São Paulo, Brazil; 3) Laboratory of Medical Investigation / LIM36, ICr-HC-FMUSP, São Paulo, Brazil; 4) Genetic Unity, Department of Pediatrics, Children Institute, HC-FMUSP, São Paulo, Brazil.

Bloom's syndrome (BS) is a rare autosomal recessive chromosome instability disorder principally characterized by pre and post natal growth deficiency, microcephaly, photosensibility, immunodeficiency and predisposition to develop neoplasias at an early age. It is caused by mutations in the BLM gene (RECQL3) which in normal conditions encodes the DNA repair protein BLM helicase, that functions in homologue recombination via. Gene expression changes in the functional absence of BLM are poorly understood. In this sense, the transcriptome profiling of mRNA could be a powerful approach to identify new transcripts, gene regulation, SNPs and indels variants that are relevant genomic markers that could be associated to Bloom's syndrome. We performed RNA-Seq profiling using the Illumina's HiSeq 2500 platform of samples derived from two patients with BS and three unaffected controls. The raw data analysis was generated and analyzed using specialized softwares (Subread, SAMtool, BEDtools, DESeq2's, VEP and DAVID database). The RNA-Seq assay revealed the precise location of transcription limits, with resolution of a single nucleotide and high level of efficiency, showing high genetic complexity. The differentially expressed (DE) analysis disclosed 216 genes in the group with BS, being most hipoexpressed genes related to immune and infection system via. The variant analysis detected 295.408 variants, being 186.239 (63%) substitutions and 109.169 (37%) SNVs for Patient 1 and 376.490 variants, being 231.947 (61,6%) substitutions and 144.543 (38,4%) SNVs for Patient 2. Indeed, we found high impact variants detected in some of DE genes. Our results suggested that gene expression network in BS could interfere in the regulation of the pathways associated with the immunological systems regulation probably caused by disturbance of DNA repair mechanisms. Furthermore, the study of the transcriptome using RNA-Seq may help to a breakthrough in the pathogenesis of BS.

SNPs from single-variant credible sets in inflammatory bowel disease can show allelic differences in expression in a reporter assay. *C.J. Cardinale, P.M. Sleiman, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Work by the International IBD Genetics Consortium (Huang et al.) has used dense genotyping on the Immunochip to elucidate 18 loci that could be fine-mapped to single variants with greater than 95% posterior probability of causality. Not surprisingly, 8 of these SNPs were coding variants due to their strong phenotypic impact. However, other loci were identified in which the causal SNP has no known motif or feature that suggests its mechanism of action, such as being contained within a transcription factor binding site, a histone modification region, or an expression quantitative trait locus. We have taken 8 loci, approximately 700 bp in size surrounding the credible SNP, and cloned both the reference and alternate allele into a luciferase reporter vector with a minimal promoter. Six of the loci did not show any expression of luciferase above the background level of the empty vector. However, both *JAK2* and *PRDM1* region SNPs showed significantly above-baseline expression as well as a difference in the expression level of the reference and alternate alleles. The *JAK2* SNP lies within the promoter region 556 bp from the transcriptional start site and showed a 20–30% allelic difference. These results suggest that credible SNPs can mediate differences in gene expression even when known functional annotations are lacking.

2001F

A set of human transcription factors (TFs) bind genomic DNA at multiple Sjögren's syndrome (SS) genetic loci. *J.B. Harley[1,2], M.T. Weirauch[1,3], X. Chen[1], M.J. Pujato[1], C.J. Lessard[4], K.L. Sivils[4], L.C. Kottyan[1].* 1) Center for Autoimmune Genomics and Etiology (CAGE), Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) US Department of Veterans Affairs Medical Center, Cincinnati, Ohio; 3) Divisions of Bioinformatics and Developmental Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio; 4) Arthritis and Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma.

   Purpose Dry eyes and mouth are the primary symptoms of Sjögren's syndrome, a chronic autoimmune disorder, mainly found in older women who often develop systemic complications. Genome wide association studies (GWASs) of Sjögren's syndrome (SS) have provided at least 17 convincing genetic associations, many of which suggest that variants involving inflammatory pathway genes are important in the mechanisms of pathogenesis. Since the vast majority of GWAS loci are in gene regulatory regions, we asked whether specific TFs were known to bind DNA at multiple genetic loci. **Methods** Logistically, we defined a locus as those variants which had disequilibrium at $r^2 > 0.8$ with the most significant marker at the locus. We assembled the chromatin immunoprecipitation with next generation sequencing (ChIP-Seq) datasets available in the public domain. We developed a simulation test for statistical significance. The null distribution is generated with 2000 records in which the linkage disequilibrium and allele frequency structure of all 17 SS loci were randomly assigned to genomic locations. The Bonferroni corrected probabilities (p_c) were calculated for each TF evaluated. We confined our attention to TF data sets that bound DNA in ≥4 SS genetic loci and that had $p_c < 0.00001$. **Results** Of the ~2000 TF datasets available from many cell types, 11 satisfied these criteria with p_c to ~10^{-15} and relative risk of 6.6 to 28.8 for the intersection of SS loci with TF binding peaks. Of the 11 TFs multiple members influence the NFκB pathway and interferon production. All 11 of these TFs datasets are from transformed lymphocyte cell lines and tend to involve the same subset of SS loci. **Summary** *These data are consistent with a common transcriptional gene control mechanism operating across a subset of SS risk loci in a shared intracellular environment that defines the site of differential allele action of causal variants.* The GWAS loci have small odds ratios (usually <1.2). If there are coordinated mechanisms across loci that alter disease risk with larger effect sizes (SS relative risks, 6.6 to 28.8), then shared gene regulatory mechanisms are relatively important in generating disease risk. In addition, the action of multiple risk variants may act across loci in the same cell type or types. That all 11 TF relationships are found in the transformed B cell nominates this cell type as a possible site for coordinated differential gene expression and gene action.

2002W

Identifying subject-specific regulatory networks in asthma. *D.C. Croteau-Chonka, K. Glass, B.A. Raby, Asthma BioRepository for Integrative Genomic Exploration (Asthma BRIDGE) Consortium.* Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

   RATIONALE: We have previously demonstrated that differential gene expression profiles of poor asthma symptom control reflect highly relevant biology, such as signaling pathways driving granulocytic inflammation. Regulatory networks are frameworks for integrating across multiple levels of biological information, including gene expression, which could provide further insights into disease mechanisms. **METHODS:** We measured whole blood gene expression using Illumina Human HT12 expression arrays (13,761 probes) in a subset of 245 asthmatic adults from Asthma BRIDGE. We used LIONESS, or Linear Interpolation to Obtain Network Estimates for Single Samples, an extension of the Passing Attributes between Networks for Data Assimilation (PANDA) method, to construct subject-specific regulatory networks. We then identified genes differentially targeted by transcription factors (TFs) between subjects with poor versus good asthma control, and determined via gene set enrichment analysis (GSEA) whether these genes clustered in specific biological processes. **RESULTS:** We constructed a collection of subject-specific regulatory networks and compared their properties among subjects with poor asthma control versus those with good control. Among the individual genes that showed the most significantly increased targeting by TFs during poor control were *TSLP* (rank #2) and *IL18R1* (rank #19), which are both well-known asthma and allergy susceptibility genes and pharmacologic candidates in asthma. Other notable genes included *TLR4* and *CASP4*, both critical components of lipopolysaccharide (LPS) signaling. Moreover, we found increased TF targeting of 140 genes (including *TSLP*) related to activation of TREM-1 signaling in monocytes – a key pathway promoting granulocytic inflammation, including in response to LPS exposure. Among TFs targeting these genes, the most influential were SP1 and EGR1, each implicated in airway remodeling and targeting ~99% of the TREM-1 genes (Fischer's Exact P ~ 1E-05). **CONCLUSION:** Comparing networks between disease states reveals important biological information about differences in gene regulation. Our identified regulatory networks helped refine previous differential expression profiles of asthma control and focus our attention on a specific pathways related to LPS exposure and TREM-1 signaling. **FUNDING:** This work was supported by grants from the National Institutes of Health (K01 HL127265, RC2 HL101543, P01 HL105339, R01 HL111759, R01 HL086601, and R01 HL118455).

Genome wide analysis of DNA methylation identifies a novel locus associated with asthma among African Americans. *Y. Li[1], M.P. Boorgula[2], R.A. Mathias[2], K.C. Barnes[3], Z.S. Qin[1], Y.J. Hu[1], Consortium on Asthma among African-ancestry Populations in the Americas(CAAPA).* 1) Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 2) Department of Medicine, Johns Hopkins University, Baltimore, MD; 3) Department of Medicine, University of Colorado at Denver, Denver, CO.

   Background Asthma is a common chronic inflammatory disease, affecting more than 32 million people in the United States. Previous research suggested that asthmatics of African descent tend to have more severe clinical symptoms than non-African populations. In addition to genetic factors, asthma has also been linked to environmental exposures, which are likely mediated through epigenetic mechanisms.   **Objective** We conduct an epigenome-wide association study (EWAS) to identify differentially methylated CpG sites between asthmatics and non-asthmatics in the African American population. We also perform a methylation quantitative trait locus (meQTL) study to enhance our understanding of the interaction between DNA methylation and genetic factors. **Methods** The samples we used are part of NHLBI-supported Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA). DNA Methylation data were collected from 79 asthmatics and 87 non-asthmatics using the Illumina Infinium Human Methylation 450K BeadChip, which covers more than 480,000 CpG sites genome-wide. We performed data filtering, quality control, and normalization. In EWAS, we used a linear regression model at each CpG site to examine the association between asthma status and methylation level after adjusting for age, gender, batch, cell type composition, and principal components that capture unmeasured sources of variation in the methylation data. In the meQTL study, we used a similar linear model examining the association between each single nucleotide polymorphism (SNP) and methylation level with the same adjustment as in EWAS.   **Results** Our analysis identified cg00326161, a CpG site on chromosome 6, to be significantly associated with the asthma trait (p value = 1.53×10^{-7}). Interestingly, we found that the neighborhood of this CpG site showed evidence of cell specific in vivo binding of a transcription factor *FOXA1* that is known to be involved in lung development, suggesting that methylation of the CpG site might be involved in the regulation process of *FOXA1*.

2004F

DNA methylation profiles of polycystic ovarian syndrome in Chinese women: A case-control study. *S. Li[1], H. Duan[2], D. Zhu[3,4], A. Ren[3,4], D. Glintborg[5], M. Andersen[5], V. Skov[6], M. Thomassen[1], T. Kruse[1], Q. Tan[1,7].* 1) Unit of Human Genetics, Department of Clinical Research, University of Southern Denmark; 2) Department of Medicine, Kolding Hospital, Kolding, Denmark; 3) Center of Reproductive Medicine, Linyi People's Hospital, Linyi, China; 4) Department of Obstetrics and Gynecology, Shandong Medical College, Linyi, China; 5) Department of Endocrinology, Odense University Hospital, Odense, Denmark; 6) Department of Hematology, Roskilde Hospital, Roskilde, Denmark; 7) Epidemiology, Biostatistics, and Biodemography, Department of Public Health, University of Southern Denmark, Odense, Denmark.

   As a universally common endocrinopathy in women of reproductive age, the polycystic ovarian syndrome is characterized by composite clinical phenotypes reflecting the contributions of reproductive impact of ovarian dysfunction and metabolic abnormalities with widely varying symptoms resulting from interference of the genome with the environment through integrative biological mechanisms including epigenetics. We have performed a genome-wide DNA methylation analysis on polycystic ovarian syndrome using Illumina's HumanMethylation450 BeadChip array. We identified a substantial number of genomic sites differentially methylated in the whole blood of 30 PCOS patients and 30 healthy controls (52 sites, false discovery rate<0.05 and corresponding p value<5.68e-06), highly consistently replicating biological pathways extensively implicated in immunity and immunity-related inflammatory disorders (false discovery rate<0.05) that were reportedly regulated in the DNA methylome from ovarian tissue under PCOS condition. Most importantly, our genome-wide profiling focusing on PCOS patients revealed a large number of DNA methylation sites and their enriched functional pathways significantly associated with diverse clinical features (levels of prolactin, estradiol, progesterone and menstrual cycle) that could serve as novel molecular basis of the clinical heterogeneity observed in PCOS women. .

2005W

Transcriptomics of liver tissue in alcoholic hepatitis. *T.M. Norden-Krichmar, Southern California Alcoholic Hepatitis Consortium (SCAHC).* Dept. of Epidemiology, University of California, Irvine, Irvine, CA.

Alcoholic Hepatitis (AH) is an alcohol-induced inflammatory liver disease with high mortality and morbidity rates. The factors that determine the progression to AH and the subsequent prognosis are not well understood. Gene expression in AH has previously been studied mainly using microarrays and qPCR. To our knowledge, this is one of the first studies using RNA sequencing for gene expression profiling of human liver tissue from patients with AH. The liver biopsies in this study were collected by the Southern California Alcoholic Hepatitis Consortium (SCAHC) from AH patients (n=9), and from patients diagnosed with decompensated liver (DL) disease (n=3) due to alcohol abuse with no episodes of AH. As normal liver tissue controls, RNA sequencing data of normal liver biopsy samples (n=3) from the Human Protein Atlas (www.proteinatlas.org) were incorporated into this analysis. RNA was extracted from the AH and DL liver biopsies and sequenced at 2x100 paired-end on an Illumina HiSeq2500. The RNAseq data was aligned to the human genome, followed by differential expression (DE) analysis with the Cufflinks software, using upper quartile normalization between the data files. Visualization and principal components analyses (PCA) were performed with cummeRbund using the entire gene expression dataset. PCA revealed that the global gene expression patterns of AH and DL clustered together, while the normal samples were clearly distinguishable. Normalized DE between the groups yielded 528 total genes with fold change >= 2, FPKM>=5, and were significant at FDR-adjusted p-value <= 0.05. Of these, there were 16 DE genes between AH and DL, 304 between AH and normal, and 471 between DL and normal. The gene expression profiles of AH and DL were similar, and distinct from the normal samples. Many of our results confirm those reported in previous microarray studies. That is, relative to normal samples, AH and DL show elevated expression of secreted phosphoprotein 1, selenoprotein, and chemokines. Additionally, genes related to drug metabolism and detoxification, such as an aldo-keto reductase and a glutathione s-transferase, were elevated in AH and DL compared to normal. The most significantly DE genes between AH and DL were related to immune function. These results suggest that there is a characteristic gene expression profile of alcoholic liver disease that may play a role and may point to treatment options for alcoholic hepatitis. (Supported by U01AA021838).

2006T

Long-range interactions organize the 11p13 cystic fibrosis modifier locus around *EHF.* *L.R. Stolzenburg[1,2], R. Yang[1,2], J. Kerschner[1,2], S. Fossum[1,2], M. Xu[1,2], S. Wachtel[1,2], S.H. Leir[1,2], A. Harris[1,2].* 1) Human Molecular Genetics, Lurie Children's Research Center, Chicago, IL; 2) Department of Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL.

Although cystic fibrosis (CF) is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, lung disease phenotypes cannot be predicted by *CFTR* mutation alone. Through genome wide association studies (GWAS), additional genetic loci associated with CF disease severity were identified by others. One such locus maps to chromosome 11p13 in an intergenic region between Ets homologous factor (*EHF,* an Ets family transcription factor) and Apaf-1 interacting protein (*APIP,* involved in apoptosis); however, the functional significance of this region is not understood. To identify *cis*-regulatory elements within the intergenic region, we used chromatin immunoprecipitation and DNase I digestion followed by high-throughput sequencing (ChIP-seq and DNase-seq). These assays identified peaks of H3K4me1/H3K27ac and DNase hypersensitive sites (DHS) across the 11p13 locus in primary lung epithelial cells and cell lines. Luciferase reporter assays in transformed bronchial epithelial cells confirmed that at least two of these DHS could function as strong enhancer elements for the *EHF* and nearby *ELF5* (another Ets family transcription factor expressed in glandular epithelium) promoters. None of the elements assayed showed significant activity with the *APIP* promoter. Next, circular chromosome conformation capture (4C-seq) was used to measure interactions between DHS and promoters across the region. The two enhancer elements showed reciprocal interactions with the *EHF* promoter, which also interacted with several other elements that appear to organize a topologically associated domain (TAD) across the region and are enriched for CTCF. No strong interactions were observed with the *APIP* promoter, which lies outside of the main TAD encompassing the GWAS signal. These results highlight the complex 3D chromatin architecture at 11p13 and suggest an important role for *EHF* in modifying CF lung disease severity.

2007F

Genome-wide regulatory roles of the C2H2-type zinc finger protein ZNF764 responsible for multiple steroid hormone resistance in a case with 16p11.2 microdeletion on the transcriptional activity of the glucocorticoid receptor. *T. Kino[1,2], A. Fadda[3], R. Mackeh[1], A. Marr[1].* 1) Experimental Genetics, Sidra Medical and Research Center, Doha, Qatar; 2) Program in Reproductive and Adult Endocrinology, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 3) Biomedical Informatics, Sidra Medical and Research Center, Doha, Qatar.

The zinc finger protein (ZNF) 764 is a transcription factor harboring one KRAB domain and seven C2H2-type zinc finger motifs respectively in its N- and C-terminal half, and we previously reported that haploinsufficiency in its encoding *ZNF764* gene may be responsible for tissue resistance to multiple steroid hormones including glucocorticoids observed in a patient with 16p11.2 microdeletion (*J Clin Endocrinol Metab*, **98**: E1557, 2012). To evaluate the mechanisms underlying ZNF764-associated multiple steroid hormone resistance, we examined genome-wide ZNF764 actions on the glucocorticoid receptor (GR), a ligand-dependent transcription factor mediating diverse actions of glucocorticoid hormones, using HeLa cells as a model system. We found that ZNF764 enhances GR-induced transcriptional activity in a dose-dependent fashion in reporter assays employing the glucocorticoid-responsive luciferase reporter and in mRNA expression of the representative glucocorticoid-responsive genes. In chromatin immunoprecipitation assays followed by high through-put sequencing (ChIP-Seq), ZNF764- and GR-binding sites demonstrated similar distribution in various genomic features. They positioned predominantly around 50-500 kbs from the transcription start site of their targeting genes, closely locating with each other with overlapping in ~37% of cases. In ZNF764 knockdown experiments, ZNF764 demonstrated differential on/off effects on GR/DNA binding and subsequent induction of glucocorticoid-responsive genes: while some genes did not require ZNF764, others were absolutely dependent on the presence or absence of ZNF764. Pathway analysis revealed that these 3 gene groups in terms of ZNF764 requirement were enriched for distinct cellular actions. Finally, ZNF764 and GR physically interacted with each other *in vitro* and *in vivo*, and their mutual binding contributed to the regulation of representative ZNF764-sensitive glucocorticoid-responsive genes. These results suggest that ZNF764 functions as a cofactor that directs GR transcriptional activity toward specific biological pathways by changing GR binding and transcriptional activity on glucocorticoid-responsive genes. The results also provide important insight to the actions of ZNF764 on other steroid receptors and the mechanisms underlying multiple steroid hormone resistance observed in our case with 16p11.2 microdeletion.

The gene expression signature associated with rheumatoid arthritis is altered during pregnancy. *D. Jawaheer[1], E. Purdom[2], A. Mittal[1], L. Pachter[2], J.L. Nelson[3], J. Olsen[5], M. Smed[4], V. Zoffmann[4], M.L. Hetland[6], H. Kjaergaard[4].* 1) Children's Hospital Oakland Research Institute, Oakland, CA; 2) University of California, Berkeley, CA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Juliane Marie Center, Copenhagen, Denmark; 5) Aarhus University, Aarhus, Denmark; 6) Glostrup Hospital, Copenhagen, Denmark.

Objective: To identify an RA-associated expression signature among women at the pre-pregnancy stage, and determine whether pregnancy-induced changes in gene expression alter the RA-associated expression signature by the third trimester. **Methods**: Blood was drawn from 9 women with RA and from 5 healthy women before pregnancy and at the third trimester. Total RNA was isolated and used to prepare cDNA libraries which were sequenced on an Illumina HiSeq2500 instrument at an average depth of 60 million reads (100bp). The pre-processed RNA sequencing (RNA-seq) data was pseudo-aligned to the reference Human transcriptome and gene expression levels were quantified using kallisto. Genes differentially expressed between groups (between RA and healthy women, or between time-points within each group of women) were identified with edgeR using a fold-change cutoff of 2 and a significance threshold of p<0.05 (FDR corrected). Functional category enrichment analysis was performed using Webgestalt. **Results**: Before pregnancy, 257 genes were differentially expressed between RA and healthy women (p<0.05), with 60 of these genes showing greater than 2-fold change in expression between the two groups. These genes were enriched in various immune-related pathways including those for defense response, innate immune response, inflammatory response and cytokine-mediated signaling. In contrast, in the third trimester of pregnancy, differential expression between the same set of RA and healthy women was limited to only 11 of the 60 baseline signature genes (>2-fold change in expression between the groups). Among the genes that lost their differential expression were OLFM4, CAMP, MMP8 and ORM1, which have been implicated in RA or in pregnancy. Interestingly, the dilution of the pre-pregnancy RA gene expression signature during pregnancy was the result of temporal changes in expression among RA and/or healthy pregnancies such that expression levels of these genes that showed RA-associated expression before pregnancy became comparable in the two groups of women by the third trimester. **Conclusions**: These findings have implications for both healthy and RA pregnancies. They suggest that, during healthy pregnancy, the immune system in the maternal periphery is active. In RA, temporal changes in expression that occur during pregnancy may be involved in the pregnancy-induced improvement of clinical symptoms of the disease.

2009T

Whole-genome methylation analysis for osteoporosis using reduced representation bisulfite sequencing (RRBS). *H. Shen, C. Qiu, H.W. Deng.* Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA.

Osteoporosis is a complex disease mainly characterized by a reduced bone mineral density (BMD) and increased risk of fractures. Peripheral blood monocytes (PBM) constitute 3-8% of human leukocytes in the blood and may act as precursors of osteoclasts, the bone resorption cells, and also produce cytokines important for osteoclast activity, and thus represent major systemic target cells for bone metabolism. Alterations in DNA methylation has been implicated as a key regulatory mechanism in the pathogenesis of various human complex diseases, such as cancers, cardiovascular disease and obesity *etc.* However, the DNA methylation profiles in humans underlying osteoporosis risk, especially at base-resolution level, are largely unknown. In this study, we performed a genome-wide DNA methylation analysis in primary human PBMs from 108 unrelated subjects, including 54 subjects with extremely high hip BMD and 54 with low BMD. By using reduced representation bisulfite sequencing (RRBS), we generated over 5.5 billion uniquely mapped reads for all the 108 samples with average uniquely mapped rate achieve to 69.7%. Genome-wide DNA methylation signals of each sample were normalized and quantified using methylKit analysis package. Differentially methylated regions (DMRs) were identified by comparing the genome-wide methylation profiles between the high and the low BMD subjects. The PBM methylome profile shows similar patterns as that in other somatic cells. For instance, most of CpG sites in the promoters are unmethylated or partially methylated, especially for promoters with high CpG density. Among the 2.04 million tested CpG sites with at least 10x coverage in promoter and CGI regions, a total of 327 CpG sites in 67 genes showed significant difference (q-value <0.01, %methylation difference >25%) in methylation levels between the high and the low BMD groups, including a number of known bone-related genes, such as the RUNX2 gene (p=1.4E-4, %methylation difference =0.47) and the BMP2 gene (p=4.3E-5, %methylation difference =0.52). We also identified non-CpG site methylation profiles and it appears to be spatially correlated with CpG methylation. For example, 34.7% of differential methylation in non-CpG sites overlapped with DMRs of CpG sites. In summary, we conducted the comparative whole genome DNA methylation analysis for PBMs and identified a number of novel epigenetic-regulated candidate genes for osteoporosis risk.

2010F

Roadmap to identifying craniofacial enhanceropathies. *J. Cotney, A. Wilderman.* Genetics and Genome Sciences, UConn Health, Farmington, CT.

Defects in embryonic patterning resulting in craniofacial abnormalities are common birth defects affecting more than 1 in 750 live births. The genetic causes of these defects have been difficult to determine, but all current evidence suggests defective gene regulation during embryonic development underlies these birth defects. Most of the individuals affected by congenital craniofacial abnormalities do not have defects in other tissues or organ systems, thus are relatively tissue specific and considered non-syndromic. The regulatory programs that build and shape the craniofacial complex require precisely controlled spatiotemporal gene expression. Much of the information that controls these gene expression programs is thought to be encoded in the large expanses of the genome between protein-coding genes and within intronic sequences. Efforts by large projects such as ENCODE and the Roadmap Epigenome Project have established associations of many biochemical features with functional portions of the genome and state of activity. These efforts have revealed that enhancers are typically tissue or timepoint specific and regulate one or a small number of genes over very large genomic distances. The tissue specific nature of enhancers coupled with the enrichment of a variety of disease phenotype associations from genome-wide association studies in these regulatory sequences suggest that defects in enhancers are at fault in many common disorders. The non-syndromic nature of most craniofacial defects indicate they are potentially enriched for defects in enhancer activity and likely to be "enhanceropathies". To date early stages of human craniofacial development have not been interrogated with modern functional genomics techniques preventing large scale integrative analysis of genetic associations and tissue-specific chromatin states. We have generated comprehensive chromatin state maps with chromatin immunoprecipitation sequencing (ChIP-Seq) for critical stages in human craniofacial development ranging from 4.5 post conception weekds (pcw) to 8 pcw. We have targeted selected tissue specific enhancer for unbiased long range interaction mapping using circularized chromosome conformation capture sequencing (4C-Seq). These chromatin profiles and enhancer-promoter contact maps have allowed identification of potential causative genetic changes in human patients with craniofacial abnormalities and develop mouse models through targeted genome editing.

2011W

An evolutionary understanding of DNA methylation patterns associated with osteoarthritis. *G. Housman[1,2], L.M. Havill[3], E. Quillen[3], A.C. Stone[1,2].* 1) School of Human Evolution and Social Change, Arizona State University, Tempe, AZ, USA; 2) Center for Evolution and Medicine, Arizona State University, Tempe, AZ, USA; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX, USA.

Background: According to the WHO, the degenerative joint disease of osteoarthritis (OA) is present in 9.6% of men and 18.0% of women ages 60 or older world-wide. Of those affected, 80% have movement limitations and 25% are unable to perform major daily activities of life. The CDC further notes that OA of the knee joint is especially prevalent in the USA. Thus, it is important to understand what factors contribute to the development of this disease. Epigenetic factors, such as DNA methylation, play an influential role, and while these molecular mechanisms have been heavily studied in humans, few efforts have taken an evolutionary perspective. **Objective:** This project assesses the relationship between DNA methylation patterns and knee OA development in a baboon primate model (*Papio anubis*) and compares these findings to previously published data for humans in order to study the evolution of OA epigenetics. **Methods:** Skeletal tissue DNA methylation patterns were assessed in cartilage and trabecular bone of the right distal femora from pedigreed, age- and sex-matched adult baboons using the Illumina HumanMethylation 450K BeadChip. **Results:** Preliminary data, collected from 12 individuals (6 with and 6 without knee OA), reveal that several loci in each tissue were significantly differentially methylated between healthy and OA individuals. Specifically, out of over 450,000 positions, approximately 2.06% were differentially methylated between the OA and control groups, 1.94% between tissue types, and 1.32% among the four combinations of tissue type and OA status. Further, genes containing differentially methylated positions, such as *HOXA9*, *PLOD2*, *IRX2*, and *MSX2* overlap with those previously identified in human OA DNA methylation studies. Analysis of cartilage and trabecular bone from an additional 56 individuals (28 with and 28 without knee OA) is currently in progress. **Discussion:** From an evolutionary perspective, these findings give us an appreciation of DNA methylation variation in skeletal tissue from one primate species and two skeletal tissues. They also give us insight into the degree to which a common skeletal condition (OA) affects that variation. Analyses of an expanded sample set will further inform our understanding of epigenetic regulation and complex trait evolution in primates.

2012T

Identification of methylome alterations associated with disease progression in osteoarthritic subchondral bone. *Y. Zhang[1,2], N. Fukui[3,4], M. Yahata[2,5], Y. Katsuragawa[6], T. Tashiro[7], S. Ikegawa[8], M. Lee[1,2,9].* 1) Lab 119, Weis Center, Geisinger Genomic Medicine Institute, Danville, PA; 2) Laboratory for International Alliance on Genomic Research, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 3) Clinical Research Center, National Hospital Organization Sagamihara Hospital, Kanagawa, Japan; 4) Department of Life Sciences, Graduate School of Arts and Sciences, the University of Tokyo, Tokyo, Japan; 5) Laboratory for Pharmacogenomics, Center for Integrative Medical Sciences, RIKEN, Yokohama, Japan; 6) Department of Orthopedic Surgery, Center Hospital of the National Center for Global Health and Medicine Center Hospital, Tokyo, Japan; 7) Department of Orthopaedic Surgery, Tokyo Yamate Medical Center, Tokyo, Japan; 8) Laboratory for Bone and Joint Diseases, Center for Integrative Medical Sciences, RIKEN, Tokyo, Japan; 9) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Methylome alterations were rarely studied in subchondral bone of osteoarthritis (OA) due to the difficulties associated with accessing to the tissue and isolating DNA with adequate quantity and quality. In this study, we employed a unique system, which allows us to access three regions of the tibial plateau that could reflect the early, intermediate and late stages of OA. The methylome of subchondral bone from 3 regions in 12 primary OA knee joints were examined using HumanMethylation450 BeadChip. Of the significant differential methylated probes (DMPs), more than half were hypermethylatedin both intermediate (72 DMPs, 22 genes) and late (397 DMPs, 134 genes) stages of OA when compared to the early stage. These DMPs showed altered composition of genome features. The differential methylated genes (DMGs) were enriched in morphogenesis and development of skeletal system. DMGs that associated with OA and bone remodeling were identified (eg: *COL4A1*, *FAM5C*). A clustered of transcription factors were also identified, particularly the HOX transcription factors, of which many harbored multiple DMPs. For example, *TBX15* had 26 hypermethylated probes, and was significantly down-regulated in the intermediate and late stage. The expression was significantly negatively correlated to the methylation (spearman's r = -0.5228, p=0.0005). Different patterns were identified in subchondral bone when compared to the findings of the site-matched cartilage. However, shared DMP and DMGs with the same trend of methylation changes were also identified, which had even higher enrichement in the morphogenesis and development of skeletal system. Shared DMGs also included genes that participate in the crosstalk between cartilage and subchondral bone. Together, our data suggested DNA methylation contributed to the OA disease progression and highlighted the common pathways and crosstalk between the cartilage and subchondral bone.

2013F

Genome-wide analysis of differential DNA methylation and methylation quantitative trait loci (meQTLs) in systemic lupus erythematosus. *J. Imgenberg-Kreuz[1], J. Carlsson Almlöf[1], D. Leonard[1], G. Nordmark[2], M.-L. Eloranta[2], L. Padyukov[2], I. Gunnarsson[3], E. Svenungsson[3], C. Sjöwall[3], L. Rönnblom[4], J.K. Sandling[1,2], A.-C. Syvänen[1].* 1) Molecular Medicine and Science for Life Laboratory, Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 2) Rheumatology and Science for Life Laboratory, Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Rheumatology Unit, Department of Medicine, Karolinska Institut/Karolinska University Hospital, Stockholm, Sweden; 4) Rheumatology/AIR, Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden.

Systemic lupus erythematosus (SLE) is a rheumatologic autoimmune disease with complex etiology. More than 50 genetic loci that contribute risk for SLE have been identified, but a large proportion of genetic susceptibility still remains unexplained. Therefore we investigated the impact of DNA methylation on SLE susceptibility and on the phenotypic variability in SLE. In an initial discovery phase we determined genome-wide DNA methylation patterns in blood cells from 347 Swedish SLE patients and 400 healthy controls using the Illumina HumanMethylation 450k array. The Minfi R package was used for quality control, normalization of intensity data and calculation of methylation beta values at 385,851 CpG sites that passed quality control. Differential blood cell count estimations, age and sex were included as covariates in the association model and a p-value of <1.3x10^{-7} for the association was considered significant (Bonferroni correction α=0.05). For independent replication, 201 SLE patients and 188 healthy controls were included.   We found that DNA methylation is perturbed at thousands of CpG sites in blood cells from SLE patients compared to healthy controls. The largest differential methylation between patients and controls was observed at interferon (IFN) regulated genes, which are hypomethylated in SLE. Analysis of DNA methylation of the X-chromosome of female SLE patients identified differential methylation at genes involved in activation of immune cells, such as *TLR8* and *VSIG4*. In addition, we identified methylation patterns associated with disease duration and clinical manifestations, such as lupus nephritis. By mapping methylation quantitative trait loci (meQTLs) we observed genetic regulation of methylation levels by SNPs in regulatory regions identified by genome-wide association studies (GWAS) of SLE. For example at the *IRF5-TNPO3* locus the SLE-associated SNP rs4728142 was associated with methylation levels at the nearby CpG site cg04864179 (p=5x10^{-9}), both located in the *IRF5* promoter. Differential analysis of meQTLs in SLE patients and controls found additional disease specific meQTLs in the patients. Our results suggest that several risk variants for SLE exert their influence on the phenotype through alteration of DNA methylation levels at regulatory regions of target genes in blood cells. Analysis of meQTLs in SLE patients may be a powerful approach for identification of genetic regulation of methylation relevant for SLE and its phenotypes.

2014W

Cell-free transcriptomics reveal dysregulation of collagen and extracellular matrix organization in synovial fluid after ACL/meniscal injury. *A.J. Griswold[1], K. Nuytemans[1], L. Wang[1,2], T. Strong[1], D.D. Vance[3], M.K. Smith[4], J.M. Vance[1,2], M.A. Pericak-Vance[1,2], L.D. Kaplan[4].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miller School Medicine, Miami, FL; 3) Department of Orthopedic Surgery, New York Presbyterian Hospital, Columbia University Medical Center, New York, NY; 4) UHealth Sports Performance and Wellness Institute, University of Miami, Miller School of Medicine, Miami, FL.

Anterior cruciate ligament (ACL) and meniscal tears are two of the most common activity-induced orthopedic knee injuries and among the leading causes of subsequent osteoarthritis (OA) of the knee. While OA usually becomes symptomatic years after the injury, we hypothesize that molecular changes, initiated soon after the initial trauma, activate pathways eventually leading to increased susceptibility to OA. This study set out to identify gene expression biomarkers by performing RNAseq of cell-free RNA obtained from synovial fluid aspirated from knees at the time of repair surgery. Our initial study cohort consisted of 12 total samples from seven patients (ages 19-47) undergoing ACL and/or meniscal repair (ranging 6-24 weeks post injury). Five patients had samples from an injured knee plus the contralateral uninjured knee (control knee), and two patients had a sample from only an injured knee. Radiograph studies found no existing OA at the time of surgery. Total RNA was extracted from 0.5-1mL of synovial fluid, prepped with the NEBNext Small RNA Library Set, and sequenced 10M single end 50bp reads on an Illumina HiSeq2500. These reads were mapped to the genome and quantified using the STAR software. General linear models implemented in the EdgeR software were used in a paired analysis to identify genes differentially expressed between injured and uninjured knees while adjusting for differences between individuals. In total, 443 genes were nominally differentially expressed (p ≤ 0.05, fold change ≥ 1.5): 122 upregulated and 321 downregulated in injured compared to control knees. Ingenuity Pathway Analysis indicated that the top enriched molecular pathway of the differentially expressed genes is "cellular assembly and organization." These include filament and fibril formation genes, including collagen type I genes (*COL1A1* and *COL1A2*) and microfibrillar-associated proteins that were upregulated by knee injury. Conversely, cytoskeletal organization genes including cortactin (*CTTN*) and tissue inhibitors of metalloproteinases (*TIMP3*) were downregulated. Both collagen-related genes and MMPs have been previously implicated in the OA disease process, but this is the first evidence that the dysregulation of these molecular pathways can be identified as synovial extracellular RNA biomarkers early after injury. Understanding the role of these biomarkers, may ultimately allow early intervention and potential therapeutics to limit damage due to injured-induced OA.

Genome-wide DNA methylation analysis identifies novel hypermethylated genes associated with hidradenitis suppurativa (acne inversa). *N.K. Jain[1], D.D. Jhala[2], M. Raveendrababu[2], N.M. Saiyed[3], R.S. Rawal[4], B.C. Gorijala[5], F.M. Al-Ali[6], L.I. AlOtaibi[6], E.A. Mohamed[6], M. Naveed[6], U. Ratnamala[7], U. Radhakrishna[8].* 1) Life Sciences, School of Sciences, Gujarat University, Ahmedabad, India; 2) Department of Zoology, School of Sciences, Gujarat University Ahmedabad, India; 3) Biotechnology, Nirma Institute of Science, Nirma University, Ahmedabad, India; 4) Department of Dermatology, V.S. Hospital, Smt NHL Municipal Medical College, Ahmedabad, India; 5) Oncology Department, Krishna Institute of Medical Sciences, Secunderabad, India,; 6) Dermatology Centre, Rashid Hospital, Dubai Health Authority, Dubai, UAE; 7) Department of Pharmacology, Creighton University, Omaha, NE, USA; 8) Department of Obstetrics and Gynecology, Oakland University-William Beaumont School of Medicine, Royal Oak, MI, USA.

  Hidradenitis Suppurativa/Acne Inversa (HS/AI) is a chronic skin disease that usually presents after puberty with painful, deep-seated inflamed lesions in the apocrine gland-bearing areas of the body. In some families HS is hereditary and correlates with specific γ-secretase mutations. However, disease etiology is heterogeneous as these mutations are involved in the pathogenesis of only some familial and/or sporadic HS cases, while the majority of HS occupancies are sporadic. The diagnosis of HS is typically based on clinical characteristics, such as history and physical exam, rather than tissue biopsy. HS is frequently misdiagnosed or overlooked, resulting in a delayed diagnosis only when the disease is in an advanced stage. We hypothezed that epigenetic modification may play a crucial role in the development of HS; thus we conducted a genome-wide DNA methylation analysis using the Illumina Infinium HumanMethylation450 BeadChip array in a cohort of 24 HS individuals previously excluded from γ-secretase mutations and 24 controls matched for age, sex, and ethnic origin. Differential methylation analysis identified significantly altered CpG methylation at 304 sites (at least 2.0 fold hypermethylation) in 304 genes in HS subjects as compared to controls (False discovery rate (FDR) = ≤ 0.00001). All 304 identified CpG sites genes have ROC AUC ≥0.75 and had ≥5% methylation difference between HS and controls. Further gene ontology analysis identified biological processes and functions for these genes including Notch pathway, histone and DNA methylation, chromatin remodeling, immunological, and inflammation pathways. Many important significant novel CpG sites that might be related to HS development were detected including cg24332422 (*APC*), cg18584561 (*GREB1*), cg21308111 (*TNFRSF10A*), cg12506373 (*CAD*), cg02209504 (*EGR2*), reinforcing the potential importance of epigenetic modification in HS.

2016F

Early alterations in the NF-kB signalling pathway may underlie psoriasis pathogenesis. *B. Rhead[1,2], P. Ghai[3], L.F. Barcellos[2], A.M. Bowcock[3].* 1) Computational Biology Graduate Group, UC Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genomics Laboratory, UC Berkeley, Berkeley, CA; 3) National Heart and Lung Institute, Imperial College, London, United Kingdom.

  Psoriasis (MIM 177900) is a chronic inflammatory disease of the skin affecting ~2% of the European population. It is accompanied by hyper-proliferation of the resident skin cell, the keratinocyte, infiltration of immune cells into the dermis and epidermis, and a disorganized skin barrier. The disease is also accompanied by increased vascularization due to proliferation and differentiation of resident endothelial cells. GWAS have revealed over 50 loci associated with disease. Many of these affect immune cell activation pathways and activation of the NF-kB pathway. We have also previously identified rare gain of function mutations in the gene encoding caspase recruitment domain protein 14 (*CARD14*) that lead to enhanced NF-kB signalling. *CARD14* is expressed in keratinocytes and endothelial cells, and we hypothesize that alterations in NF-kB signalling in both cell types, accompanied by genomic changes, are the early events in psoriasis pathogenesis. To investigate this hypothesis, we examined altered CpG methylation in both keratinocytes and endothelial cells following TNFα stimulation, which activates a number of signalling pathways including those of NF-kB. We measured transcriptional response to TNFα in 40 human umbilical vein endothelial cell (HUVEC) and 35 normal human epidermal keratinocyte (NHEK, 24 fetal and 11 adult) primary cell lines. Genome-wide genotyping and gene expression profiling via microarray, before and 24 hours after stimulation with TNFα, were performed on all 75 cell lines. Genes with differential expression in response to TNFα across all cell types were identified. Genome-wide methylation profiles were generated with Illumina HumanMethylation450 (450k) and EPIC BeadChips on 8 cell lines before and 24 hours after TNFα stimulation (16 profiles) and 21 HUVEC lines at 6 timepoints (126 profiles). Analysis of changes after 24 hours in 3 HUVEC, 3 fetal NHEK, and 2 adult NHEK lines shows significant increases in global mean methylation in all 3 cell types, with shifts in mean β values from 0.46 to 0.47, 0.43 to 0.44, and 0.45 to 0.46, respectively (p-values <0.001). Correlation between methylation response and transcriptional response to TNFα stimulation was observed, most notably: an increase in β value of 5-9% for 4 CpGs upstream and in the 5' UTR of *COL21A1* corresponded with decreased expression upon TNFα stimulation in HUVECs. Work to further elucidate early changes in the NF-kB signalling pathway in these cell types is underway.

2017W

Functional intronic *MAPT*-haplotype single nucleotide polymorphisms regulate *MAPT* exon 3 alternative splicing through differential binding of splice factors. *T.M. Caffrey[1,2], M.C. Lai[1,2], A.L. Bechy[1], F. Denk[1], M. Gavriliouk[1], B.J. Ryan[1,2], R. Wade-Martins[1,2].* 1) Physiology, Anatomy and Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Parkinson's Disease Centre, University of Oxford, Oxford, United Kingdom.

Genome wide association studies have identified H1 microtubule-associated protein tau (*MAPT*) haplotype single nucleotide polymorphisms as leading common risk variants for Parkinson's disease, progressive supranuclear palsy and corticobasal degeneration. In the absence of protein coding changes, differences in *MAPT* expression and splicing of alternate exons are proposed to contribute risk or protection to these diseases. Expression studies performed in both cell lines and post-mortem brain tissue have demonstrated greater haplotype-specific expression of *MAPT* exon 3-containing transcripts from the protective H2 haplotype compared to the H1. Here, we investigate the regulation of *MAPT* exon 3 alternative splicing by common, non-coding, haplotype-specific single nucleotide polymorphisms (SNPs) through a novel use of whole-genomic locus expression vectors. Firstly, we generate *MAPT*-PAC expression vectors bearing 143 kb of either the H1 or H2 *MAPT* loci. These vectors contain 8 kb of upstream promoter, all exonic and intronic sequence, as well as 5 kb of 3' untranslated region. Together, the *MAPT*-PACs capture 86% of the documented variation within the gene. Secondly, we interrogate the polymorphic differences between these haplotype vectors, initially in silico, followed by generation and analysis of haplotype-hybrid vectors in a neuronal culture model. We identify rs17651213, located near the exon 3 5' splice site, as a polymorphism that regulates the haplotype-specific expression of exon 3. Thirdly, using RNA:electrophoretic mobility shift assays (RNA-EMSA), we show differential RNA:protein complex formation at the H1 and H2 sequence variants of SNP rs17651213 and identify candidate trans-acting splicing factors interacting with rs17651213 sequences by RNA:protein pull-down experiment and mass spectrometry. Finally, by paring knockdown of the mass-spectrometry identified candidate splice factors with a novel allele-specific expression assay, we demonstrate a role for hnRNP F and hnRNP Q in the haplotype-specific regulation of exon 3 inclusion. In this study, we dissect the *MAPT* locus to fine map sequences regulating alternative splicing of exon 3 and provide a starting point for mechanistic insights into how common non-coding H1/H2 *MAPT* haplotype-specific SNPs may contribute to the risk of neurodegeneration at a complex gene locus.

2018T

Investigating the role of *FAST-1* in Friedreich ataxia. *H. Mikaeili, M. Sandi, A. Bayot, S. Al-Mahdawi, M.A. Pook.* Life Sciences, Brunel University London, Uxbridge, Middlesex, United Kingdom.

Friedreich ataxia (FRDA) is an autosomal recessive neurodegenerative disorder caused by a GAA trinucleotide repeat (TNR) expansion within the first intron of the *FXN* gene, leading to severe deficiency of *FXN* transcript. FRDA patients have disease-related epigenetic changes, which may be the underlying cause of *FXN* gene silencing. Furthermore, it has previously been shown in other TNR diseases that increased antisense RNA expression can induce heterochromatin formation and epigenetic silencing of the corresponding sense gene. The frataxin antisense transcript, *FAST-1*, is overexpressed in FRDA patient-derived fibroblasts, associated with depletion of CTCF, a chromatin insulator protein, and heterochromatin formation. We have overexpressed *FAST-1* in both HEK293 and HeLa cell lines and we have identified a corresponding 30-70% decrease of *FXN* expression levels compared to control cells. Additionally, we identified a positive correlation between *FAST-1* copy number and *FAST-1* expression ($R^2 = 0.7$, P=0.04) and a negative correlation between *FAST-1* copy number and *FXN* expression level ($R^2 = -0.58$, P=0.04). Chromatin immunoprecipitation (ChIP) of *FAST-1* overexpressing HeLa cells showed reduced occupancy of CTCF at the 5'UTR of the *FXN* gene. It is plausible that increased *FAST-1* transcription is involved in the displacement of CTCF from the 5'UTR, resulting in heterochromatin formation and *FXN* gene silencing. Therefore, inhibition of *FAST-1* expression may be an effective approach to pursue for future FRDA therapy.

2019F

Identification of chemicals that mimic transcriptional changes associated with autism, brain aging and neurodegeneration. *J. Simon, B. Pearson, E. McCoy, G. Salazar, G. Fragola, M. Zylka.* University of North Carolina at Chapel Hill, Chapel Hill, NC.

Environmental factors, including pesticides, have been linked to autism and neurodegeneration risk using retrospective epidemiological studies. Here we sought to prospectively identify chemicals that share transcriptomic signatures with neurological disorders, by exposing mouse cortical neuron-enriched cultures to hundreds of chemicals commonly found in the environment and on food. We find that rotenone, a pesticide associated with Parkinson's disease risk, and certain fungicides, including pyraclostrobin, trifloxystrobin, famoxadone and fenamidone, produce transcriptional changes *in vitro* that are similar to those seen in brain samples from humans with autism, advanced age and neurodegeneration (Alzheimer's disease and Huntington's disease). These chemicals stimulate free radical production and disrupt microtubules in neurons, effects that can be reduced by pretreating with a microtubule stabilizer, an antioxidant, or with sulforaphane. Our study provides an approach to prospectively identify environmental chemicals that transcriptionally mimic autism and other brain disorders.

2020W

DNA methylome of human brain cortex and susceptibility of Parkinson's disease. *X. Chen[1], C. Kani[2], S. Tashiro[2], K. Dashtipour[2], C. Wang[1].* 1) Center for Genomics, Basic Science Department, Loma Linda University, Loma Linda, CA; 2) Division of Movement Disorders, Department of Neurology & Movement Disorders, Loma Linda University, Loma Linda, CA.

The current diagnosis of Parkinson's disease (PD) is primarily based on clinical signs and symptoms, and only an autopsy can confirm diagnosis. As such, identifying early pathological changes is crucial to enable therapeutic interventions before a major neuropathological damage occurs. As PD is a multifactorial disease where environmental and genetic factors are intricately associated, epigenetic modifications are the key interface between the environment and genome and may play a major role in PD susceptibility. These changes accumulate over time in response to lifestyle and environmental exposures, subsequently affecting gene expression. The association between epigenetic modifications and some diseases such as cancers has been recently established, but the link between aberrant DNA methylation and neurodegenerative disorders is only beginning to be explored. The objective of our current pilot study is to determine and compare DNA methylation patterns between patients with PD and the age- and sex-matched non-PD controls. We hypothesized that the methylation status of CpG islands are different in PD patients from non-PD individuals and a global differential methylation is related to the susceptibility of PD. DNA was extracted from frozen human brain cortex (superior frontal gyrus at the level of genu of the corpus callosum) from twelve PD patients and twelve controls. The human brain tissues were obtained from the Banner Sun Health Institute Brain and Body Donation Program. A genome-wide DNA methylation profiling was performed using the Illumina HumanMethylation 450k BeadChip array. We identified 2,795 differentially methylated CpG sites (DMSs) between PD cases and controls with a FDR ≤ 0.01 and 328 DMSs with a FDR ≤ 0.001. The majority of differentially methylated regions were hypomethylated suggesting overall hypomethylation in the brain of PD cases compared to controls. Unsupervised hierarchical clustering analysis based DMSs showed a distinct separation between PD and non-PD subjects, and there was a pattern of robust hypermethylation of synphilin-1, α-synuclein interacting protein (SNCAIP) gene in PD cases (P = 4.93×10^{-7} and $\Delta\beta = 0.60$). Our results suggest that a global differential DNA methylation is associated with the susceptibility of PD and there is a link between SNCAIP methylation and PD risk. The methylation level of SNCAIP may be a biomarker for PD diagnosis and treatment.

Allele-specific brain expression and association with CNS disease in 419 individuals. *Z. Zhang[1,2], S. Mostafavi[4], D.J. Philip[2,3], M. Kellis[1,2].* 1) EECS, Massachusetts Institute of Technology, Cambridge, MA; 2) The Broad Institute of Harvard and MIT; 3) Brigham & Women's Hospital and Harvard Medical School; 4) University of British Columbia.

Systematic differences in gene expression between the two alleles of the same individual can yield important insights in gene regulation. Here, we study allele-specific gene expression in human cortex across 419 individuals from two longitudinal aging cohorts (ROS and MAP). We find evidences of imprinting in 28 genes with mono-allelic expression across individuals, including 6 novel imprinted genes in the aging brain: PM20D1, AC091814, LTF, MIMT, COPG2, and NAA60. Some of these 28 genes also show evidence of regulatory region imprinting in their histone modification patterns, with consistent directionality. Interestingly, we show genomic imprinting could happen in a small regulatory region instead of the whole gene body using H3K9ac ChIP-seq and DNA methylation data in the same set of individuals. Also, to our best knowledge, our result is the first evidence to show that the imprinting regulatory region controlling allelic expression of their target genes. For one third of allelic genes, we predict 4701 driver cis-regulatory variants based on strict evidence of activity-correlated variants in separate haplotype blocks. Moreover, we develop a novel statistical method which utilizes that correlation between TF expression and target gene allelic expression on the heterozygous binding sites could be a good indicator for identifying driver regulators in the brain, including BHLHE40, ZBTB7A and BCL6. This result is supported by the published ChIP-seq data and the independent cohort GTEX data. Further, we note that many susceptibility variants for CNS diseases have potential regulatory effect, which can cause allelic expression in our data. Finally, we identified 18 genes whose allelic expression are affected by brain pathologies (i.e., Amyloid Beta, Neurofibrillary Tangle, Lewy Bodies and Cognitive Decline Rate) through cis-variants. Our approach links cis-regulatory variants, disease pathology and target gene and paves a new way for understanding disease mechanism through allelic activity. .

2022F

Dopaminergic neuron chromatin signatures refine a novel Parkinsonian-associated interval and establish a pipeline for informing future genetic studies of neurological disease. *S.A McClymont[1], P.W. Hook[1], M.A. Beer[1,2], O.A. Ross[3], A.S. McCallion[1].* 1) Johns Hopkins University School of Medicine, McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD; 2) Johns Hopkins University, Department of Biomedical Engineering, Baltimore, MD; 3) Mayo Clinic College of Medicine, Department of Neuroscience, Jacksonville, FL.

Non-coding sequence variation plays an important role in complex disease risk. However, the search for biologically appropriate regulatory sequences in which causative variation may act is not facile. It relies on the selection and isolation of appropriate cell types, and on the scrutiny of the chromatin landscape at appropriate developmental stages or following exposure to the correct stimuli/insults. In an effort to explore variation implicated in disorders of the basal ganglia, including Parkinson disease (PD), we have used ATAC-seq to define regions of open chromatin in subsets of lineage-identified dopamine (DA) neurons. We generated multiple enhancer catalogs, each from 50,000 FAC-sorted *ex vivo* DA neurons either from the forebrain (n=3) or midbrain (n=3) of E15.5 (Tg(Th-EGFP)DJ76Gsat) transgenic mice. Each ATAC-seq library yielded ≤28 million high quality mapped reads, producing catalogs with strong evidence of functional sequence constraint (PhastCons>0.3) and significant enrichment for processes and functions appropriate to neuronal function and dysfunction by GREAT/GO. These high quality catalogs facilitate the development of a regulatory vocabulary (computational classifier) of DA neurons using support vector machine learning. With preliminary filtering alone, our data yield a classifier with high predictive power (auROC=0.823) that is already providing insight into transcription factors active in DA neurons and the nature of the regulatory variation that might influence DA enhancer function. To improve the classifiers, we are now applying more stringent filters. Importantly, our catalogs can inform our understanding of the biology at GWAS-implicated intervals. Our data has already highlighted a putative enhancer in an intron of *SNCA*, overlapping a GWAS hit for Lewy body dementia. In preliminary zebrafish transgenic reporter assays of enhancer function, over 90% of mosaic embryos exhibit reporter activity in the CNS, driven by this putative enhancer sequence. Transgenic reporter mice assaying this enhancer are currently being evaluated. Beyond this locus, we are establishing massively parallel reporter assays to both functionally validate the enhancer catalogs and assess our ability to predict the function of regulatory sequence variation, particularly at GWAS-implicated loci. We will report progress in our efforts to assay the impact of PD and related movement disorders GWAS-implicated variation on DA neuron function and disease pathology.

2023W

Transcriptional programs defining functional domains in the human brain. *A.C. Watts, K.T. Siebenthall, J. Halow, R. Sandstrom, S. Ibarrientos, K. Lee, A. Castillo, A.K. Johnson, R. Kaul, J.A. Stamatoyannopoulos.* University of Washington, Seattle, WA.

Functional domains of the human brain have been mapped at a fine level, but the transcriptional programs by which these regions develop and are maintained are poorly understood. Knowledge of these transcriptional programs can provide insight into the pathology of neurological disorders and cancers. Human post-mortem brain tissue from 13 different brain regions was obtained from cognitively and pathologically normal individuals who participated in the Adult Changes in Thought Study at the University of Washington. Additionally, neuronal and glial cells were isolated from the same tissue to obtain paired cell-type specific data. We generated reference maps of accessible chromatin utilizing the DNase I assay, and transcription using RNA-sequencing. Thus far we have identified clusters of DNase I hypersensitive sites (DHSs) that are present in a specific sub-structure (e.g. occipital lobe) as well as in larger nuclei (e.g. basal ganglia). We are currently dissecting the clusters of DHSs to identify transcription factor motifs, as well as incorporating data from neurons and glial cells. We will further characterize the functionality of these DHSs utilizing genome editing technology to introduce mutations within them in human-specific model systems, including cerebral organoids, followed by comparative analysis of cell morphology, spatial organization, chromatin accessibility and gene expression. This research has the potential to elucidate the regulatory programs underlying region-specificity and functionality in the human brain, and provide insight into the molecular pathways involved in neurological disorders.

The epigenetics of normal and disordered human sleep are largely unknown. The Epworth Sleepiness Scale (ESS) is a widely-administered clinical questionnaire used to assess sleepiness. Excessive daytime sleepiness is a frequent symptom of Obstructive Sleep Apnea (OSA) and other sleep disorders, and increase risk for motor vehicle crashes and work related injuries and reduce quality of life. Daytime sleepiness is most prevalent in African Americans, and this association is not completely explained by measured sleep disorders or sleep duration. We performed the first epigenetic-wide association study of ESS scores and DNA methylation marks from purified monocytes in the Multi-Ethnic Study of Atherosclerosis (MESA). 619 individuals of African, European, and Hispanic ancestry, ages 54 to 91, with both ESS data and epigenomic results were analyzed using 64,785 high-varying probes on the M-value scale (inter decile range greater than 0.1). Models were adjusted for age, sex, cell-type enrichment, and site of enrollment. Technical covariates were adjusted prior to analyses via ComBat. An African-American analysis (n=132) found one Bonferroni-significant probe and an additional 12 probes with q-values less than 0.05. Mean ESS was 6.7 +/- 4.5. Two genes were associated with 6 of the 13 probes, *RAI1* and *KIFC3*. The Bonferroni-associated probe was found at *KIFC3* (p-value of 4.18E-07) and was associated with a -.6 decrease in the ESS score for every .1 unit increase in DNAm. cg14720773 and cg27208169 near *RAI1,* a gene associated with disruptions in sleep-wake cycles and recently found to be associated with OSA, were associated with a -.6 and -.7 decrease in ESS score for every .1 unit increase in the DNAm M-value (p-values of 1.41E-06 respectively). An increase in DNAm is thus associated with a decrease in sleepiness. These results were not impacted by the inclusion in the model of socio-economic or other sleep variables. This pattern was found for all significant or suggestive probes except for two: one near *COQ2* and another near *MEIS2*. There were no significant probes found in the other ethnic groups or in a multi-ethnic analysis. This study provides evidence that altered methylation patterns associate with daytime sleepiness in African Americans and suggest the potential impact of epigenetic factors in influencing this trait.

2025F

Genome-wide methylation patterns are associated with Parkinson's disease. *Y. Chuang[1], S. Horvath[2,3], K. Paul[1], J. Bronstein[4], Y. Bordelon[4], B. Ritz[1,4,5].* 1) Epidemiology, UCLA, LA, CA., USA; 2) Human Genetics, UCLA, LA, CA., USA; 3) Biostatistics, UCLA, LA, CA., USA; 4) Neurology, UCLA, LA, CA., USA; 5) Environmental Health, UCLA, LA, CA., USA.

   Background: There is growing interest in understanding the role of DNA methylation in Parkinson's disease (PD). Yet, genome-wide studies of methylation in PD are still rare. Weighted co-methylation network analysis (WGCNA) is a system biology method to build robust genetic network and to identify trait-associated co-methylation modules. Using genome-wide DNA methylation data from whole blood and saliva, we aim to identify gene-specific CpG sites and co-methylation modules that would implicate mechanisms or pathways in PD etiology or could possibly serve as blood based biomarkers. **Methods:** We used Illumina 450k microarrays to investigated whole blood methylation profiles in 335 PD and 237 controls and saliva methylation profiles in 128 PD and 131 controls in a population-based study in Central California that enrolled subjects of European and Hispanic ancestry. We used correlations analysis to identify individual CpGs associated with PD and conducted a meta-analysis across ethnic groups. Moreover, using WGCNA we assessed the relation of modules of co-methylated CpGs with PD. The gene set enrichment analysis tool -DAVID- provided us with gene functional annotations for PD-associated genes and modules. **Results:** In blood samples, we identified 82 CpGs significantly associated with PD at the genome-wide level. PD-associated CpG with the strongest association was on the mitochondrial gene. Employing WGCNA, three out of 6 PD-associated modules remained significant after Bonferroni correction and were significantly enriched for genes related to immune response. After adjusting for blood cell composition, PD-associated modules were enriched for genes related to neuron projection morphogenesis and the Wnt signaling pathway. We replicated our blood based findings - with and without adjustment for blood cell composition- in saliva samples from an independent case control sample. Moreover, in saliva samples PD-associated CpG was found on the ferritin gene. **Conclusions:** Our study provides the first evidence for epigenetic differences related to mitochondrial and immune-related genes in PD also identify underappreciated pathways of importance in PD like the cytoskeleton, the Wnt signaling pathway, and brain iron and ferritin. It is standard to adjust for blood cell composition in DNA methylation studies using blood samples. However, our results suggest that this approach may miss important signals when blood cell composition and immunologic factors play a role as in PD.

2026W

Variegated hypermethylation of the *FXN* CpG island shore in Friedreich ataxia. *Y.K. Chutake[1], C.C. Lam[1], G. Wiley[2], S.I. Bidichandani[1].* 1) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK.

   Friedreich ataxia (FRDA) is caused by an expanded GAA triplet-repeat (GAA-TR) mutation in intron 1 of the *FXN* gene that results in epigenetic silencing of the *FXN* promoter. Bisulfite treatment and deep sequencing revealed that while the promoter is located within an unmethylated CpG island (CGI), the CpG island shore (CGI-shore), situated immediately downstream of the CGI in intron 1, is hypermethylated in FRDA but remains largely unmethylated in the non-disease state. The CGI-shore, which functions as a FRDA-specific differentially methylated region (FRDA-DMR), is hypermethylated due to enhanced spreading of DNA methylation from the expanded GAA-TR mutation in FRDA. The hypermethylated FRDA-DMR was detected in patient-derived lymphoblastoid cells, primary fibroblasts and peripheral blood samples. Analysis of individual DNA molecules revealed a variegated pattern of DNA methylation, with apparently stochastic methylation of individual CpG dinucleotides within the FRDA-DMR, the magnitude and extent of which was dependent on the length of the expanded GAA-TR mutation. Treatment with 5-aza-2'-deoxycytidine enhanced the ability of a class I histone deacetylase inhibitor that is known to ameliorate epigenetic promoter silencing in FRDA, to increase *FXN* transcript levels in patient-derived cells, indicating that DNA methylation contributes to *FXN* silencing in FRDA. Given that variable CGI shore methylation determines differential expression of genes in normal and disease states, the FRDA-DMR represents a novel and tractable model of variegated silencing in the context of a human genetic disease.

2027T

Abnormal methylome is present in an animal model of temporal lobe epilepsy. *D.B. Dogini[1,3], A.S. Vieira[1,3], A.H.B. Matos[1,3], W. Souza[1,3], R. Gilioli[2], I. Lopes-Cendes[1,3].* 1) Departments of Medical Genetics, School of Medical Sciences, UNICAMP, Campinas, Sao Paulo, Brazil; 2) Laboratory of Animal Quality Control (CEMIB), School of Medical Sciences, UNICAMP, Campinas, Sao Paulo, Brazil; 3) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN).

Epigenetics summarizes alterations to the chromatin template that collectively establish and propagate different patterns of gene expression without changes in DNA sequence. To better understanding the role of epigenetic changes in epilepsy, we determined the methylation profile of an animal model of temporal lobe epilepsy in comparison with control animals. We used laser capture microdissection to obtain tissue from hippocampus of rats treated with pilocarpine (*n*=2) as well as control animals. DNA was extracted using proteinase K protocol with modifications and it was converted by bisulfite with EZ DNA Methylation-Lightning™ Kit (Zymo Research). After conversion libraries were generated using TruSeq DNA Methylation and sequencing was performed in a Illumina HiSeq 2500. Bioinformatics analysis found 18 differently methylated regions along the 20 rat chromosomes. In these regions we identified several genes, including Mef2a (myocyte enhancer factor 2) – a transcription factor; Atp10d (ATPase, class V, type 10D) – involved with ATP binding and Puf60 (poly-U binding splicing factor 60) – involved with RNA/DNA binding. This is a pilot study and the candidate regions are still under analysis in order to characterize all genes within the abnormally methylated regions. However, it is already clear that the epileptogenic insult induced by pilocarpine injections in rats resulted in significant methylation changes, which may be implicated in the mechanisms underlying epilepsy.

2028F

Epigenetics of plantation work and exposure to organochlorines in the Japanese male Kuakini Honolulu Heart Program Cohort with Parkinson's Disease. *R.C. Go[1,2,7], A.K. Maunakea[4], M.J. Corley[4], G.W. Ross[2,5,6], H. Petrovich[2,5,6], K.H. Masaki[1,5], Q. He[1,5], M. Tirikainen[3].* 1) Kuakini Health Systems, Honolulu, HI; 2) Pacific Health Research and Education Institute, Honolulu, HI; 3) University of Hawaii Cancer Center, University of Hawaii Manoa, Honolulu, HI; 4) Department of Native Hawaiian Studies, John A. Burns School of Medicine, University of Hawaii Manoa, Honolulu, HI; 5) Department of Geriatric Medicine, John A. Burns School of Medicine, University of Hawaii Manoa, Honolulu, HI; 6) Neurology, Veterans Affairs Pacific Islands Health Care System, Honolulu, HI; 7) Department of Epidemiology, School of Public Health, University of Alabama at Birmingham, Birmingham, AL.

Parkinson's Disease (PD) is a disease with multiple etiologies. Epidemiological studies have provided evidence that exposure to agricultural related occupations or agrichemicals elevate a person's risk for PD. However, the mechanism(s) underlying this association remains unknown. Here, we sought to test the possibility that exposure impacts epigenetic processes, in particular DNA methylation, that may consequently influence risk for development of PD. To this end, we determined whether working on a plantation on Oahu, HI and/or exposure to organochlorines are associated with differentially methylated loci (DML) between PD cases with high and low exposures, utilizing a prospective cohort assessed for years of work on a plantation and exposures to 21 OGC in occipital lobe tissues. Blood buffy coat and temporal lobe DNAs were extracted and the Illumina Infinium Human Methylation 450K Bead Chip platform was used to assess DNA methylation. Cases were tested for DML across 480K+ loci using ANCOVA. The comparison of 10+ to 0 years of plantation work exposure, detected 8 DML and 129 DML at a significance level of 0.0001 in brain and blood respectively. The comparison of cases with 4+ to 0-2 detectable levels of OGC, identified 11 and 18 DML at a p<0.0001, for brain and blood respectively. Hierarchical clustering and Principal Components Analyses of DML showed that the highest were separable from the lowest exposure groups. Glial origin of these signals and pathway analyses revealed links to key PD neuropathological pathways.

Variants in chromatin factors such as SMCHD1 and DNMT3B modify the epigenetic repression of the D4Z4 repeat and disease penetrance in facioscapulohumeral dystrophy. *R.J.L.F. Lemmers[1], M.L. van den Boogaard[1], J. Balog[1], P.J. van der Vliet[1], K.R. Straasheijm[1], R.F.P. van der Akker[1], M. Kriek[1,2], K.B.M. Hanson[2], M. Wohlgemuth[3], B.G.M. van Engelen[3], M. Auranen[4], S. Kiuru-Enari[4], S. Mitsuhashi[5], I. Nishino[5], R. Tawil[6], S.J. Tapscott[7], S.M. van der Maarel[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 3) Department of Neurology, Radboud University Medical Center, Nijmegen, the Netherlands;; 4) Clinical Neurosciences, Neurology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; 5) Department of Neuromuscular Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo, Japan; 6) Department of Neurology, University of Rochester Medical Center, Rochester, NY; 7) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA.

Facioscapulohumeral dystrophy (FSHD) is mainly characterized by progressive weakness and atrophy of the facial, shoulder and upper arm muscles. FSHD is associated with partial loss of chromatin condensation, marked by CpG hypomethylation, at the D4Z4 repeat locus on chromosome 4 and transcriptional derepression of the D4Z4-encoded *DUX4* gene in skeletal muscle. In most cases FSHD is caused by a contraction of the D4Z4 repeat array to a size between 1-10 units (FSHD1), while the normal size ranges between 8-100 units. In rare cases (FSHD2), the disease can be caused by mutations in the chromatin repressor SMCHD1 that is required for the maintenance of CpG methylation at D4Z4. Variants in SMCHD1 can also modify the disease severity in FSHD1 families. Since not all FSHD2 cases can be explained by *SMCHD1* mutations, we performed whole exome sequencing in SMCHD1 mutation-negative FSHD families and identified heterozygous mutations in *DNMT3B* segregating with D4Z4 hypomethylation and increased penetrance of FSHD. DNMT3B is one of the de novo DNA methyltransferases that is necessary for the establishment of CpG methylation at specific loci during development. Recessive *DNMT3B* mutations were previously shown to cause Immunodeficiency, Centromeric instability and Facial anomalies (ICF) syndrome. *DNMT3B*-associated FSHD patients have no immunodeficiency, but ICF patients and their parents are at risk of expressing DUX4 and developing FSHD. Similar to what is observed for *SMCHD1* mutations, the effect of *DNMT3B* mutations on DUX4 expression and disease severity depends on the residual activity of the D4Z4 chromatin repressors and the size of the D4Z4 repeat. While overexpression of SMCHD1 can reverse D4Z4 chromatin decondensation and silence DUX4 expression in muscle cells, overexpression of DNMT3B fails to do so, perhaps because of a mismatch with the developmental window in which DNMT3B is normally functional. These results suggest that a combination of genetic and epigenetic factors that act on the D4Z4 repeat array determine the probability of DUX4 expression in skeletal muscle and disease penetrance and progression. FSHD thereby facilitates the study of chromatin factors that control accurate establishment and maintenance of chromatin structure and transcriptional activity from repeat DNA.

2030T

Genome-wide meta-analysis identifies SNPs associated with epigenetic age acceleration across multiple brain regions. *A. Lu[1], E. Hannon[2], M. Levine[1], E. Crimmins[3], K. Lunnon[2], J. Miller[2,4], D. Geschwind[5], S. Horvath[1,6].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) University of Exeter Medical School,Exeter, UK; 3) Davis School of Gerontology, University of Southern California, Los Angeles, CA; 4) Institute of Psychiatry, King's College London, London,UK; 5) Department of Neurology and Center for Autism Research and Treatment, Semel Institute, UCLA, Los Angeles, CA; 6) Biostatistics, School of Public Health, UCLA, Los Angeles, CA.

We recently developed a biomarker of aging based on DNA methylation (DNAm) levels that is referred to as "epigenetic clock". This biomarker of aging applies to all human tissues, organs and cell types and results in a highly robust estimate of age. By contrasting the resulting age estimate (DNAm age) with chronological age, one can define a measure of epigenetic age acceleration. We have shown that epigenetic age acceleration in postmortem prefrontal cortex samples relates to pre-mortem estimates of cognitive decline and neuropathological measures even after adjusting for chronological age and other confounders. We propose that epigenetic age acceleration can also be used in a QTL analysis to identify SNPs that affect the epigenetic aging rate of the brain. Using DNA methylation data from cerebellar samples, we identified a mTOR associated gene *MLST8* and the RNA helicase gene *DHX57* in a genome-wide meta analysis. Here we extend these studies to non-cerebellar brain regions as well. We analyzed 1,796 brain tissue samples from 1,163 individuals across 7 studies. GWAS was performed on ~ 7M genotyped and imputed markers for epigenetic age acceleration in cerebellum, (pre)frontal cortex, pons and temporal cortex. The association results were combined across brain regions and studies using fixed effects meta analysis weighted by inverse variance. We identified a total of 7 SNPs associated at genomewide significance level of 5.0×10^{-8}. These GWAS SNPs are close to a calcium signaling associated gene. The risk allele of the leading SNP increases the epigenetic age estimate by 1.4 years in the frontal cortex, by 1 year in prefrontal cortex, temporal cortex and pons, and by 0.8 years in the cerebellum. These association signals are corroborated by 210 surrounding SNPs that are significant at a suggestive significance threshold of 5.0×10^{-7}. A large-scale *cis*-eQTL analysis (n=3,943) implicates the respective genes ($P=1.5 \times 10^{-19}$) for the underlying biological process. A MAGENTA enrichment analysis of the GWAS results implicated GTPase inhibitor activity ($P_{MAGENTA} = 2.0 \times 10^{-4}$). Furthermore, the genes implicated in brain age acceleration exhibit suggestive overlap with those found by GWAS of dementia ($P=5.8 \times 10^{-3}$) and Alzheimer's disease ($P=4.9 \times 10^{-3}$). Overall, our study suggests that it will be useful to use epigenetic age acceleration as quantitative phenotype for studying the genetic determinants of brain aging. .

2031F

Molecular mechanisms of pathogenicity: Why truncating variants in *KIAA2022* cause epileptic encephalopathy in some (but not all) females. *C. Saunders[1,2,3], J.B. LePichon[4], E. Farrow[1,3], S. Soden[1,3,4], S. Parikh[5], I. Thiffault[1,2,3].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO; 2) Department of Pathology and Laboratory Medicine, Children's Mercy Hospitals, Kansas City, MO, USA; 3) University of Missouri–Kansas City School of Medicine, Kansas City, MO, USA; 4) Department of Pediatrics, Children's Mercy Hospitals, Kansas City, MO, USA; 5) Center for Pediatric Neurology, Cleveland Clinic, Cleveland, OH, USA.

   X chromosome inactivation is a mechanism that modulates the expression of X-linked genes in females to achieve a proper balance between X-linked and autosomal genes. In humans 15-25% of X-linked genes have been shown to 'escape' from X-chromosome inactivation (XCI), being expressed to some extent from the inactive X chromosome. A significant subset of such escapees are genes associated with intellectual disability. The expression of X-linked genes in females lies on a continuum between those subjected to inactivation, and those that escape. Recent genomic studies have yielded contradictory results and fueled debate over the possibility that genomic imprinting is not limited to autosomes and the X-inactivation center. We report two females with intractable epilepsy caused by *de novo* loss of function variants in *KIAA2022*, an X-linked gene associated with severe intellectual disability in males. This is perplexing since the carrier mothers of affected males are unaffected. Random patterns of XCI have been observed in both affected females and unaffected carrier mothers so is not sufficient to explain these differences. We offer indirect evidence that *KIAA2022* escapes XCI, review what is known about *KIAA2022* and argue parent-of origin mono-allelic expression as a possible mechanism for the apparent dichotomous phenotypic expression of *KIAA2022*.

2032W

Multiple system atrophy: Are epigenetics to blame? *E.N. Scott[1], I. Guella[1], A. Rajput[2], A.H. Rajput[2], L. Parkkinen[3], M.S. Kobor[4], M.J. Farrer[1].* 1) Centre for Applied Neurogenetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Royal University Hospital, Saskatoon, Saskatchewan, Canada; 3) Oxford Parkinson's Disease Centre, University of Oxford, Oxford, United Kingdom; 4) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, University of British Columbia, Vancouver, British Columbia, Canada.

   Multiple system atrophy (MSA) is an adult-onset neurodegenerative disorder with prominent autonomic dysfunction, poorly levodopa-responsive parkinsonism, and alpha-synuclein (*SNCA*)-immunopositive oligodendroglial pathology. The two predominant subtypes are MSA-P with clinical parkinsonism and MSA-C with cerebellar ataxia. Clinical heterogeneity in MSA has been a major stumbling block in the identification of pathogenic variants. Certain clinical features overlap with similar disorders, and, due to the lack of a 'hallmark' clinical presentation, the rate of misdiagnosis is high. Given the fact that it is a rare, sporadic disease, large sample sets are needed to have enough power to detect a true disease-causing variant. Whole exome sequencing has become a fundamental tactic for the identification of pathogenic variability in many rare diseases. However, if using only sporadic MSA cases, hundreds of shortlisted variants may be identified. Prioritization of variability in genes previously implicated in MSA, involved in neurodegeneration, and found within relevant pathways are only a few of the approaches taken to narrow down the list of candidates. Genome-wide genotyping, investigating copy number variability and regions of homozygosity, may implicate loci but even the largest meta-analyses will be underpowered. We and others have employed many of these methods, but have failed to identify any disease-causing variability in MSA. We hypothesize genetic, epigenetic, and expression changes in *SNCA* influence the distribution and burden of alpha-synuclein pathology in the brains of patients with MSA. Using striatal tissue from brains with pathologically-confirmed MSA, Parkinson's disease, dementia with Lewy bodies, and unaffected control subjects (n=32, 8/group), we pilot genome-wide SNP, methylation, and gene expression analyses. We will report on differential methylation and expression between tissues, patients, and control subjects, adjusting for SNP variability and considering the burden of inclusion pathology. Understanding the pathogenesis of MSA may provide insight into the propagation of alpha-synucleinopathies and inform the development of novel therapeutics.

2033T

Aberrant DNA methylation of the non-coding *VTRNA2-1* (*MIR886*) gene in Parkinson disease. *S.K. Sivasankaran[1,2], A. Ali[1,2], A. Mehta[1,2], D.C. Mash[1,2], G. Beecham[1,2], E.R. Martin[1,2], J. Vance[1,2], L. Wang[3], J.I. Young[1,2].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 2) John T. Macdonald Foundation Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL; 3) Department of Public Health Sciences, Division of Biostatistics, Miller School of Medicine, University of Miami, Miami, FL.

Parkinson disease (PD) is a common neurodegenerative disorder pathologically defined by the presence of Lewy bodies and extensive loss of dopaminergic neurons in the substantia nigra. Epidemiological studies have shown that there are many environmental exposures that modify the risk of PD, but the mechanism of these interactions is not known. As DNA methylation is one the known mechanisms through which environment can influence biological process, we investigated whether methylation differences exist between PD and controls. However, since it is well established that methylation profiles in the brain are region specific, we utilized brain regions known to be involved at different stages of PD. Previously, the majority of PD cases have been shown to have the earliest signs of Lewy body formation in the olfactory bulb and dorsal motor nucleus of the vagus (DMV), which have direct connections to the environment, through the olfactory and vagus nerves. In this study, we investigated genome-wide DNA-methylation profiles in the DMV of autopsy-confirmed PD cases and controls using Illumina 450K beadchip. A total of 34,942 CpGs were differentially methylated (FDR<0.05) in our analysis. Methylation patterns have been shown to be highly correlated, leading to the identification of differentially methylated regions (DMR), highly correlated CpG clusters that are less subject to identification artifacts than single site methylation. We identified 1,775 DMR in the DMV (adjusted P<0.05), including some in previously known PD associated genes like *MAPT* and *EIF4G1*. Of particular interest is a DMR associated with *VTRNA2-1*, which contains 20 differentially methylated CpGs including 9 CpGs in the promoter region. *VTRNA2-1* was previously reported found to lie within the 1-LOD score peak of a PD linkage region and is reported to be upregulated in "early" PD, suggesting it may contribute to the disease mechanism. Further, multiple studies have reported it is both imprinted and environmentally susceptible to methylation. This finding supports the hypothesis that environmental risks factors for PD may act early through the DMV and that the *VTRNA2-1* gene is a candidate gene for involvement in early PD.

2034F

iPSC-derived neurons as a model system for studying cis and trans factors regulating *SNCA* gene expression and their role in synucleinopathies. *O. Chiba-Falek[1,2], L. Tagliafierro[1,2].* 1) Neurology, Duke Univ, Durham, NC; 2) Center for Genomic and Computational Biology, Duke Univ, Durham, NC.

Accumulating evidence has suggested that *SNCA* expression levels are critical for the development of Parkinson's Diseases (PD), Dementia with Lewy Bodies (DLB) and other synucleinopathies. Common and distinct regulatory mechanisms of *SNCA* gene expression might be involved in the etiology of the different synucleinopathies. To study the *cis* and *trans* genetic factors that regulate *SNCA* expression in PD compared to DLB we established a model system of induced Pluripotent Stem Cells (iPSCs)-derived neurons from a normal subject and a patient with *SNCA*-triplication. These iPSC lines were differentiated into dopaminergic and cholinergic neurons to model PD and DLB, respectively. Each neuronal type was characterized throughout the stages of differentiation: iPSCs, Neural Precursor Cells (NPCs), final neurons, and aged neurons. *SNCA*-mRNA and protein expression in the *SNCA*-triplication cells exhibited two-fold increase compared to the cells from normal control for each neuronal type across differentiation, recapitulating the observations in human tissues and demonstrating the suitability of our model system for studying up-regulation of *SNCA* expression. TargetScan analysis identified five conserved miRNA binding sites in *SNCA*-3'UTR. Noteworthy, previously three of these miRNAs showed direct interactions with *SNCA*-3'UTR and down-regulated *SNCA*-mRNA and protein levels. The miRNAs demonstrated distinct expression patterns in the dopaminergic compared to the cholinergic neurons and across the differentiation stages of each neuronal type. Remarkably, miR-7 was expressed exclusively in mature dopaminergic neurons, while miR-223 was expressed predominantly in cholinergic neurons. Also, the overall lower levels of the miRNAs in final neurons compared to NPCs corresponded to higher *SNCA*-mRNA levels. Transcription factors previously reported to regulate *SNCA* transcription were also differentially expressed during differentiation and between the dopaminergic and the cholinergic neurons. For example, GATA2 levels were elevated in mature neurons and were 2-fold increased in cholinergic compared to dopaminergic neurons. Genome editing experiments (CRISPR/Cas9) are underway to examine how *cis*-variants modulate *SNCA* expression via their interactions with the *trans*-acting factors. In conclusion, we developed and are using an isogenic iPSC-based model system to discover the *cis* and *trans* acting factors that contribute to the regulation of *SNCA* expression in the context of PD and DLB.

2035W

Exploring the human genome for functional, non-coding variation reveals a far-upstream regulatory SNP at *TUBB2B***.** *W. Law[1,2], A. Vester[1], A. Antonellis[1].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

   Sequence variations within transcription factor binding sites (TFBS) can result in dysregulation of gene expression and directly cause or alter the severity of human disease. The implicated variants are often single-nucleotide polymorphisms (SNPs) within TFBS that alter DNA binding affinity. We hypothesize that such regulatory SNPs (rSNPs) impact the function of genes important for peripheral nerve development and function, and represent excellent candidate modifier loci for peripheral nerve disease. To address this hypothesis, we developed a computational pipeline to identify and functionally characterize novel rSNPs impacting the peripheral nervous system. Specifically, we computationally identified candidate TFBS across the human genome based on: (1) conservation of 5 base pair (or longer) genomic segments between human, mouse, and chicken; (2) overlap with a known, validated SNP; and (3) localization to non-protein-coding sequences. These efforts revealed 6,164 conserved SNPs in the human genome. We further refined our computational pipeline to identify rSNPs in a transcription-factor centric manner focusing on SOX10, which is essential for peripheral nerve function. We filtered the above 6,164 SNPs to find those that reside within a SOX10 consensus binding site or a SOX10 ChIP-Seq binding peak. These efforts revealed 22 putative SOX10-relevant rSNPs. To evaluate the regulatory potential of our predicted rSNPs, a genomic segment surrounding each rSNP was cloned upstream of a luciferase reporter gene and transfected into immortalized Schwann cells. Luciferase assays were performed to identify genomic segments with at least a 5-fold increase in activity over a control vector. This revealed four novel genomic segments with enhancer activity, of which two showed a significant difference in luciferase activity between the major and minor alleles. We deeply characterized one region using transgenic LacZ reporter mice, which revealed tissue-specific enhancer activity in SOX10 relevant tissues. We further assessed this element by deleting the region in cultured Schwann cells using CRISPR/Cas9 followed by RNA sequencing to identify a novel candidate target gene: *Tubb2b*. Both the identified rSNP and *Tubb2b* represent excellent candidate modifiers of peripheral nerve-related diseases. Additionally, the computational and functional pipelines developed here will be applicable to additional transcription factors.

2036T

APOE **and** *TOMM40* **gene regulation.** *L. Bekris[1,3], Y. Shao[1], J. Leverenz[2].* 1) Genomics Medicine Institute, Cleveland Clinic Lerner Research Institute, Cleveland, OH; 2) Cleveland Clinic, Neurological Institute, Cleveland Clinic Lou Ruvo Center for Brain Health, Cleveland, OH; 3) Cleveland Clinic Lerner College of Medicine of Case Western Reserve University, Cleveland, OH.

  Background: The *APOE* gene is the strongest genetic risk factor for late-onset Alzheimer's disease (AD). Multiple regulatory elements have been described within and surrounding the *APOE* gene. Our group, and others have described a statistical, as well as mechanistic, relationship between *TOMM40* regulatory region genetic variants and *APOE* expression. *TOMM40* is located directly adjacent to and upstream from *APOE*. Interestingly, a potential regulatory element has been described within the distal region of *APOE* suggesting 3'UTR regulation. However, little is known about the influence of miRNA post-transcriptional regulation at this locus. MicroRNA (miRNA) play an essential role in post-transcriptional gene regulation in the brain. Genetic variants located across the *APOE* locus are the strongest risk factors for late-onset AD described to date. **Objective:** The aim of this investigation was to determine if the *APOE* 3'UTR and miRNA play a role in regulation of *APOE* or *TOMM40*. **Method:** *APOE* exon 4 and the 3'UTR were inserted into a luciferase reporter vector upstream from the poly-A. A library of reporter constructs containing either the *TOMM40* promoter or the *APOE* promoter and in combination with *APOE* exon 4 - 3'UTR haplotypes were produced. These reporter haplotypes were transiently transfected into several different human cell lines. MiRNA were tested for their influence on regional gene regulation, including regulation of the *TOMM40* promoter. **Results:** *APOE* exon 4 - 3'UTR ε2 and ε3 haplotypes, but not the ε4 haplotype, inhibit both the *APOE* and *TOMM40* promoters in the human neuronal SHSY5Y cell line. A miR-744 transiently transfected mimic further inhibits the *APOE* exon 4 - 3'UTR ε3 haplotype influence on the *TOMM40* promoter, but not the *APOE* promoter, suggesting that an interaction between a 3' regulatory element and the *APOE* promoter does not involve miR-744 in SHSY5Y cells. **Conclusion:** These results suggest that a complex regulatory structure within and surrounding *APOE* may be fine-tuned by miRNA post-transcriptional modulation.

2037F

A novel method for achieving single cell resolution of epigenomic status.

La Jolla, CA; 5) Computational Neurobiology Laboratory, The Salk Institute for Biological Studies, La Jolla, CA.

When performing whole genome bisulfite sequencing (WGBS), highly efficient conversion of DNA fragments into library molecules is necessary when input quantity is limited. To meet this need, we developed an efficient library preparation using Adaptase for NGS adapter ligation to single-stranded, bisulfite-converted DNA fragments. This method significantly improves library complexity compared to existing commercially available methods. Since comprehensive methylome coverage was achievable from low DNA inputs, this method was modified and applied to single cells for classification of mammalian brain cell types based on methylation pattern. Approximately 20% of the mouse genome contains differential methylation that allows neuronal cell types to be distinguished by low pass WGBS. For example, >200,000 differentially methylated regions were identified among three cortical excitatory and inhibitory neuron types. Starting from single neuronal nuclei isolated from mouse frontal cortex that had undergone lysis and bisulfite conversion, NGS adapters were incorporated onto DNA fragments using a single cycle of random priming followed by Adaptase. The resulting low pass WGBS sequence demonstrated robust neuron type classification, readily separating excitatory and inhibitory cells, and further identified distinct populations of inhibitory cells. This method enabled unbiased characterization of brain epigenomic diversities without the need for the isolation of specific cell populations. Compared to other single cell bisulfite sequencing methods, the Adaptase workflow was faster and produced a higher percentage of aligned reads that increased the per cell data output. This method will meet the need of large-scale single cell methylome profiling of thousands of cells to enable discovery of single cell epigenomic variation.

2038W

Integrated analysis of miRNA and mRNA transcript profiles reveals different molecular mechanisms underlying seizure and *status epilepticus*-like in the zebrafish brain. *C. Maurer-Morelli, R. Oliveira, A. Vieira, A. Matos, W. Souza, C. Rocha, B. Carvalho, I. Lopes-Cendes, V. Zago.* Genetica Medica, UNICAMP, Campinas, Sao Paulo, Brazil.

Purpose: MicroRNAs (miRNAs) are key molecules associated with seizures. This study aimed to integrated miRNA/mRNA transcript profile data of two protocols of seizure-induced in the zebrafish model in order to identify molecular mechanisms underlying seizures. **Methods:** Seven days post fertilization larvae were separated into (i) control (CTL, n=3), (ii) acute seizure (AS, n=2) and (iii) *status epilepticus*-like (SE, n=3) groups. Larvae from AS and SE groups were exposed to pentylenetetrazole 15mM for 20 minutes and 3h, respectively. After seizure-induced, animals were anesthetized and their heads isolated, quickly frozen and stored at -80°C. Each sample was composed by pooling 20 heads to obtain material for RNA extraction. Illumina's Sample Prep Kit was used according to instructions to get miRNA and mRNA libraries. Validated and pooled libraries were sequenced in the Illumina HiSeq 2500 System. We used FastQC, DESeq2, and TopHat tools for bioinformatic analyses. MiRNA and mRNAs differentially expressed were determined (adj p<0.01) and the target genes investigated by the TargetScanFish 6.2. Animal Ethical Committee/UNICAMP (# 3045-1). **Results**: We found (i) two miRNAs (dre-miR-460-3p and dre-miR-725-3p) and 2897 mRNAs in the AS *vs* CTL groups, (ii) three miRNAs (dre-miR-31, dre-miR-132-5p and dre-miR-459-3p) and 4622 mRNAs differentially expressed in the SE *vs* CTL groups, and (iii) four miRNAs (dre-miR-725-3p, dre-miR-221-5p, dre-miR-192 and dre-miR-460-3p) and 2841genes between the AS *vs* SE groups. **Discussion:** After miRNA-mRNA integration data, we highlight the dre-miR-460-3p (down-regulated) and its up-regulated target, *inhbaa* gene in the AS group. The *inhbaa* gene is related to cellular growth, survival, and differentiation, and this up-regulation could represent a response toward reduce the cell damage. From the SE-like group, we highlight the association between the up-regulated dre-miR-459-3p and the repression of *adar, grm2a* and *pcdh19* genes. The *pcdh19* gene is a protocadherin that plays an important role in brain development, and mutations in this gene are associated with severe seizures in children. To our knowledge, this is the first study showing the miRNA profile after seizures or SE-*like* states using the zebrafish. By integrating global miRNA-mRNA transcript profile, we hope to shed some light on the molecular pathways underlying seizures at different conditions and their impact on the brain. **Supported by** FAPESP 14/15640-8 and CEPID-BRAINN.

2039T

CpG methylation at the *DMPK* locus as a prenatal indicator of congenital myotonic dystrophy. *S. Lanni[1], L. Barbe[2], A. Lopez-Castel[1], S. Tome[1], C. Spits[2], K. Keymolen[3], S. Seneca[3], Z. Musova[4], D. Chitayat[5], C. Gagnon[6], J. Matthieu[6], J. Letourneau[6], K. Sermon[2], C.E. Pearson[1].* 1) Genetics & Genome Biology, The Hospital for Sick Children, toronto, Ontario, Canada; 2) Department for Reproduction and Genetics, Vrije Universiteit Brussel, Belgium; 3) Centre for Medical Genetics, Universitair Ziekenhuis Brussel, Belgium; 4) Department of Biology and Medical Genetics, Charles University 2nd Medical School and University Hospital Motol, Prague, Czech Republic; 5) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Groupe de recherche interdisciplinaire sur les maladies neuromusculaires, Saguenay, Quebec, Canada.

Myotonic dystrophy type 1 (DM1) is caused by the expansion of CTG repeats in the 3' UTR of the *DMPK* gene. The repeat tract tends to expand through transmission, causing more severe phenotypes in the progeny, a phenomenon called genetic anticipation. A parent-of-origin effect is evident in DM1, where larger expansions and more severe pathogenesis are associated with inheritance of the mutant allele from mothers. Congenital myotonic dystrophy (CDM), the most severe form of DM1, represents the most extreme example of parent-of-origin effect with a bias for maternal transmission, where offspring often have exceedingly large repeat expansions (>1000 repeats). However, not all CDM individuals have massive expansions, and not all individuals with massive expansions have the congenital form, suggesting that some other mark is responsible for the maternal transmission and presentation of CDM. The *DMPK* gene is located in a CpG island flanked by two CCCTC-binding factor (CTCF) binding sites. Using Massive Parallel Sequencing, we determined the CpG methylation status of the CTCF binding sites flanking the DM1 CTG repeat in a unique collection of 70 DM1 patients and 19 families, 19 of which showed CDM with maternal inheritance, and 4 DM1 human embryonic stem cell lines (hESCs). All CDM patients, but one, showed complete methylation both upstream and downstream of the CTG repeat. The same methylation pattern was observed in two hESCs carrying maternally-derived expansions, and in one third of the classical DM1 patients with maternal inheritance of the expansion. Apart from blood samples, we analyzed 4 maternally-derived CVS that also showed methylation both up- and downstream of the repeat. In contrast, two hESC lines with paternally-derived DM1 expansions, along with all DM1 patients with paternal inheritance of the mutation, never showed methylation upstream of the CTG repeat. Three CVS with paternally-derived expansions also showed methylation downstream but not upstream of the CTG repeat. Importantly, methylation patterns did not strictly correlate with CTG tract length. Analysis of this large and comprehensive collection highlights CpG methylation at the CTCF binding sites flanking the CTG repeat as a prenatal indicator of CDM that is stronger than the repeat size itself.

2040F

Differential regulation of amyloid-β precursor protein (APP) and β-secretase 1 (BACE1) by transcription factor (TF) modulating drugs in human cells. *B.L. Bayon[1,3], K. Nho[2], B. Maloney[3], N. Chopra[3,4], D.K. Lahiri[1,3,4].* 1) Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Radiology, Indiana University School of Medicine, Indianapolis, IN; 3) Psychiatry, Indiana University School of Medicine, Indianapolis, IN; 4) Program of Neuroscience, Indiana University School of Medicine, Indianapolis, IN.

TFs play a role in the survival of neuronal cells and regulate genes associated with Alzheimer's disease (AD). Expression levels of some TFs are perturbed in AD. BACE1 is responsible for the rate-limiting cleavage of APP to amyloid-β (Aβ). The TF Sp1 positively regulates APP and induces BACE1. To test the involvement of Sp1 in APP regulation, we treated human cells with Sp1 inhibitors mithramycin A (MTM) and tolfenamic acid (TA). We also transfected a variety of mammalian cell lines, a primary human neuron culture, and mixed brain cultures derived from human neurospheres with siRNAs. Minimal changes in confluence, cytotoxicity, neurite length, and neurite outgrowth were seen after Sp1 knockdown via siRNA or treatment with Sp1 modulating drugs. TA did not change Aβ40 levels, or affect APP and BACE1 levels. MTM led to a significant decrease in the expression of APP and BACE1, and significantly decreased Aβ40 levels. Neither treatment with Sp1-inhibiting drugs alone nor transfection with Sp1 siRNA alone affected cell viability of human cells illustrating that Sp1 levels can be safely reduced in cells. However, combination treatments of MTM plus TA or of Sp1 inhibition by siRNA in combination with TA treatment led to high cytotoxicity. To better understand the activation of multiple TFs and elucidate the status of signaling pathways after MTM or TA treatment, we used a TF luciferase transactivation reporter array. This array revealed decreased activation of several TFs with MTM treatment that correspond with a decrease or no change with TA treatment. These TFs were used as a preliminary screen for future assays. To understand the relationship between genetic variants in screened TFs and AD-related endophenotypes, we performed an association analysis of single nucleotide polymorphisms (SNPs) in select TFs with biomarkers in the AD Neuroimaging Initiative cohort. We identified a SNP (rs2551922) in *CREB1* significantly associated with Aβ levels in the cerebrospinal fluid. A SNP (rs11170553) in *SP1* is significantly associated with entorhinal cortex thickness and with global cortical Aβ load measured by Florbetapir PET. These associations demonstrate a possible correlation with these TFs and AD pathology. Compounds that can modify TF binding to sites on the BACE1 and APP promoters could provide a means to limit the production of Aβ and slow the symptoms of AD. These data show that modulation of TFs could potentially be a novel drug target for AD.

2041W

The *SMN1* mutation c.22-23 insA(;p.Ser8lysfs*23);causes spinal muscular atrophy by nonsense-mediated mRNA decay. *J. Bai, Y. Qu, Y. Cao, L. Ge, Y. Jin, H. Wang, F. Song.* Capital Institute of Pediatics, Bei Jing, China.

Background: Spinal muscular atrophy (SMA) is a common autosomal recessive neuromuscular disorder with an incidence of 1 in 6,000 ~ 10,000 among newborns. Most of the patients are with homozygous deletion of *SMN1* gene, and 5%-10% SMA patients are believed to have *SMN1* subtle mutations. Recently, the mutation c.22-23 insA (p.Ser8lysfs*23) has been identified as the most frequent mutation in the Chinese SMA population and be associated with a severe phenotype. In our previous study, *SMN1* mRNA and SMN protein in peripheral blood cells of this patient were much lower than that those of controls. However, the exact molecular mechanism of the mutation on the pathogenesis of SMA remain is unclear. **Objective:** The aim of this study is to investigate whether c.22-23 ins A mutation of *SMN1* gene causing SMA by triggering nonsense-mediated mRNA decay (NMD). **Methods**: Two-stage validation of NMD mechanism was supplied in our study. We firstly measured changes in the transcript levels and *SMN1* gene by real-time quantitative PCR after immortalized B-lymphoblasts of the SMA patient carrying c.22-23 insA mutation were treated with the inhibitors of NMD pathway, including puromycin and cyclohemide. Next, lentivirus-mediated knock-down of the regulator of nonsense transcripts 1(*UPF1*) was performed in the fibroblasts of the patient to detect whether the mutation lead to NMD. In our experiments, SC35 1.7Kb transcripts, a physiological NMD substrate was measured as a NMD positive gene. **Results:** The two inhibitors result in a dramatic escalation of full-length *SMN1* (*fl-*SMN1) transcript levels. And SC35 1.7kb mRNA level are also increased, which suggests that NMD pathway is suppressed by the two inhibitors. For puromycin and cycloheximide, the maximum increases of mRNA levels reach about 22- and 10-fold for *SMN1*, and about 9.6- and 7.9-fold for *SC35* in immortalized B-lymphoblasts derived from the patient, respectively. Meanwhile, lentivirus-mediated *UPF1* knock-down lead to reduction of UPF1 protein level to 22.5% compared to the negative control lentivirus. And knockdown of *UPF1* gene also promotes mRNA expression of *SC35* gene and *fl-SMN1* gene. The increases of *SMN1* and *SC35* mRNA levels reach about 4- and 7-fold in fibroblasts derived from the patient, respectively. **Conclusion:** our study provides the first evidence that c.22-23 insA mutation in *SMN1* gene triggers NMD. The SMA pathogenesis in the patient is associated with mRNA degradation of *SMN1*, but not the truncated SMN protein.

2042T

Investigating the role of SOX10-regulated alternative promoter use in Schwann cells. *E. Fogarty[1], M. Brewer[2], J. Rodriguez-Molina[3], W. Law[2], K. Ma[3], J. Svaren[4,5], A. Antonellis[1,2].* 1) Neuroscience Graduate Program, University of Michigan, Ann Arbor, MI; 2) Human Genetics, University of Michigan, Ann Arbor, MI; 3) Cellular and Molecular Pathology Program, University of Wisconsin-Madison, Madison, WI; 4) Waisman Center, University of Wisconsin-Madison, Madison, WI; 5) Comparative Biosciences, University of Wisconsin-Madison, Madison, WI.

Remarkable genomic complexity is achieved in part by the use of multiple transcription start sites (TSSs) within a single locus. The use of alternative TSSs can be regulated through the activity of cell type-specific transcription factors and defining these interactions provides insights into the biology of the cell type of interest. Schwann cells are the myelinating cells of the peripheral nervous system and the transcription factor SOX10 is critical for their development and maintenance. Many SOX10 target genes have been functionally characterized, including other transcription factors critical for myelination and genes implicated in inherited demyelinating peripheral neuropathies. Thus, identifying SOX10 targets is relevant to Schwann cell biology and pathology. As Schwann cell gene expression has been relatively understudied, we performed cap analysis gene expression on cultured Schwann cells to globally identify TSSs. Our efforts to date resulted in the identification of 10,679 putative TSSs. To investigate novel transcriptional biology, we assessed this dataset for TSSs that map at least 5 kb from an annotated RefSeq exon, and found 407 potentially novel TSSs. Given the importance of SOX10 and to prioritize TSSs for functional characterization, we integrated these data with SOX10 and H3K4me3 ChIP-Seq and DNase-Seq datasets. This revealed 55 previously unannotated promoters that bind to SOX10: 33 within known RefSeq loci and 22 not associated with an annotated gene. Importantly, RNA-Seq of cultured Schwann cells validate the presence of these newly identified TSSs. Gene ontology analyses of the 33 known loci showed no enrichment of particular biological processes, but genes with known or predicted roles in myelinating cells were identified. For example, we revealed an alternative promoter at the demyelinating peripheral neuropathy locus MTMR2. Functional studies showed that SOX10 is necessary and sufficient for the activity of the alternative promoter and expression of the associated transcript. The resulting alternative protein isoform shows differential nuclear localization, suggesting that it may have a divergent function. We propose that this SOX10-regulated gene product explains the sensitivity of Schwann cells to loss of MTMR2, which is broadly expressed. Our data support further identification of SOX10-regulated TSSs genome-wide and indicate that this will be a fruitful approach for investigating isoform-specific gene function in Schwann cells.

2043F

Allele-specific silencing as therapeutic strategy to tightly modulate gene expression in disorders due to gene duplication: A proof-of-principle in Autosomal Dominant Leukodystrophy (ADLD). *E. Giorgio[1], A. Bartoletti-Stella[2], A. Brussino[1], C. Mancini[1], S. Cavalieri[1], E. Di Gregorio[3], L. Gasparini[4], P. Cortelli[2], S. Capellari[2], A. Brusco[1,3].* 1) Dep. Medical Sciences, University of Torino, Torino, Italy; 2) Dep. of Biomedical and Neuromotor Sciences, University of Bologna, Bologna, Italy; 3) "Città della Salute e della Scienza" University Hospital, Medical Genetics Unit, Torino, Italy; 4) Dep. Neuroscience and Brain Technologies, Istituto Italiano di Tecnologia, Genova, Italy.

Allele-SPecific silencing by RNA Interference (ASP-iRNA) is a therapeutic strategy to downregulate a single mutant allele with minimal suppression of the corresponding wild-type (WT) allele. This approach has been effectively used to target autosomal dominant mutations or single nucleotide polymorphisms (SNPs) linked with aberrantly expanded trinucleotide repeats. We reasoned that ASP-iRNA could have been the paramount choice to target also genetic diseases due to gene duplication. Its main advantage is avoiding a harmful excessive downregulation of the target gene, a potential side effect of iRNA strategies. Here, we demonstrate the utility and efficacy of ASP-iRNA in Autosomal Dominant adult-onset demyelinating LeukoDystrophy (ADLD), a hereditary, progressive and fatal disorder affecting myelin in the central nervous system. ADLD is generally caused by lamin B1 (*LMNB1*) overexpression due to gene duplication. It stands to reason that a genetic modulation of lamin B1 mRNA represents a promising strategy to treat ADLD, and on the other way its excessive reduction may cause severe neurologic disorders, as shown by knockout mouse model. We choose to targeted the non-duplicated allele of the *LMNB1* gene by ASP-siRNAs, exploiting a frequent single nucleotide polymorphism (SNP) located in its coding sequence (MAF: 0.45), with the aim of reducing expression close to a wild-type. We designed and screened a siRNA library with a 19+2 geometry centred on the SNP and evaluated siRNAs efficacy and specificity by using a customized dual luciferase reporter system (modified from the psiCHECK™-2 system, Promega). We identified four siRNAs with a high efficacy (silencing 65%-87%; p<0.0001) and allele-specificity (p<0.001). These were further tested in four ADLD patient-derived fibroblast lines. Three out of four siRNAs selectively silenced the target allele (p< 0.0005) and restored *LMNB1* mRNA levels to controls values [*LMNB1* expression in patients / controls: before treatment = 2.42 (p<0.0005); after treatment =1.07 (p=ns)]. Most importantly, siRNA treatments almost completely rescued ADLD-specific splicing alterations, suggesting that ASP-iRNA may be useful in recovering cell function in ADLD. Our work is a proof-of-concept that ASP-silencing can be a therapeutic option for diseases with gene overexpression, opening new therapeutic possibilities for all Mendelian and syndromic disorders associated with gene(s) duplication.

2044W

Prenatal stress of *Cntnap2* heterozygous mice demonstrates a gene by environment interaction model for developmental brain disorders. *R.S. Alisch[1], Q. Zhang[2], K. Chen[3], S. Li[1], S. Keles[3], L.S. Papale[1].* 1) Psychiatry, Univ. of Wisconsin SOM - Madison, Madison, WI; 2) Statistics, University of Nebraska, Lincoln, NE; 3) Statistics, Biostatistics, and Medical Informatics, and, University of Wisconsin, Madison, WI.

The autism spectrum disorders refer to a group of complex neurodevelopmental brain disorders. Alterations in environmentally sensitive epigenetic mechanisms (*i.e.,* DNA methylation) have been reported in numerous genetic disorders associated with autism, suggesting that epigenetic mechanisms involving gene and environment interactions are a common pathway for many cases of autism. 5-hydroxymethylcytosine (5hmC) is a novel environmentally sensitive DNA modification that is highly enriched in post-mitotic neurons and perturbations of 5hmC are linked to brain-related disorders, leading us to hypothesize a role for 5hmC in the complex etiology of developmental brain disorders, including autism. As a first test of this hypothesis, we generated a genome-wide profile of striatal 5hmC in an autism mouse model (*i.e.,* a *Cntnap2[-/-]* homozygote) that exhibits core autism features, including deficits in striatal GABAergic signaling. Homozygous mice exhibit a genome-wide disruption of 5hmC in the orthologs of a significant number of genes implicated in human autism (*N*=68/233), suggesting a role for 5hmC-mediated epigenetic modulation in the pathogenesis of autism. Notably, *Cntnap2[+/-]* heterozygous mutant mice lack autistic-like features. Since 5hmC levels are environmentally sensitive, we next hypothesized that heterozygous mice subjected to an early environmental stress would have disruptions in 5hmC and may exhibit autistic-like behaviors similar to the homozygous mice. To test this hypothesis, we subjected heterozygous mice to seven days of variable prenatal stress and subsequently examined a variety of adult behaviors, including anxiety, depression, and sociability. Unlike wild-type littermates, prenatally stressed female heterozygous mice exhibited autistic-like social deficits. In addition, genomic profiling revealed disruptions in 5hmC throughout the striatal genome, which were similar to those seen in homozygous mice. Finally, integration of the above data with striatal gene expression data revealed that differential hydroxymethylation correlated with altered transcript levels of genes shown to contribute to the deficits in GABAergic signaling and social behavior of the homozygous mouse (*e.g.,* GABA receptors and *Oxytocin*). Together, these data demonstrate a gene by environment interaction that leads to deficits in social interactions and suggest that 5hmC likely contributes to this outcome and may be involved in the etiology of developmental brain disorders.

2045T

Altered DNA methylation in autism spectrum disorder: Sex differences and potential for biomarker development. *V. Hu[1], Y. Hong[1,2], M. Xu[1,3]*. 1) Biochemistry & Molecular Medicine, George Washington Univ School of Medicine & Health Sci, Washington, DC; 2) School of Life Sciences, Anhui Univ., Hefei City, Anhui 230601, P.R. China; 3) Shanghai East International Medical Center, Shanghai, P.R. China.

   Statement of purpose: The goals of this study were to: 1) investigate changes in the DNA methylation profiles of lymphoblastoid cell lines (LCL) derived from individuals with autism and their respective sex-matched siblings; 2) describe ASD-relevant pathways and functions that may be impacted by the differentially methylated genes; 3) identify sex-dependent differences in methylation patterns; and 4) examine the potential for class prediction based on epigenetic biomarkers in peripheral tissues. Methods: To reduce the effects of clinical heterogeneity on the methylation analyses, we subtyped individuals with ASD on the basis of cluster analyses of scores from the Autism Diagnostic Interview-Revised diagnostic instrument as previously described (Hu and Steinberg, Autism Research 2:67, 2009), and limited the cases for this study to those with severe language impairment. All diagnostic and phenotypic data was obtained through the Autism Genetic Resource Exchange (AGRE), from which LCL were obtained for the methylation analyses. LCL from sex-matched unaffected siblings were used as controls. Affymetrix Human Promoter 1.0R GeneChips were used to investigate differentially methylated promoter regions in the DNA of cases and controls. For each sample, methylation-enriched DNA prepared using a MeDIP protocol and input (total) DNA were hybridized on separate chips. Partek GS Software was used to identify differentially methylated regions using the workflow recommended by Affymetrix for methylation analyses on tiling arrays, and Multi-experiment Viewer (MeV) microarray analysis software was used for additional statistical and class prediction analyses, with the samples divided into a training set for identification of putative biomarkers, and a test set for validation of the biomarkers. Pathway and functional analyses of the differentially methylated genes were performed using Ingenuity Pathway Analysis (IPA) software. Summary of results and conclusion: This study revealed significant differences in DNA methylation in LCL derived from individuals with ASD and from their sex-matched siblings without ASD and showed, for the first time, sex-dependent differences in methylation profiles. Class prediction analyses further demonstrated that limited panels of differentially methylated genes may be used to classify ASD-affected and unaffected individuals with moderately high sensitivity and specificity, suggesting the potential for their use as epigenetic biomarkers.

2046F

MicroRNA biomarkers in whole blood for diagnosis of autism spectrum disorder. *M. Nakata[1], R. Kimura[1], K. Tomiwa[2], T. Awaya[3], T. Kato[3], Y. Funabiki[4], T. Heike[3], M. Hagiwara[1]*. 1) Anatomy and Developmental Biology, Kyoto University Graduate School of MedicineTodaiji Medical and Educational Center, Kyoto, Japan; 2) Todaiji Medical and Educational Center, Nara, Japan; 3) Pediatrics, Kyoto University Graduate School of Medicine, Kyoto, Japan; 4) Human Coexistence, Kyoto University Graduate School of Human and Environmental Studies, Kyoto, Japan.

   Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and a pattern of repetitive stereotyped behaviors. Many studies have been reported that high rates of mental health problems are observed commonly in ASD, especially depression and anxiety. Therefore, early detection is important to intervene early and prevent later psychiatric symptoms. Despite all the research efforts, however, reliable diagnostic biomarkers are not established as it stands. MicroRNAs (miRNAs) are a class of short non-coding RNAs that regulate gene expression. Increasing evidence has shown that miRNAs may play essential roles in neurodevelopmental disorders. In this study, we evaluated blood-based microRNAs as novel biomarkers for diagnosis of ASD. We determined miRNA expression profiles of ASD using Agilent miRNA microarray analysis in discovery sample set (30 ASD patients and 30 Controls). An independent replication sample set was used for the biomarker validation by real-time RT-PCR. Further we constructed ROC (Receiver Operating Characteristics) curves to determine the sensitivity and specificity of individual miRNA as a diagnostic biomarker. We found that three miRNAs had significantly altered in ASD patients compared to healthy controls and also got a good ROC curve according to the accepted classification of biomarker utility. These miRNAs were expressed in not only blood but also human brain. Our findings provide novel and reliable biomarkers for diagnosis of ASD.

2047W

Functional study of lncRNAs that associate with synaptic vesicles in autism spectrum disorder. *L. Zhao[1], W. Ju[2], M. Zhong[1], Y.H. Yu[1], W.T. Brown[2], N. Zhong[1,2].* 1) Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong, China; 2) 1.New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY, USA.

Studies have demonstrated that epigenetic regulation of long non-coding RNA (lncRNA) is involved in brain development and neuro-psychiatric diseases, including autism spectrum disorder (ASD). However, there are few reports on the lncRNAs that associate with synaptic vesicle (SV) cycling. We have previously reported differential expression of SV-associated lncRNAs/mRNAs among 25 pairs (ASDs *vs.* controls) of children's blood. We further validated 15 pairs of synaptic lncRNAs-mRNAs with an independent set of 100 cases, including 25 with ASD compared to age- and gender-matched controls that include 25 of attention deficit hyperactivity disorder, 50 non-syndromatic mental retardation, and 25 normal controls. In addition to ASD blood specimens, two fibroblast cell lines in four groups (ASD, normal control, fragile X with autism, and fragile X without autism) were subjected to RNA sequencing. Our data showed 26 SV-lncRNAs were differentially expressed. These eight fibroblast lines were applied to generate iPSC lines, in addition to two epithelial lines (one from a child with ASD, and the other from a normal control). From the 10 fibroblast re-programmed iPSCs, NPCs were differentiated. After comparing lncRNAs between ASD *vs.* non-ASD in neuronal progenitor cells (NPCs) and between lncRNAs identified from NPC *vs.* iPSC, bioinformatic analyses were conducted and the involved pathways were characterized. Two SV-associated lncRNAs have been subjected to functional analysis. The lncRNA-SYT15 was knocked out with CRESPR-Cas9 system that showed decreased lncRNA-SYT15 resulted deduction of mRNA-SYT15 in both neuronal and trophoblast cell cultures, suggesting lncRNA-SYT15 cis-regulates the mRNA-SYT15 transcription that was also confirmed by over expressed lncRNA-SYT15. Longitudinal assessment of lncRNBA-STX8 has demonstrated that lncRNA-STX8 is differentially expressed from the first trimester to the late stage of pregnancy, parallel to the differential expression pattern of mRNA-STX8, suggesting that lncRNA may have a regulatory function during the entire pregnant period. Our studies have provided evidence that SV-lncRNA is one of the epigenetic regulators, likely involved in SV cycling that may play a pathogenic role in ASD. .

2048T

Histone deacetylase deficiency leads to changes in hippocampal histone lysine profiles and is involved in anxiety and depression-like behavior in mice. *S. Röh[1], C.T. Wotjak[2], T. Strom[4], W. Wurst[3], E.B. Binder[1], J.M. Deussing[2], M. Jakovcevski[2].* 1) Max Planck Institute of Psychiatry, Department of Translational Research, Munich, Germany; 2) Max Planck Institute of Psychiatry, Department of Stress Neurobiology and Neurogenetics, Munich, Germany; 3) Helmholtz Center Munich, institute of Developmental Genetics, Neuherberg, Germany; 4) Helmholtz Center Munich, Institute of Human Genetics, Neuherberg, Germany.

It has been shown that broad spectrum deacetylase inhibitors (HDACi) can alter and improve depression-related symptoms in humans and that stressors affect the epigenome by changing histone acetylation. Therefore, understanding the essential molecular mechanisms of how single histone deacetylases (HDACs) contribute to ameliorate stress-related pathologies can improve the efficacy of current antidepressant drugs through increased specificity. In our study, we focus on one specific histone deacetylase (HDAC), a common target of HDACi, and its effects on the behaviour of adult mice under non-stressed and stressed conditions. Using a loss of function mouse model (Hdac knock-out mice), we tested behavior as well as epigenomic and gene expression changes by next generation sequencing. Our results suggest that HDAC is involved in basal, non-stressed anxiety-related behavior, the locomotor response to novelty, and anhedonia, indicating altered stress resilience. Hdac knockout mice from two independent batches were more susceptible to the effects of chronic social defeat stress. Altered behavior was accompanied by changes in bulk histone acetylation levels for several histone marks in knock-out mice at baseline and in stressed wild-type mice. Accordingly, ChIPseq data of histone acetylation show massive acetylation changes between all conditions. In stark contrast, transcriptional activity was only mildly affected and rather uncorrelated to acetylation changes between all conditions. To shed light on the question of whether this outcome could be explained by cell type/specific effects of acetylation, we have generated data sets to investigate this further.

2049F

Establishment of a strong link of smoking with cancer pathogenesis through DNA methylation analysis. *Y. Ma[1], M. Li[1,2].* 1) State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, Zhejiang, China; 2) Institute of NeuroImmune Pharmacology, Seton Hall University, South Orange, NJ USA.

Tobacco smoking is a well-documented risk factor for various cancers, which are regulated by complex mechanisms, including DNA methylation and other epigenetic reprogramming. Previous epigenome-wide association studies revealed a large number of methylation sites associated with smoking. However, to date, no study has established a link between smoking-associated DNA methylation and cancer. To attack this issue, we identified two sets of genes methylated by smoking from blood and buccal samples, and then determined whether these methylated genes were enriched in pathways implicated in the pathogenesis of cancers. For the methylated genes from the blood samples, we identified 57 significantly enriched pathways; many of them are reported to be associated with different types of cancer. Among these pathways, 11, including RAR activation, actin cytoskeleton signalling, and aryl hydrocarbon receptor signaling, were also significantly overrepresented by the methylated genes in the buccal samples. Furthermore, our findings indicate that the aryl hydrocarbon receptor signalling pathway plays an essential role in the initiation of smoking-attributable cancer. Based on the findings from the current study and prior biological evidence, we propose a schematic model to elucidate the biological effects of smoking on cancer pathogenesis. Finally, we constructed a subnetwork consisting of 48 non-redundant genes in the 11 oncogenic pathways detected in both the blood and buccal samples. Of them, several genes, such as *DUSP4*, *AKT3*, *SMARCA4*, and *SMAD6*, show strong evidence for involvement in smoking-related lung cancer. In conclusion, our findings provide the first robust and systematic evidence supporting the idea that smoking is indeed an important inducer of cancer at an epigenetic level.

2050W

Genes and memory: A comprehensive study of the association between quantitative trait loci and memory in independent samples. *V.V. Vukojevic[1,2,5], A.M. Milnik[1,4,5], P.D. Demougin[1,2], F.P. Peter[1,2], D.Q. de Quervain[3,4,5], A.P. Papassotiropoulos[1,2,4,5].* 1) University of Basel, Department of Psychology, Division of Molecular Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 2) University of Basel, Department Biozentrum, Life Sciences Training Facility, Klingelbergstrasse 50/70, 4056 Basel, Switzerland; 3) University of Basel, Department of Psychology, Division of Cognitive Neuroscience, Birmannsgasse 8, 4055 Basel, Switzerland; 4) University of Basel, University Psychiatric Clinics, Wilhelm Klein-Strasse 27, 4055 Basel, Switzerland; 5) Transfaculty Research Platform Molecular and Cognitive Neurosciences, University of Basel,CH-4055 Basel, Switzerland.

Background: Complex traits, e.g. cognitive performance, exhibit a striking amount of phenotypic variability. A large amount of this phenotypic variation across population is due to the underlying genetic architecture. Therefore, understanding the genetic basis of the quantitative trait variation, e.g. quantitative trait loci (QTL), is one of the major challenges in current biology of complex cognitive traits. **Analysis:** In the present study we performed a genome wide analysis of DNA methylation and expression cis-QTLs (meQTLs and eQTLs, respectively) in a European sample of healthy young adults (N = 533). We validated our findings in an independent sample of similar size and origin (N = 319), and further investigated the association of the significant loci with episodic and working memory performance across two samples. Finally, we extended our analysis to a third sample of an African decent (N = 380), and investigated the amount of conserved QTLs. **Results:** The cross-investigation of cis-meQTLs in the discovery and replication sample revealed 154'135 unique meQTLs (corrected for 1.4×10^{11} tests; 448'243 CpGs, 313'505 SNPs). These meQTLs were significantly associated to 19'929 unique CpGs, targeting a total of 8'599 genes (FDR of 5%). The same set of SNPs was additionally enriched in eQTLs: 37'721 SNPs associated to 6'578 transcripts (4'330 genes, 67% concordance with meQTLs overlapping genes; FDR of 5%). Extended analysis of QTLs in an African sample revealed a significant overlap with European samples, suggesting a high level of conservation across populations (92'399 meQTLs, 12'217 CpGs; FDR of 5%). A second level analysis revealed that meQTL associated CpGs were pronouncedly related to cognitive phenotypes across two investigated European samples (310 CpGs, 286 genes; FDR of 5%). **Discussion:** Our findings suggest that QTL associated CpGs also show an enrichment of significant hits in association analyses with complex traits. This might be of special importance for studies that rely on proxy tissues, like in the case of cognition and psychiatric disorders.

2051T

Alcohol use is associated with dose-dependent DNA methylation and alternative transcript expression of synaptic genes. *R.P. Cervera-Juanes, L.J. Wilhem, C. Huang, R. Shah, S. Gonzales, K.A. Grant, B.M. Ferguson.* Oregon National Primate Research Center, Oregon Health and Science University, Beaverton, Oregon.

Alterations in DNA methylation have been associated with alcohol exposure, and proposed to contribute to escalating alcohol abuse; however the specific molecular mechanisms involved remain obscure. Clarifying the genes regulated by DNA methylation and distinguishing their contributions to alcohol dependence are critical for fully understanding and treating alcohol use disorders (AUDs). In addition, understanding the effects of the dose of alcohol consumed will be critical for developing more specific approaches in the treatment of AUDs. We used the rhesus macaque alcohol self-administration model to investigate the relationship between the amount of alcohol consumed and the effects on DNA methylation and gene expression in the nucleus accumbens (NAc). We combined a genome-wide approach for the targeted selection of CpG rich genomic regions, bisulfite sequencing and a regional clustering to identify significant differentially methylated regions (DMRs) among subjects that differed in their alcohol consumption levels. The methylation levels of 2.7 million CpGs were compared between light-moderate and heavy drinking subjects. We identified 17 DMRs, 15 of them were located in the gene body, coinciding with predicted enhancer and promoter regions. In 14 of these DMRs, the average CpG methylation level was significantly correlated with the average daily amount of ethanol consumed. Eight of the DMRs map to genes encoding proteins with functions linked to cell adhesion, cytoskeleton binding, neurotransmitter release and receptor trafficking, underlining their relevance to alcohol-associated synaptic adaptation. Moreover, gene expression data revealed a prominent role of the DMRs in regulating alternative transcript expression of synaptic genes. For instance, *JAKMIP1*, which is known to regulate GABA-B and NMDA receptor signaling, is associated with a DMR that was significantly correlated with both the amount of ethanol consumed and the differential expression of two alternative 1st exons. Thus, our results suggest that some of the neural adaptations induced by alcohol are mediated by changes in DNA methylation and alternative transcript expression of synaptic genes, such as *JAKMIP1*. Moreover, the genes identified by this study implicate new targets for the development of alcohol dependence treatments. This study was supported by NIH grant U01AA020928, R24AA019431 and OD011092.

Hippocampal DNA methylation changes affect oxidative stress genes in fetal alcohol-exposed adolescent mice. *E.J. Chater-Diehl, B.I. Laufer, S.M. Singh.* Department of Biology, Western University, London, Ontario, Canada.

Alcohol use during pregnancy can lead to a range of neurological abnormities termed Fetal Alcohol Spectrum Disorders (FASD). The mechanisms by which alcohol (ethanol) induces FASD are poorly understood. We have previously developed a model to generate FASD-like mice showing characteristic learning and memory impairment. Our laboratory has explored whether epigenetic modifications are related to these changes. We found persistent fetal-ethanol-exposure-induced changes in histone modification, DNA methylation, and gene expression of oxidative stress genes in adult mouse hippocampus. Oxidative stress is a key component of the primary effects of ethanol in FASD etiology. It is unclear if these changes arose later in life as a compensatory long-term response, or were maintained from the initial early-life exposure. Here, we hypothesized that changes to oxidative stress genes were also present in adolescent mice. Mouse pups were injected with saline or ethanol on postnatal days 4 and 7, the period neurodevelopmentally equivalent to human trimester three. At 21 days of age, hippocampi were isolated and used for gene and miRNA expression microarray, and methylated DNA immuno-precipitation & sequencing (MeDIP-seq). The gene expression analysis on the hippocampus identified enrichment of oxidative phosphorylation genes (*Cox7b2*, *Ndufa1*, *Ndufa7*, *Uqcrq*) as well as genes implicated in alcoholism and olfactory transduction. Long non-coding RNA expression changes and reciprocal microRNA/target gene expression changes were also identified. We next performed MeDIP-seq. Similar to our previous adult data, similar oxidative stress pathways were implicated, through few genes overlapped with the expression data. Our results support a growing body of evidence that early ethanol exposure, epigenetics, and oxidative stress are related late into life. Specifically, these data support a role for changes in oxidative stress gene expression and DNA methylation in FASD at several stages. The emergence of this theme from our group and others raises the possibility of diagnostic and therapeutic interventions for FASD individuals. It is also relevant beyond alcohol research, furthering our understanding of the scale and duration of environmental effects on the (epi)genome. .

TET1-mediated epigenetic modulation in stress-induced response. *Y. Cheng[1], Z. Miao[2], L. Chen[1], Y. Li[1], L. Lin[1], B. Yao[1], Z. Wang[1], N. Xin[2], L. Huang[1], X. Xu[2], P. Jin[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322, USA; 2) The Institute of Neuroscience, Soochow University, Suzhou 215006, P.R. China.

Depression is a common but serious mental disorder that characterized by a pervasive and persistent low mood. Depression can be triggered by various causes, in which chronic stress has been shown to directly link to depression. 5-hydroxymethylcytosine (5hmC) has been reported highly enriched in the central neural system, and is now recognized as an important epigenetic mark in developmental and neurological disease. In the present study, we show that chronic restraint stress (CRS) can induce the depression-like behavior in wild type (WT) mice, and results in the global 5hmC decrease in prefrontal cortex (PFC). We profiled genome-wide distribution of 5hmC and identified stress-induced dynamically hydroxymethylated loci in WT mice (WT-SI-DhML). Gene ontology (GO) analyses indicated these WT-SI-DhML were located in the genes that involved in the pathways associated with major depressive disorder. We then utilized global Ten-eleven translocation protein 1 knockout (Tet1-KO) mice to investigate the role of Tet1 in stress-response. Interestingly we found that the loss of Tet1 led to the resistance to CRS. To link the 5hmC status with stress-resistant phenotype, we further profiled 5hmC using the PFC DNA samples of Tet1 KO mice, and identified phenotype associated SI-DhML (PA-SI-DhML). Go analyses indicated that these PA-SI-DhML were significantly associated with the genes involved in the response to stimulus and neuronal function as well as those involved in axon guidance. Subsequent motif search revealed a strong enrichment of hypoxia-induced factor (HIF) binding motifs among PA-SI-DhML. Biochemically we demonstrated the physical interaction between TET1 and HIF1α under CRS condition, although CRS had no impact on the expression of TET1 and HIF1α. By using anti HIF1α antibody, our ChIP-seq data of WT PFC identified differentially changed HIF1α binding regions (HBRs) upon CRS. The HBRs with increased ChIP-seq reads (Stress/Control) were highly associated with WT-SI-DhML and PA-SI-DhML, suggesting TET1 may be recruited by HIF1α upon CRS and influence the 5hmC dynamics. These results together suggest that TET1, by interacting with HIF1α, plays important role(s) in stress-induced responses.

2054T

The efficacy of oxBS and the Infinium MethylationEPIC array to characterize variations in 5-methylcytosine and 5-hydroxymethylcytosine between different human tissue types. *J. Gross[1], F. Lefebvre[2], P.E. Lutz[1], F. Bacot[3], D. Vincent[3], G. Bourque[3,4], G. Turecki[1,5].* 1) McGill Group for Suicide Studies, Douglas Mental Health Univ Inst, Montreal, Quebec, Canada; 2) Canadian Centre for Computational Genomics, Montreal Node, McGill University, Montreal, Quebec, Canada; 3) McGill University and Genome Quebec Innovation Centre, McGill University, Montreal, Quebec, Canada; 4) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 5) Department of Psychiatry, McGill University, Montreal, Quebec, Canada.

Investigating 5-methylcytosine (5mC) has led to many hypotheses regarding molecular mechanism underlying human diseases and disorders. Many of these studies, however, utilize bisulfite sequencing, which cannot distinguish 5mC from its recently-discovered oxidative product, 5-hydroxymthylcytosine (5hmC). Furthermore, previous array-based technologies do not have the necessary probes to adequately investigate both modifications simultaneously. Here, we use DNA from post-mortem human brain, human blood, and human saliva to validate the efficacy of oxidative bisulfite conversion and Illumina's Infinium MethylationEPIC array to analyze 5mC and 5hmC. We show the presence of 5mC and 5hmC at greater than 650,000 and 450,000 relevant loci, respectively, in the human brain. While the number of loci containing 5mC remains stable across tissue-types, the number of 5hmC-containing probes drops drastically in human blood and saliva. Nevertheless, 5mC- and 5hmC-containing probes are equally distributed across chromosomes, genomic features, and, in particular, distal regulatory regions. Our results confirm the sensitivity of the EPIC array to detect 5mC and 5hmC in all three tissue-types and show this methodolgy to be an important and cost-effective advancement in profiling cytosine modifications in human phenotypes.

2055F

Beyond DNA methylation: Characterizing H3K27ac using ChIP-seq in post-mortem human brain tissue in a multi-omics analysis of Alzheimer's disease. *S.J. Marzi[1], T. Ribarska[4], A. Smith[2], K. Lunnon[2], L. Schalkwyk[3], J. Mill[1,2].* 1) King's College London, London, United Kingdom; 2) University of Exeter, Exeter, United Kingdom; 3) University of Essex, Colchester, United Kingdom; 4) DKFZ, Heidelberg, Germany.

Alzheimer's Disease (AD) is a progressive neurodegenerative disorder characterized by cognitive decline and progressive neuropathology in specific regions of the brain. As the most common form of dementia that affects an increasingly ageing population it is a growing public health problem. Disease progression is accompanied by an accumulation of amyloid β and neurofibrillary tangles across the cortex, however the underlying aetiology is still not fully understood. Several studies have implicated epigenetic processes in disease progression. Our lab recently identified widespread changes in DNA methylation associated with AD, and in particular reported a robust association with cortex-specific methylomic variation in the *ANK1* gene, which has now been replicated across 4 independent cohorts. Building on this work we used chromatin immunoprecipitation sequencing (ChIP-seq) to profile differences in histone acetylation (H3K27ac) – a histone modification found in active promoter and enhancer regions – associated with AD in an overlapping set of post-mortem entorhinal cortex samples from AD cases and matched controls (n=50). Modelling normalised read counts in ~155,000 robustly detected peak regions, we identify ~550 differential peaks between AD cases and controls. Several of these are associated with neuronal pathways and most are explained by differences in neuronal vs glia proportion estimates, which were obtained based on DNA methylation profiles. Analyses correcting for neuronal proportion, sex and age at death result in 21 differential peaks at Bonferroni-corrected significance level of a=0.05. This is the largest study of H3K27ac undertaken in post-mortem brain samples to date and to our knowledge the first one of Alzheimer's Disease. In addition to histone acetylation the samples have been profiled for DNA methylation, DNA hydroxymethylation and genotypes, which we are currently using to identify co-localized signals identified across multiple layers of (epi-) genetic information, and characterize functional consequences of non-coding variation.

2056W

Quantitative DNA methylation analyses using digital droplet PCR sensitively detects surreptitious smoking in adolescents. *R.A. Philibert[1,3], A. Andersen[1], S. McElroy[1], K. Vercande[1], L. Delevan[1], E. Papworth[1], N. Hollenbeck[1], W. Lugo-Morales[1], M. Gerrard[2], R. Gibbons[2].* 1) Psychiatry, University of Iowa, Iowa City, IA; 2) Dept of Psychology, University of Connecticut, Stoors, CT; 3) Behavioral Diagnostics Inc, Iowa City, IA.

The initiation of smoking is associated with the initiation of other externalizing disorders including drinking, risky sex and conduct disorder spectrum illness. Psychoeducational interventions can arrest the escalation of each of these disorders. Unfortunately, their implementation is hindered by the unreliability of self-report- which can range as high as 50% in high-risk populations. Previously, we have shown that quantitative DNA methylation analyses can accurately detect smoking in adult populations. However, whether these measures can be used to detect smoking in adolescents is not known. We present the initial results from a longitudinal examination of 450 high school students at elevated risk for cigarette smoking using repeated biological measures including exhaled carbon monoxide, ELISAs, and digital droplet PCR (ddPCR) assessments of methylation in DNA from whole blood. According to self-report, only 4 of the first 192 sophomores surveyed reported any type tobacco consumption in the past week. However, 17 of the first 213 serum samples from sophomores subjects show elevated cotinine levels with many levels clearly consistent with active smoking. Similarly, only 8 of the first 192 sophomores surveyed report any use of THC in the week prior to intake, but at least 26 of the 213 first serum samples surveyed showed elevated serum levels of tetrahydrocannabinol. Finally, summative smoking history of the first 184 subjects was assessed via ddPCR measurement of cg05575921 methylation, an established epigenetic biomarker of cigarette consumption in adults. All subjects with established histories of smoking via self-report or through clear serological detection demonstrated significant demethylation at cg05575921. Logistic regression analysis demonstrates that a model that incorporates self-report, parent smoking status and serological status significantly predicts DNA methylation status. In summary, these data demonstrate that adolescents show high levels of unreliable self-report as evidenced by cross section serological assessment. Exploratory methylation analyses suggest that the true rate of smoking in these adolescent subjects may be even higher. We conclude that biological indexes that incorporate DNA methylation measures may be useful in assessing smoking histories in adolescent subjects and that further studies to examine the sensitivity and specificity of methylation analyses for the detection of adolescent smoking are in order.

2057T

Epigenetic effects of glucocorticoids exposure during hippocampal neurogenesis. *N. Provencal[1], J. Arloth[1,2], C. Anacker[3], A. Cattaneo[4,5], T. Klengel[6], N.S. Mueller[2], C.M. Pariante[4], E.B. Binder[1].* 1) Translational Research in Psychiatry, Max Planck Institute of Psychiatry, Munich, Germany; 2) Institute of Computational Biology, Helmholtz Zentrum München, Germany; 3) Columbia University, and Division of Integrative Neuroscience, New York State Psychiatric Institute/Research Foundation for Mental Hygiene, Inc., New York; 4) Psychological Medicine Dept, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK; 5) IRCCS Fatebenefratelli, University of Brescia, Brescia, Italy; 6) Psychiatry Dept, School of Medicine, Emory University, Atlanta and McLean Hospital, Harvard Medical School, Belmont, Massachusetts.

Exposure to early life stress (ELS) is a well-known major risk factor for developing psychiatric and behavioural disorders later in life. A growing body of evidence indicates that exposure to ELS can lead to long lasting changes in a number of systems including the endocrine system, the immune system and brain structure and function. However, our understanding of the mechanisms underlying these effects is limited. One proposed mechanism that might lead to some of these long-lasting effects is that excessive glucocorticoids (GC) release after ELS exposure induces long-lasting epigenetic alterations in important regulatory genes. Indeed, accumulating evidences suggest that epigenetic mechanisms are in part responsible for the embedding of ELS where the type and timing of stress exposure are important moderating factors. Using human hippocampal progenitor cells (HPCs) and multi-omic data analysis integrating gene expression, DNA methylation (5mC) and hydroxymethylation (5hmC) at a genome-wide level, we identified long-lasting 5hmC and 5mC alterations induced by GCs exposure during neurogenesis, where a significant portion of these marks were maintained after neuronal differentiation. Moreover, the sites showing GC-induced methylation changes are enriched in regulatory regions as well as in genes differentially methylated during fetal brain development as well as in genes previously associated with child abuse in human hippocampus and blood cells. To some extend, they also reflect epigenetic changes induced by acute GCs exposure in human blood cells. Together, these results suggest that GC-induced epigenetic alterations in HPCs might reflect GC actions during ELS and be in part responsible for the increased risk for psychopathology. A mechanistic understanding of the long-term epigenetic consequences of early life stress using both, cellular models where we can study in depth the molecular mechanisms at play, as well as patients exposed to ELS may allow novel, targeted intervention and prevention strategies for behavioral, psychiatric and other stress-associated disorders.

2058F

Epigenome-wide association analysis of DNA methylation in panic disorder. *M. Shimada-Sugimoto[1], T. Otowa[2], T. Miyagawa[1,3], M. Tochigi[4], N. Sugaya[5], Y. Kawamura[6], T. Umekage[7], H. Kaiya[8], K. Kasai[9], H. Tanii[10], Y. Okazaki[11], K. Tokunaga[1], T. Panic disorder (PD) is a major anxiety disorder and characterized by recurrent unexpected panic attacks and anticipatory anxiety. According to previous twin and family studies, PD is considered to be a multifactorial disorder emerging from interactions among multiple genetic and environmental factors. To date, genetic studies reported several susceptibility genes with PD. Nevertheless, the pathogenesis of PD remains to be clarified. Epigenetics is considered to play an important role in etiology of complex traits and diseases, and DNA methylation is one of the major forms of epigenetic modifications. It has been reported that DNA methylation may play a certain role in pathogenesis of psychiatric disorders. In this study, we performed an epigenome-wide association study of DNA methylation in PD. The methylation levels of DNA samples extracted from peripheral blood of 48 PD patients and 48 age- and sex-matched healthy control individuals were studied. We applied the stringent data filtering and data normalization method for an accurate quantification of DNA methylation. Totally, methylation levels of 376,602 probes were determined. As a result, 42 CpG sites showed significant differences of methylation between PD and healthy control subjects at 5% FDR correction, though the methylation differences were relatively small. Many of the significant CpG sites (30/42 CpG sites) were located upstream of genes and such 30 CpG sites were all hypomethylated in PD subjects. According to previous studies, hypomethylation of upstream of gene region is often associated with higher gene expression. Therefore, the hypomethylation of the 30 CpG sites may be related to higher expression of the annotated genes. Additionally, we predicted cell mixture distributions of leukocyte subsets using DNA methylation data in order to examine the possibility that the significant associations were derived from a bias of leukocyte subsets' proportions. A pathway analysis using genes annotated to the significant 42 CpG sites revealed several intriguing pathways. Although future studies with larger number of samples are necessary to confirm the small methylation abnormalities related to PD, there is a possibility that several CpG sites might be associated with PD.

2059W

Reducing epigenetic heterogeneity in autism spectrum disorder by sub-stratifying based on genetic variants. *M.T. Siu[1], D.T. Butcher[1], S. Choufani[1], A.L. Turinsky[1,2], C. Cytrynbaum[1,3,4], D.J. Stavropoulos[5,6], S. Walker[7], Y. Lou[1], S.W. Scherer[1,4,7], M. Brudno[1,2,8], R. Weksberg[1,3,4,9,10].* 1) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Centre for Computational Medicine, Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 5) Pediatric Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 6) Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada; 7) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, ON, Canada; 8) Department of Computer Science, University of Toronto, Toronto, ON, Canada; 9) Institute of Medical Science, School of Graduate Studies, University of Toronto, Toronto, ON, Canada; 10) Department of Pediatrics, University of Toronto, Toronto, ON, Canada.

Autism spectrum disorder (ASD), the most common pediatric neurodevelopmental disorder (NDD), demonstrates a significant amount of etiologic and phenotypic heterogeneity. Over 200 ASD-risk genes have been identified, but genetics alone can only account for ~25% of cases. Aberrant epigenetic mechanisms are known to negatively impact biological pathways important for normal brain development (e.g. Angelman syndrome). A role for epigenetic dysregulation in ASD etiology is suggested by the number of ASD-risk genes that function as epigenetic regulators. Some studies have also identified epigenetic alterations, specifically DNA methylation (DNAm), in ASD. However, the impact of these findings is limited by small sample sizes and inconsistent results across studies, likely due to variance across tissue types, different analytical methods and the heterogeneity of the ASD groups examined. In order to investigate the role of epigenetic dysregulation in ASD, genome-wide DNAm, the most commonly assessed epigenetic mark, was measured using the Illumina Infinium HumanMethylation450 BeadChip array in blood from a heterogeneous ASD group (n=52). This was contrasted with individuals substratified based on known genetic alterations, forming more homogeneous comparison groups; DNAm was also assessed in blood from patients with heterozygous loss of function mutations in *CHD8* (*CHD8*[+/-]; n=7), a chromatin modifier, and 16p11.2 deletions at the 600 kb risk locus (16p11.2del; n=9). These represent two of the most common genetic alterations associated with a significantly increased risk for ASD. No ASD-specific DNAm patterns were found to fully distinguish heterogeneous ASD cases from controls. However, unique DNAm patterns were identified for the *CHD8*[+/-] and 16p11.2del groups when compared with controls. These DNAm patterns consist of specific sets of differentially methylated sites (adjusted p<0.05, absolute difference >5%) comprising a DNAm signature. These signatures classified individuals with *CHD8*[+/-] mutations and 16p11.2del distinctly from each other, as well as from the heterogeneous ASD group and controls. Furthermore, these signatures properly classified additional *CHD8*[+/-] sequence variants, 16p11.2del cases and independent controls. These data demonstrate an improved method of molecular classification of a heterogeneous NDD such as ASD and will help to enhance our understanding of the underlying biological mechanisms of this disorder.

2060T

Differential DNA methylation at birth associated with psychiatric phenotype in individuals with 22q11.2 deletion syndrome. *S. Weinsheimer[1], A. Starnawska[2], C. Søholm-Hansen[3], T. Sparsø[1], W. Mazin[1], L. Olsen[1], M. Bertalan[1], A. Buil[1], J. Bybjerg-Grauholm[3], M. Bækvad-Hansen[3], D. Hougaard[3], M. Nyegaard[2], T. Werge[1], iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research.* 1) Institute for Biological Psychiatry, Mental Health Center Sankt Hans, Roskilde, Denmark; 2) Aarhus University, Aarhus, Denmark; 3) Statens Serum Institute, Copenhagen, Denmark.

Individuals with 22q11.2 deletion syndrome (DS) have an increased risk of comorbid psychiatric disorders including schizophrenia, attention deficit hyperactivity disorder, depression, as well as mental retardation. Most carriers of the 22q11.2 deletion have the long 3 Mbp form of the hemizygous deletion; however, there remains a large variation in the development and progression of psychiatric disorders, which suggests that alternative factors such as epigenetic dysfunction contribute to the pathogenesis. **Purpose:** We performed the first epigenome-wide association study (EWAS) in 22q11.2 DS to investigate DNA methylation associated with psychiatric phenotype. **Methods:** DNA methylation was measured from neonatal dried blood spots using the Illumina 450k methylation array in a cohort of 164 individuals with 22q11.2 DS, including 48 diagnosed with a psychiatric disorder. We used regression models to identify differentially methylated CpG sites with adjustment for sex, type of 22q11.2 deletion and age of the blood spot. **Results:** Among several CpG sites with p-value < 10^{-6}, we identified cg23546855 (p-value = 2.15×10^{-7}) mapping to *STK32C* to be associated with psychiatric diagnosis in 22q11.2 carriers. Pathway analysis of the top findings resulted in the identification of ten Gene Ontology pathways to be significantly enriched (p-value < 0.05 after Benjamini-Hochberg correction) including 'Neurogenesis', 'Neuron development', 'Neuron projection development', 'Neuron projection morphogenesis', and 'Cell morphogenesis involved in neuron differentiation'. Additionally, we identified differentially methylated CpG sites in *LRP2BP* (p-value = 5.37×10^{-8}) to be associated with mental retardation, *TOP1* (p-value = 1.86×10^{-7}) with behavioral disorders, *NOSIP* (p-value = 5.12×10^{-7}) with disorders of psychological development, and *SEMA4B* (4.02×10^{-7}) with schizophrenia. In conclusion, our study suggests an association between differential DNA methylation at birth and development of psychiatric disorder later in life in 22q11.2 DS individuals.

2061F

Epigenome-wide changes in hypothalamus following enhanced maternal care reprogram stress responses in early life. *D. Yasui[1], A. Vogel Ciernia[1], K. Dunaway[1], A. Singh[4], T. Baram[4], J. LaSalle[1,2,3].* 1) UC Davis Med Sch Dept of Med Microbiology & Immunology, Davis, CA; 2) UC Davis Genome Center, Univ California Davis, Davis, CA; 3) UC Davis MIND Institute, Sacramento, CA; 4) UC Irvine, Department of Anatomy and Neurobiology, Irvine, CA.

In mammals, the hypothalamic-pituitary-adrenal (HPA) circuit regulates stress responses. In this "augmented maternal care" (AMC) paradigm, enhanced licking and grooming from postnatal days 2-9 (P9) leads to reduced corticotrophin releasing hormone (Crh) expression in the hypothalamic paraventricular nucleus (PVN) thereby attenuating the hypothalamic-pituitary-adrenal (HPA) circuit throughout development. We hypothesize that AMC epigenetically sets future gene expression levels and thus behavior by altering specific DNA methylation patterns. In support of this hypothesis, *Crh* promoter methylation levels were found to be significantly higher in AMC than control PVN when assayed by bisulfite pyrosequencing analysis, consistent with *Crh* repression. However, *Crh* methylation levels were unaffected in thalamus where HPA responses are not engaged, suggesting that elevated *Crh* methylation levels induced by AMC are specific to the PVN. To identify genome wide DNA methylation changes produced by AMC, whole genome bisulfite sequencing (WGBS) analysis was performed on AMC and control PVN to identify additional differentially methylated regions (DMRs). Surprisingly, there was a significant (P>0.042) 2.91% reduction in genome wide CpG methylation in PVN in response to AMC. To identify potential DMRs between the two regions we focused on partially methylated (>70% CpG methylation) domains (PMDs), as they comprise up to 40% of the genome in early life and are enriched in repressed genes. A hidden Markov model (HMM) trained to detect PMDs identified 38 DMRs, covering ~5% of the uniquely aligned rat genome. Selected DMRs were validated by pyrosequencing. RNA-seq analysis on AMC and control PVN yielded a total of 759 differentially expressed transcripts including *Crh*, *Galanin*, *Ube3a* and other transcripts involved in HPA neuronal responses. This combined WGBS and RNA-seq analysis has led to the identification of key hypothalamic gene networks involved in the epigenetic regulation of the attenuated stress response underlying the resilience paradigm. These results provide insight into the early-life epigenetic programming of hypothalamic genes with implications for treatment of human stress-related disorders.

2062W

Mapping methylation and expression quantitative trait loci in human prefrontal cortex. *H. Zhang, F. Wang.* Department of Psychiatry, Yale University School of Medicine, New Haven, CT.

Genetic variants associated with neuropsychiatric disorders are potential expression and/or methylation quantitative trait loci (eQTLs and/or mQTLs) in the brain. They may alter the expression or epigenetic status of genes in specific brain regions such as the prefrontal cortex (PFC; implicated in cognition, perception, memory, and decision making), thus leading to an increased risk of the illness. The present study aimed to map eQTLs and mQTLs in human brain PFC, thus facilitating characterizing the function of disease-associated genetic variants and understanding the role of the PFC in the development of neuropsychiatric disorders. A joint analysis of the relationship among genetic variants, gene expression, and DNA methylation was performed using genotype data of 254,286 common single nucleotide polymorphisms (SNPs) (identified by the Illumina Infinium HumanExome BeadChip 12 v1 array assay), expression data of 16,553 transcripts (or exons) (profiled by the Illumina HumanHT-12 v4 Expression BeadChip assay), and methylation data of 430,407 CpGs (generated by the Illumina Infinium HumanMethylation450 BeadChip assay) from postmortem PFC tissues of 46 Caucasian Australians (32 males and 14 females; half them were affected with alcohol use disorders or AUDs). The correlation of SNP genotypes (in an additive model) and expression levels of exons (or methylation levels of CpGs) was analyzed using the R package Matrix eQTL, with sex, age, AUDs, and postmortem intervals (PMI) as covariates. A total of 1,464 eQTLs (1,245 cis-eQTLs and 219 trans-eQTLs mapped to 549 genes) and 48,041 mQTLs (26,846 cis-mQTLs and 21,195 trans-mQTLs mapped to 6,525 genes) identified in the PFC survived multiple testing correction ($q<0.05$). Moreover, 356 SNPs (mapped to 45 genes) were found to be both eQTLs ($q<0.05$) and mQTLs ($q<0.05$). Among them, 120 SNPs showed an influence on gene expression and DNA methylation in the same direction, whereas the remaining 236 SNPs showed an influence on gene expression and DNA methylation in the opposite direction. DAVID functional annotation analysis indicated that the 45 genes mapped by the 356 SNPs were enriched in pathways such as glutathione metabolism, drug metabolism, and post-translation modification. Additional bioinformatics analysis is need to understand whether these eQTLs and mQTLs identified in the PFC are enriched in neuropsychiatric disorder-associated genetic variants identified by genome-wide association studies (GWAS).

2063T

Methylome-wide association analysis in blood implicates *NLRC5 and TRIM69* **genes for intravenous drug use in HIV-infected patients.** *X. Zhang[1], A. Justice[4], Y. Hu[2], H. Zhao[3], Z. Wang[3], J. Krystal[1], K. Xu[1].* 1) Department of Psychiatry, Yale Medical School, New Haven, CT; 2) Center for Biomedical Bioinformatics, National Institute of Cancer, MD; 3) Department of Biostatistics, Yale School of Public Health, New Haven, CT; 4) Yale University School of Medicine, New Haven Veterans Affairs Connecticut Healthcare System, West Haven, CT.

IMPORTANCE: Intravenous drug (IVD) use is the second most common risk factor for human immunodeficiency virus (HIV-1) infection and IVD use worsens HIV progression. However, the mechanisms of how IVD impacting HIV risk and outcomes is still unknown. **OBJECTIVE:** To identify differential DNA methylation patterns between IVD users and non-IVD users in HIV-infected patients and to identify IVD-associated biological pathways. **MATERIALS AND METHODS:** A total of 553 HIV-infected male veterans were selected from the Veteran Aging Cohort Study. DNA was extracted from peripheral blood. We profiled DNA methylation for 485,521 CpG sites using Illumina HumanMethylation 450K Beadchip. Data processing and normalization was followed by the recent developed pipeline (Lehne et al, 2015). We removed 11,648 probes on X and Y chromosomes and an additional 36,535 probes within 10bp SNPs. Probe intensity was normalized using quantile method. Cell type proportion was estimated with Houseman method using minfi R package. Linear regression model was applied as: *β value (Quantile normalized) ~ IVD + age + race + WBC+ cell types*. Significant level was set at false discovery rate <0.05. Genes with FDR < 0.1 were used for a gene set enrichment analysis to identify IVD-associated pathways by using Ingenuity Pathway Analysis. **RESULTS:** We identified 37 CpG sites reached methylome-wide significance for HIV-infected IVD use. Two CpG sites in the promoter region of the *NLR family, CARD domain containing gene 5 (NLRC5)*, which plays an important role in regulating major histocompatibility complex class I gene expression, were significantly less methylated in IVD users compared to non-IVD users (cg07839457: t=-6.02, p_{adj}=0.0014; cg08159663: t=-4.7, p_{adj}=0.045). In addition, 3 CpG sites in the promoter region of *tripartite motif containing 69 (TRIM69)* were also less methylated in IVD users (cg10439456: t=-5.53, p_{adj}=0.004; cg22107533: t=-5.19, p_{adj}=0.013; cg10439456: t=-5.53, p_{adj}=0.004). *TRIM69* is related with immune system and antigen processing through ubiquitination and proteasome degradation. More interestingly, we found the significant enrichment of genes in the antigen presentation pathway ($p_{nominal}$=4.3x10^{-8}) and the interferon signaling pathway ($p_{nominal}$=1.2x10^{-4}) for HIV-infected IVD use. **CONCLUSIONS:** Our findings suggest IVD use changes DNA methylation in the genes involving immune regulation and antigen processing that are critical for HIV-1 infection and progression.

2064F

Enhancer and super-enhancer gene targets in genetic disease. *C. Barr[1,2], Y. Feng[1,2], A. Dineen[1,2], A. Sarkar[1,2].* 1) Genetics & Development, Krembil Research Institute, UHN, Toronto, ON, Canada; 2) Program in Neurosciences and Mental Health, Hospital for Sick Children, Toronto, ON, Canada.

A major challenge confronting genetic studies of complex traits is moving from GWAS findings to identifying the genes in these regions creating risk and the mechanisms by which genetic variants alter function. For most of the association findings, the associated markers reside in gene regulatory regions, particularly enhancers and super-enhancers. Enhancers can reside anywhere within, or megabases (MB) from the gene that they regulate (target gene). Further, they can enhance transcription of multiple genes (~2.5) and their targets are often not the nearest gene (27-40% target the nearest gene). Thus, the assumption that the gene nearest a GWAS-significant marker will be the risk gene will in many cases be incorrect. To identify the target genes of the enhancers with associated markers for schizophrenia and for immune mediated disorders, we analyzed Capture-HiC data sets. The results identify the target genes of the enhancers, with targets located both inside and outside of the associated region. For example, for the 36 brain super-enhancers within the 108 published schizophrenia GWAS regions, we identified 229 interacting genes, with some of these key suspects located outside the associated region. Specifically, the brain and neural precursor cell (NPC) super-enhancer located within the schizophrenia associated *RERE* gene region interacts with multiple genes over a 2 MB region, including those implicated in neuronal survival (e.g. *LZIC*, *NMNAT1*), genes implicated in Parkinsons (*PARK7*) and bipolar disorder (*PER3*). Using CRISPR/Cas9, we deleted part of the *RERE* super-enhancer in human neural precursor cells (hNPCs) and HEK293 cells. Quantitative reverse transcriptase PCR (RT-PCR) of the targets are in progress and preliminary results indicate that in HEK293 cells that *RERE* and *PER3* were reduced in expression while *PARK7* was unaffected. RT-PCR studies for these genes are in progress for the CRISPR/Cas9 edited hNPCs. In parallel studies, we are using RT-PCR and chromatin conformation capture (3C) in a genotyped panel of human brain tissues to correlate associated alleles with transcription and altered promoter interactions of the predicted target genes. In summary, Capture-HiC analysis provides important new leads in pinpointing the target genes of enhancer-mediated regulation emanating from the GWAS findings. Identification of the multiple gene targets allows for functional studies and has important implications for modeling disease.

2065W

Methylome-wide association study of major depressive disorder in post-mortem brain tissues from 212 subjects. *K. Aberg[1], G. Turecki[2], A. Shabalin[1], L.Y. Xie[1], G. Kumar[1], R.F. Chan[1], M. Zhao[1], M.W. Hattab[1], H. Herman[1], S.L. Clark[1], B. Dean[3], E.J.C.G. van den Oord[1].* 1) Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, USA; 2) Department of Psychiatry, McGill University, Canada; 3) The Florey Institute of Neuroscience and Mental Health, The Victorian Brain Bank Network, Australia.

We performed a methylome-wide association study (MWAS) using 212 post-mortem brain tissue samples from Broadmann area (BA) 10, to study the disease etiology of major depressive disorder (MDD) [MIM#608516]. To further study the potential consistency/variation in disease-associated methylation marks across brain regions we investigated a second brain tissue (BA25), from the same individuals, for a subset of 63 subjects. The brain tissues were obtained from the Victorian Brain Bank Network, Douglas–Bell Canada Brain Bank, Harvard Brain Tissue Resource Center, Stanley Medical Research Institute and The Netherlands Brain Bank. The methylomes were assayed with a sequencing-based methylation enrichment approach that applies a high affinity methyl-binding domain protein (MBD-seq). In contrast to standard bisulfite conversion methods, MBD-seq uniquely detects CpG methylation, but not hydroxymethylated CpGs, and, as the approach does not require conversion of nucleic acids, the DNA sequence retains its full integrity thus alleviating the challenges of aligning bisulfite-converted genomes. Furthermore, in contrast to commonly used methylation arrays, typically targeting 2-3% of CpGs in the human genome, MBD-seq allows for the investigation of the majority of all >26 million CpGs. Specifically, in direct comparison with whole-genome bisulfite sequencing (WGBS) MBD-seq can correctly identify the methylation status of 94% of the CpGs detected by WGBS. After rigorous quality control, our analysis involved methylation measures from >17 million CpGs that were evaluated for association with MDD. Our main analysis, including all 212 samples from BA10, suggested many markers with small effects (lambda=1.068; 253 CpGs with p<1e-05). These markers, which all showed the same direction of effect in the main subsets of the samples, are further investigated for their combined poly-epigenetic risk involved in MDD etiology. Furthermore, the comparison of the results from BA10 and BA25 identified a significant overlap (p=0.0082) of MDD-associated sites, suggesting considerable consistency in methylation marks of potential importance in the brain regions. Top findings included CpGs in *ANKS1B* [MIM*607815], a gene with a suggested role in normal brain development, that are currently followed-up for functional relevance in human cells using epigenetic editing. This study presents a rigor investigation of human brain that identified methylation marks of potential importance for MDD etiology.

2066T

DNA methylation profiles of monozygotic twins discordant for ADHD. *T.V.M.M. Costa[1], F.A. Marchi[2], C. Milani[1,3], J.G. Damasceno[1], E.A. Zanardo[1], G.M. Novo-Filho[1], M.M. Montenegro[1], F.A.R. Madia[1], A.T. Dias[1], A.M. Nascimento[1,3], M. Rocha[4], M.B. Veronesi[1], C.A. Kim[3], V. Schuch[5], C.B. Mello[5], M. Muszkat[5], L.D. Kulikowski[1,3,4].* 1) Laboratório de Citogenômica, Departamento de Patologia, Faculdade de Medicina da USP, São Paulo, Brasil; 2) Laboratório NeoGene, AC Camargo Cancer Center, São Paulo, Brasil; 3) Laboratório de Citogenômica, Unidade de Genética, Departamento de Pediatria, Instituto da Criança, HC/FMUSP, São Paulo, Brasil; 4) Centro de Reprodução Humana e Genética, Departamento de Saúde Coletiva, Faculdade de Medicina do ABC, Santo André, Brasil; 5) Núcleo de Atendimento Neuropsicológico Infantil Interdisciplinar (NANI), Departamento de Psicobiologia da Escola Paulista de Medicina, UNIFESP, São Paulo, Brasil.

Attention deficit hyperactivity disorder (ADHD) is one of the most common neurobehavioral disorder diagnosed in childhood. It has high heritability (around 80%) and is etiologically heterogeneous. However, the genetic architecture of ADHD is still largely unknown. Behavioral genetic studies have demonstrated that genetic influences play a role in the etiology of ADHD. It is also known that environmental factors are also important in development of the disorder. Therefore, it is necessary to study whether epigenetic factors are related to the etiology of ADHD. Thus, DNA methylation profiles of monozygotic twins are an important tool to study the role of epigenetic factors in ADHD. Diagnosis was performed according to Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR). DNA was extracted from blood lymphocytes of one ADHD patient and his twin brother – without ADHD (two boys, ages 12). After, DNA methylation profiles were performed using Illumina Infinium HumanMethylation450 BeadChip. Arrays data were processed within the environment R. We calculate the difference between the β values (Δβ) of all probes of both twins (with and without ADHD). Limma package was used to obtain significant probes considering Bonferroni correction and p < 0.05. Finally, we selected the probes with Δβ > 0.1. The probes were annotated according to the data provided by Illumina using the genome hg19 reference. In total, 1,023 probes were selected. 631 of these probes are hypomethylated in the ADHD patient relative to his twin without ADHD. Thus, our results suggest that DNA methylation profile of ADHD patient is hypomethylated when compared with his twin brother without ADHD. However, it is important to investigate methylation profiles of more cases of twins discordant for ADHD to verify if indeed there is a relationship between hypomethylated methylation profiles and the development of ADHD. Grants: FAPESP: 2015/05350-5, 2014/02565-8 and FINEP-CT INFRA 0160/12 SP8.

WGBS reveals autism-associated hypomethylation and differentially-methylated regions in umbilical cord blood samples from the prospective MARBLES study. *C.E. Mordaunt[1,2,3,4], K.W. Dunaway[1,2,3,4], R.J. Schmidt[3,4,5], C.K. Walker[3,4,6], S. Ozonoff[3,7], I. Hertz-Picciotto[3,4,5], J.M. LaSalle[1,2,3,4].* 1) Medical Microbiology and Immunology; 2) Genome Center; 3) MIND Institute; 4) Center for Children's Environmental Health; 5) Public Health Sciences; 6) Obstetrics and Gynecology; 7) Psychiatry and Behavioral Sciences; University of California, Davis; Davis, CA.

   Autism spectrum disorders (ASD) have complex etiologies, likely involving multiple genetic and environmental insults in perinatal life. Genetic susceptibility can interact with environmental risk factors such as pesticides, air pollution, and persistent organic pollutants. The perinatal period is critical for both nutritional protective factors, such as the methyl donor folate, and interactions with genetic regulators of one-carbon metabolism. The epigenetic layer of DNA methylation, at the interface of genetic and environmental risk and protective factors, holds promise for earlier diagnosis and improved understanding of complex ASD etiologies. In this study, we investigated human umbilical cord blood samples from the MARBLES (Markers of Autism Risk in Babies - Learning Early Signs) prospective study by whole-genome bisulfite sequencing (WGBS) to identify DNA methylation differences predictive of ASD diagnosis by age three. ASD cord blood samples showed significantly lower global percent CpG methylation compared to typically-developing (TD) controls (ASD 76.6% vs TD 77.3%, p = 0.01; n = 26 ASD, 26 TD). ASD-associated hypomethylation was observed across most chromosomes, within gene bodies, and within early-life partially-methylated domains (PMDs), defined from human placenta. 20 kb windowing of the genome demonstrated a global shift of hypomethylation, with 74% of windows hypomethylated in ASD samples. This suggests a methylation deficiency in ASD during perinatal life, which could be a cumulative effect of genetic variants, environmental exposures, and/or shortage in methyl donors. Smaller differentially-methylated regions (DMRs) enriched for CpG islands were also identified in ASD cord blood (5,863 total DMRs). 56% of DMRs were hypomethylated, and all were less than 2.5 kb in size. DMRs hypomethylated in ASD cord blood overlapped genes significantly enriched for functions in synaptic transmission (62 genes, Bonferroni-adjusted p = 3.3x10^{-5}) and for the oxytocin signaling pathway (35 genes, Bonferroni-adjusted p = 2.1x10^{-7}). In addition to examining WGBS in association with ASD diagnosis and neurodevelopmental outcome measures, WGBS will be examined in relation to demographic, genetic, environmental, and nutritional information collected in the MARBLES study. These results are expected to improve understanding of perinatal factors in ASD etiology and aid in future preventative and therapeutic treatments.

2068W

Genomewide DNA methylation analysis in an antipsychotic naive first episode of psychosis cohort. *P.N. Moretti[1,2,3], M.L. Santoro[1,2,3], V.K. Ota[1,2,3], S. Jong[4], E.S. Gouvea[5], C.S. Noto[1,3], L.M.N. Spíndola[1,2,3], G. Xavier[2,3], C.M.F. Carvalho[2,3], Q. Cordeiro[5], R.A. Bressan[1,3], A. Gadelha[1,3], G. Breen[4], S.I. Belangero[1,2,3].* 1) Morphology and Genetics, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 2) Psychiatry Department – Universidade Federal de Sao Paulo (UNIFESP), Sao Paulo, Brazil; 3) Interdisciplinary Laboratory of Clinical Neurosciences (LiNC), Psychiatry Department – Universidade Federal de Sao Paulo (UNIFESP), Sao Paulo, Brazil; 4) MRC Social Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK; 5) Psychiatry Department, Irmandade da Santa Casa de Misericórdia de Sao Paulo (ISCMSP), Sao Paulo, Brazil.

   Schizophrenia is a severe psychiatric illness with considerable morbidity and motality as well as a very high cost of care. The first episode of psychosis (FEP) usually occurs in adolescence or early adulthood, and is a critical period for future schizophrenia prognosis. The evaluation of FEP patients can be helpful for understanding the onset and progression of the disorder, especially before treatment with antipsychotics, without the influence of the progression of symptoms and pharmacological treatment. Beyond successful GWAS analyses, the identity of other biomarkers for the disease remains uncertain. Our objective was to analyze genomewide DNA methylation in a longitudinal cohort of antipsychoticnaïve Brazilian FEP patients, followed up after two months (FEP2M) of antipsychotic (Risperidone) treatment. We selected 60 healthy controls, 60 FEP samples before and after treatment, aged 1835 yo and fulfilling DSMIV criteria for psychotic diagnoses . Blood was collected from all participants and DNA was extracted. For DNA methylation analysis, we performed sodium bisulfite treatment, and used the Infinium HumanMethylation450 BeadChip Kit according to the manufacturer's protocol. Ten differently methylation regions (DMR) were observed between FEP and FEP2Min in a paired analysis. Notably, three of the ten regions were identified before in PGC2 Schizophrenia GWAS (regions on chromosome 6, 2 and 17). We did not observe any DMRs between healthy controls and antipsychotic-naïve FEP subjects, suggesting the observed changes were a consequence of treatment.

Differential DNA methylation in the dorsal and ventral striatum of individuals with chronic cocaine dependence. *K. Vaillancourt[1,2], C. Ernst[1,3], G.G. Chen[1], A. Bramoulle[1], J-F. Théroux[1], D.C. Mash[4], G. Turecki[1,2,3].* 1) McGill Group for Suicide Studies, Douglas Hospital Research Center, Verdun, QC, Canada; 2) Integrated Program in Neuroscience, McGill University, Montreal, QC, Canada; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada; 4) Department of Neurology, University of Miami Miller School of Medicine, Miami, FL, USA.

   Background: Cocaine dependence is a chronic relapsing disorder whose development and trajectory is impacted by multiple genetics and environmental factors. Transcriptional changes accompany the transition from recreational cocaine use to cocaine dependence and epigenetic mechanisms may mediate these effects. Recently, several studies have identified epigenetic marks that are associated with the acquisition of compulsive drug seeking in animal models, but little is known about the role of epigenetics in human cocaine dependence. Of particular interest is DNA methylation as it represents a mitotically stable mark that has been shown to be altered by environmental experience. **Methods**: We used Reduced Representation Bisulfite Sequencing (RRBS) on post mortem nucleus accumbens and caudate tissue from 25 dependent cocaine users and 25 drug-free and age-matched controls. This approach has allowed us to detect genome-wide cytosine methylation at base pair resolution. Differentially methylated regions (DMRs) were validated in this cohort, and replicated in an independent cohort of cases and controls (n=18 per group), using targeted deep bisulfite sequencing. We used fluorescence activated cell sorting (FACS) to separate neuronal (NeuN+) from non-neuronal (NeuN-) nuclei in order to identify cell type specificity of our results. **Results**: Our study has identified multiple clusters of hyper- and hypomethylation associated with chronic cocaine dependence, in both brain regions. Differential methylation spans gene bodies, including introns and exons, as well as promoter and intergenic regions. High throughput discovery of cocaine-associated networks and pathways allow us to investigate cell-type specific epigenetic changes that accompany the development and persistence of chronic cocaine dependence. miR-1202 potentially important in regulating dopaminergic neuron differentiation. *D. Cao, L. Li, W. Law, J. Tu, K. Miu, H. Cheung, W. Chan.* School of Biomedical Sciences, Faculty of Medicine, the Chinese University of Hong Kong, Shatin, Hong Kong SAR, China.

   Micro-RNAs (miRNAs) comprise a distinct class of small non-coding RNAs identified to be potentially important post-transcriptional gene regulators. Their activities in cells have important consequences for normal development and physiology, diseases, and evolution. In the past decades, many miRNAs have been shown to be dynamically expressed in brain or during neural differentiation from stem cells. However, it remains largely unknown about how specific miRNAs regulate neurogenesis. Through analyzing miRNA expression profile at different time points during neural induction from hiPSCs, hsa-miR-1202 was identified to be significantly increased during the process. hsa-miR-1202 is a primate-specific microRNA. Interestingly, hsa-miR-1202 was recently shown to be dysregulated in brain tissues of patients suffering from major depression syndromes suggesting that hsa-miR-1202 may have important functions in human brain. Downstream target prediction and in silico functional analysis showed that hsa-miR-1202 is probably involved in regulating development and activities of dopamine neurons. To study how hsa-miR-1202 regulates dopaminergic (DA) neuronal development, we differentiated human iPSCs into DA neurons. We showed that expression of has-miR-1202 was elevated in the DA neuron progenitors and DA neurons. We are in the process of manipulating the expression of hsa-miR-1202 during DA neuronal patterning stage in order to define its role in DA neuronal differentiation. This study will extend our understanding of the specific function of hsa-miR-1202 in DA neuronal development and reveal specific role of hsa-miR-1202 in DA neuron-related diseases. .

Small nucleolar RNA and antidepressant response. *R. Lin[1], J.P. Lopez[1], L. Fiori[1], C. Cruceanu[1], R. Belzeaux[1], CANBIND Working Group[3], J. Foster[2], S. Kennedy[2], G. Turecki[1].* 1) Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Department of Psychiatry, University Health Network, University of Toronto, Toronto, Ontario, Canada; 3) CANBIND.

Statement of Purpose: Major depressive disorder (MDD) is a prevalent disorder treated primarily by antidepressants. Although effective, on average 30%-40% of patients experience an inadequate response to treatment after several attempts. Thus, there is a great need to identify biomarkers associated with MDD that predict and/or mediate response to antidepressant treatment. Recent discoveries have pointed towards small non-coding RNAs (sncRNAs) as feasible biomarkers. While the majority of studies have focused on microRNAs, evidence suggests that small nucleolar RNAs (snoRNAs), which are involved in alternative splicing and chemical modifications of RNAs, may also act as novel biomarkers for antidepressant response. **Methods:** A sample of 258 depressed patients were treated either with the antidepressant duloxetine (N=124) or placebo (N=134) for a period of 8 weeks. Blood samples were collected at baseline (T0) and 8 weeks into treatment (T8), and RNA sequencing was performed to detect expression changes of sncRNAs. At T8, patients were grouped into responders or non-responders to duloxetine, where responders were characterized as having a 50% reduction in the MADRS score from T0 to T8. The expression of the top snoRNAs, from responders of duloxetine, showing significant differences in their expression profiles from T0 to T8 was assessed in neural progenitor cells (NPCs) treated with duloxetine using qRT-PCR. **Results:** Small RNA sequencing revealed SNORD43, SNORD11B, SNORD17, SNORD77, SNORD99, and SNORD52 to be significantly up-regulated in responders 8 weeks after duloxetine treatment. NPCs treated with duloxetine for 2 weeks also showed a significant up-regulation of all 6 candidate snoRNAs when compared to untreated controls. This is the first study profiling snoRNAs in MDD and antidepressant response, and these preliminary results suggest that the candidate snoRNAs may be good biomarkers of antidepressant response.

2072T

Differential DNA methylation of neuro-immune regulatory genes associated with symptom severity and amygdala-prefrontal dysfunction in pediatric post-traumatic stress disorder. *T.J. Keding[1,2], L.A. Papale[2], R.S. Alisch[1,2], R.J. Herringa[1,2].* 1) Neuroscience Training Program, University of Wisconsin-Madison, Madison, WI; 2) Department of Psychiatry, University of Wisconsin-Madison School of Medicine & Public Health, Madison, WI.

Studies of adult post-traumatic stress disorder (PTSD) suggest a role for DNA methylation on genes related to hypothalamic-pituitary-adrenal (HPA) axis regulation, including the glucocorticoid receptor gene *NR3C1* and its regulator *FKBP5*, as well as genes involved in the regulation of the immune system. Furthermore, DNA methylation levels on such genes are dynamically related to symptom severity and improvement. However, studies have yet to investigate whether these relationships exist in pediatric PTSD, especially with regards to symptom severity, trauma-exposure, and abnormalities in brain circuitry. Saliva from youth with trauma exposure and PTSD (n = 22, 8-18 years) and age- and sex-matched healthy comparison youth (n = 22) was collected. DNA was extracted and genome-wide 5-methylcytosine (5mC) was profiled using the HumanMethylation450 BeadChip. Differentially methylated regions (DMRs) between groups were examined using a mixed effect model, controlling for age, sex, and cell type composition. False discovery rate (FDR)-corrected multivariate and partial correlation analyses were conducted to relate methylation at DMRs to symptom severity, trauma-related measures, gray matter volume, and task-based brain activation and amygdala functional connectivity within the PTSD group. Eighty-one group-associated DMRs were identified, 79 of which showed hypermethylation within the PTSD group relative to healthy controls. Enrichment analyses revealed that 14 of these genes were associated with signal transduction regulation and 11 with immune response regulation. Additionally, a subset of these genes (N = 28) showed significant associations with symptom severity, trauma-exposure, and amygdala-prefrontal structure and function within the PTSD group (FDR-corrected p < 0.05). Eleven of these genes were related to cellular and organismal development processes, including *GABRA3*, *GABRA5*, and *SYNGAP1*, which showed specificity to the nervous system. Systems pathways analysis further revealed that these three genes are heavily involved in the development and migration of neurons, neuronal apoptosis, as well as learning, memory, and cognition. Together, these findings link DNA methylation to symptom severity and trauma-related brain measures in pediatric PTSD. The DMRs found here represent potentially modifiable molecular substrates in the brain that ultimately could be targeted to aid children exposed to early life trauma that otherwise may result in PTSD.

2073F

Exploring the etiology of FASD: Hippocampal gene expression after continuous prenatal alcohol exposure plus postnatal maternal separation in mice. *B. Alberry, S.M. Singh.* Biology, Western University, London, Ontario, Canada.

Prenatal alcohol exposure (PAE) can result in Fetal Alcohol Spectrum Disorder (FASD), characterized by behavior abnormalities. In earlier experiments using a mouse model, we established the effect of alcohol on long-term neural gene expression, which may come about through additional epigenetic modifications resulting in altered gene expression. This research extends the model to include early life stress (ELS) via postnatal maternal separation. To generate PAE mice, pregnant C57BL/6 females had access to water and 10% ethanol in water, while control mice had access to water only. ELS treatment followed with half the pups from each litter isolated from the dam and littermates postnatal days 2-14 for 3 h/day. All pups underwent various behavioral tests during development and into adulthood, including the Barnes Maze Test for learning and memory. Mice were sacrificed on postnatal day 70. Hippocampal RNA was isolated for assessment of gene expression including microRNAs using two independent methods: Affymetrix Mouse Gene 2.0 ST gene expression arrays and RNA-Seq. Genes implicated by both measures were compared for pathway and network analysis. Results show many genes have altered expression in the adult hippocampus following PAE, with and without ELS. The results are compatible with observed behavioral alterations resulting from PAE and ELS. A number of pathways, including alcoholism, common in FASD are implicated. Results argue that the effect of PAE and ELS in FASD is realized by alterations in gene expression in a large number of genes affecting numerous pathways. This experimental model represents a more realistic model of FASD and critical genes and pathways identified may provide a foundation for prospective interventions following early FASD diagnosis.

2074W

Long noncoding RNAs regulation of glucocorticoid signaling in brain and blood tissue across psychiatric disorders. *G. Guffanti[1], A. Wingo[2], T. Jovanovic[2], C. Nemeroff[3], A. Myers[3], F. Macciardi[4], K. Ressler[1].* 1) Harvard Medical School, Belmont, MA; 2) Emory University, Atlanta, GA; 3) 3Univ. of Miami, Miami, FL; 4) University of California Irvine, Irvine, CA.

BACKGROUND: Evidence is accumulating that non-coding RNAs might play arole in GR-mediated regulation of glucocorticoid signaling. lncRNA GAS5 has recently been characterized as a suppressor of transcriptional activity of glucocorticoid responsive genes in mice. Human genetic studies examining stress pathways have mostly focused on the glucocorticoid receptor (GR) and its target genes. Transcriptional and post-transcriptional regulatory function of lncRNAs might explain the missing "link" between the genetic make-up predisposing to PTSD and stress- and trauma-related disorders and GR-related neurobiology in a tissue specific way. We set up to test the hypothesis that lncRNA GAS5 regulation might be perturbed in PTSD. METHODS: The sample derives from the larger cohort of the Emergency Department (ED) collaboration for the analysis of the transcriptome of peripheral blood of PTSD patients. PTSD was diagnosed immediately after the trauma and confirmed up to three months later, yielding 23 cases and 23 trauma-exposed controls. Raw paired-end RNA-sequencing was aligned to the hg19 genome build using the Tuxedo pipeline. Further processing to delineate the transcriptional profiles of lncRNA was performed using the ad hoc lncRNA pipeline called PLAR. We tested for statistical significance of observed changes in gene expression between PTSD patients and trauma-exposed controls using the statistical negative binomial model implemented in R-Bioconductor EdgeR. RESULTS: We have characterized GAS5 expression profiles in a subset of 46 subjects among cases and controls from the GTP peripheral RNA-seq cohort. Out of the 29 non-redundant isoforms of GAS5, we were able to detect the expression of 12 isoforms. At least two GAS5 isoforms revealed significant down-regulation in PTSD patients compared to trauma-exposed controls (p < 10-4). Based on the information reported in the gene expression database GTEx, these isoforms seem to be expressed in peripheral blood tissue but do not seem to be expressed in AM nor HC in favor of other isoforms. CONCLUSIONS: The results highlight the importance of tissue specificity in the assessment of lncRNA expression profiles, and support the original hypothesis that lncRNA GAS5 plays a role in PTSD, and suggest that lncRNA GAS5 may be differentially expressed in stress-related syndromes compared to traumatized controls. The mechanism by which GAS5 performs its regulatory function remains to be elucidated. .

Disruption of activity-dependent signaling pathways in Potocki Shaffer Syndrome. *R.S. Porter[1,2], Y. Nakamura[1], S. Agarwal[1], H.G. Kim[3], S. Iwase[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Medical Scientist Training Program, University of Michigan, Ann Arbor, MI; 3) Section of Reproductive Endocrinology, Infertility & Genetics, Department of Obstetrics & Gynecology, Augusta University, Augusta, GA.

Histone modifications and histone variants are important epigenetic factors that can lead to differential higher-order structures of the genome. A variety of protein factors are responsible for placing, reading, and removing the various histone marks. Many of these factors when mutated lead to neurodevelopmental disorders such as intellectual disability and autism, suggesting that proper epigenetic regulation is crucial for normal brain development. Potocki Shaffer Syndrome (PSS) is a contiguous gene deletion syndrome involving multiple genes on chromosome 11p11.2. PSS is characterized by intellectual disability, craniofacial abnormalities, and bone malformation. Intellectual disability in PSS has been attributed to loss of *PHF21A*, a protein that recognizes unmethylated histone 3 lysine 4 (H3K4me0) and is part of the Lysine Specific Demethylase 1 (*LSD1*) complex. *LSD1* acts to demethylate mono- or di-methylated histone 3 lysine 4(H3K4me1/2) to repress nearby genes. The *LSD1-CoREST* complex is important for mediating repression of neuron-specific genes in non-neuronal cells. However, the mechanisms by which *PHF21A* contributes to brain development remain unknown. Our lab recently performed RNA-Sequencing on two patient samples with PSS and two unaffected control individuals. Preliminary pathway analysis using LR Path and GSEA MSigDB of differentially regulated genes suggested disruption of learning and memory pathways, in line with the clinical phenotype. Specifically, *CREB* target genes were differentially regulated more than expected by chance. Transcription factor target pathway analysis showed misregulation of neuronal activity dependent signaling pathways, specifically *CREB*, *AP1*, and *MEF2*. With the hypothesis that *PHF21A* is required for proper induction of activity-dependent signaling in the nervous system, these disrupted pathways will be functionally tested in binding assays with *PHF21A* as well as luciferase assays to examine whether the expression of these transcription factor targets changes upon *PHF21A* loss. This work will provide insight into the molecular mechanisms of intellectual disability in PSS and can be the basis for the design of rational therapeutics.

2076F

A unique epigenetic fusion protein on a ring X chromosome found in a patient with Kabuki syndrome. *G.O. Pilarowski[1,2], J.D. Robertson[1,2], C. Applegate[1], E.S. Wohler[3], D.A. Batista[1,3], L.A. Goff[1,4], H.T. Bjornsson[1,5].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States; 2) Predoctoral Training Program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States; 3) Cytogenetics and Microarray Laboratory, Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States; 4) Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States; 5) Department of Pediatrics at the Johns Hopkins University School of Medicine, Baltimore, Maryland, United States.

Kabuki syndrome (MIM: #147920; #300867) is a genetic disorder characterized by unique facial features, growth retardation, and intellectual disability. The majority of patients (70%) have a mutation in either of two genes encoding histone modifying enzymes (KMT2D and KDM6A), resulting in an inability to open chromatin. A subgroup of Kabuki syndrome patients with unknown genetic etiology have a Turner syndrome karyotype (45,X) and most of these are mosaic for a ring X chromosome (45,X/46,X,r(X)). This ring X does not include the *XIST* locus, indicating that the ring is constitutively active. We studied the breakpoints in one such patient with a clinical diagnosis of Kabuki syndrome and a cytogenetic diagnosis of Turner syndrome (46,X, t(1:9)(q21;q32) ,+r.ish r(X)(DXZ1+,XIST-) [16]/45,X, t(1:9)(q21;q32)[4]), no mutations in *KMT2D/KDM6A* and a non-consequential translocation inherited from a healthy father. One possibility is that overexpression of one of the 107 genes on the ring would cause the Kabuki phenotype; yet none of these genes involve histone machinery. Surprisingly, we found that the fused ends of the ring X chromosome form a novel fusion transcript of two histone modifiers, created by the 5' end of *PHF8* and the out of frame 3' end of *HDAC8*. PHF8 normally functions to remove H3K9 mono- and di-methylation, showing enhanced activity when bound to H3K4 tri-methylation. Here we demonstrate that the fusion protein is produced in cells, it localizes to the nucleus, and contains an intact PHD finger domain. Therefore, we hypothesize that the fusion protein acts in a dominant negative manner by binding to H3K4me3 with its PHD finger domain. Such binding could mask the H3K4me3 mark from the full length PHF8, thus rendering it unable to remove the closed chromatin mark H3K9me1/2. We are employing single cell RNA-sequencing on both populations of cells found in the patient (45,X cells and 46,X,r(X) cells). Through single cell analysis we will explore whether the presence of this ring X leads to transcriptional dysregulation and subsequently we will interrogate the effects of the fusion protein itself. Although the paradigm of novel fusion proteins leading to disease has been established in cancer, to our knowledge this may be the first example of a Mendelian disease caused by the creation of a novel fusion protein. Our findings also suggest that disruption of sequential stages of chromatin opening forms a unifying mechanism of disease in Kabuki syndrome.

2077W

Genome-wide DNA methylation testing in patients with developmental delay and intellectual disabilities. *B. Sadikovic[1,2], K. Boycott[3], C. Schwartz[4], G. Pare[5], C. Howlett[1,2], P. Ainsworth[1,2], L. Schenkel[1]. 1) Department of Pathology and Laboratory Medicine; Western University; London, ON, Canada; 2) Molecular Genetics Laboratory; Molecular Diagnostics Division, London Health Sciences Centre, London, ON, Canada; 3) Children's Hospital of Eastern Ontario Research Institute; University of Ottawa, Ottawa, ON, Canada; 4) Center for Molecular Studies, J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, South CA, USA; 5) Department of Pathology and Molecular Medicine and Department of Clinical Epidemiology and Biostatistics; McMaster University; Hamilton, ON, Canada.*

Developmental Delay and Intellectual Disabilities (DD/ID) are caused by the interaction of genetic and environmental factors that is facilitated by epigenetic mechanisms. The most widely studied epigenetic mechanism is the DNA methylation, which is a covalent modification occurring primarily at cytosines within CpG dinucleotides. DNA methylation defects have been shown to play a key role in many pediatric and adult onset disorders, including imprinting diseases and carcinogenesis. However, there is little known about genome-wide DNA methylation changes in patients with DD/ID. Our laboratory has performed a genome-wide DNA methylation testing in 1000 patients with a wide range of disorders associated with DD/ID to clinically validate the use of a genome-wide DNA methylation assay and define epi-signatures of various DD/ID conditions. Briefly, the DNA methylation array was performed in peripheral blood using the Infinium HumanMethylation450 Beadship. And results were analyzed using a custom algorithm with Partek Genomic Suite software. Methylation patterns of individual patients were compared to normal reference cohort of >300 individuals and were prioritized based on the statistical parameters including methylation difference, *p* value, and F value; and functional parameters including distance to the CpG islands and gene promoter, and the proximity to the known disease-causing genes. We have validated this approach for sensitive detection of imprinting disorders including Angelman, Prader-Willi, Beckwith Wiedemann, and Russell-Silver syndrome, as well as Fragile X syndrome. We also discovered novel highly specific diagnostic epigenetic signatures in the peripheral blood of patients with Alpha Thalassemia/Mental Retardation syndrome X-Linked, Floating-Harbor syndrome, Autosomal Dominant Cerebellar Ataxia with Deafness and Narcolepsy (ADCA-DN) and Claes-Jensen X-linked Mental Retardation syndrome. These findings demonstrate clinical utility of genome-wide DNA methylation testing in patients with a wide-ranging spectrum of epi/genetic conditions, and provide better understanding for the pathology of DD/ID syndromes, in which specific DNA methylation changes could lead directly to an aberrant expression of genes. .

2078T

Genome-wide DNA methylation analysis of atypical 7q11.23 rearrangements implicate *GTF2IRD1* **and** *GTF2I* **in DNA methylation.** *E. Strong[1], C.B Mervis[2], C.A Morris[3], L.R Osborne[1,4]. 1) Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Department of Psychological and Brain Sciences, University of Louisville, Louisville, KY; 3) Department of Pediatrics, University of Nevada School of Medicine, Las Vegas, NV; 4) Department of Medicine, University of Toronto, Toronto, Ontario, Canada.*

Williams syndrome (WS) is a developmental disorder caused by the hemizygous deletion of approximately 25 protein-coding genes on chromosome 7q11.23. The reciprocal duplication leads to a distinct disorder, 7q11.23 duplication syndrome (Dup7). Both syndromes present with variable cognitive and behavioural phenotypes, including intellectual ability that is more limited than other family members', anxiety disorders and attention deficit hyperactivity disorder, however little is known about their underlying molecular mechanisms. Five genes within 7q11.23 have been associated with epigenetic mechanisms and we have recently shown that deletion or duplication of this chromosome segment causes dose-dependent changes in DNA methylation. To better understand the molecular mechanism of aberrant DNA methylation in these disorders and identify the gene(s) responsible we assessed genome-wide DNA methylation in participants with atypical deletions or duplications of 7q11.23. We measured genome-wide DNA methylation in whole blood samples derived from 3 participants with atypical deletions and 3 with atypical duplications of 7q11.23 using the Illumina HumanMethylation450k array. Atypical rearrangements had differing contributions of the genes previously linked with epigenetic regulation (*BAZ1B, BCL7B, WBSCR22, GTF2IRD1, GTF2I*). By comparing DNA methylation profiles across the top 1000 most variable positions in 18 typically developing controls (TD), 6 atypical, 20 WS and 10 Dup7 participants, we found that only the atypical rearrangements that affect the *GTF2IRD1* and *GTF2I* genes clustered with their respective syndromic cohorts. Likewise, hierarchical clustering of the top 500 most differentially methylated (DM) sites within the WS cohort and top 500 most DM sites within the Dup7 cohort revealed that only atypical rearrangements spanning *GTF2IRD1* and *GTF2I* cluster with their respective syndromic cohorts. Pyrosequencing validation of several sites confirmed these methylation changes and showed close correlation with array findings. These data suggest that loss or gain of the GTF2I genes at the telomeric end of the 7q11.23 interval are key contributors to the large changes in DNA methylation we have reported in our WS and Dup7 cohorts. Current work focuses on validating and investigating the individual contribution of *Gtf2i* and *Gtf2ird1* to aberrant methylation using mouse models to better understand the molecular mechanism of aberrant DNA methylation in WS and Dup7.

2079F

SMCHD1 regulates a limited set of gene clusters on autosomal chromosomes. *A.G. Mason[1], R.C. Slieker[2], J. Balog[1], R.J.L.F Lemmers[1], C.J. Wong[5], J.W. Lim[5], G.N. Filippova[5], B.T. Heijmans[2,3], R. Tawil[4], S.J. Tapscott[5], S.M. van der Maarel[1].* 1) Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Molecular Epidemiology, Leiden University Medical Center, Leiden, The Netherlands; 3) Netherlands Consortium for Healthy Aging, PO Box 9600, Leiden 2300, RC, The Netherlands; 4) Neuromuscular Disease Unit, Department of Neurology, University of Rochester Medical Center, Rochester, NY, USA; 5) Division of Human Biology, Fred Hutchinson Cancer Research Center, Seattle, WA, USA.

Facioscapulohumeral muscular dystrophy (FSHD) affects approximately 1 in 20,000 to 1 in 8,500 individuals. It is clinically characterized by the progressive and often asymmetrical weakness and wasting of the facial and upper extremity muscles. The most common form of FSHD, FHSD1, is caused by the deletion of a subset of D4Z4 macrosatellite repeats on chromosome 4, whereas the less common form, FSHD2, is most often caused by mutations in the *SMCHD1* gene. Both mutations result in the incomplete epigenetic repression of the D4Z4 encoded retrogene *DUX4 in somatic cells*, leading to the variegated expression of DUX4 in skeletal muscle cells. *SMCHD1* encodes for a protein that regulates chromatin repression at different loci, having a role in methylation establishment and/or maintenance. To investigate the global effects of SMCHD1 mutations on methylation we carried out 450k methylation analysis on mononuclear monocytes obtained from 23 female *SMCHD1* mutation carriers and 24 female unaffected controls. In addition, we performed reduced representation bisulfite sequencing (RRBS) on two FSHD2 and unaffected control myoblast cell lines. From the assays we identified several clustered genomic loci with decreased methylation: the clustered protocadherin (*PCDH*) locus on chromosome 5, the tRNA and 5S rRNA clusters on chromosome 1, the *HOXB* and *HOXD* clusters on chromosomes 17 and 2 respectively, and the D4Z4 macrosattelite repeats on chromosomes 4 and 10. In addition an increase in RNA expression was seen in FSHD2 myoblast cells for some of the *PCDHβ* cluster isoforms, tRNA isoforms, *HOXB* isoforms, and 5S rRNA in comparison to controls, as well as the increased DUX4 expression from the D4Z4 repeats previously described. We identified SMCHD1 binding at the DNAseI hypersensitivity sites HS17-17' and HS19-20, known to regulate the expression of the *PCDHβ* cluster, and within the chr1 tRNA cluster, with SMCHD1 binding being significantly decreased at HS17-17' and HS19-20 in *SMCHD1* mutation carriers compared to controls. These studies suggest that in a myogenic context SMCHD1 acts as a repressor on the *PCDH* cluster and some additional autosomal gene clusters, with *SMCHD1* mutations resulting in hypomethylation of the cluster, increased expression of some gene cluster isoforms, and in the case of the *PCDH* cluster decreased binding of SMCHD1 to cluster regulatory sites.

Expression of selected circular RNAs in myotonic dystrophy type 1. *K. Czubak, M. Wojciechowska, P. Kozlowski.* European Centre for Bioinformatics and Genomics, Institute of Bioorganic Chemistry, Polish Academy of Sciences, Poznan, Poland.

Recent studies have discovered a new class of RNA molecules called circular RNAs (circRNAs), whose generation depends on a non-canonical form of alternative splicing. Unlike the other types of RNA, circRNAs are covalently closed circular molecules. Most of them contain exons of protein-coding genes and are processed cotranscriptionally, which implies that their formation competes with the formation of linear transcripts. To date, several mechanisms of circRNAs biogenesis have been proposed. One of them involves RNA-binding protein, muscleblind (MBNL). The MBNL protein is a splicing factor acting as an activator or repressor of splicing. The downregulation of this protein, caused by its sequestration by expanded CUG tract in *DMPK* transcript, plays an important role in the pathogenesis of myotonic dystrophy type 1 (DM1). Taking into account the sequestration of MBNL in DM1 cells and the crucial role of this protein in circRNA biogenesis, one may expect decreased level of circRNAs in DM1. To investigate this issue, from circRNA databases and from the literature we selected several circRNAs, taking into account their expression, ratio to linear transcript, and the presence of MBNL binding sites in surrounding introns. For 7 of the selected circRNAs, including circHIPK3, circN-FATC3 and circMBNL, we designed and optimized splicing-specific droplet digital PCR (ddPCR) assays. The specificity of all designed circRNA-specific amplicons was confirmed by the Sanger sequencing method. Each designed assay allows both absolute quantification of circRNA copies and estimation of its ratio to the linear counterpart. With the use of the designed assays, we analyzed the expression of the circRNAs in samples derived from muscle biopsies of DM1 patients and from DM1 myoblast cell lines, and compared it with the expression in the corresponding normal samples. As expected, our preliminary results showed decreased expression of some of the analyzed circRNAs in DM1. However, since these results are limited to highly-expressed circRNAs, in the next step we will extend the analysis to a higher range of different types of circRNAs (high/low expression, single-exonic/multiexonic, exonic/intronic). In conclusion, our analysis showed the downregulation of the selected circRNAs in DM1 samples and confirmed the suitability of ddPCR technique for the parallel analysis of the expression of circular and linear RNA. Acknowledgements: NCN 2015/17/B/NZ2/01182.

Variation in mitochondrial DNA copy number is associated with epigenetic modification of the nuclear genome. *C.A. Castellani[1], S.E. Ellis[1], F.N. Ashar[1], R.J. Longchamps[1], A. Tin[2], J.A. Lane[3], J. Bressler[4], J. Coresh[2], J.S. Pankow[5], M. Fornage[4], N. Pankratz[3], E. Boerwinkle[4], D.E. Arking[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Epidemiology and the Welch Center for Prevention, Epidemiology and Clinical Research, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) Department of Laboratory Medicine and Pathology, University of Minnesota School of Medicine, Minneapolis, MN; 4) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX; 5) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, MN.

Reduced mitochondrial DNA copy number (mtDNA-CN) has been associated with human disease and overall mortality. Changes in mtDNA-CN have been proposed to have a role in regulating epigenetic changes as evidenced by the observation of both hyper- and hypo- methylation of nuclear genes in cell lines depleted for mitochondria. Thus, increased understanding of the cross-talk between nuclear and mitochondrial DNA is critical to elucidating the impact of mtDNA-CN on human health and disease. To measure nuclear DNA methylation, DNA was extracted from buffy coat for 1,567 African American participants from the Atherosclerosis Risk in Communities (ARIC) study and hybridized to the Illumina Infinium 450K microarray. We used the Genvisis software to determine mtDNA-CN from genotyping microarray raw probe intensities (Affymetrix Human SNP 6.0). Linear mixed effect regression analyses were performed to determine the association between nuclear DNA methylation and mtDNA-CN, adjusted for age, sex, collection site, visit, chip position, plate, smoking status, imputed cell composition and surrogate variables. Residual bootstrapping was performed to determine the probe-specific genome-wide significance cutoff (p<6.22e-08). Twenty-five independent loci were genome-wide significant. The top associations include two CpG probes found in the 5'UTR of *KIAA0825* on chromosome 5 (p=1.12e-43; p=9.25e-30). Interestingly, we also observe that increased mtDNA-CN is associated with global hypermethylation (p<2.2e-16, ß=0.149). The results establish that variation in mtDNA-CN is associated with nuclear epigenetic modifications.

Effects of World Trade Center (9-11) particulate matter on mitochondrial damage observed in human lung cell in vitro. *A. Dilorenzo, V. Gatson, M. Hassan, C. Gonzales, R. Madrid, L. Seder, E. Tobias.* Dept Biol, Sci Hall - 109, Montclair State Univ, Upper Montclair, NJ.

An array of chronic health conditions have been associated exposure to the dust generated from the New York City World Trade Center (WTC) attack and collapse on September 11, 2001. This study seeks to isolate cellular mechanisms thought to play a role in the decreased lung function of World Trade Center (WTC) workers and victims. Human Lung Fibroblast Cells were exposed to World Trade Center (WTC) Dust at various ppm concentrations and simulated stress environments (via decreased serum levels). Previous studies have shown that the exposed cells showed decreased levels of cell proliferation as WTC Dust ppm in test media increased. The particle concentrations of WTC Dust assessed for each serum concentration ranged between 25 and 250 ppm. The serum concentrations used included 10% Fetal Bovine Serum (FBS) as the non-stressed level, followed by levels simulating stress environments. Exposure levels as low as 25 ppm WTC have shown increased levels of apoptosis. Experiments are in progress to determine if the components of the WTC dust specifically damage mitochondria which can be shown by reduced ATP output using the Promega Mitochondrial Tox-Glo Assay. Another marker of mitochondrial damage is the formation Reactive Oxidative Species (ROS). Promega ROS- Glo Assay will be employed to determine if the toxic, apoptotic and mutagenic effects of WTC dust can be shown as the result of oxidative stress. If WTC Dust is influencing free radical formation, then increases in ROS can be measured by hydrogen peroxide as a marker of cellular damage.

microRNA-328 suppresses scleral stem cells leading to an increase risk for myopia. *S.H. Juo[1], E. Hsi[1], C.L. Liang[2].* 1) Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Asian University, TaiChung, Taiwan.

Myopia has become a pandemic disease, however, the underlying mechanism for myopia development is poorly understood. During the development of myopia, the sclera has dynamic changes and remodeling leading to an elongation of eyeball. We previously reported that over-expression of microRNA-328 can increase a risk for myopia. Recent studies identified the existence of rodent scleral stem cells (SSCs) that highly express CD44. Since microRNA-328 can directly target CD44, we explored the relationship among microRNA-328, SSCs and myopia development in teh mouse model. Myopia is induced by the following method: the right eye was covered to induce form deprivation myopia (FDM) in a mouse of 23 days old, while the fellow eye (i.e. left eye) was not covered. The normal control mice were not treated in either eyes. Since the myopic eyes have the longer axial length (AXL), the difference of AXL of the same animal is a surrogate of myopia. SSCs were isolated from the right eyes from either experimental or control mice for the measurement of SSC number and ability of differentiation to various cell types. The correlation between stem cell abundance and myopia severity was tested. In addition, microRNA-328's effects on CD44 expression and stem cell functions were assessed. Using fluorescent staining, we showed that most SSCs reside in the ciliary body. The induction of myopia was failed in some mice, and therefore we had 3 types of eyes (myopic, normal and "fail" to be induced to myopic eyes). The SSC percentage in normal eyes, myopic eyes and the "fail" eyes was 3.02%, 1.95% and 2.39%, respectively. The difference of SSCs between myopic and normal eyes was statistically significant (p= 0.015). In addition, the correlation between the difference of AXL and stem cell abundance is -0.7 (p=0.0024) in the experimental mice, which means more SSCs less myopic. These results indicate sufficient SSCs are important to prevent myopia development. Since microRNA-328 can target CD44 mRNA, a reduction of microRNA-328 level by its anti-sense could increase the SSC proliferation rate (p<0.0001), elevate ALP expression (p=0.03) and ALP activities (p=0.0003). In addition, a decrease of microRNA-328 could substantially enhance the stem cell differentiation to osteocytes, chondrocytes and adipocytes. In conclusion, we demonstrated the relationship among microRNA-328, SSCs and myopia development, which implies a potential application of stem cell treatment in myopia.

Functional role of an intronic SNP rs2279590 in *CLU* gene and its regulators in the progression of pseudoexfoliation syndrome. *B. Padhy[1], B. Hayat[1], G.G. Nanda[1], R. Mendke[2], P. Mohanty[2], D.P. Alone[1].* 1) School of Biological Sciences, National Institute of Science Education and Research, Khurda, Odisha, India; 2) JPM Eye hospital and Research institute, Cuttack, Odisha, India.

Purpose: An intronic SNP in clusterin gene rs2279590 is a risk factor for age related disorders like Alzheimer's, Diabetes and pseudoexfoliation. Following work depicts the functional significance of rs2279590 and role of its regulators in progression of pseudoexfoliation. Methods: Anterior eye tissues of study subjects (Control, pseudoexfoliation syndrome-PEXS and pseudoexfoliation glaucoma-PEXG) were collected in accordance with declaration of Helsinki and target gene expression was checked by quantitative real-time PCR (qRT-PCR). Electromobility shift assays (EMSA) were carried out using Light Shift chemiluminescent kit. Chromatin immunoprecipitation (ChIP) assays were done by Pierce-Agarose ChIP kit and Dual-Luciferase (R) reporter assay (DLR Promega) system was used for reporter assays. Results: Clusterin mRNA was two-fold upregulated in individuals with "GG" homozygosity at rs2279590 compared to "AA". TFSEARCH revealed a putative binding element for Heat shock factors (HSFs) in the flanking region of rs2279590. EMSA confirmed a defined binding of HSFs to the flanking region of rs2279590 with wild allele "A" but not with allele "G". Binding was further confirmed by *in vivo* ChIP assays with specific antibodies for HSFs for immunoprecipitation. Luciferase reporter vector containing an insert (18bp) identical to the surrounding region of rs2279590 with allele "A" showed reduced expression compared to that of allele "G" whereas insertion of a larger fragment (200bp) surrounding rs2279590 drastically reduced reporter activities suggesting a nearby region cumulatively acting as a negative regulator. EMSA also validated the presence of another putative binding site for an unknown regulator located at a nearby 3' region of rs2279590. qRT-PCR revealed a significant upregulation of heat shock factor-1 in anterior eye tissues (lens capsule and conjunctiva) of PEXS but not in PEXG individuals whereas heat shock protein-70 a major cytosolic chaperone is found to be significantly downregulated in PEXS individuals. Conclusions: HSFs negatively regulate clusterin expression by binding to allele "A" at rs2279590. They do so together with another unknown regulator located 3' to rs2279590. "G" being a risk allele for age related neurodegenerative disorders, Alzheimer's and PEXG, support a neurotoxic role of increased Clusterin despite its chaperonic functions. Furthermore, status of HSF1 and HSP70 suggests an impaired cytosolic unfolded protein response in PEXS individuals.

Epigenetic changes in monozygotic twins discordant for nonsyndromic cleft lip and palate. *A. Vedenko[1], J.I. Young[1], S. Lang[1], J.T. Hecht[2], S.H. Blanton[1].* 1) Dr.John T. Macdonald Foundation Department of Human Genetics, John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL; 2) Department of Pediatrics, McGovern Medical School, University of Texas Health, Houston, TX.

Nonsyndromic cleft lip with or without cleft palate (NSCLP) is the most common craniofacial birth defect, with an estimated birth prevalence of 1/700 newborns. Etiologic studies have traditionally focused on genetic and environmental risk factors, but recent work has highlighted a role for epigenetic processes in mediating susceptibility to complex disorders. To investigate the contribution of epigenetic factors to NSCLP, we examined epigenetic changes in monozygotic twins discordant for NSCLP. The study of discordant monozygotic twins allows the assessment of the epigenome virtually independent of the influence of underlying genomic sequence variation. Thus, we performed whole genome bisulfite sequencing on saliva DNA from 3 monozygotic twin pairs discordant for NSCLP. Analysis of the full methylome identified significantly distinct methylation patterns within the twin pairs. We searched for intra-twin methylation differences using a candidate gene approach as well as a genome-wide unbiased manner. Following the hypothesis that genes previously associated with NSCLP are candidates for carrying metastable epialleles, we first examined our set candidate genes for evidence of differential methylation. We identified and confirmed differentially methylated sites for *GSK3B*, *TP63*, *VEGFC*, *FGF9*, *FGF14*, *PDGFC*, *PDGFRA* and *CAV3*. In addition, high stringency genome-wide analysis of the discordant methylomes revealed 436 genes containing significant methylation differences. Notably, pathway enrichment analysis of the differentially methylated genes identified cell-cell adhesion as the top biological process (GO:0098742, adjusted p-value: 0.001). Altogether, our data suggest that DNA methylation differences originating from stochastic or environmentally induced factors play a critical role in mediating phenotypic differences within MZ twins and, therefore, in the etiology of NSCLP.

2086W

Identification of regulatory element variants in craniosynostosis. *Y. Zhou[1], A.L. Fenwick[1], S.J. McGowan[2], J.R. Hughes[3], A.O.M Wilkie[1], S.R.F Twigg[1].* 1) Clinical Genetics Group; 2) Computational Biology Research Group; 3) MRC Molecular Haematology Unit, MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, UK.

Craniosynostosis, the premature fusion of the cranial sutures, is a serious disorder with a prevalence of 1 in 2,100. Monogenic causes are associated with an increased frequency of complications, often leading to long-term health problems. Despite recent successes in identifying new genetic causes, a significant proportion of patients (~60%) analysed by exome or whole genome sequencing remain undiagnosed. One potential explanation is that some causative variants lie in non-coding DNA, in regions not routinely analysed in NGS data. As an initial step towards identifying such mutations, we carried out genome-wide chromatin analysis of human fetal (12-14 weeks post conception) cranial sutures and suture-derived cells (human & mouse), using histone H3 K27ac and K4me1 marks to map active regulatory elements (REs). In addition, ATAC-seq and Capture C were performed on suture-derived cells, probing open chromatin regions and revealing looping interactions between selected promoters and putative enhancers. As the search space is large, we have initially focused on genes for which haploinsufficiency leads to craniosynostosis, as RE mutations in such genes could lead to pathological under-expression. Saethre-Chotzen syndrome, for example, is caused by heterozygous loss-of-function mutations of *TWIST1*, which encodes a bHLH transcription factor. The intersection with targeted resequencing data from the *TWIST1* locus of 152 patients with craniosynostosis has pinpointed several candidate RE variants. These include 1) a cluster of single nucleotide variants from 6 patients within a 500 bp region that intersects with a putative RE (human & mouse) ~5 kb from the *TWIST1* transcription start site (TSS) and 2) a ~2.9 kb deletion in a patient with craniosynostosis, mediated by non-allelic homologous recombination between *AluY* elements, enriched for H3K27ac/K4me1 (human & mouse) ~14 kb from the *TWIST1* TSS. In summary these chromatin data illustrate the feasibility of identifying putative REs from early-stage embryonic tissues and primary cells, and suggest that several key REs are conserved between humans and mice, enabling further functional testing of their developmental role. Intersection with resequencing data from craniosynostosis patients highlights possible causative non-coding variants around *TWIST1*. This combined approach will lead to a better understanding of craniosynostosis, improve molecular diagnosis and increase understanding of cranial suture development.

2087T

The emerging landscape of dynamic DNA methylation in early childhood. *C.J. Xu[1,2], M.J. Bonder[2], C. Söderhäll[3,4], M. Bustamante[5,6,7,8], N. Baïz[9], U. Gehring[10], S.A.    DNA methylation is known to influence many aspects of life, but it is unknown how genome, environment and disease influence DNA methylation dynamics in childhood. By analysing 538 paired DNA blood samples from children at birth and at 4-5 years old and 726 paired samples from children at 4 and 8 years old from four European birth cohorts using the Illumina Infinium Human Methylation 450k chip, we have identified 14,150 consistent age-differential methylation sites (a-DMSs) at epigenome-wide significance. Genes with an increase in age-differential methylation were enriched in pathways related to 'development', while genes with a decrease were enriched in 'regulation'. Changes in 101 a-DMSs (0.71%) were partly regulated by single nucleotide polymorphisms with more prominent genetic effects seen in later childhood. Maternal smoking was associated with more strongly decreased methylation levels in early life. a-DMS-associated genes were significantly more likely to be linked with disease. Our study provides new insights into the dynamic epigenetic landscape of the first 8 years of life.

2088F

Dissecting the epigenetic and transcriptional landscapes in spermatogonial stem cells ageing. *T. Lee, J. Liao, S. Ng, W. Chan.* School of Biomedical Sciences, The Chinese University of Hong Kong, Shatin, NT, Hong Kong.

   Spermatogenesis maintains male fertility through a highly complicated process, consisting of spermatogonial proliferation, meiosis of spermatocytes and spermiogenesis of haploid spermatids. This process is sustained by a pool of rare male germline stem cells known as spermatogonial stem cells (SSCs) that either self-renew or differentiate to progenitor spermatogonia to initiate spermatogenesis. Similar to other developmental programs, this process is tightly coordinated through epigenetic and transcriptional programs and any failure in this process could have catastrophic effects on male reproductive biology and cause significant health impacts in the offspring. One of the ageing-associated characteristics in the male reproductive system is the dramatic decline in stem cell content. However, the molecular regulations underlying the function deterioration of aged SSCs remain largely elusive. In this study, we used highly purified SSCs from young and aged mice along with an integrated genomic approach to evaluate ageing-associated alterations in the transcriptome and epigenome. We first examined the transcriptional landscapes of SSCs and delineated the molecular mechanisms underlying SSC ageing, which are characterized by the dynamic interplay between cell-intrinsic and environmental signals. We also constructed an in-depth map of epigenetic regulation of SSCs including DNA methylation (5mC), DNA hydroxymethylation (5hmC) and histone modifications (H3K4me3/H3K27me3). Our analysis demonstrated that alterations in both DNA methylation and histone modifications influence changes in gene expression and represents one of the driving forces behind ageing-related declined in the functionality of SSCs. Taken together, the findings of this study have uncovered comprehensive information of the transcriptional and epigenetic regulation in SSC ageing, which will provide the foundation for novel therapeutic options against spermatogenic failure and reproductive ageing.

2089W

Difference in plasma circulating cell-free microRNAs between young and aged mice: Effects of miRNAs that are predominantly present in young mouse serum on myogenic differentiation in C2C12 cells and primary myoblasts. *M. Fukuoka[1], N. Ito[2], S. Takeda[2], H. Hohjoh[1].* 1) Department of Molecular Pharmacology, National Institute of Nuroscience, National Center of Neurology and Phychiatry, Kodaira, Tokyo, Japan; 2) Department of Molecular Therapy, National Institute of Nuroscience, National Center of Neurology and Phychiatry, Kodaira, Tokyo, Japan.

MicroRNAs (miRNAs) that are 21~23-nucleotide-long small non-coding RNAs function as mediators in gene silencing, and play essential roles in gene regulation by inhibiting translation of messenger RNAs (mRNAs) and by digestion of mRNAs. Recently miRNAs have been found in various body fluids including plasma/serum as well as inside cells, and a part of such miRNAs appear to be enclosed in extracellular vesicles such as exosomes and be associated with RNA-binding proteins, e.g., Argonaute2. Such cell-free (extracellular) miRNAs might be implicated in cell-cell communication and be capable of becoming useful biomarkers. Aging is characterized by a progressive loss of physiological integrity, in which functional declines in physiology such as a decrease in hearing, visual acuity, muscle strength and memory skills occur. To see such aging at a molecular level, we investigated plasma-circulating (cell-free) miRNAs prepared from young (6-week-old) and aged (2-year-old) C57BL6/J mice by expression profile analyses in this study. The results indicated that the level of myogenic miRNAs, which are involved in myogenic differentiation, was higher in the plasma of young mice than in that of aged mice. In addition, young mouse serum, but not aged serum, appeared to have the potential for inducing myogenic differentiation of mouse C2C12 cells (a myoblast cell line). We further investigated the effects of the miRNAs increased in young mouse serum on myogenic differentiation using C2C12 cells: miRNAs of interest were introduced into C2C12 cells and the expression of the *Myogenin* and *Myh1* genes that were used as indicators for myogenic differentiation was examined. As a result, a certain miRNA appeared to have a strong induction for myogenic differentiation relative to other examined miRNAs, and might be associated with the increase in the level of miR-1, which plays a role in gene regulation during myogenic differentiation. In addition to the above experiments, we introduced synthetic mimics of that miRNA into mouse primary myoblasts and confirmed their induction to myogenic differentiation. Our findings indicated that miRNAs played an important role in gene regulation during myogenic differentiation, and suggested the possibility that decrease in certain miRNAs in aged mouse plasma might be associated with inefficient muscle regeneration in aged mice. Our further studies are in progress, and we would like to discuss this topic together with additional data in the meeting.

2090T

Early-life socio-economic status is associated with accelerated epigenetic ageing in monocytes. *E. Gatev[1], N. Gladish[1], J. MacIsaac[1], L. McEwen[1], M. Jones[1], G. Miller[2], S. Mostafavi[1], M. Kobor[1].* 1) UBC, Vancouver, British Columbia, Canada; 2) Northwestern University, USA.

Socio-Economic Status (SES) during Early Life (EL) has been associated with susceptibility to chronic diseases in adulthood. With their first years in difficult socio-economic conditions, children have increased vulnerability to infectious, cardiovascular, respiratory and cancer diseases in adulthood. Low SES increases the likelihood of chronic psychological stress from living in unfavourable conditions. There is evidence that chronic stress contributes to the development and progression of pathologies. The plasticity of dynamic DNAm suggests a mechanism where persistent environmental factors, like chronic stress, cause chromatin modifications that affect developmental programming, and remain detectable in adult life. In this way, variability of environmental exposures across individuals is reflected in age-related DNAm trajectories. "Epigenetic age" constructs measure deviations from the average age-related DNA methylation trajectory in a population, and quantify inter-individual variability of age-related DNAm. We develop a novel bioinformatic approach to construct a monocyte-specific (MS) epigenetic clock that incorporates prior knowledge about DNAm sites associated with age. We use this MS epigenetic clock to asses epigenetic age acceleration. Our MS epigenetic clock has greatly improved accuracy over the pan-tissue clock of Horvath, while using much fewer MS DNAm sites. It includes novel MS DNAm sites that are associated with multiple genes involved in cell differentiation, growth and transcription factor binding.

2091F

The effect of age on sex-specific DNA methylation patterns in a Bangladeshi population. *R.J. Jansen[1], L. Tong[2], M. Argos[3], F. Jasmine[2], M.G. Kibriya[2], J.A. Baron[4], H. Ashan[2], B.L. Pierce[2].* 1) North Dakota State University, Fargo, ND; 2) University of Chicago, Chicago, IL; 3) University of Illinois, Chicago, IL; 4) University of North Carolina, Chapel Hill, NC.

It is well-known that epigenetic changes occur as human age, and there is a growing interest in characterizing age-related changes in DNA methylation. In this study, we set out to characterize the effect of age on DNA methylation in a sex-specific manner and determine if these effects vary by genomic context. We used the Illumina HumanMethylation 450K Beadchip and DNA derived from whole blood for 400 adult participants (189 males and 211 females) from Bangladesh to identify age-associated CpG sites and regions, and characterize to what extent these age-associated sites were located in CpG islands (vs. shore, shelf, or open sea), and gene regions (vs. intergenic). We conducted a genome-wide search for age-associated CpG sites (among 423,604 sites) in two ways: 1) using a reference-based adjustment for cell type proportion (the R package: MethylSpectrum) and 2) using a reference-free approach for cell type proportion adjustment (the R package RefFreeEWAS). Using method 1 there was a noticeable shift of the model estimates toward hypermethylation which was not present using method 2; potentially representing the effects of unmeasured confounding variables. As is consistent with previous reports, CpG sites that were differentially methylated with respect to age were more likely to be hypermethylated compared to hypomethylated, and to be found in CpG Islands and promotor gene regions compared with other locations. For men and women respectively, significant associations with age (p-values < 10^{-8}) for individual CpG sites were 568 and 1819, of these 272 (47.9%) and 707 (38.9%) CpGs were found in island regions while 185 (32.6%) and 631 (34.7%) were found in promotor gene regions. Although we observed good correlation with previously developed methylation age models (r≈0.8), among the top 100 CpG sites only 2 for males and 5 for females are included in these prediction models. Our results indicate that age-associated methylation tends to be consistent for both sexes (correlation among top 100: 0.98, and 0.99 males and females, respectively). Our population may have unique age-related methylation changes that are not included in the established methylation age prediction models.

2092W

DNA methylation in the apolipoprotein E locus in late life. *I.K. Karlsson[1], A. Ploner[1], P. Garagnani[3,4], C. Franceschi[3,4], T. Morris[5], S. Hägg[1], N.L. Pedersen[1,2].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Department of Psychology, University of Southern California, Los Angeles, California, USA; 3) Department of Experimental, Diagnostic and Specialty Medicine, University of Bologna, 40126 Bologna, Italy; 4) Interdepartmental Center "L. Galvani", University of Bologna, 40126 Bologna, Italy; 5) Medical Genomics Group, UCL Cancer Institute, University College London, London, UK.

The Apolipoprotein E (*APOE*) gene has been shown to be of importance in both dementia and cardiovascular disease (CVD), as well as longevity. Recent evidence suggests a role for epigenetics in several diseases, including dementia and CVD, and epigenetic mechanisms may mediate gene-environment interactions that promote disease. This project aims to investigate if variation in DNA methylation of the *APOE* gene differs in relation to dementia, CVD, and healthy aging. For this purpose, DNA methylation levels were measured using the Illumina 450K array in 426 Swedish twins (mean age 78.4), as well as in 82 healthy Italian centenarians (mean age 105.5), 63 offspring to healthy centenarians (mean age 71.6), and 47 controls who were offspring to non-long lived parents (mean age 69.8). DNA methylation levels in the *APOE* gene have previously been categorized in three groups: a hypermethylated region in the promotor, a hypomethylated region in the first two introns and exons, and a hypermethylated region in the 3´exon. The mean M-values across these three groups were used in linear regression models to compare differences in methylation between dementia cases and controls, CVD cases and controls, centenarians, their offspring, and offspring controls. We found a higher level of DNA methylation in the *APOE* promotor in dementia cases compared to controls after adjusting for sex and age at blood sample (β 0.07, 95% CI 0.02-0.12). Healthy centenarians were found to have a significantly lower level of DNA methylation in the same region, and also in the 3´exon when compared to offspring controls after adjusting for sex (β -0.04, 95% CI -0.05 to -0.02 and β -0.02, 95% CI -0.03 to -0.01, respectively). We did not detect any difference in methylation levels between CVD cases and controls, or between offspring to centenarians and controls. In conclusion, we found that DNA methylation levels in the promotor region of the *APOE* gene were higher in dementia compared to controls, and lower in centenarians compared to controls. No difference was found in methylation of the *APOE* gene in relation to CVD or in offspring to centenarians. This may shed more light on the strong but largely unexplained association between *APOE* and dementia.

2093T

A longitudinal study of stochastic epigenetic mutations and aging. *Y. Wang[1], R. Karlsson[1], J. Jylhävä[1], T. Morris[2], P. Garagnani[3,4], A.K. Hedman[5], N.L. Pedersen[1], S. Hägg[1].* 1) Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Medical Genomics Group, UCL Cancer Institute, University College London, London, UK; 3) Department of Experimental, Diagnostic and Specialty Medicine Experimental Pathology, University of Bologna, Bologna, Italy; 4) Center for Applied Biomedical Research, St. Orsola-Malpighi University Hospital, Bologna, Italy; 5) Department of Medical Sciences & SciLife Lab, Uppsala University, Uppsala, Sweden.

   DNA methylation plays an important role in gene regulation together with other epigenetic markers. Aberrant DNA methylation patterns can result in genomic instability, be involved in pathogenesis of age-related diseases and be associated with human aging. In a cross-sectional study, Gentilini et al. 2015 found that the number of stochastic epigenetic mutations (SEMs) increased exponentially with chronological age, defining SEMs as extreme outliers in a population with methylation levels three times interquartile below the first quartile ($<Q1-3 \times IQR$) or above the third quartile ($>Q3+3 \times IQR$). Here we replicated those results and furthermore investigated if SEMs could persist and accumulate over the aging process in a longitudinal perspective. We characterized DNA methylation patterns in whole blood using HumanMethylation450 BeadChip array. Samples (n=1011) were collected from 385 old Swedish twins up to five times over 20 years (age from 48 to 94 at the baseline). A longitudinal analysis using a mixed-effects model showed that the number of SEMs grows exponentially with age ($p=1.26 \times 10^{-11}$). However, technical variance (detection p-value), batch effect and cellular composition were found to be strong confounders even though they had been adjusted for in prior preprocessing steps. In single site analysis, we identified some SEMs arising from a normal methylation level at one time point and maintained as mutations in later time points. Moreover, we observed that 3443 CpG sites have a much higher chance of mutation than other sites ($p=2.2 \times 10^{-16}$). These CpG sites are more prone to epigenetic mutations and they are different from previously identified age-associated CpG sites. In summary, we verified that the number of SEMs increase exponentially with age from longitudinal observations, indicating that acquired SEMs can be persistent and accumulate in the aging process.

2094F

Longitudinal study of gene expression in a Swedish population sample. *B. Balliu[1], K.S. Smith[1], C. Lindgren[2], A. Morris[3], L. Lind[4], E. Ingelsson[4,5], S. Montgomery[1,6].* 1) Department of Pathology, Stanford University School of Medicine, Stanford, CA; 2) Wellcome Trust Centre for Human Genetics; 3) Institute of Translational Medicine, University of Liverpool; 4) Department of Medical Sciences, Uppsala University; 5) Department of Medicine, Stanford University School of Medicine, Stanford, CA; 6) Department of Genetics, Stanford University School of Medicine, Stanford, CA.

   While DNA sequence is more or less stable throughout life, gene regulation and expression is dynamic, fluctuating in response to different environmental exposures. Increased knowledge about how genes are regulated and expressed, and how this changes over time in relation to environmental triggers and disease outcomes can give important insights to fundamental questions about gene function. Using a unique study sample with repeated sampling, we performed whole-genome RNA sequencing analysis in white blood cells at two time points with ten years apart. The PIVUS study was initiated in 2001-2004, where 1,016 70-year-old individuals from the general population participated in an extensive examination of their health, including biological samples and subsequent genome-wide SNP genotyping. Participants were re-examined at age 75 and 80. We sequenced the blood transcriptomes of 62 PIVUS participants at both age 70 and 80 (104 samples) and observed that gene expression is strongly correlated (mean=.97) between the two time points, and that for the majority of samples (~66%), measurements in the same individual at the two different ages cluster together. The remaining of the samples clustered with samples from the same age group. This illustrates that although most individuals demonstrate an expression pattern that is relatively similar to themselves over 10 years of aging, there is also a large proportion who are more similar to peers from their age group than themselves 10 years earlier or later. The latter is likely to reflect the aging process, changes in environment, subclinical traits or disease outcomes. Moreover, we identified 2,699 genes showing differential expression between the two time points (1% FDR), and a strong enrichment (.01%FDR) for age related GO terms (immune and stress response), KEGG pathways (MAPK signaling and metabolic pathways), and disease-associated genes (inflammation, vascular disease). We further discovered 403 and 303 eGenes, *i.e.* genes with a cis-eQTL (1% FDR), at the first and second time point, respectively. cis-eQTLs detected at both time points were largely shared ($\pi 1= 73$ %) indicating that genetic regulation of gene expression is mostly stable over time. In summary, we have performed one of the first long-term longitudinal studies of genetics of gene expression that highlights transcriptome dynamics late in life.

2095W

DNA methylation and aging in mice and humans. *K. Mozhui[1,2], A.K. Pandey[2].* 1) Preventive Medicine, University of Tennessee Health Science Center, Memphis, TN; 2) Department of Genetics, Genomics and Informatics, University of Tennessee Health Science Center, Memphis, TN.

Aging has a profound influence on the epigenetic structure of the DNA. In humans, methylation patterns at specific CpG sites have been used to define the 'epigenetic clock', a molecular biomarker of age that could provide a means to discern the health and fitness of an individual. The mechanisms that establish these intriguing patterns in the methylome remain largely elusive. It is also unclear whether CpG markers for age identified in humans (that rely mostly on microarrays) can be generalized to experimental models such as the mouse. Here we use an affinity-based capture of DNA using methyl-binding domain (MBD) protein and high-throughput DNA sequencing (MBD-seq) for a genome-wide assay of DNA methylation in aging mouse liver. Consistent with previous reports, we find that the most pronounced effect of age is an increase in methylation at CpG sites encompassing the transcription start site (TSS) of genes (e.g., *C1ql3*, *Srd5a2*, and *Rfx4*). In contrast to the hypermethylation at specific CpG islands, there is age-dependent hypomethylation at most other regions. The differentially methylated regions (DMRs) identified in mice have high sequence conservation in humans and the age-dependent patterns are consistent between the two species, and detected in more than one human tissue (blood and liver). In humans, these conserved age-hypermethylated regions are binding sites for members of the polycomb repressor complex (PRC), including EZH2. A targeted chromatin immunoprecipitation assay confirms that these DMRs are associated with EZH2 in mice, and there may also be age-dependent reduction in EZH2 occupancy. This adds to growing body of evidence that EZH2 and other members of PRC are part of the protein machinery that establish and shape the aging epigenome. Given the level of conservation and consistency, the mouse model can serve as a powerful experimental basis to study the nature and molecular modifiers of the epigenetic clock.

2096T

DNA methylation in aging twins across 10 years: Heritable and environmental contributions. *C.A. Reynolds[1], E. Munoz Diaz[1], Y. Wang[2], T. Morris[3], N.L. Pedersen[2,4], S. Hägg[2].* 1) Department of Psychology, University of California, Riverside, Riverside, CA, USA; 2) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 3) Medical Genomics Group, UCL Cancer Institute, University College London, London, UK; 4) Department of Psychology, University of Southern California, Los Angeles, CA, USA.

DNA methylation may result from environmental exposures as well as be influenced by genetic factors, with dynamics in methylation associated with increasing age in adulthood. Age-related change in DNA methylation in adulthood has been examined largely using cross-sectional data, with few investigations of genetic and environmental influences that may contribute to stability and change in late life. Methylation profiles (Illumina HumanMethylation450 array) were evaluated in 53 pairs of twins from the Swedish Adoption Twin Study of Aging (SATSA). The pairs selected for analysis included 21 MZ and 32 DZ pairs with an average of 10 years between two in-person assessments. At the first assessment the average age was 62.9 years (range 50.7 - 77.9 years) and 72.5 years at the second (range 59.9 – 86.8). Pre-processing of data included QC adjustments at the sample and probe level, and normalizations and adjustments for confounders (cell counts, batch effects), resulting in an analysis set of 329,341 probes. Biometrical model fitting was conducted on M-values adjusted for age and sex. ACE and ADE models were evaluated for each CpG site, where A represents additive genetic contributions, D non-additive genetic contributions, C common environmental contributions, and E nonshared or stochastic environmental contributions to variation in M-values. E was the sole contributor to variation in methylation across 77.1% of sites at age 62.9, and to 80.5% of sites 10 years later. C contributed to variation on 7.1% and 7.0% of sites, respectively at each age, where common environmentality was .28 on average. At age 62.9 years, 15.8% of sites evidenced some genetic variance (A and/or D), and broad heritabilities were .46 on average; 10 years later, 12.4% evidenced genetic variance with broad heritabilities of .45 on average. Genetic influences were statistically signficant (p < 1.00E-07) for 1.8% sites at age 62.9 and 1.4% sites 10 years later. Persistence of significant genetic influences across the two ages was observed for 0.50% of CpG sites, whereas 0.56% were significant at one age but not another. Overall, results suggest small genetic contributions to variation in DNA methylation in late adulthood. New influences emerge over time, primarily in terms of stochastic environmental contributions and for a subset of CpG sites, novel genetic influences may contribute to variation.

2097F

Transcriptional heterogeneity in the lactase gene within cell-type is linked to the epigenome. *R. Jeremian[1], E. Oh[1], G. Oh[1], D. Groot[1], A. Petronis[1], V. Labrie[2].* 1) Krembil Family Epigenetics Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Center for Neurodegenerative Science, Van Andel Research Institute, Grand Rapids, MI, USA.

Transcriptional variation in histologically- and genetically-identical cells is a widespread phenomenon in tissues, yet the processes conferring this heterogeneity are not well understood. To identify contributing factors, we analyzed epigenetic profiles associated with the *in vivo* transcriptional gradient of the mouse lactase gene (*Lct*), which occurs in specialized epithelial cells (enterocytes) along the proximal-to-distal axis of the small intestine. We found that epigenetic signatures at enhancer and promoter elements align with transcriptional variation of *Lct*. Age- and phenotype-specific environmental cues (lactose exposure after weaning) induced changes to epigenetic modification density and CTCF binding at select regulatory elements, which corresponded to alterations in the intestinal *Lct* mRNA gradient. Thus, epigenetic modifications in combination with CTCF binding at regulatory elements account for the transcriptional gradient in *Lct* in cells of the same type, and this epigenetic divergence within enterocytes may contribute to the functional specialization of intestinal subregions. Our findings emphasize the importance for future studies examining epigenetic contributions to the transcriptional variances in multiple genes within a cell type, as these could help explain why tissue subregions can perform diverse biological functions and vary widely in disease susceptibility and treatment. In addition, our findings provide an important lesson for epigenetic studies of phenotypes, as failure to consider within cell-type transcriptional variation and epigenetic divergence limits the detection of biologically significant effects. Future epigenetic and gene regulation studies in health and disease will be greatly refined by not only isolating the cell type of interest, but by sampling a single cell type across tissue subregions, and across aging and environmental parameters. .

2098W

3' UTR fragments accumulate in aging neuronal subtypes of mice and humans. *P.H. Sudmant[1], M. Heiman[2], C.B. Burge[1].* 1) Biology, Massachusetts Institute of Technology, Cambridge, MA; 2) Picower Institute for Learning and Memory Massachusetts Institute of Technology, Cambridge, MA.

Molecular differences among cell types and tissues can result in varied responses to genetic or environmental insults such as those incurred during aging. To assess how the transcriptome of closely related neuronal subtypes diverges during development and aging we performed translating ribosome affinity purification (TRAP) and sequencing of mRNA from D1 and D2 medium spiny neurons (MSNs) of the mouse striatum across various time-points. Surprisingly, aged (2yrs) D1 MSNs diverged substantially in their expression patterns from aged D2 MSNs specifically in translation initiation factors and components of oxidative phosphorylation. These gene expression patterns were accompanied by the pronounced accumulation of ~2000 RNA fragment species consisting of the 3' UTRs of genes without their cognate CDS and 5' UTR sequences. We find that these 3'UTR fragment species also accumulate in aging human brains to varying degrees among different neuronal tissues and provide evidence that 3' UTR fragments can be induced by oxidative stress. These results shed light on a putative novel RNA species that may impact the aging nervous system.

The role of the ENCODE Data Coordination Center. *J.M. Davidson[1], E.T Chan[1], I. Gabdank[1], J.A. Hilton[1], A.K. Narayana[1], K.C. Onate[1], M.O. Ho[1], B.T. Lee[2], L.D. Rowe[1], N.R. Podduturi[1], D.I. Glick[1], U.K. Baymuradov[1], V.S. Malladi[2], S.R. Miyasato[1], T.R. Dreszer[1], J.S. Strattan[1], F.Y. Tanaka[1], B.C. Hitz[1], C.A. Sloan[1], E.L. Hong[1], J.M. Cherry[1], ENCODE CONSORTIUM.* 1) Department of Genetics, School of Medicine, Stanford University, Stanford, CA 94305; 2) Center for Biomolecular Science and Engineering, School of Engineering, University of California Santa Cruz, Santa Cruz, CA 95064.

In recent years there has been an influx in the quantity of publicly available, large genomic datasets from individual labs and large consortia. Here we describe the efforts of the Data Coordination Center (DCC) in improving the accessibility of data available for the Encyclopedia of DNA Elements (EN-CODE) project. ENCODE is a collaborative effort to generate a comprehensive catalog of functional elements in human and mouse genomes. The ENCODE database currently includes more than 40 experimental techniques in over 400 tissue types and cell lines to analyze DNA and RNA-binding proteins, transcription and chromatin structure. All experimental data and computational analyses of these data are submitted to the DCC for validation, tracking, storage, and distribution to the scientific community. To ensure that the data generated by the production labs and the analysis performed on these data are accurately represented, the ENCODE DCC works closely with members of the Consortium groups to capture structured metadata related to experimental conditions, data quality metrics, and analysis methods. These experiments can be accessed via the ENCODE portal (http://www.encodeproject.org). Portal users query the database by searching for specific metadata terms, such as "p53", or "K562" or by utilizing faceted searching of the structured metadata. The portal also supports the visualization of certain data files by launching a Genome Browser track hub. Data files can be downloaded either directly from the experiment pages at the portal or via bulk download by programmatically accessing the ENCODE REST API. By providing direct data downloads based on flexible and powerful search capabilities that rely on highly organized metadata, the DCC strives to expand the access of ENCODE data to the scientific community.

2100F

The contribution of epigenetics to the phenotypic variation in a set of monozygotic twins with Gaucher disease. *N. Tayebi[1], S. Hassan[1], F. Donovan[2], S. Chandrasekharappa[2], M. Biegstraaten[3], C. Hollak[3], E. Sidransky[1].* 1) Section on Molecular Neurogenetics, Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Cancer Genetics and Comparative Genomics Branch/Genomics Core, NHGRI/NIH, Bethesda, MD; 3) Academic Medical Center, Amsterdam, The Netherlands.

Background: Gaucher disease (GD) is an inherited autosomal recessive disorder characterized by mutations in *GBA1*, encoding the lysosomal enzyme glucocerebrosidase. The defective enzyme leads to lysosomal accumulation of glucocerebroside, characteristically in macrophages. Phenotypic heterogeneity among patients with the same genotype, even between sib pairs and identical twins, has prompted the search for genetic modifiers or epigenetic modification. Studying the contribution of epigenetic marks, such as DNA methylation, MicroRNAs and histone modifications, has been challenging due to the large variance between genomes. One approach to investigating epigenetic variation has been to evaluate samples from twins. In 2011 we described twin sisters, confirmed to be monozygotic by DNA fingerprinting, who both had GD, but with divergent phenotypes. Mutational analysis revealed that they were homozygous for the *GBA1* mutation N188S, c.670C>T. On examination, one sister exhibited severe visceral involvement, epilepsy, and cerebellar atrophy, while the other had no signs or symptoms related to GD.   **Method**: To detemine the cause of this discrepancy, we performed epigenetic evaluation of gene inactivation by looking at methylation of CpG islands from the genomic DNA of each twin. The bisulfite-based DNA modification was used to discriminate between cytosine and methylated cytosine in genomic DNA extracted from peripheral blood. Treated DNAs were applied to an Illumina HumanMethylation450 BeadChip. Data were analyzed using GenomeStudio and GeneMANIA for network analysis. **Results:** In the more affected twin, five methylated, and three demethylated genes were identified at CpG islands (P-value= 0.01-0.001) as well as two methylated genes from enhancer regions (P-value 0.05-0.01). The significant methylated genes, which included *CACNA1A*, were validated using bisulfite-treated DNA and Sanger sequencing. RNA expression of the selected genes is being evaluated by real-time PCR, using RNA extracted from at least two different tissues from each twin. **Conclusions:** This study enhances our understanding of the complex genotype-phenotype relationship in GD, and identifies a possible cause of phenotypic variation. Additionally, the data suggest an effect of epigenetic events on disease manifestations, which may contribute to phenotypic variation in monogenic and multifactorial diseases.

Gestational age acceleration in neonates predicts NICU course. *A. Knight[1], A.K. Smith[1], K.N. Conneely[1], P. Dalach[2], Y.L. Loke[2], J. Cheong[2,3,4], J.M. Craig[2,4], L.W. Doyle[2,3,4], C. Theda[2,3,4].* 1) Emory University, Atlanta, GA; 2) Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 3) Royal Women's Hospital, Parkville, Victoria, Australia; 4) University of Melbourne, Parkville, Victoria, Australia.

DNA methylation changes with age, and can be used to accurately predict chronological age in adults. We have recently developed a methylation-based predictor of gestational age (DNAm GA) for neonates using cord blood or blood spot samples at birth that is highly correlated to clinically-estimated gestational age (GA) based on ultrasound (r=.91; p<2.2E-16) and is accurate within 1.24 weeks in >1,200 samples. DNAm GA increased steadily in longitudinal samples taken from birth to term equivalency in two preterm neonates admitted to the neonatal intensive care unit (NICU). We hypothesized that GA acceleration, which is the residual between clinically estimated GA and DNAm GA, would predict neonates requiring the most intensive interventions in the NICU. The Victorian Infant Collaborative Study (VICS, Victoria, Australia) provides a unique resource to address this hypothesis as preterm infants born before 37 weeks gestation in 1991/1992 were prospectively enrolled in a longitudinal follow-up study. DNA was extracted from dried blood spots used for newborn screening of 183 participants (26.7±2.1 weeks) and was processed on the Human Methylation450 BeadChip. DNA methylation data was used to estimate DNAm GA. Data regarding common NICU interventions (surfactant administration, postnatal steroids, oxygen supplementation) and complications (bronchopulmonary dysplasia) were retrieved from the VICS database. Linear regression models that controlled for cellular heterogeneity and GA were used to evaluate the association of GA acceleration and each NICU outcome. Decreased GA acceleration (lower DNAm GA relative to GA) associates with increased administration of postnatal steroids (31.1% given steroids; p=.002) and surfactant (43.7% given surfactant; p=.02). Similarly, GA acceleration was lower in neonates that required more days on oxygen supplementation (p=.002). Finally, lower GA acceleration associated with the development of bronchopulmonary dysplasia, a chronic lung disorder affecting 36.0% of these neonates (p=.01). This suggests that GA acceleration may be indicative of developmental maturity at birth. Further studies should evaluate DNAm GA and GA acceleration to determine how these measures could contribute to more accurate and individualized predictions of NICU course and short and long-term outcomes.

2102T

Integrated metadata-driven access of ENCODE, modENCODE, REMC, GGR and modERN data through a common portal. *E.T. Chan, J.M. Davidson, I. Gabdank, J.A. Hilton, J.S. Strattan, A.K. Narayanan, M.C. Ho, K.C. Onate, U.K. Baymuradov, T.R. Dreszer, D. Glick, F.Y. Tanaka, B.C. Hitz, C.A. Sloan, J.M. Cherry.* Genetics, Stanford University, Palo Alto, CA.

The efforts of large-scale NIH-funded projects such as the Encyclopedia of DNA Elements (ENCODE), its model organism corollary (modENCODE), and the Roadmap Epigenomics Mapping Consortium (REMC) have resulted in the accumulation of genome-wide maps of candidate functional sequence elements and epigenetic marks in a large variety of cells and tissues in human and other model organisms. Consideration of the provenance of experimental reagents and transparency of computational analyses is crucial to the interpretation and comparison of these data. Tracking this information consistently across different biochemical assays employed in thousands of experiments across hundreds of cell and tissue types is particularly challenging at the scale of these projects.The ENCODE Data Coordination Center (DCC) has developed a flexible and rich data model to capture information such as key experimental variables, details of experimental and analysis methods, what software and pipelines were used to produce which files for the ENCODE project, and calculated quality metrics, known collectively as metadata. This data model has since been extended to additionally integrate curated data and metadata from related projects such as REMC, modENCODE, Model organism Encyclopedia of Regulatory Networks (modERN) and the Genomics of Gene Regulation (GGR). The resulting publicly accessible data corpus encompasses over 10,000 experiments and is accessible through the ENCODE portal (https://www.encodeproject.org), which features a powerful faceted browsing interface, full-text search, and a REST API so users can easily search, filter, download and visualize the collection. Data integration and release is ongoing and continual. Learn more about how to get started on the ENCODE portal here: https://www.encodeproject.org/help/getting-started/.

2103F

The validation of array determined, differentially methylated CpG sites using targeted next-generation bisulfite sequencing. *L. Yan, R. Drennan, A. Meyer, A. Miller, E.A. Mead, S. Miller, J. Xu, M. Poulin.* EpigenDx, Hopkinton, MA.

The identification of differentially methylated regions of the genome is the focus of many epigenetic studies. The Infinium HumanMethylation450 Bead-Chip (or EPIC Array) allows researchers to interrogate more than 485,000 methylation sites (or 850,000 CpG sites) per sample. This technology is useful as an initial screening process to isolate potentially differentially methylated regions in many disease states or following specific drug treatments in epigenome-wide association studies (EWAS). The need to validate hundreds of potential CpG sites has become a challenge for many researchers. We have developed a validation system based on targeted next-generation sequencing (tNGS) that allows the validation of large numbers of array determined CpG sites at single-nucleotide resolution within a single validation panel. Panels are developed using a stepwise strategy that begins with bioinformatically validating the CpG loci and obtaining the target CpG sequence and 500 nucleotides up and downstream of the CpG. Utilizing the RepeatMask program of the UCSC genome browser, those CpGs within repeat sequence of the genome are discarded. The sequences are then *in silico* bisulfite converted and bisulfite sequencing assays are designed for each CpG site. Assays are multiplexed based on the assay design score and primer annealing temperature. Multiplex PCR reactions are performed and analyzed for amplification and PCR bias following next-generation sequencing. In this study we began with 280 possible CpG sites in which 164 (greater than 50% of assays) successful in silico designs were generated. 18 multiplex PCR reactions were carried out on a methylation mixing series of DNA. 96 of the 164 assays resulted in next-generation sequencing reads which will be analyzed for PCR Bias. Although it may seem that validation of only approximately 60% of the initial assay is low return, it allows researchers to begin formulating further experiments and hypotheses while different combinations of the other 40% of the assays are recombined in multiplex PCRs or in simplex PCR reactions to increase the percentage of successfully validated assays. .

2104W

DNA methylation analysis of Sox2 regulatory regions during osteogenic differentiation of mouse embryonic stem cell. *S. Batool.* Biosciences, COMSATS Institute of Information Technology, Islamabad, Punjab, Pakistan.

Embryonic stem cells (ES) have been shown to be able to differentiate into all lineages derived from embryos *in vitro* and hence can be used as a model system not only to study developmental programming and reprogramming events but also, once these events are known can be used to create differentiated cell types for transplantation therapies in clinical applications. Sox2 has been reported to be indispensable for mouse embryonic stem cells self-renewal and also, is one of the transcription factors used to reprogram somatic cells. This study was undertaken to study the role of DNA methylation in regulation of Sox2 during differentiation of mouse embryonic stem cells. Mouse embryonic stem cells were differentiated to osteogenic lineage through the formation of embryo bodies (EBs) – cellular aggregates partially recapitulating the early embryonic development. ES were found to be differentiating as evidenced by changes in cellular morphologies, alizarin red staining and upregulation of lineage-specific markers. Gene expression and immunocytochemistry analysis showed downregulation of Sox2 during osteogenic differentiation. SRR1 and SRR2, two conserved regulatory region of Sox2, were found to be methylated by methylation-sensitive PCR at all time-points chosen for analysis in differentiating cells. Three individual CpGs in SRR2 region were then further analysed by bisulphite sequencing which appeared unmethylated in both undifferentiated and differentiated embryonic stem cells. This data shows the involvement of DNA methylation in regulating the expression of Sox2 in differentiating embryonic stem cells and so need further exploration. The preliminary results described here show that ES cell differentiation is a good experimental system to profile expression of Sox2 and investigate the modulation of epigenetic changes at its regulatory regions as cells differentiate.

2105T

Methylome analysis in non-syndromic cleft lip/palate shows methylation differences both in Brazilian and British cohorts. *L. Alvizi[1], S.A.M. Ezquina[1], P. Stanier[2], M.R. Passos-Bueno[1].* 1) Genetics and Evolutionary Biology, University of São Paulo, São Paulo, Sao Paulo, Brazil; 2) Genetics and Genomic Medicine, UCL Institute of Child Health, London, UK.

Non-syndromic cleft lip/palate (NSCL/P) is the most common congenital craniofacial malformation, with a prevalence of 1 affected individual to 700 live-births worldwide. NSCL/P is a complex disease and heritability studies show a genetic contribution ranging from 40% to 85%.. Even though GWASs have been extensively applied for the elucidation of NSCL/P genetic factors, the identified *loci* explain only a small fraction of the observed heritability. On the other hand, epidemiologic studies show an association between low socioeconomic status and NSCL/P, pointing out an important environmental contribution. Those data suggest that alternative mechanisms might be involved in the NSCL/P etiology, as dysregulation of epigenetic markers triggered by environmental factors. Aiming to better identify epigenetic factors for NSCL/P, we propose the investigation of DNA methylation differences between NSCL/P and control samples using an EWAS (Epigenome-Wide Association Study) approach. We hypothesized that DNA methylation sites act as epialleles in relevant genes for the craniofacial development and differences in their methylation levels predispose to NSCL/P. To test those hypotheses we performed a methylome analysis comparing 68 NSCL/P with 59 control samples (whole blood DNA), using the Infinium Human Methylation 450K platform (Illumina) and RnBeads pipeline. We found 578 methylation variable positions (MVPs) at $p<10^{-7}$. EpiExplorer analysis revealed an enrichment of those MVPs in active regions of the genome, as gene promoters, in comparison to the 450K distribution. We also found a significant intersection of MVPs with 18 previously reported NSCL/P candidate genes (Fisher´s Exact Test, p=0.00044). Using Ingenuity Pathway Analysis, we identified "Regulation of the Epithelial-Mesenchymal Transition Pathway" and "WNT Beta-Catenin Signaling" amongst the top 5 significant canonical pathways in the MVPs. We selected 11 MVPs for replication in an independent cohort of 171 NSCL/P and 177 controls samples from the United Kingdom using a Bisulfite Amplicon Sequencing approach. We found significant methylation differences for 4/11 tested MVPs in the replication cohort. Our data suggests a different methylome profile between NSCL/P and controls and point out common methylation epialleles associated to NSCL/P in two distinct populations. Our result also suggests that epigenetic factors, possibly directed by the environment, may play a role in NSCL/P etiology. Support:FAPESP/CNPq.

DNA methylation alterations in cord blood of children exposed to gestational diabetes mellitus *in utero. D.T. Butcher[1], R. Retnakaran[3], A. Hanley[3], R. Weksberg[1,2], J. Hamilton[2].* 1) Genetics & Genome Biology, Sickkids Research Inst, Toronto, Ontario, Canada; 2) The Hospital For Sick Children, Toronto, Ontario, Canada; 3) Mount Sinai Hospital, Toronto, Ontario, Canada.

Obesity, diabetes and heart disease are now serious global health issues. Substantial evidence from epidemiologic studies suggests fetal and early postnatal environment, including *in utero* exposure to maternal gestational diabetes mellitus (GDM), significantly impacts the development of these conditions. GDM, defined as glucose intolerance first recognized during pregnancy, is increasingly common, occurring in up to 25% of pregnancies. The biological processes underlying the effect of *in utero* exposure to GDM, although not well understood, are likely to include alterations to the epigenome in fetal life. Such alterations may shift set points for insulin response and lipid metabolism resulting in postnatal growth trajectories that favor an obesogenic phenotype and increase the risk of cardiometabolic problems in adult life. Genome wide DNA methylation (DNAm) was assessed using the Illumina Infinium Methylation450 Beadchip array from cord blood samples of children exposed to GDM *in utero* compared to controls. We identified 453 CpG sites, representing 273 genes, which have an absolute DNAm difference of 5% with p<0.05. Multiple CpG sites in paraoxonase-1 (PON1) demonstrated a gain of DNAm in the cord blood of children exposed to DNAm compared to controls. Sodium bisulfite pyrosequencing validated the gain of DNAm of PON1 across these CpG sites. PON1 protein associates with high density lipoprotein (HDL) which hydrolyzes a number of lactones as well as additional substrates. Fetal programming via DNAm may shift the expression profile of PON1. Interestingly, in obese children and adolescents decreased activity of PON1 has been shown to correlate with central obesity, oxidative stress and inflammation. Also studies of PON1 levels and activity have been shown to be lower in serum of adults with cardiovascular, diabetes and obesity then in controls. This study allowed us to begin to evaluate the impact of maternal metabolic events during pregnancy on DNAm status in the child. Long-term follow-up of the children in this cohort will enable us to determine whether the identified DNAm alterations in the cord blood can be used as biomarkers for future metabolic disease providing opportunities for screening and intervention studies.

Conjoint SNP-SNP effects influence the human methylome - Results from an epi-genome-wide interaction analysis. *A. Milnik[1,2,3], V. Vukojevic[1,2,4], T. Egli[1,2], T. Sengstag[6,7], M. Jacquot[6], C. Vogler[1,2,3], V. Freytag[1,2], A. Heck[1,2,3], D. Coynel[2,5], D.J.F. de Quervain[2,3,5], A. Papassotiropoulos[1,2,3,4].* 1) Division of Molecular Neuroscience, University of Basel, Basel, Basel City, Switzerland; 2) Transfaculty Research Platform Molecular and Cognitive Neurosciences, University of Basel, CH-4055 Basel, Switzerland; 3) Psychiatric University Clinics, University of Basel, CH-4055 Basel, Switzerland; 4) Department Biozentrum, Life Sciences Training Facility, University of Basel, CH-4056 Basel, Switzerland; 5) Division of Cognitive Neuroscience, Department of Psychology, University of Basel, CH-4055 Basel, Switzerland; 6) sciCORE, Scientific Computing Center, University of Basel, CH-4056; 7) SIB - Swiss Institute of Bioinformatics.

   Background: The epigenome is an important regulatory factor in the context of cell development, aging and disease pathogenesis. DNA methylation is an epigenetic hallmark and can be measured at both high resolution and high throughput. While it is known that single nucleotide polymorphisms (SNPs; mQTLs) influence DNA methylation levels (CpG), pairs of SNPs may also conjointly influence methylation levels. **Analysis:** To further address this question, we analyzed 2nd-order dependencies of SNPs (SNP-SNP interactions) on CpG DNA methylation (DNA derived from blood) on an epi-genome-wide scale (1.5×10^{16} tests; 395'431 CpGs; 192'955 SNPs) in a sample of N = 533 healthy young adults. Replication was done in an independent sample of N = 319 healthy young adults. **Results:** We could identify 7'532'307 Bonferroni corrected significant CpG-SNP-SNP triplets. When applying a stringent QC in the replication sample (permuted P-values; same direction of effect), 2'119 CpG-SNP-SNP triplets survived replication (based on 764 unique CpGs). 94% of all replicated SNP-SNP pairs were located on the same chromosome as the CpG. Hence, we further filtered out SNP-SNP-pairs with an R^2 > 0.1 to reduce potential confounding effects of haplotypes, resulting in 1'531 CpG-SNP-SNP triplets (575 unique CpGs). For these CpGs, adding the SNP-SNP interaction term in the model increased the amount of variance explained from 30% to 44%. **Discussion:** The results of this epi-genome-wide interaction analyses suggest that especially mQTLs in *cis* conjointly influence DNA methylation levels.

2108T

Principal component informed dimensionality reduction approach for 450k methylation data. *T.G. Richardson, N.J. Timpson, C.L. Relton, T.R. Gaunt.* MRC Integrative Epidemiology Unit, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

   The high dimensional Illumina HumanMethylation450 (450K) BeadChip array has become a widely used platform in the field of epigenetics. However, measuring DNA methylation at over 480,000 sites poses both computational and statistical challenges. We have developed a framework to reduce the dimensionality of 450K data by taking the principal components of methylation across individual CpG islands. These regions of the genome are involved in transcription initiation and chromatin structure and therefore allowed us to retain important features of the data when reducing dimensionality. We applied our approach to 450k data across 5 time points from the Accessible Resource for Integrative Epigenomic Studies (ARIES) project using 1018 mother-offspring pairs. We observed association signals between prenatal smoking and methylation at previously reported key genes (*AHRR*, *MYO1G*, *CYP1A1* & *GFI1*) when analysing the dimensionally reduced dataset. This analysis required only 35,416 tests in comparison to the >480,000 undertaken in a conventional epigenome wide association study. We also observed an attenuation in average p-value for hits when uncovering methylation quantitative trait loci (mQTL) in our dataset in comparison to analysing the raw 450k data. A possible explanation for this could be a reduced impact of measurement error at single probes when quantifying methylation across CpG islands. Furthermore, the mQTL analysis using the dimensionally reduced dataset required over 10 times fewer tests compared to the raw 450k data. Dimensionality reduction for large scale omics data is becoming increasingly important as different data types continue to grow in scale across multiple tissue types. The results of this study demonstrate the value of our approach in achieving a greater than 10 fold dimensionality reduction whilst still uncovering real biological effects.

2109F

Epigenetic signature of preterm-birth in adult twins. *Q. Tan, K. Christensen, L. Christiansen.* University of Southern Denmark, Odense , Denmark.

Preterm birth (PTB) represents a major problem for modern obstetrics due to its increasing frequency and the accompanying socioeconomic impact. As stress and depression are major causes of premature births, such conditions could alter the epigenome and thus affect long-term health in the victims. We performed a relatively large epigenome-wide association study (EWAS) on PTB using genome-wide DNA methylation data. The study samples consist of 73 pairs of indetical twins aged from 30 to 36 who have their gestational ages (33-42 weeks) recorded by The Danish Medical Birth Registry. Among them, there are 25 preterm birth pairs with gestational age<37 weeks and 48 term control pairs. Genome-wide DNA methylation data have been collected using the Illumina's Infinium HumanMethylation450 Beadchip assay. Our EWAS aimed at identifying differentially methylated genomic sites between preterm birth cases and term controls. We found 2 CpGs methylated for PTB with p value 4.7e-6 for cg09668047 on chromosome 16 and p value 4.84e-6 for cg00718694 on chromosome 2. Both CpGs are hypomethylated in preterm subjects. In addition, we also found 2 CpGs displaying sex-specific methylation patterns for PTB with p value 7.75e-7 for cg20459037 on chromosome 17 and p value 4.51e-6 for cg21146474 on chromosome 20. Interestingly, both are hypomethylated in males. The CpG site cg20459037 is linked to WDR16 gene on chromosome 17, a gene that plays crucial roles in a wide range of physiologic functions. Our results provide evidence for altered DNA methylation patterns observed in adult subjects in association with PTB.

Puberty-associated DNA methylation changes in females are near estrogen responsive genes and implicated in immune processes. *E.E. Thompson[1], J. Nicodemus-Johnson[1], K.W. Kim[1], J.E. Gern[2,3], D.J. Jackson[2], R.F. Lemanske[2,3], C. Ober[1].* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Department of Pediatrics, University of Wisconsin School of Medicine and Public Health, Madison, WI; 3) Department of Medicine, University of Wisconsin School of Medicine and Public Health, Madison, WI.

The biological changes that occur following puberty in females are associated with increased risks for immune-mediated diseases, such as asthma and autoimmune diseases, both of which become more prevalent in females post-puberty. Many genetic and environmental factors are known to contribute to variation in the onset or delay of puberty, and recent evidence suggests a role for epigenetics in the timing of puberty as well. However, relatively little is known about specific epigenetic changes that arise during this window, or the genes that they potentially affect. To address this gap in knowledge, we studied global DNA methylation changes that occur during puberty in girls by focusing on peripheral blood mononuclear cells (PBMCs) collected from 38 girls pre- and post-puberty (8yrs and 14yrs, respectively), in whom puberty status was confirmed by Tanner staging. DNA from PBMCs collected from 43 boys at the same ages was used to identify and then exclude 715 age-related differentially methylated CpGs (DMCs). Of the remaining 326,556 probes on the Illumina 450K array that passed quality control, we identified 1,171 puberty related DMCs (5% FDR) in females that are in or near 1,036 unique genes. We first determined that genes near puberty-associated DMCs are enriched for estrogen responsive genes (P=3.2x10^{-6}; Fisher's Exact Test), suggesting that at least some of the effects of estrogen signaling in puberty are modified through epigenetic mechanisms. We then asked whether the genes near puberty-associated DMCs showed functional interactions by constructing protein-protein interaction analysis networks using Ingenuity Pathway Analysis (IPA). The closest genes to each of the 1,171 puberty-associated DMCs in females were connected in three significant networks (network score P<10^{-30}) that were enriched for genes involved in inflammatory response, inflammatory disease, and respiratory disease processes. Taken together, our results provide evidence for female puberty effects on global DNA methylation patterns at CpGs whose nearby genes are enriched for estrogen responsiveness and form networks centered on respiratory and inflammatory processes. These data further suggest that epigenetic changes that occur during puberty in females may contribute to sex-specific differences in susceptibility to immune-mediated diseases later in life. Supported by HL070831.

Effects of gestational alcohol alteration on the *Igf2/H19* **imprinted locus in a mouse model.** *H. Marjonen, N. Kaminen-Ahola.* Department of Medical and Clinical Genetics, Medicum, University of Helsinki, Helsinki, Finland.

Alcohol is a known teratogen, and usage during pregnancy affects the developing fetus and causes life-long health effects. The severest end of the spectrum, fetal alcohol syndrome, includes clinical features such as morphological malformations, central nervous system impairment and growth restriction. The most widely studied epigenetic mechanism, DNA methylation, is known to mediate gene-environment interactions and have a crucial role during the embryonic development. To search the interactions between maternal alcohol consumption and epigenome we have focused to investigate the *Insulin-like growth factor 2 /H19* locus which is a well characterized imprinted region and acts as important regulator of both fetal and placental growth during pregnancy. As a material, we are using an inbred mouse model (C57BL/Rcc). The model is based on maternal consumption of 10% (v/v) ethanol for the first 8 days of gestation, from preimplantation period to the beginning of neurulation. This kind of moderate and chronic exposure period is developmentally equivalent to the first three-four weeks of human pregnancy. To investigate the alcohol-induced alterations in DNA methylation and gene expression of the *Igf2/H19* locus we have collected ethanol-exposed and control E9.5 and E16.5 embryos and placentas. We have explored possible alterations in DNA methylation of the locus by Sequenom EpiTyper method and in gene expression by quantitative PCR method. Our preliminary qPCR results show that alcohol causes downregulation of the *Igf2* expression in both E9.5 and E16.5 placentas. However we did not observe significant alcohol-induced alterations in DNA methylation in *Igf2/H19* imprinting control region or in *Igf2* differentially methylated region.

Genetic variation in MHC proteins is associated with T-cell receptor expression biases. *E. Sharon[1,2], L.V. Sibener[3,4,5], A. Battle[6], H.B. Fraser[2], K.C. Garcia[3,4,7], J.K. Pritchard[1,2,7].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Biology, Stanford University, Stanford, CA; 3) Department of Molecular Physiology, Stanford University School of Medicine, Stanford, CA; 4) Department of Structural Biology, Stanford University School of Medicine, Stanford, CA; 5) Program in Immunology, Stanford University, Stanford, CA; 6) Department of Computer Science, Johns Hopkins University, Baltimore, MD; 7) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

In each individual, a highly diverse T-cell receptor (TCR) repertoire interacts with peptides presented by major histocompatibility complex (MHC) molecules. Despite extensive research, it remains controversial whether the germline-encoded TCR-MHC contacts promote TCR-MHC specificity and if so, whether there are differences in the compatibilities between different TCR V-genes and different MHC alleles. Here, we applied eQTL mapping to test for association between genetic variation and TCR V-gene usage in a large human cohort. We observed strong trans associations between genetic variation in the MHC locus and usage biases in TCR V-genes. Fine mapping of the association signals reveals particular amino acid residues in MHC genes that influence TCR V-gene usage. Remarkably, many of these residues are in direct contact or spatial proximity to either the TCR or the presented peptide in co-crystal structures. Our results show that MHC variants, several of which are linked to autoimmune diseases, can directly affect TCR-MHC interaction, and provide the first examples of *trans*-QTLs mediated by protein-protein interactions.

Toll-like receptor signaling pathway genes in association with trauma induced sepsis. *D.O. McDaniel[1], S. Martin-Robertson[1], L.S. McDaniel[2], G. Timberlake[1].* 1) Dept Surgery, Univ Mississippi Med Ctr, Jackson, MS; 2) Dept Microbiology and Immunology Univ Mississippi Med Ctr, Jackson, MS.

   Immunogenetic markers have been proposed as contributing factors in the development of trauma-induced clinical complications such as sepsis. Some patients with a similar degree of variables such as severity of injury, age, gender and preexisting clinical conditions develop post-trauma complications and die, but others recover. Such variation in the outcome might have association with the individual's genetic difference in immunoregulatory components of their innate immunity. The innate immune responses mediated by toll-like receptors (TLRs), induce early inflammatory response to the pathogen or damage associated molecular patterns (DAMPs) associated with trauma injury. A panel of molecular markers corresponding to TLR signalling-pathway genes were tested to evaluate trauma patients within the first week of admission. Blood was drawn at 24 hr time intervals up to one week from patients that met the inclusion criteria. Leukocytes were utilized in mRNA transcript analysis for TLR signalling-pathway genes using a gene-array. TLR-1, -4, -8 and -10 were almost equally expressed at day 1 in all patients. But, TLR-2 was 2.7 fold increased comparing day 1 vs. day 3 in monocytes of patients who later developed sepsis. TOLLIP, a toll inhibitory protein, also known as Cox-2 gene was 4-fold increase in patient with no sepsis. The IRAK-1 (IL-1 associated kinase-1), a major mediator of the TLR signalling-pathway was 2.5-fold increased in patients with no sepsis and reduced in patients with sepsis. The HMGB-1 a DAMP associated molecule was increased 5.7-fold, and CD86 an HLA-Class II receptor molecule was 15.2-fold increased in patients who later developed sepsis. In conclusion, profiling the innate immune response signalling-genes was informative and correlated with clinical outcomes which may help to predict the development of sepsis.

2114T

Chromatin state variability: A guide to uncover non-coding functional genomic regions and potential regulated genes. *L. Pinello[1], A. Gusev[2], H. Finucane[2], J. Huang[1], A. Price[2], G.C. Yuan[1].* 1) Department of Biostatistics and Computational Biology, Dana-Farber Cancer Institute, Boston, MA; 2) Department of Epidemiology, Harvard TH Chan School of Public Health, Boston, MA.

   With the increasing amount of epigenomic data, a pressing challenge is to understand the mechanisms underlying chromatin states changes and their role in cell-type specific establishment and maintenance. Here we propose a computational method based on information theoretic approaches to systematically quantify the variability of chromatin states and study its association with gene expression variation and non-coding variants from GWAS and eQTL studies.   Using histone modification data from 9 human cell lines from the ENCODE project we identified Highly Plastic Regions (HPRs) for chromatin state variation. HPRs cover about 2% of the genome and correspond to regions with the highest Shannon's entropy calculated using the frequency of chromatin states across cell types. We found that HPRs are enriched for many important regulatory elements such as super-enhancers, promoters and Polycomb repressed regions. Moreover we find that the HPRs are highly enriched for GWAS-associated (1.5x, p<1E-4 permutation test) and eQTL non-coding variants (1.4x, p<1E-4 permutation test), and for some traits or diseases, provide significant additional power in explaining heritability than well-characterized elements (14.7x, p<1E-20, non-overlapping partition heritability analysis excluding coding, promoters, DHS and H3k27ac).   We also identify regions of co-variability based on histone modification data, and show that such regions can predict high confidence long-range interaction obtained by Hi-C and ChIA-PET assays (AUC = 0.87) and also correlate well with observed interactions counts (Pearson's correlation = 0.54). In addition, the average co-variability profile around topological associated domains (TAD) boundaries, qualitatively shows a precise depletion in correspondence with the boundary and more enrichment in the flanking regions. This pattern is in agreement with the chromosome neighborhoods defined by the TADs, and suggesting that this measure could be helpful to highlight or predict functional subdomains within the TAD.   Our analysis provides new insights into the organization of cell-type specific chromatin structure during development, and a valuable tool for investigating the mechanisms of chromatin state establishment and usage in regions subjected to dynamic changes important in gene regulation. The HPRs obtained from our analysis provide also an important guide to search for functionally important genetic variants and linked genes. .

2115F

Analysis of monoallelic expression in 1084 human single-cell fibroblasts revealed novel putative imprinted genes including *ADTRP, ATP5EP2,* *SMOC1, ERAP2* **and** *PRIM2.* C. Borel[1], F. Santoni[1], E. Falconnet[1], P. Ribaux[1], S.E. Antonarakis[1,2,3]. 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) University Hospitals of Geneva, Geneva, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, Switzerland.

Genomic imprinting is defined as the mutually exclusive expression of either the paternally or maternally inherited allele. Imprinted genes are implicated in the etiology of rare syndromes and have been associated with common diseases such as diabetes and cancer. Less than 100 human imprinted genes have been identified so far, and the predicted number is in the range of a few hundreds. The aim of the project is to identify novel imprinting genes with single-sell (SC) RNA sequencing. This approach has the potential to improve the detection of average to low expressed genes and to provide a comprehensive profiling of the allelic imbalance of each gene. Using samples from the probands of 2 family trio and 3 unrelated individuals, 1084 individual primary fibroblasts were RNA sequenced and more than 770'000 informative heterozygous SNVs were genotyped (WGS, 25 x depth). For each gene, we analyzed the allelic specific expression (ASE) through an in-house pipeline (read mapping with Tophat, mapping quality=50). For each individual we modeled the likelihood of a gene to be monoallelically expressed with a beta-binomial distribution and evaluated the significance of the aggregate monoallelic ratio (reads sum of the most frequent allele per site / total reads) with the log-likelihood test. Fifty two genes were retained (adj. p-value < 0.01, ASE: 0.8-1 in each individual where the gene is detectable) for the identification of the allelic parent of origin in the two trios. We were able to identify 10 novel putative imprinted genes and 8 known imprinted genes. We carefully analyzed the imprinting status of 93 known imprinted genes in our SC dataset. Among the 50 detected genes in fibroblasts, we validated the imprinting status of 24 genes. Remarkably, 26 known imprinting genes show evidence of individual variability or biallelic expression in fibroblasts questioning their imprinting status in all the tissues. To elucidate the advantages of SC RNAseq for imprinted gene finding, we investigated the ASE of the 52 genes in 201 primary fibroblast cell lines from the GenCord collection. When detected in bulk samples, novel putative imprinting genes are validated but their statistical significance is mostly insufficient for imprinting discovery. Overall, the SC approach revealed novel putative imprinting genes that were undetectable in the respective bulk samples. C.B. and F.S. contributed equally.

Altered imprinting in miscarried products of conception. C. Demetriou[1], A. Thomas[1], M. Ishida[1], S. Abu-Amero[1], S. Stanier[1], L. Regan[2], P. Stanier[1], G. Moore[1]. 1) Genetics and Genomic Medicine, Institute of Child Health, UCL, London, United Kingdom; 2) Department of Obstetrics and Gynaecology, St Mary's Campus, Imperial College London, London, UK.

Fetal growth involves a complex interaction between genes and the environment. Genomic imprinting is an epigenetic form of gene regulation that gives rise to differential expression of a given allele, depending upon its parental inherited origin. A study was undertaken to investigate imprinting anomalies in a 100 products of conception (POC), collected from miscarried pregnancies around the 10th week of gestation. With a hypothesis that a proportion of miscarried POC that are cytogenetically normal will have abnormal expression profiles at imprinted loci, possibly contributing to embryonic lethality, we investigated the imprinting status of the placental paternally expressed genes *IGF2, PEG3* and *DLK1* and the maternally expressed genes *H19, GRB10* and *PHLDA2*. This work first involved a detailed analysis of the POC DNA to establish levels of maternal cell contamination (MCC). Surprisingly, only 7 POC were free of MCC and 16 were partially contaminated, while 74% of the cohort was exclusively maternal decidua. The 23 POC with fetal material were tested for heterozygosity for each gene to identify informative samples. *IGF2* is a well-known paternally expressed gene. All 11 informative POC samples for *IGF2* were monoallelically expressed; however, 4 of these were maternally expressed. Bisulfite sequencing to test methylation status revealed normal methylation profiles. Sequencing of the *H19* imprinted control region and the CTCF binding factor revealed no mutations. Although paternal imprinting of *IGF2* is seen in brain tissue, to our knowledge, this is the first time maternal *IGF2* expression has been observed in human placental tissue. The other imprinted genes tested were expressed as would normally be expected. *HLA-C* was also tested and was found to be biallelically expressed in fetal, placental and maternal decidua tissue. Interestingly, although *HLA-C* was biallelically expressed in chorionic villi collected at 12 weeks of gestation from successful pregnancies, it was monoallelically expressed in all POC, showing either maternal or paternal expression, thus suggesting random allele switching off of *HLA-C* in the miscarried tissue. It is therefore possible that a proportion of miscarriages can be explained by gene deregulation at imprinted loci which lead to embryonic lethality. Genome-wide epigenetic remodeling occurs during the early stages of development and if disrupted may lead to aberrant gene expression with consequences to maintenance of a healthy pregnancy. .

2117T

Investigating DNA methylation as a marker for historical smoke exposure and a mediator of disease risk. *R.C. Richmond, M. Suderman, P. Haycock, G. Hemani, C. Relton, G. Davey Smith.* MRC Integrative Epidemiology Unit, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

Cigarette smoke is a powerful modifier of DNA methylation and epigenome-wide changes in response to smoke exposure in-utero have been established. We previously conducted work showing the persistence of some of these methylation marks through childhood and into adolescence. Of interest is whether signals persist into adulthood. We performed an analysis to investigate associations between maternal smoking in pregnancy and DNA methylation in peripheral blood among women in the Avon Longitudinal Study of Parents and Children. We found that, among women with a mean age of 29 years (N=866), there was an inflated signal above that expected by chance at CpG sites previously associated with in-utero smoke exposure in newborns (lambda=2.80 vs. 1.05 for all CpG sites on the Illumina Infinium HM450 array). In-utero smoke exposure was associated with hypermethylation at cg22132788, cg12803068 and cg04180046, located in the *MYO1G* gene region, at Bonferroni significance. These signals remained in sensitivity analyses adjusted for own smoking and when restricted to non-smokers. The same signals were observed in peripheral blood when the women were a mean age of 47 years (N=885). We replicated findings of a persistent methylation signal related to in-utero smoke exposure in whole blood and LCLs from participants in the 1958 Birth Cohort (mean age=45 years; N=40) and in saliva from participants in the Aberdeen Folic Acid Supplementation Trial (mean age=47 years; N=83). Persistent changes in DNA methylation might mediate some of the associations between in-utero smoke exposure and later life health. However, disentangling mediation from other mechanisms that lead to association -such as confounding and reverse causation- warrants further evaluation. We investigated whether persistent methylation at *MYO1G* plays a causal role in the aetiology of disease using a hypothesis-free Mendelian randomization approach. We first identified cis-SNPs associated with methylation at *MYO1G* and then performed an agnostic look-up of these SNPs in GWAS summary data using the "MRBase" platform (http://www.mrbase.org/). We found enrichment for a causal effect of *MYO1G* methylation on a range of metabolites. These findings could have useful applications in epidemiological studies, by using DNA methylation as a refined indicator and biosocial archive for historical exposure. The downstream health implications of methylation change in response to smoke exposure in-utero requires further evaluation.

2118F

DNA methylation gives insight into different etiologies in early-onset and late-onset preeclampsia and intrauterine growth restriction. *S.L. Wilson[1,2], K. Leavey[3], B. Cox[3,4], W.P. Robinson[1,2].* 1) Healthy Starts, Child and Family Research Institute, Vancouver, BC, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Department of Physiology, University of Toronto, Toronto, ON, Canada; 4) Department of Obstetrics and Gynecology, University of Toronto, Toronto,ON, Canada.

Preeclampsia (PE), a maternal hypertensive disorder, and intrauterine growth restriction (IUGR), a pathologically small fetus, often co-occur and are both associated with an inadequately functioning placenta. Placental dysfunction is more common in early-onset PE (EOPE), diagnosis <34 weeks gestation, than late-onset PE (LOPE). However, the relationship between these disorders remains unclear. Placental DNA methylation (DNAm) profiles of EOPE, LOPE, and normotensive IUGR (nIUGR) placentas were compared to healthy controls to better understand their etiology and relationships to one another. Placental DNA from both a discovery (43 controls, 22 EOPE, 18 LOPE, and 11 nIUGR) and a validation cohort (18 controls, 19 EOPE, 11 LOPE) were run on the Illumina HumanMethylation450 array. Each cohort was normalized (functional normalization) and batch-corrected (ComBat). To minimize gestational age (GA) effects, EOPE samples were compared to pre-term control samples (GA<37 weeks), while LOPE and nIUGR were compared to term controls (GA>37 weeks). Linear regression, correcting for GA and sex was used to identify differentially methylated (DM) sites (FDR<0.05, Δβ>0.1). Within the discovery cohort, 2115 sites were DM in EOPE placentas, however no sites were DM for the LOPE or nIUGR groups. At a nominal p-value<0.01, EOPE DNAm changes were enriched for GO terms: regulation of inflammatory response, hormone transport/secretion, mesoderm development, and cell aging using ErmineJ. As we identified no DM sites in LOPE or nIUGR, we focused on validating the EOPE hits. In the validation cohort, 240 DM sites were identified for EOPE. Changes in DNAm at EOPE DM sites were correlated between the discovery cohort and the validation cohort (R=0.62, p<2.2e-16) with 69 sites meeting FDR<0.05 and Δβ>0.1 in both cohorts. These persistent hits include CpGs associated with previously reported PE-associated genes such as: *PAPPA2*, *INHBA*, and *JUNB*. Clustering on these persistent hits largely separates EOPE from controls, while some LOPE samples cluster with both EOPE and controls. Many DNAm changes were observed in EOPE and a significant portion were validated in a separate cohort. The persistent hits provide the best candidates for biomarker development for improved diagnosis. In contrast, we were unable to identify DNAm changes specific to LOPE or nIUGR. This may be due to a less severe placental phenotype, limited sample size, and/or increased disease heterogeneity as compared to EOPE.

2119W

Circulating microRNAs and prediction of asthma exacerbation in the Childhood Asthma Management Program (CAMP) Cohort. *J.S. Davis[1,2], A.T Kho[2,3], K.G. Moore[1], J.M. Sylvia[1], S.T. Weiss[1,2], K.G. Tantisira[1,2].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Children's Hospital Informatics Program, Boston Children's Hospital, Boston, MA.

   Identification of children at the highest risk for asthma exacerbations could result in decreased costs, tailored care and improved outcomes. Prior studies have yielded variable results in predicting exacerbations. Circulating microR-NAs (miRNA) are attractive biomarkers that may have predictive power for asthma exacerbations. This study examines circulating miRNA and asthma exacerbations in the 12 months following randomization to the inhaled corticosteroid arm in a subset of 153 subjects in the Childhood Asthma Management Program (CAMP) cohort. The study hypothesizes that a miRNA model or combined miRNA-clinical model may have superior predictive capability compared to a clinical prediction score for childhood asthma exacerbations. Serum samples obtained at randomization from the subjects were profiled using a TaqMan miRNA array set containing 754 miRNAs. Logistic regression was performed with dichotomized steroid burst count as the binary response variable and miRNA cycle threshold and a clinical asthma exacerbation prediction score as the explanatory variables. Stepwise feature selection was performed, and predictive capability was assessed. There were 125 (16.6 %) detected in at least 70 % of the samples with 12 significant miRNA in the univariate models with the strongest predictor being miR-206 with an OR 0.60. All miRNA demonstrated odd ratios < 1 indicating decrease risk of asthma exacerbation with increase in miRNA cycle threshold. Stepwise selection yielded a three miRNA model including miR-206, -146b, and -720. The clinical score model had a positive coefficient with resultant OR greater than 1 indicating an increased risk of asthma exacerbation with increase in clinical score. For testing/training sets, the combined miRNA-clinical score demonstrated good predictive power with an AUC of 0.807, which was significantly better than either clinical score model (0.671) or miRNA model (0.714). In conclusion, this study examined circulating serum miRNA in childhood asthmatics prior to treatment with inhaled corticosteroids to predict exacerbations in the subsequent year and found 12 miRNAs significantly associated with future exacerbations with each doubling of these miRNA associated with a 25-67 % increase in risk of exacerbation. A three miRNA model provided comparable predictive power to an established clinical model of exacerbations. Furthermore, a combined miRNA-clinical model had significant increase in the ability to predict future exacerbations.

2120T

MicroRNAs and their regulatory interactions in the human hair follicle. *S. Heilmann-Heimbach[1,2], L.M. Hochfeld[1,2], T. Anhalt[1,2], N. Fricker[1,2], A. Hofmann[1,2], M.M. Nöthen[1,2].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics; Life&Brain Center, University of Bonn, Bonn, Germany.

   Human hair follicle (HF) cycling involves numerous signaling cascades and cellular processes that have been reported to be controlled by micro(mi)RNAs. However, our current knowledge on the expression and function of these miRNAs in hair biology is largely based on murine data or cell culture experiments and little is known about their exact role in the human HF. We therefore sought to gain a deeper understanding of the role of 9 previously reported miRNAs in human hair biology by systematically investigating their expression and regulatory interactions in HF samples from 25 healthy male donors. After nucleic acid extraction, we performed a genome-wide miRNA and mRNA expression profiling and subsequently correlated miRNA expression levels with mRNA-expression levels from the same samples to identify potential target genes. Moreover, we tested for an enrichment of target genes in biological pathways and searched for protein-protein interactions (PPIs). Our analysis confirmed the expression of 7 of the 9 candidate miRNAs. For 3 of them (miR-24, miR-31, miR-106a), significant miRNA/mRNA correlations were detected. The identified target genes included genes with known functions in hair biology (e.g. *ITGB1*, *SOX9*), genes where the biological function of the encoded protein reflected the reported miRNA-function (e.g. *RXRA*) and numerous genes that had not previously been implicated in hair biology. A subsequent pathway- and PPI-based analysis revealed an enrichment of target genes in relevant pathways such as integrin and GnRH signaling and confirmed the interaction of target gene products in PPI-networks. In summary, our data provide novel insights into the role of miRNAs and their regulatory interactions in the human HF and will eventually contribute to a deeper understanding of healthy hair growth and the pathobiology of hair loss disorders.

2121F

Role of miR-133b in the regulation of *Col1A1***,** *TGF-β1* **and** *ACTA2* **in scleral fibroblasts.** *R. Metlapally[1], A.V. Tang[1], K.K. Wang[1], H.M. Do[1], C.F. Wildsoet[1,2].* 1) School of Optometry University of California at Berkeley; 2) Vision Science Graduate Group University of California at Berkeley.

   Purpose: The sclera, outermost white layer of the eye, comprises a collagen dominated extracellular matrix that undergoes active remodeling to maintain eye size and shape during early development. In myopia (near-sightedness), the most common eye disorder, increased remodeling leads to scleral thinning and excessive eye enlargement, increasing the risk for irreversible ocular complications. micro(mi)-RNAs have been implicated in scleral matrix remodeling during both normal ocular growth and myopia development. In this study, we investigated the role of miR-133b in the regulation of *Col1A1* (the predominant scleral collagen subtype), *TGF-β1* and *ACTA2* (alpha-smooth muscle actin), scleral genes linked to myopia as well as implicated in miR-133b driven matrix remodeling in wound healing. The long-term goal of this research is to target scleral miRNAs for developing novel therapies to retard myopia progression. **Methods:** Human scleral fibroblasts from donor eyes were cultured using standard methods. At 80% confluence, they were transfected with miRVANA™ miR-133b mimic or negative scramble control (30 nM and 100 nM, n=4), using electroporation. After 48 h, cells were lysed and reverse transcriptions performed using Ambion® Cells to CT kit, and the expression levels of *Col1A1*, *TGF-β1*, and *ACTA2* were quantified using Taqman™ QPCR assays. Analyses were performed using the deltaCt method; all data were normalized to the expression of snoRNAs RNU44 and RNU6B and negative controls, and fold changes calculated. Calcein-AM ethidium homodimer (EthD-1) cell viability assay was performed to rule out cytotoxicity due to the treatment. **Results:** As expected, transfection of scleral fibroblasts with miR-133b mimic resulted in increased expression of miR-133b for both concentrations tested (> 300-fold, p < 0.05), and decreased expression of *Col1A1* gene expression (~2-fold, p < 0.01). There were no significant changes in the expression of *TGF-β1* and *ACTA2* genes following miR-133b mimic treatment. Tests for cytotoxic effects of the applied miRNA mimic yielded negative results. **Conclusion:** miRNA expression can be predictably manipulated in scleral fibroblast cultures. Our findings implicate miR-133b in the regulation of *Col1A1*, but not *TGF-β1* and *ACTA2*, in scleral fibroblasts. These observations could prove useful in devising myopia-control therapies aimed at preventing or reversing the scleral changes seen in myopia.

2122W

Sex-specific effects of testosterone on the sexually dimorphic transcriptome and epigenome of embryonic neural stem/progenitor cells. *M. Bramble, L. Roach, A. Lipson, N. Vashist, A. Eskin, E. Vilain.* Human Genetics, UCLA, Los Angeles, CA.

   The direct effects of gonadal hormones and chromosomal sex on gene regulation in undifferentiated neural stem cells, a cellular model for brain sexual differentiation, are poorly understood. We isolated embryonic neural stem cells (NSCs) from XX and XY 13.5-14 C57/BL6/J mice to investigate gene expression differences and epigenetic changes in multipotent neural stem cell populations, prior to, and post testosterone exposure. Transcriptionally, Using RNA sequencing we identified novel sex differences in gene expression in NSCs that have not had prior exposure to endogenous gonadal hormones. Additionally, we identified unique sex-specific effects in gene expression post exogenous T exposure. We found 103 genes that are differentially expressed between XY and XX murine NSCs (FDR=0.05). After treatment with T, we found that in XX cells, 2854 genes were differentially expressed, compared to XY cells, which showed 792 transcripts differentially expressed (FDR 0.05). These findings indicate that testosterone exposure on XX cells may have a more robust effect with regards to altering gene expression than on XY cells. Most interestingly, it was found that by exposing XX NSCs to T, 42% of the original 103 basal sex differences that existed were masculinized and shifted towards a XY typical gene expression pattern. Unexpectedly, we also determined that 25% of basal sex differences were actually feminized in an XY background post T. This suggests modular effects of T exposure on sexual development. In addition to determining how T alters gene expression in NSCs we also investigated how testosterone perturbed the epigenome of our cell population. We found that testosterone is capable of causing global hypo-methylation events in neural stem cells, but most interestingly these effects are maintained over cellular linages even in the absence of testosterone. Our novel approach is the first to identify sex differences in gene expression in NSCs, and demonstrate the effects of testosterone exposure on gene expression. Additionally, we have identified that testosterone has the ability to alter the epigenome within a stem cell population and elicit changes that are maintained in downstream cellular lineages. Collectively these data have identified a new role for testosterone's influence on the developing CNS in addition to possibly unlocking key mechanistic changes that are responsible for permanent hormonal organization of the sexually dimorphic mammalian brain.

The landscape of regulatory post-transcriptionally derived small non-coding RNAs in the human transcriptome. *Y.Y. Leung[1,2], P.P. Kuksa[1,2], A. Amlie-Wolf[1,2,3], L.-S. Wang[1,2,3].* 1) Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 2) Institute for Biomedical Informatics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Genomics and Computational Biology Graduate Group, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

Mature small RNA products resulting from post-transcriptional processing of precursor transcripts play major roles in gene regulation by binding to protein and mRNA targets. While these small noncoding RNAs (e.g., miRNAs and tRNA fragments) are emerging as biomarkers and regulators in human diseases including cancer and neurodegenerative disorders, the genome-wide landscape of functional mature small noncoding RNAs (sncRNAs) remains poorly characterized. To delineate the genome-wide post-transcriptional processing and expression of sncRNAs, we performed the largest study to date by curating and integrating all short total and small RNA-seq data from 36 human cell lines with 72 samples from ENCODE and 42 human cell types and tissues with 198 samples from DASHR (Database of small human noncoding RNA), respectively. We applied *ab initio* annotation-free methodology, SPAR, to these datasets to systematically characterize the extent of sncRNA (15-44nt) expression across tissues and cell lines. We found 150,997 and 121,466 specifically processed sncRNAs expressed in at least 3 samples in ENCODE and DASHR. By expression, these sncRNAs are enriched for RNA length classes 20-24nt (66%), 15-17nt (10%), 32-36nt (4%). Of these expressed sncRNAs, 70% sncRNA genes were previously uncharacterized. Both annotated and uncharacterized sncRNA loci are conserved (mean 100-way conservation score = 0.3-0.4 with top quartile score >0.7-0.9), indicating that these previously unannotated loci may also be functional. 3,146 out of all loci are ubiquitously expressed suggesting that they may perform fundamental regulatory roles, whereas 90% are tissue-regulated. We integrated all results into our DASHR database (http://lisanwanglab.org/DASHR). Of the annotated mature product loci in the top 10% of expression, 39% are miRNAs. 70% of miRNAs display average expression or more. Surprisingly, the expression of 61% of piRNA loci are above average, but this pattern was not observed in snoRNAs and tRNAs. SPAR has been implemented as a web server where users can quickly view their own smRNA-seq analysis results and compare them with ENCODE and DASHR and as a standalone tool for offline batch analysis. These tools serve as a valuable resource for biomarker development and characterization of small noncoding RNAs. Together, SPAR and DASHR provide novel insights into the landscape of the small RNA processing and expression landscape across human tissues and cell types.

A role for YY1 in sex-biased transcription revealed through X-linked promoter activity and allelic binding analyses. *C. Chen[1,2], W. Shi[1,2], A. Matthews[1], Y. Li[1], D. Arenillas[1], A. Mathelier[1], C. Brown[3], W. Wasserman[3], FANTOM Consortium.* 1) Centre for Molecular Medicine and Therapeutics, Child and Family Research Institute, University of British Columbia, Vancouver, British Columbia, Canada; 2) Graduate Program in Bioinformatics, University of British Columbia, Vancouver, British Columbia, Canada; 3) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

Sex differences in susceptibility and progression have been reported in numerous diseases. Female cells have two copies of the X chromosome with X-chromosome inactivation imparting mono-allelic gene silencing for dosage compensation. Such differences in transcriptional status between the copies in female and copy numbers between sexes pose a challenge to genomic data analyses of the X. A subset of genes, named escapees, escape silencing and are transcribed bi-allelically resulting in sexual dimorphism. Here we conducted analyses of the sexes using human datasets to gain perspectives in such regulation. We first identified transcription start sites of escapees (escTSSs) based on higher transcription levels in female cells using FANTOM5 Cap Analysis of Gene Expression data. Greater similarity of DNA methylation levels between the sexes was found to be consistent with bi-allelic activity at these escTSSs. The significant over-representations of YY1 transcription factor binding motif and ChIP-seq peaks around escTSSs highlighted its positive association with escapees. Furthermore, YY1 occupancy is significantly biased towards the inactive X (Xi) at long non-coding RNA loci that are frequent contacts of previously reported Xi-specific superloops in female GM12878 cells. While revealing the unique properties of the X as reflected by genomic datasets, our study elucidated the importance of YY1 on transcriptional activity on Xi in general through sequence-specific binding, and its involvement at anchor regions of Xi-specific chromatin superloops.

Identification of lncRNAs involved in smooth muscle contraction pathway in preterm birth. *J. Wang[1,2], Z.H. Tu[1], X.L. Zhao[2,3], W. Ju[4], N. Zhong[2,3,4].* 1) Laboratory Medicine, Hainan Provincial Maternal and Children's Hospital, Haikou, Hainan, China; 2) China Alliance of Translational Medicine for Maternal and Children's Health, Beijing, China; 3) Peking University Center of Medical Genetics, Beijing, China; 4) New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY, USA.

Preterm birth (PTB) is the most common etiological factor causing neonatal mortality and the second most common factor for the death of children under five. It is also one of the common causes for the lifetime morbidity. Each year, there are 15 millions of PTB neonates delivered globally. Clinically, spontaneous PTB (sPTB) accounts for about 80% of PTB and may present as preterm labor (PTL) or preterm premature rupture of membrane (pPROM). The PTL shows uterine contraction without rupture of fetal membrane. Many studies have determined that infection and inflammation during, or prior to, the pregnant period may trigger the labor. The underlying mechanism, however, is yet unknown. We have conducted exome sequencing on 160 sPTL and obtained 147 clean data. SNPs, SNVs, InDels, can be identified at exons, introns, UTR3 and UTR5, and ncRNA regions. On the basis of exome data, we selectively focused on smooth muscle contraction (SMC) pathways, with targeting lncRNA that associated with the gene loci that encode proteins involved in SMC pathway. Microarray of genome wide lncRNAs, along with overlapped mRNAs, were analyzed and results were validated with quantitative RT-PCR. The lncRNA-AL590431.2 overlapped with tropomysin (TPM3), an actin-binding protein, was found down-regulated in placentas of sPTL, however, the lncRNA-AL590431.2 overlapped mRNA-TPM3 was up-regulated. Longitudinally, expression of lncRNA-AL590431.2 in maternal bloods were significantly in the second and third trimesters, compared to the first trimester among normal pregnancies. However, there was no significant alteration of the lncRNA-AL590431.2 between the second and third trimesters, compared to the first trimester among the placentas of sPTL and pPROM. The pattern of longitudinal expression of lncRNA/mRNA of Desmin, a muscle-specific class III intermediate filament, showed a similarity to the lncRNA-AL590431.2/mRNA-TPM3. Our studies demonstrated that epigenetic the regulation of lncRNA not only are involved in placentas but also present in maternal circulations.

Inter-individual variation in microRNA regulatory network. *T. Annilo, M. Kals, R. Mägi, T. Esko, A. Metspalu.* Estonian Genome Center, University of Tartu, Riia 23b, 51010 Tartu, Estonia.

The dynamic nature of evolution of miRNA gene families and their targets has been demonstrated by comparative genomics studies in a wide range of species. Genetic variation can affect all aspects of miRNA functionality, including transcription, biogenesis and binding to the target. We present a study to assess the miRNA function using naturally occurring genetic variation in the context of individual whole-genome sequences (WGS). We have combined WGS (N=2244) and ample phenotypic data collected at the Estonian Genome Center for identification of the target modulation effect caused by genetic variation in miRNA networks. Such approach allows assessment of miRNA function in the defined individual genetic and phenotypic background. Genomic coordinates for miRNA genes and flanking regions were obtained from UCSC Genome Browser and miRBase v21. Sequence variants in miRNA genes were grouped into categories: (i) seed region, (ii) mature miRNA sequence, (iii) "passenger" strand, (iv) loop region, and (v) flanking regions of 100 nucleotides. The functional impact of genetic variants on miRNA binding was estimated using PolymiRTS v3.0, miRSNP, and mrSNP databases. Experimentally validated miRNA target sites were obtained from miRTarBase v4.5, TarBase v6.0, and miRecords v4. Using this approach, we have identified more than 1000 different genetic variants in miRNA genes, approximately 60% of them novel with median allele frequency 0.14%. More than 50% of miRNA genes contained one or more genetic variant. We are currently testing the effect of these variants on mRNA expression using matched RNA-seq data (N=600).

HipSci data resources: High quality genomic and cell biological data for a reference panel of human iPSC lines. *Y. Memari[1], I. Streeter[2], R. Halai[1], R. Nelson[1], R. Durbin[1] on behalf of the HipSci Consortium (http://www.hipsci.org/).* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge CB10 1SA, UK; 2) EMBL-EBI, Wellcome Genome Campus, Hinxton, Cambridge CB10 1SD, UK.

The Human Induced Pluripotent Stem Cells Initiative (HipSci) has developed a pipeline to derive, expand, assay and bank iPS cell lines on a production scale. This collection of well-characterised iPSCs is a valuable resource for studies of cell biology and clinical genetics, and it is accompanied by systematic data sets that can be accessed through public archives and web sites. To date HipSci has derived iPSC lines from 282 healthy individuals and 26 individuals with monogenic disease. By 2017 we aim to increase these numbers to over 450 healthy donor and 200 patient donor iPS lines. To generate the iPSCs, primary tissue is reprogrammed using a Sendai viral vector system. From each donor, 2 candidate iPS cell lines are derived, each of which is subjected to extensive quality checking including quantification of pluripotency using gene expression microarray data and the software PluriTest, and screening for genetic stability and chromosomal abnormalities using genotyping and a newly developed CNV calling software[1]. Successfully reprogrammed lines are banked for distribution and future use, and further studied to identify major drivers of molecular and cellular heterogeneity in iPSCs. Further HipSci project assays include profiling with methylation array, whole-exome and RNA sequencing, proteomic mass spectrometry and cellular phenotyping. Selected lines are banked at ECACC and EBiSC and the entire quality control and subsequent assay data are deposited to open-access (ArrayExpress, EVA, PRIDE) or managed-access (EGA) repositories, with links to these available via the project coordination web site www.hipsci.org. Initial results from the project are available in a biorxiv preprint[2]. We wish to encourage wide use both of the data sets and cell lines. This poster will provide information about the data processing workflow and data resources available for HipSci, with a summary of major results and up to date numbers for data and sample availability. 1) A Method for Checking Genomic Integrity in Cultured Cell Lines from SNP Genotyping Data, Danecek et al. San Diego, CA, USA; 8) Bioinformatics and Systems Biology Program, University of California at San Diego, La Jolla, CA, USA; 9) Institute for Genomic Medicine, University of California at San Diego, La Jolla, CA, USA.

Since induced pluripotent stem cells (iPSCs) were first reported, considerable effort has focused on examining the molecular consequences that follow this type of cellular conversion. Several studies have reported that some CpGs differ in methylation status between individual iPSC lines (methylation variation) as well as that some CpGs differ in methylation status between iPSCs and embryonic stem cells (ESCs) (methylation aberrancy). Because iPSCs and ESCs differ in their genetic background, it is currently unclear how much of the perceived methylation variation and aberrancy can be contributed to genetic variants and how much is due to other variables. Here, to examine the roles of genetic background, clone lines and passage in methylation variation and aberrancy at CpG sites in the iPSC lines, we generated 22 iPSC clonal lines from six individuals (3 pairs of older monozygotic twins), and profiled early (passages 5 (p5) and 9 (p9)) and late (passage 20 (p20)) passages as well as fibroblasts (tissue of origin) using genome-wide methylation arrays. Because the vast majority of genetic variants are not assayed by genotyping arrays, we performed whole genome sequencing (WGS) to test whether genetic variants near the CpG could explain genetic background effects. We show that divergent methylation patterns in twin fibroblasts are reset after reprogramming based on genetic background, with samples derived from twins more similar to each other. Using ANOVA analyses, we show that methylation at CpGs is most associated with genetic background rather than clone or passage alone. Genetic-background associated sites are more likely to be close to genetic variants identified through WGS and to be affected by established methylation quantitative trait loci (meQTL), suggesting that CpGs are more similar between twins due to genetic variation. We further show that aberrantly methylated CpGs are also enriched for being near genetic variants and associated with meQTLs, suggesting that a significant proportion of aberrant sites are due to genetic variation among lines. However, methylation aberrancy can also be strongly associated with clone-specific effects independent of genetics. Of note, aberrant sites are enriched in specific chromatin states and recurrent across studies. Our study shows that while genetic variation regulates most genome-wide methylation levels, there appears to also be a non-genetic chromatin-based mechanism underlying some variant and aberrant sites.

Systematic identification and characterization of regulatory elements derived from human endogenous retroviruses. *J. Ito[1,2], S. Yamada[1], R. Sugimoto[1], T. Kimura[1], H. Nakaoka[1], I. Inoue[1,2].* 1) Human genetics, National Institute of Genetics, Mishima, Japan; 2) School of Life Science, The graduate university for advanced studies (SOKENDAI), Hayama, Japan.

Human genome contains numerous copies of HERVs (human endogenous retroviruses) harboring their own transcriptional regulatory elements. These HERV regulatory elements are important for evolution of host regulatory networks because these elements are shared among numerous copies of HERVs and can affect not only a single gene but also many genes as a coordinate manner. We systematically identified and characterized HERV regulatory elements based on ChIP-Seq datasets produced by *ENCODE* and *Roadmap Epigenomics*. We particularly focused on regulatory elements that originally existed in HERVs before their integrations, termed HERV conserved regulatory elements (HCREs). Total 1,300 types and 85,000 sites of HCREs were identified from 300 HERV types. HERVs frequently have HCREs working in pluripotent cells, endoderm linages, and hematopoietic cells, besides CTCF binding sites. Some HERV types such as LTR5_Hs and LTR7 have subtype-specific HCREs, indicating regulatory elements of them were dynamically changed during genomic expansions of them. Genomic positions of some kinds of HCREs were significantly enriched in regions around genes associated with specific biological processes such as innate immune response, and furthermore, three-dimensional interactions between those types of HCREs and promoters of such genes were confirmed by using chromatin-interactome data generated by Hi-C method, indicating those types of HCREs cooperatively reinforced or modified regulatory networks concerned with such biological processes. Overall, we identified various HCREs that might have been involved in evolution of host regulatory networks. This study provides not only fundamental information to understand impacts of HERVs on host transcriptions but also new insights into transcriptional modulation systems that HERVs or their ancestral retroviruses originally had.

2130F

Environmentally-induced epigenetic variability is associated with metabolic traits. *E. Carnero-Montoro[1], A. Visconti[1], C. Sacco[1,2], P.C. Tsai[1], T.D. Spector[1], M. Falchi[1], J.T. Bell[1].* 1) Department of Twin Research, King's College London, London, London, United Kingdom; 2) Department of Statistical Sciences, University of Bologna, Italy.

Epigenetic modifications have been proposed to play a key role in mediating individuals' phenotypic responses to environmental exposures. Recent epigenome-wide association studies (EWAS) confirm that environmental exposures, such as smoking, are strongly associated with DNA methylation levels in human populations. To date EWAS have predominantly focused on identifying differences in methylation levels. We hypothesize that environmental factors can increase epigenetic variability at functionally relevant genomic regions in individuals after exposure, and that the environmentally-induced epigenetic variability can in turn trigger metabolic responses relevant to disease. Here, we used a twin-based cohort (TwinsUK) to identify CpG-sites within the Illumina Infinium HumanMethylation450 array where the variance in methylation differed between smokers and non-smokers, and we denote these as *environmental variable methylated sites* (envVMS). We identified more than 80 envVMS using two approaches: i) a population-based approach, in which we compared the methylation mean and variance between smokers and non-smokers, and ii) a smoking-concordant MZ twin study, in which we assessed the methylation differences within twin pairs. Heritability analyses confirmed that higher environmental contribution to epigenetic variance was observed at envVMS in smokers. Population-based envVMS are likely to partly capture gene-environment interactions, as opposed to envVMS obtained from the MZ-twin design, and consistent with this hypothesis we observed an enrichment of genotype-by-smoking interactions effects on DNA methylation levels at CpG-sites that were population-unique envVMS. We also assessed the association between envVMSs and metabolic and healthy ageing traits to explore the hypothesized impact of environmental-induced epigenetic variability on disease-related phenotypes. We detect significant associations between methylation at envVMS and a number of metabolic traits only in smokers. Our results support the hypothesis that epigenetic changes can mediate phenotypic plasticity in response to environmental exposures.

2131W

Enabling high throughput next generation sequencing from low input ChIP and cfDNA. *K. Cunningham[1], A. Heguy[2], P. Meyn[2], D. Horvath[3], J. Laliberte[1], S. Sandhu[1], C. Schumacher[1], L. Kurihara[1], V. Makarov[1], T. Harkins[1].* 1) Swift Biosciences, Ann Arbor, MI; 2) New York University, New York, NY; 3) Beckman Coulter, Indianapolis, IN.

Preparation of large quantities of limiting, difficult samples such as cfDNA and ChIP DNA can be a time consuming, challenging process, with the end result of sequencing data that does not support the desired goals of the project. Here we present enabling the generation of high quality data from these limiting, difficult samples by harnessing the power of Accel-NGS® 2S library preparation kits with high-throughput automation on the Beckman Coulter Biomek® FX*ᴾ* Liquid Handling Workstation to prepare large quantities of samples in a timely, robust manner. Highly efficient library preparations that maximize complexity and uniform representation of the genome make the most efficient use of next generation sequencing (NGS) reads and enable comprehensive analysis of DNA samples of limited quality or quantity. End repair of both the 3' and 5' DNA termini utilized in the Accel-NGS 2S Plus and PCR Free DNA Library Kits allows greater efficiency of adapter ligation. Additionally, sequential adapter attachment requires no adapter titration for lower input quantities. Together, these deliver a more complex library requiring less sequencing, reducing the overall sequencing cost for a given sample and enabling production of high quality libraries from low yield ChIP and 10ng input of circulating, cell-free DNA. As little as 100pg of ChIP starting material can be used to generate confident peak calls that are equivalent to ng input quantities, which decreases the number of cells required without loss of data quality. Low input PCR-Free library construction of cfDNA is enabled by Swift's highly efficient adapter ligation and relatively undamaged cfDNA ends, resulting in even higher conversion efficiency of input DNA into functional library molecules. The minimal sequence-dependent bias of Accel-NGS 2S adapter attachment results in libraries that faithfully represent the cfDNA sample. Data quality was determined by analysis of data generated from sequencing on an Illumina® MiSeq®. Optimized Accel-NGS 2S configuration combined with the flexible workflow options and optimized pipetting of the Biomek FX*ᴾ* Liquid Handler minimize consumable use and sample loss and increase lab efficiencies with a walk-away solution capable of generating up to 96 libraries in 4.5 hours. The technology provides the opportunity to use one kit and one automated program to generate libraries from multiple sample types, regardless of their quality and quantity, in a reproducible and accurate manner.

2132T

Joint allelic imbalance analysis of RNA and ATAC sequencing to explore the genomic regulatory landscape. *C.E. Krebs[1], T. Wu[2], L.M. Olde Loohuis[2], R.A. Ophoff[1,2].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA.

The assay for transposase-accessible chromatin using sequencing (ATAC-seq) is a fast and comprehensive way to characterize genomic regulatory variation with regard to chromatin accessibility. Along with other sequencing-based molecular phenotypes, these assays provide precise information about the regulatory landscape of cells, including allele-specific differences between maternal and paternal chromosomes, which can occur as the result of heterozygous *cis*-acting quantitative trait loci (QTL). But, unlike QTL mapping, which requires large sample sizes, detection of allelic imbalance can be done in as few as one individual with simple binomial testing of allelic ratios. In this study, we sought to explore the landscape of allelic imbalance in RNA-seq and ATAC-seq data from lymphoblast cell lines (LCLs) of a HapMap trio, hypothesizing that allele-specific expression (ASE) would coincide with allele-specific chromatin accessibility (ASCA). We were able to determine statistically significant allelic imbalances at heterozygous sites called from whole genome sequencing by using the GATK tool ASEReadCounter, then performing a binomial test at each site using a null allelic ratio of 0.5, followed by a 5% FDR correction of p-values, and finally by filtering out sites with an effect size less than 0.15. Of an average of 2,347,885 heterozygous sites per sample, an average of 16,942 RNA-seq sites and 67,114 ATAC-seq sites per sample passed filters for mapping and base quality and were subject to allele counting by the tool. Of these, an average of 4,556 sites per samples displayed statistically significant ASE and 4,829 displayed ASCA, and an average of 978 genes per sample shared an allelic imbalance in chromatin accessibility and gene expression. Considering that some of these imbalances are caused by base calling errors or by silencing due to imprinting, these numbers are in line with previous studies and indicate that at least some genetic regulation of gene expression is probably mediated by chromatin accessibility. Overall, the joint analysis of allelic imbalance in multiple sequencing-based molecular phenotypes is a powerful way to explore individual genomic regulatory variation and, when scaled up, these assays can be used to elucidate population-level epigenomic variation and could potentially provide insight into the mechanisms of disease-associated genetic variants.

2133F

Global analysis of transcription factor affinity *in vivo.* *A. Stergachis[1,2], H. Wang[2], M. Maurano[2], A. Reynolds[2], L. Yang[3], S. Neph[2], M. MacCoss[2], R. Rohs[3], J. Stamatoyannopoulos[2,4,5].* 1) Internal Medicine, Brigham and Women's Hospital, Boston, MA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Molecular and Computational Biology Program, University of Southern California, Los Angeles, CA; 4) Department of Medicine, University of Washington, Seattle, WA; 5) Altius Institute for Biomedical Sciences, Seattle, WA.

The affinity of a transcription factor (TF) for individual genomic recognition sites in vivo is fundamental to regulatory DNA function, yet remains virtually undefined. We used graded salt perturbation of TF-DNA electrostatic interactions to quantify the relative affinity of the genome regulator CTCF at >20,000 occupancy sites in human cells. We find that the occupancy landscape is fundamentally partitioned between strictly affinity-dependent elements and cooperativity-dependent elements relying on neighboring TFs. The former localize chiefly within compact distal regulatory regions, while the latter are found primarily within promoters and larger distal elements. Cell-selective occupancy is achieved mainly by cooperative utilization of low-affinity binding sites. Affinity appears to be the predominant driver of evolutionary constraint at TF recognition sites, and explains observed occupancy patterns in diverse mammals.

2134W

Epigenomic signatures of high-altitude adaptation. *A. Childebayeva[1,2], D.C. Dolinoy[2], J.M. Goodrich[2], F. Leon-Valerde[3], M. Rivera-Ch[3], M. Kiyamu[3], T.D. Brutsaert[4], A.W. Bigham[1].* 1) Anthropology, University of Michigan, Ann Arbor, MI; 2) Environmental Health Sciences, University of Michigan Ann Arbor, MI; 3) Departamento de Ciencias Biológicas y Fisiológicas, Universidad Peruana Cayetano Heredia, Lima, Peru; 4) Exercise Science, Syracuse University, Syracuse, NY.

High-altitude adapted individuals show distinct circulatory, respiratory, and hematological adaptations to chronic hypoxia. Emerging genetic data support an evolutionary origin and a genetic basis for these observed physiological adaptations to high altitude. However, the epigenetic contribution to adaptation to hypobaric hypoxia has not been characterized. We performed a genome-wide Illumina Infinium MethylationEPIC array on n=28 whole blood samples from individuals of Quechua high-altitude ancestry living in Peru. We performed a differential methylation analysis of the samples between a group recruited at high altitude and a group recruited at low altitude. After normalization of the data, we found n=253 differentially methylated CpG sites between our groups at FDR cutoff 0.05 corresponding to signaling regulation, signaling transduction, cell division, apoptosis, as well as other pathways based on a pathway analysis performed in DAVID. These data show that exposure to high altitude may have an effect on the epigenome, and contribute to our understanding of ways in which the human organism can respond and adapt to environmental conditions. This project was funded by National Science Foundation grant 1132310, the Leakey Foundation and the Department of Anthropology at the University of Michigan.

2135T

Smoking associated methylation quantitative trait loci preferentially map to neurodevelopmental pathways. *M. Dogan[1,2], S.R.H. Beach[3], R. Philibert[1,2,4].* 1) Biomedical Engineering, University of Iowa, Iowa City, IA; 2) Psychiatry, University of Iowa, Iowa City, IA; 3) Center for Family Research, University of Georgia, Athens, GA; 4) Behavioral Diagnostics, Iowa City, IA.

Smoking is the leading preventable cause of morbidity and mortality in the United States. Smoking exerts its effects indirectly by increasing susceptibility to common complex diseases such as coronary heart disease. Our understanding of the molecular mechanisms through which smoking increases vulnerability for these disorders could still be improved. This is especially true for disorders than preferentially involve the central nervous system. Our study was designed to understand the effects of smoking on DNA methylation (DNAm) in the presence and absence of genetic context in the Framingham Heart Study (FHS). Data from 1599 individuals from the FHS Offspring cohort were used. These individuals were in their early to mid-sixties with a self-reported smoking rate of 7.6%. Genome-wide DNAm and SNP data were profiled using the Illumina HumanMethylation 450k BeadChip and Affymetrix GeneChip HumanMapping 500k Array Set, respectively. To understand the effects of smoking on DNAm in the absence of genetic variation, we regressed smoking against DNAm, controlling for age, gender and batch. After correction for multiple comparisons, methylation status at 525 sites was significant at a 0.05 level. Consistent with prior studies, the top-ranking probe was cg05575921 from the *AHRR* gene (p-value of 7.65×10^{-155}). Subsequently, to determine the effects of smoking on DNAm in the presence of genetic variation, cis- and trans-methylation quantitative trait loci (meQTL) analyses were conducted to determine the significant effects of SNP on DNAm given smoking status, controlling for age, gender and batch. A total of 126,369,511 cis and 195,068,554,297 trans analyses were performed. Of those, 5294 (0.00419%) and 422,623 (0.00022%) significant cis- and trans-meQTL were generated after correction for multiple comparisons at a 0.05 significance level. To better visualize and compare the connectivity and gene ontology enrichment between the results of both analyses, we generated protein-protein interaction networks. While the DNAm analysis mapped to inflammatory pathways, the cis- and trans-meQTL analyses mapped to neurodevelopmental pathways. These neurodevelopmental pathways could provide additional insight into the association of smoking to psychiatric disorders. Furthermore, this study demonstrates that combined genetic and epigenetic analyses may be crucial in better understanding the interplay between environmental variables such as smoking and pathophysiological outcomes.

2136F

Systematic detection of spatiotemporal patterns of epigenetic changes. *P. Fiziev, J. Ernst.* Biological Chemistry, University of California, Los Angeles, Los Angeles, CA.

Post-translational histone modifications associate with important regulatory regions such as promoters and enhancers that control the expression of genes. Time-course genome-wide maps of these epigenetic marks have become available in a growing number of biological systems. Here, we present a novel computational method for systematic detection of major classes of spatio-temporal patterns of epigenetic changes. It takes as input data from a series of chromatin immunoprecipitation followed by high throughput sequencing (ChIP-seq) experiments for a single histone mark that are performed at consecutive time points during a given biological process. The method identifies regions for which the mark either expands or contracts significantly with time or holds steady. The classification is based on a Bayesian network that models explicitly the movements of domain boundaries across time points. We show applications of our method on multiple available datasets that characterize chromatin dynamics in different biological systems. We find that spatial dynamics of specific histone marks are coordinated and occur at key locus control regions that regulate genes involved in establishing and defining cell type identity. Expanding and contracting domains also associate with differential transcription factor binding. In addition, our method enables uniquely to study asymmetric spatial patterns such as unidirectional expansions and contractions and compare them to bidirectional patterns. We find that asymmetric directional dynamics are overrepresented in promoter proximal regions and correlate strongly with direction of transcription. Our method is generally applicable to a wide range of time series ChIP-seq data and thus can help in understanding the chromatin dynamics in many biological systems.

2137W

Effects of socioeconomic status on early life DNA methylation. *S.J. Goodman[1,2], W.T. Boyce[3,4,5], S. Lam[4], J.L. MacIsaac[1], M.J. Jones[1], S.M. Mah[1], A. Zaidman-Zait[4], M.S. Kobor[1,2,3,4].* 1) Centre for Molecular Medicine and Therapeutics, BC Children's Hospital, Vancouver, British Columbia, Canada; 2) Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 3) Child and Brain Development, Canadian Institute for Advanced Research, Toronto, Ontario, Canada; 4) Human Early Learning Partnership, University of British Columbia, Vancouver, British Columbia, Canada; 5) Pediatrics, UCSF School of Medicine, San Francisco, California, USA.

   Rationale: Socioeconomic status (SES) is a potent environmental determinant of human health. Childhood experiences of SES alter development and lead to health disparities later in life, suggesting that they become 'biologically embedded'. DNA methylation represents an ideal candidate mechanism of biological embedding as it mediates interactions between genetic background and the environment and is especially plastic during developmental periods. Therefore, it has been proposed that epigenetic patterns established in early life as a result of unique experiences and exposures may influence future health outcomes. One major obstacle to uncovering these differences is that SES is heavily confounded with ethnicity in both Canada and the US; this presents a challenge as genetic background strongly contributes to epigenetic variation. We hypothesize that socially driven differential DNA methylation exists in children from diverse socioeconomic backgrounds and, importantly, these methylation patterns can be teased apart from ethnically driven DNA methylation differences. **Methods:** Gene Expression Collaborative for Kids Only (GECKO) is a cohort of 400 socioeconomically diverse, 8-10 year old children which was established to study the biological embedding of early life socioeconomic-related adversity. Using the Illumina Human Methylation 450K array platform to assay DNA methylation and the Illumina PsychArray BeadChip to evaluate SNPs, we have examined genetic, epigenetic, and environmental interplay as it relates to childhood SES. **Results and implications:** Genetic heritage was calculated from the PsychArray data and used to correct for the unequal division of ethnic groups across SES. Epigenetic correlates of childhood SES, as measured by family income, parent occupation and education, uncovered a set of candidate loci, irrespective of genetic heritage. These loci may underlie biological embedding of early life SES. These findings were supported by a parallel weighted gene co-expression network analysis (WGCNA), applied to uncover networks of co-methylated CpGs associated with SES. The strength of WGCNA is that it not only assesses the relationship between DNA methylation and a variable of interest, but it also uncovers relationships between the CpGs themselves. This tool, when paired with traditional EWAS methods may bring us closer to identifying epigenetic disturbances common to early childhood adversity and their relationship to later health outcomes.

DNA methylation concordance in pediatric blood and buccal tissues. *S.A. Islam[1,2], S.J. Goodman[1,2], J.L. MacIsaac[1,2], R.G. Barr[3,6], W.T. Boyce[4,6], M.S. Kobor[1,2,5,6].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Centre for Molecular Medicine and Therapeutics, BC Children's Hospital, Vancouver, BC, Canada; 3) Department of Pediatrics, University of British Columbia, Vancouver, BC, Canada; 4) Departments of Pediatrics and Psychiatry, University of California, San Francisco, USA; 5) Human Early Learning Partnership, University of British Columbia, Vancouver, British Columbia, Canada; 6) Canadian Institute for Advanced Research, Toronto, Ontario, Canada.

   Recently, population epigenetic studies have become prominent in the field of developmental origins of health and disease (DOHaD). To date, this research has largely focused on identifying differences in DNA methylation (DNAm) associated with early life exposures, demographic factors, or disease states using accessible human tissues, such as peripheral blood and buccal epithelial cells (BECs). Although it is well established that tissue of origin is a main driver of DNAm variability, along with genetic background, there is relatively little known about intra-individual DNAm variation across tissues particularly in pediatric samples. It is also unclear how genetic variation may influence tissue-specific DNAm. Given the widespread use of these accessible tissues for inferring phenotype associations to DNAm, it is important to ask how these tissues compare in terms of DNAm variability at various developmental stages and to assess how genetic differences impact DNAm variance. In this study, we assessed the concordance of genome-wide DNAm profiles between matched peripheral blood mononuclear cells (PMBCs) and BECs in two independent cohorts of children aged 3-4 years old (n = 16) and 8-9 years old (n = 77). Specifically, we compared DNAm variance across ~430,000 sites, measured using the Illumina Infinium HumanMethylation450 BeadChip. Correlation of DNAm measures across individuals within a tissue revealed an appreciable number of highly-correlated sites with discrete distributions, signifying a potential genetic influence on DNAm at these sites. Using the Illumina Infinium PyschArray, we measured genetic variation at over ~500,000 single nucleotide polymorphisms (SNPs) and identified sites, known as methylation quantitative trait loci (mQTLs), which significantly associated with DNAm within a 5 kb window (FDR < 0.05). We found that although a substantial number of these cis-mQTLs were tissue-specific, there were also many sites which were shared across tissues as well as a number which showed a regional association with DNAm. Taken together, the work presented here offers insight into tissue-specific DNAm variability in pediatric samples and the influence of genetic variation on DNAm variance to help guide decisions on the selection of appropriate tissue samples and the interpretation of findings in population epigenetic studies.

DNA methylation at birth is associated with prenatal exposure to alcohol, cigarette smoke, and illicit drugs. *M.J. Jones[1], N. Koen[2], J.L. MacIsaac[1], A.M. Morin[1], K. Donald[2], A. Vanker[2], K.C. Koenen[3], H.J. Zar[2], M.S. Kobor[1], D.J Stein[2].* 1) University of British Columbia, Vancouver, British Columbia, Canada; 2) University of Cape Town, Cape Town, South Africa; 3) Harvard University, Boston, Massachusetts, USA.

Rationale: Alterations in DNA methylation at birth have been associated with prenatal exposures, and the potential for these marks to last throughout the lifetime presents a possible mechanism for the developmental origins of health and disease. We assessed DNA methylation changes present at birth in a cohort of 150 children from Drakenstein, South Africa, with high frequency of prenatal exposure to alcohol, cigarette smoke, and illicit drugs, in an effort to understand how these early exposures can be associated with lifelong health. Methods: We evaluated DNA methylation in cord blood collected at birth using the Illumina 450k array. We identified a subset of samples showing contamination with maternal blood, and created a screening protocol to identify and exclude these contaminated samples from this and future analyses. As cord blood cell types had not been measured, we used a reference-free method to control for inter-individual differences in cell type. Results: We identified DNA methylation changes associated with alcohol, smoking, and illicit drug exposure. Cigarette smoke exposure results were consistent with previous reports, exhibiting changes at the *AHRR* and *CYP1A1* genes among others. We also compared all three types of exposure to determine whether they cause independent or overlapping signatures of DNA methylation at birth, and whether they were occurring at similar or different types of genomic features. Conclusions and future directions: Prenatal exposures to alcohol, cigarette smoke, and illicit drugs leave behind a residue of exposure in the form of DNA methylation changes present at birth. These changes have the potential to last and influence health trajectories for the rest of the child's life. It is important to assess the persistence of these marks as well as the molecular-level outcomes to fully understand how DNA methylation may connect early life exposures to later life health. Longitudinal studies with detailed data collection may also be able to identify the timing of windows of opportunity when these exposures may become biologically embedded.

Identifying differentially methylated regions (methylome changes) in response to heavy, long-term cannabis use, in a large longitudinal cohort. *A.J. Osborne[1], J.F. Pearson[4], L.J. Horwood[5], D. Macartney-Coxson[3], T.A. Hore[2], N.J. Gemmell[2], M.A. Kennedy[1].* 1) Department of Pathology, University of Otago Christchurch, Christchurch, Canterbury, New Zealand; 2) Department of Anatomy, University of Otago, Dunedin, Otago, New Zealand; 3) Environmental Science and Research, Kenepuru Science Centre, Porirua, New Zealand; 4) Dean's Department, University of Otago Christchurch, Christchurch, Canterbury, New Zealand; 5) Psychological Medicine, University of Otago Christchurch, Christchurch, Canterbury, New Zealand.

Cannabis use is an important global public health issue, and a growing topic of controversy and debate. There is strong evidence that heavy cannabis use is associated with increased risk of adverse outcomes in a number of areas, including educational achievement, mental health, other illicit drug use and motor vehicle collisions. Many of these findings are drawn from the work of the Christchurch Health and Development Study (CHDS), a longitudinal study of a birth cohort of 1265 children born in 1977 in Christchurch, New Zealand, who have been studied on 23 occasions from birth to the age of 35 (n=987). In the early 1990s, research was initiated into the development and consequences of cannabis use. Drug metabolism, response and addiction have strong genetic components, and multiple genome-wide association studies (GWAS), including studies on the CHDS cohort, have identified genes and allelic variants that are likely contributors to substance use disorders. However, it is clear that not all biological responses are determined by direct changes in DNA sequence. Environmental factors, including drugs, can lead to epigenetic alterations, which are an important source of variation and regulation in the genome. Methylation is one such alteration, and can influence chromatin structure and alter gene expression. This can result in an epigenetic pattern that is quite specific to individual environmental exposures. For example, differentially methylated regions (DMRs) have been identified that are specifically modified in smokers versus non-smokers. It stands to reason that long-term, heavy cannabis use will also similarly affect the methylation status of users and that there will be epigenetic hallmarks of cannabis use. We are utilising Illumina EPIC 850K methylome arrays to identify DMRs in a subset of CHDS participants. The rich, lifetime psychosocial data available for the CHDS cohort mean we are able to control for cigarette smoking and other important environmental factors, during the discovery phase of this study. We anticipate that DMRs we discover may be located in genes, or regulatory regions, that are important in the biological response to cannabis. By highlighting genes and pathways that are influenced by long term cannabis use, we will better understand the impacts of cannabis on genome function, provide insights into human responses to cannabis, potential adverse and medical effects, and inform current public debates about cannabis.

2141T

Genomic context drives the conservation of enhancer activity across species. *A. Fish[1], L. Chen[2], J. Capra[1,2].* 1) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 2) Biological Sciences, Vanderbilt University, Nashville, TN.

Despite broad conservation of gene expression and transcription factor (TF) binding preferences across species, there is substantial turnover in enhancer activity patterns. Analyses of sequence-level differences between orthologous regions do not explain the majority of variance in enhancer activity. In this study, we evaluated whether DNA sequence patterns and functional genomics data could distinguish enhancers active in the livers of ten diverse mammalian species (activity-conserved) from those with orthologous sequence present across the ten species, but active only in human (human-specific). Activity-conserved and human-specific liver enhancers exhibit some differences at the DNA sequence level; e.g., activity-conserved enhancers have twice the density of TF binding motifs. However, a support vector machine (SVM) classifier trained on DNA sequence patterns (6-mer spectra) had only a modest ability to distinguish activity-conserved from human-specific enhancers (ROC AUC: 0.65). Integrating epigenetic modifications, TF binding, and chromatin accessibility significantly improved prediction of enhancer activity across species (ROC AUC: 0.84). Functional genomics features traditionally associated with enhancers, such as H3K27ac and H3K4me1, were most predictive of activity conservation, including those from cellular contexts other than liver. Further, activity-conserved liver enhancers overlapped enhancers active in other human cellular contexts at a significantly higher rate than human-specific enhancers. Our results illustrate that sequence changes alone are likely insufficient to account for the variable enhancer activity of orthologous sequences across species, and that the genomic environment influences conservation of activity patterns.

2142F

Genetic and transcriptional analysis of human host response to healthy gut microbiome. *A. Richards[1], M. Burns[2,3], A. Alazizi[1], L. Barreiro[4], R. Pique-Regi[1,5], R. Blekhman[2,3], F. Luca[1,5].* 1) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI; 2) Departments of Genetics, Cell Biology, and Development, The University of Minnesota, Minneapolis, MN; 3) Department of Ecology, Evolution, and Behavior, The University of Minnesota, Minneapolis, MN; 4) Department of Pediatrics, Sainte-Justine Hospital Research Centre, University of Montreal, Montreal, QC, Canada; 5) Department of Obstetrics and Gynecology, Wayne State University, Detroit, MI.

The gut microbiome has been shown to play a role in both healthy and diseased states. Several recent studies have linked human genetic variation to changes in the composition of the microbiome. However, establishing the causality of host-microbiome interactions in humans is still challenging. Here, we present a novel experimental system to characterize the transcriptional response induced by the microbiome in human cells and shed light on the molecular mechanisms underlying host-gut microbiome interactions. We cultured primary human colonic epithelial cells in low oxygen to recapitulate the gut environment together with the gut microbiome of healthy individuals extracted from fecal samples. We sequenced the RNA from each sample and identified over 6,000 host genes that change expression following co-culturing with the gut microbiome as compared to colonocytes cultured alone. The differentially expressed genes are enriched for genes associated with several microbiome-related diseases, such as obesity and colorectal cancer. In addition, we identified 87 host SNPs that show allele-specific expression in 69 genes. For 12 SNPs in 12 different genes, allele-specific expression is conditional on the exposure to the microbiome. Of these 12 genes, eight have been associated with diseases linked to the gut microbiome, specifically colorectal cancer, obesity and type 2 diabetes, suggesting that these genes may link the microbiome mechanistically to these diseases. For example, *LASP1*, a gene involved in the cytoskeleton and cell migration, had an elevated total expression as well as allele-specific expression only following co-culturing with the microbiome. Furthermore, *LASP1* expression is increased in colorectal cancer suggesting that the microbiome may influence colorectal cancer through modulation of *LASP1* expression in a genotype-specific manner. Our study demonstrates a scalable approach to study host-gut microbiome interactions and can be used to identify putative mechanisms for the interplay between host genetics and microbiome in health and disease.

2143W

The analysis of conserved non-coding elements and topologically associating domains reveals strong spatial correlation between them. *B. Ambroise, J.C. Fischer, L.E. Hunt, G. Elgar.* The Francis Crick Institute, London, United Kingdom.

The recent development of genome wide chromosome conformation capture (Hi-C) has permitted the study of chromatin interactions within the nucleus. The resulting interactions maps show that that genomes can be divided into large local chromatin domains termed Topologically Associated Domains (TADs). Within TADs, the genome appears to be organized to favour strong internal chromatin interactions rather than external interactions with neighbouring TADs. It has also been suggested that TADs might help to de-lineate basic genomic functions such as gene regulation. Interestingly, TADs also appear to be conserved across species and cell types. Identifying cis-regulatory elements of genes has been a major challenge. Comparative genomics has revealed the existence of conserved non-coding elements (CNEs) in vertebrates. Multiple lines of evidence suggest that these non-coding units are cis-regulatory elements associated with key developmental genes. Using CNEs clusters extracted from the CONDOR database, we investigated whether CNEs and TADs were spatially correlated in the human genome. We looked at different parameters such as absolute and relative distances, overlap of the regions and correlation of the boundaries. In addition, we performed 10,000 simulations to measure the statistical robustness of our analysis. In some cases, we observed that CNE clusters were split between multiple TADs. As a result, CNEs within such clusters were tested for enhancer activity in GFP-reporter gene assays in zebrafish embryos. Our results show that CNE clusters are not randomly distributed across the genome but are in fact distributed with respect to the TAD architecture. Furthermore, zebrafish reporter assays showed that CNEs within one cluster can be associated with more that one developmental gene. This confirmed that TAD boundaries are true functional boundaries and could potentially help to better identify cis-regulatory elements among CNEs.

2144T

Outlier gene expression networks identify functional rare variants. *J.R. Davis[1], E.K. Tsang[2], B. Strober[3], X. Li[4], Z. Zappala[1], L. Fresard[4], A. Battle[5], S.B. Montgomery[1,4].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Biomedical Informatics Program, Stanford University, Stanford, CA; 3) Department of Biomedical Engineering, Johns Hopkins University, Baltimore, MD; 4) Department of Pathology, Stanford University, Stanford, CA; 5) Computer Science Department, Johns Hopkins University, Baltimore, MD.

Although well powered to discover common regulatory variants, *cis*-eQTL studies have largely overlooked the impact of rare regulatory variation (MAF < 1.0%). Recent efforts have leveraged gene expression outliers to study the effects of functional, rare regulatory variants; however, these studies have been limited by sample size and mostly focused on individual genes. Existing methods to discover expression outliers across genes in a regulatory module have been limited to single tissues and have focused only on cohorts lacking genome-sequencing data. In this project, we extend methods to detect outlier gene expression across multiple genes in a regulatory network and compare results across tissues. By examining the correlation of outlier effects through a network, we can enrich for high quality expression outliers and rare regulatory variants with broad effects across multiple genes. We applied our detection methods to the 5 most widely sampled tissues in the GTEx dataset: muscle, whole blood, skin, adipose subcutaneous, and tibial artery (minimum sample size of 285). For each tissue, we first constructed gene expression networks using a multivariate normal model with L1-regularization to induce sparsity. Using the estimated covariance matrices, we then identified individuals who show significant outlier expression across a given module. We show that these multi-gene outliers are enriched for potentially functional, rare regulatory variants such as promoter variants and highly conserved non-coding variants. By examining specific outlier modules, we show that these rare variants appear to directly influence only a subset of genes, though their effects can appear throughout the module. Finally, we use our methods in a recently developed dataset of undiagnosed rare disease samples to discover regulatory modules with outlier expression compared to healthy GTEx controls. By combining information across gene modules, we assess our power to discover outlier expression effects that are enriched for disease-relevant genes. Our results highlight the importance of considering gene networks to detect functional, rare regulatory variants.

2145F

Functional annotation of the genome using a high-throughput enhancer assay that retains sequence and chromosomal context. *J.C. Klein[1], J. Shendure[1,2].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Functional annotation and variant effect prediction in DNA regulatory elements remain major challenges for the field. ChIP-seq, chromatin accessibility and computational approaches have addressed these questions in part, but fail to provide functional validation of specific elements. Massively-parallel reporter assays (MPRAs) allow the direct read-out of the effects of thousands of sequences on transcriptional activity. However, current MPRAs test the ability of short sequences to increase transcription of a nearby reporter on a plasmid. This design inherently misses several characteristics of *in vivo* enhancer elements: 1) enhancers can be longer than the 200bp limit imposed by array-synthesis, 2) it is unlikely that plasmids reflect native chromatin, and 3) enhancers can be located as far as 1MB from their target promoter. To address these limitations, we developed a new class of MPRAs to screen libraries of assembled synthetic sequences for enhancer function in the context of a native, chromosomal locus.   The assay measures the ability of a given sequence to increase the expression of *LMO2*, a gene whose up-regulation resulted in leukemia-like symptoms in several SCID gene therapy patients, when inserted into *LMO2*'s 3' UTR. Unlike conventional episomal MPRAs, where up to 20% of randomly selected sequences can drive transcription, our assay appears to have high specificity. When negative control and LTR fragments were inserted at a similar ratio into the 3'UTR of *LMO2,* 99.8% of all RNA transcripts contained a LTR fragment. Of the 0.2% of RNA transcripts containing the negative control sequence, none were enriched relative to genomic DNA. We are currently screening libraries of thousands of putative enhancer elements in several cell types, including Jurkat T cells, Hek293T cells, HepG2 and GM12878. Using multiplex pairwise assembly of array-derived oligonucleotides, we are screening the same set of putative enhancers both as 173-mers and 352-mers to directly compare the effects of additional sequence context on function.   We are also using this assay to characterize the effects of thousands of GWAS-implicated variants on enhancer function in their appropriate cell lines, with the goal of identifying causal variants for these associations.

2146W

Pinpointing noncoding sequence variation affecting transcription factor occupancy. *M.T. Maurano[1], J.M. Halow[2,3], R. Byron[4], M. Groudine[4], M.A. Bender[4], J.A. Stamatoyannopoulos[2,3].* 1) Institute for Systems Genetics, New York University Langone Medical Center, New York, NY 10016, USA; 2) Department of Genome Sciences, University of Washington, Seattle, WA 98195, USA; 3) Altius Institute for Biomedical Sciences, Seattle, Washington, USA; 4) Fred Hutchinson Cancer Research Center, Seattle, WA 98109, USA.

The function of human regulatory regions depends exquisitely on their local genomic environment and on cellular context, complicating experimental analysis of common disease- and trait-associated variants that localize within regulatory DNA. Allelic profiling of chromatin accessibility across individuals has shown that a minority of sequence variation affects transcription factor (TF) occupancy, yet the low sequence diversity in human populations means that no experimental data are available for the majority of disease-associated variants. We performed deep allelic profiling of chromatin accessibility in F1 hybrids of highly diverged mouse strains and generated high-resolution maps of variants affecting TF activity at their native locus and chromatin environment. The high density of heterozygous sites in these strains enables a precise quantification of the effect size and cell-type specificity of variants associated with altered chromatin accessibility throughout the genome. We develop a compendium of TF-specific sensitivity profiles to account for genomic context effects and model cell-type specific perturbations of the protein-DNA interface. Taking advantage of the high conservation of TF coding sequence among mammals, we apply these models to the classification of single nucleotide polymorphisms in the human genome. These models enable quantitative prediction of the effect of non-coding variation on TF activity across a variety of cellular contexts, facilitating both fine mapping and systems-level analyses of common disease-associated variation in human genomes.

2147T

Genetics of local gene expression across 44 human tissues. *S. Montgomery[1], C. Brown[2], GTEx Consortium.* 1) Departments of Genetics and Pathology, Stanford University, Stanford, CA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Genetic studies of gene expression provide powerful means to identify functional non-coding variants influencing local gene expression and underlying disease pathogenesis. However, to date, many of these studies have been performed in a limited number of tissues in diverse cohorts and individuals. Moreover, such studies have been biased towards tissues that are more readily obtained but may be less relevant for the interpretation of human disease. We present the identification of cis-eQTLs from 44 distinct tissues examined in 70 to 361 individuals in the latest release of the GTEx project (v6). Relative to the GTEx pilot release, this analysis represents a large expansion that has now surveyed an additional 35 tissues and identified thousands of additional eSNPs and eGenes. We discover that 87% of genes have an eQTL and uncouple multiple signals of association for each gene. This abundance of eQTL highlights the need for increased care in using these data for the interpretation of GWAS; indeed, we find that 94% of all SNPs are nominally associated with the expression of one or more genes across GTEx. Further, we discover an increasing number of tissue-type specific eQTLs that are uncovered due to increases in sample size and highlight a unique identity in each surveyed tissue. By integrating large-scale epigenomics data, diverse genome annotation and state-of-the-art fine-mapping algorithms, we provide high resolution analysis of the relationship between cross tissue gene regulation and genetic control of gene expression and identify the features of tissue-specific and shared causal variants. By integrating broader maps of allele-specific expression across tissues we enhance measures of sharing of eQTL. The broad tissue sampling design of GTEx enables us to assess the relationship between studies with large numbers of samples versus large numbers of tissues and their relative utility in interpreting GWAS signals. Finally, we highlight the growing compendium of data available on the GTEx Portal (from v7 onwards). Together, the GTEx project delivers an increased understanding of the genetic control of gene expression across a broad range of cell types and demonstrates exceptional utility for improving our understanding of gene regulation and human genetics.

2148F

Dissecting the functional architecture of local and distal gene expression regulation in multiple human tissues. *X. Liu[1], H.K. Finucane[1,2], A. Gusev[1], G. Bhatia[1], S. Gazal[1], B. Bulik-Sullivan[3,4], F.A. Wright[5], P.F. Sullivan[6], B.M. Neale[3,4], A.L. Price[1,7].* 1) Department of Epidemiology, Harvard Chan TH School of Public Health, Boston, MA; 2) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Bioinformatics Research Center, North Carolina State University, Raleigh, North Carolina, USA; 6) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 7) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Genetic variants that modulate gene expression levels play an important role in the etiology of human diseases and complex traits. Large-scale eQTL mapping studies routinely identify large numbers of local eQTLs, but the molecular mechanisms by which genetic variants regulate expression is as yet unclear, particularly for distal eQTLs, which these studies are not well-powered to detect. In this study, we use a heritability partitioning approach to dissect the functional architecture of local and distal gene expression regulation in 15 human tissues. Using an extended version of stratified LD score regression to analyze large expression data sets, we leverage all variants—not just those that pass stringent significance thresholds—to achieve this goal. For both local (within 1Mb of TSS) and distal gene regulation, we estimate the proportion of SNP-heritability explained by SNPs in each functional category and define enrichment as this proportion divided by the proportion of SNPs in each category. We compute standard errors via a block jackknife on genomic regions. In analyses of gene expression in peripheral blood (N=2,494) (Wright et al. 2014 Nat Genet), the top enriched functional categories in local regulation included super enhancers (5.18x), coding regions (3.73x), conserved regions (2.33x) and four histone marks ($p < 3 \times 10^{-7}$ for all enrichments). These enrichments were more statistically significant (though somewhat smaller) than analogous enrichments previously reported for complex traits, emphasizing the large amount of signal in gene expression data. Very similar enrichments were observed across 14 tissues from the GTEx (GTEx Consortium 2015 Science) and MuTHER (Grundberg et al. 2012 Nat Genet) data sets. We also observed pervasive enrichments for distal regulation of peripheral blood gene expression: super enhancers (1.91x), coding regions (4.47x), conserved regions (4.51x) and two histone marks ($p < 3 \times 10^{-7}$ for all enrichments). These results are the first to systematically identify enrichments of distal regulatory elements. Genetic correlation of gene expression across tissues suggests that local gene expression regulation is largely consistent across tissues (average $r_g=0.738$), whereas distal regulation of gene expression is highly tissue-specific (average $r_g=0.084$). Overall, our study quantifies the importance of super enhancers, conserved regions, coding regions and histone modifications in the local and distal regulation of gene expression.

2149W

Finer analysis of the correlation between SNP, CpG methylation and gene expression. *F. Takeuchi.* Research Institute, Nat Cntr for Global Health & Med, Shinjuku-ku, Tokyo, Japan.

It has been known that CpG methylation level in promoter and gene expression level are negatively (i.e, inversely) correlated. However, recent studies involving genome-wide assays in hundreds of human samples discovered many positively-correlated loci as well as those negatively-correlated. Aiming to understand the molecular mechanism behind the complex relation, I analyzed the correlation between SNP, CpG methylation and gene expression. I used publicly available experimental data and applied statistical analyses including 1) classification of CpG sites according to locations in genes, 2) prediction of transcription factor binding motif disruption by SNP, and 3) extraction of sparse primary relations from the graph representing the correlation between SNP, CpG methylation and gene expression. This approach can help understand inter-individual variation of epigenomes, which likely underlies susceptibility to complex diseases.

2150T

Synthetic long non-coding RNAs (SINEUPs) rescue defective gene expression *in vivo.* A. Indrieri[1], C. Grimaldi[1], S. Zucchelli[2,3], R. Tammaro[1], S. Gustincich[2,4,5], B. Franco[1,6]. 1) Telethon Institute of Genetics and Medicine (TIGEM), 80078, Via Campi Flegrei 34, Pozzuoli (NA), Italy; 2) Area of Neuroscience, SISSA, 34136, Trieste, Italy; 3) Dipartimento di Scienze della Salute, Universita' del Piemonte Orientale, Novara, Italy; 4) Department of Neuroscience and Brain Technologies, Italian Institute of Technology, 16163, Genova, Italy; 5) TransSINE Technologies, 1-7-22 Suehiro-cho Tsurumi-ku, Yokohama, Kanagawa 230-0045 Japan; 6) Medical Genetics Services, Department of Translational Medicine, Federico II University, 80131, Naples, Italy.

Non-coding RNAs provide additional regulatory layers to gene expression as well as the potential to being exploited as therapeutic tools. Non-coding RNA-based therapeutic approaches have been attempted in dominant diseases, however their use for treatment of genetic diseases caused by insufficient gene dosage is currently more challenging. SINEUPs are long antisense non-coding RNAs that up-regulate translation in mammalian cells in a gene-specific manner, although, so far evidence of SINEUP efficacy has only been demonstrated in *in vitro* systems. We now show that synthetic SINEUPs effectively and specifically increase protein levels of a gene of interest *in vivo*. We demonstrated that SINEUPs rescue haploinsufficient gene dosage in a medakafish model of a human disorder leading to amelioration of the disease phenotype. Our results demonstrate that SINEUPs act through mechanisms conserved among vertebrates and that SINEUP technology can be successfully applied *in vivo* as a new research and therapeutic tool for gene-specific up-regulation of endogenous functional proteins.

2151F

Family studies identify transcripts with strong parent-of-origin effects in whole blood. *W.-C. Hsueh[1], J.E. Curran[2], H.H.H. Göring[2], R.L. Hanson[1].* 1) NIDDK, Phoenix, AZ; 2) South Texas Diabetes and Obesity Institute, School of Medicine, University of Texas Rio Grande Valley, Brownsville, TX.

A parent-of-origin effect (POE) describes the phenomenon where differential effects are observed depending on which parent transmitted the allele. In model systems and human studies, a growing number of examples of POEs are found to influence phenotypic variation, and some studies suggest that POEs are widespread. In studies of complex traits, the incorporation of POE can increase statistical power to identify risk variants by the use of a more precise genetic model. In this study, we analyzed the role of POEs in transcripts expressed in whole blood measured on the Illumina Human-HT12-v4 BeadChip in a family study including 750 Southwestern Native Americans. This sample is comprised of 3,408 self-reported relative pairs, including 610 full-sib pairs and 203 half-sib pairs. Levels of 15,521 transcripts that were expressed above background and which did not contain SNPs were analyzed. Familial resemblance was modeled using classic pedigree-based variance components methods with models assessing the additive heritability (h^2), dominance (d^2) and POE with separate maternal and paternal effects (h^2_M, h^2_P). Models were adjusted for effects of age, sex, Amerindian heritage and tribal affiliations. A false discovery rate (FDR) of ≤0.05 was considered significant. Of all transcripts analyzed, the mean heritability was 0.26, and 79% had significant additive heritability (mean h^2=0.30±0.09). None was found to have significant dominance (mean d^2=0.07). Over all transcripts mean h^2_M=0.20 and mean h^2_P=0.12. We identified 20 transcripts (from 20 genes) with significant POEs and significant differences in h^2_M and h^2_P; 18 showed significant evidence for increased paternal expression and 2 had significantly increased maternal expression. The h^2 for these 20 transcripts with significant POEs was higher compared to h^2 for those without significant POE (0.41±0.11 vs. 0.26±0.12, p<0.0001). None of these 20 genes are known imprinted genes. Heritability of transcripts expressed in whole blood is substantial and might be mostly explained by additive effects; however, our study identified a subset of transcripts that with strong POEs. Their effects on traits may be more appropriately modeled by incorporating POE, which will increase the statistical power to detect their effects. In addition, statistical modeling of POE may help to identify candidate genes of greater priority for experimental verification of imprinting.

A high-resolution landscape of transcriptional regulation unraveled by Transcription Initiation QTL (tiQTL). *H. Kwak[1,2], H.M. Kang[2].* 1) Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Uncovering the functional elements of the human genome is accelerating the expansion of our basic biological knowledge of the regulation of gene expression. Recently, transcription at the regulatory elements such as enhancers has been discovered by high depth RNA-seq and nascent RNA sequencing methods, and some were shown to have direct functional role in target gene activation. However, it is still unclear what the impact of genetic variation is on the enhancer transcription, how the variations of the chromatin accessibility and modification states interpret into the transcription of target promoters, and whether the enhancer transcription is a mediator or a byproduct of enhancer activity. Therefore it becomes critical to directly map and measure the transcriptional activities at these regulatory elements. To address these questions, we present a genetic landscape of the transcriptional activity, by sequencing nascent RNAs of lymphoblast cell lines of 69 individuals in the Yoruban population. The nascent RNA sequencing revealed a precise map of enhancer transcription activities and transcription at promoters. We performed a Transcription Initiation Quantitative Trait Loci (tiQTL) analysis, and identified 1,053 unique transcription sites significantly associated with at least one genetic variant at FDR <0.1. While the majority of cis-tiQTLs were <10kb away from the corresponding TSS, 18% of cis-tiQTLs were located >100kb away from the TSS, suggesting long-range interaction between genetic variants and enhancer transcription activities. We observed that 34% of tiQTLs overlap with DNase hypersensitivity QTLs (dsQTLs), and these overlapping tiQTLs show 40% larger effect sizes than corresponding dsQTLs on average. We present examples of tiQTLs that have constantly open chromatin and not dsQTLs but are eQTLs. These findings suggest that enhancer transcription provides specific information on the mechanism by mediating target promoter activation and is not just a byproduct of chromatin accessibility. We also present examples of tiQTLs at upstream antisense transcription sites and the first intronic regions of which the effect sizes anti-correlate with the eQTL, suggesting possible repressive mechanisms of these previously less understood transcriptional activities. Results of our study will further expand the understanding of the genetic variation of active enhancer transcription, and their relationship with gene expression levels.

Fine mapping gene expression associations in IPS-derived sensory neurons with ATAC-seq. *J. Schwartzentruber[1], J. Rodrigues[1], A. Knights[1], K. Alasoo[1], A. Goncalves[1], M. Patel[1], S. Foskolou[2], R. Ferreira[2], C. Benn[2], A. Wilber[2], M. Bictash[2], E. Impey[2], L. Cao[2], L. Vincente[2], A. Loucif[2], P. Whiting[2], A. Gutteridge[2], D. Gaffney[1], HIPSCI Consortium (http://www.hipsci.org).* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) Pfizer Neuroscience and Pain Research Unit, Pfizer Ltd., Great Abington, Cambridge, United Kingdom.

Sensory neurons relay information from the tissues to the central nervous system, but are extremely challenging to study in humans, with primary cells only available via invasive tissue biopsy. Pain-sensing neurons are of particular interest because pain symptoms are a component of many diseases, and at least 10% of adults suffer from chronic pain. Sensory neurons derived from human induced pluripotent stem cells (hIPSCs) are a potentially promising *in vitro* model for pain. We differentiated sensory neurons from 97 IPS lines derived from healthy individuals by the Human Induced Pluripotent Stem Cell Initiative (HIPSCI) and measured gene expression (RNA-seq N=97), chromatin accessibility (ATAC-seq N=31), and neuron electrophysiology (N=30 to 56). We used single cell RNA-seq from one reference sample to identify markers of sensory neurons and other contaminating cell types, which enabled us to estimate the purity of our cell lines lacking scRNA-seq data. Using an allele-specific method, we detect over 3000 eQTLs, 2000 splice QTLs, and 6000 chromatin accessibility QTLs at an FDR of 10%, and show how the data can be used to fine map putatively causal variants for human neurological disease. Using our electrophysiology data we also find several genes with significant associations between gene expression and neuronal excitability across individuals. Our study illustrates how IPS-based model systems can be used to understand the functions of common genetic variants in neuronal cell lineages.

2154F

Identifying factors which control variable escape from X chromosome inactivation. *B. Balaton, C. Brown.* Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

X chromosome inactivation is the epigenetic silencing of one of the two X chromosomes in female eutherian mammals, to dosage compensate with males who have a single X chromosome. Not all X-linked genes are silenced; 15% escape inactivation while another 15% differ in their inactivation status between individuals, tissues and studies. This latter class of variable escape genes provides an opportunity to study a gene that is escaping inactivation and one which is subject to inactivation in the same genomic context, allowing identification of the underlying genetic and epigenetic causes of escape from inactivation. By combining the results of 3 previous studies using four different methods to obtain a gene's X-inactivation status, we assigned a consensus inactivation status call to 639 genes, including 78% of X-linked protein coding genes which are expressed in females. Eight percent of genes were found to variably escape between individuals and tissues while another 7% were variable between studies. We are interested in identifying which features correlate with a gene's X-inactivation status within a cell line. Our list of consensus X-inactivation status calls identified regions of variable escape from inactivation, suggesting possible co-regulation; however, preliminary results suggest that neighboring variable escape genes are independently regulated. We therefore hypothesized that promoter CpG methylation of variable escape genes would be predictive of their X-inactivation status; however, variable escape genes tended to have a broad range of methylation levels and did not correlate completely with their X-inactivation status. Our results show that methylation may be contributing to the variability of these genes' X-inactivation statuses, but that there must be other unaccounted factors. We are now investigating CTCF binding occupancy, topologically associated domain boundaries, and retrotransposon polymorphisms to determine whether or not they are also contributing to this variable regulation. Genetic or epigenetic features which are strongly associated with a gene's X-inactivation status may be causative of escape or silencing. Understanding the cause of escape from inactivation will allow us to more easily test for and predict which variable escape genes are being expressed in individuals. This knowledge may eventually allow us to change the genetic or epigenetic context surrounding a gene and inactivate or reactivate the copy on the inactive X.

2155W

Role of *Dxz4* in the 3D bipartite structure of the inactive X chromosome.
X. Deng[1], G. Bonora[2], V. Ramani[2], W. Ma[7], R. Qiu[2], Z. Duan[3,4], J. Shendure[2], W.S. Noble[2,5], C.M. Disteche[1,6]. 1) Pathology, University of Washington, Seattle, WA., USA; 2) Genome Sciences, University of Washington, Seattle WA., USA; 3) Institute for Stem Cell and Regenerative Medicine, University of Washington, Seattle WA., USA; 4) Hematology, University of Washington, Seattle WA., USA; 5) Computer Science and Engineering, University of Washington, Seattle WA., USA; 6) Medicine, University of Washington, Seattle WA., USA; 7) Statistics, University of California, Riverside CA., USA.

X inactivation is associated with *XIST* RNA coating, epigenetic modifications, and compaction of the X chromosome. To determine the 3D structure of the X chromosomes based on allele-specific chromatin contacts in female cells we employed a new in situ Hi-C assay in mouse F1 hybrid systems (brain and Patski cells) in which alleles can be distinguished based on single nucleotide polymorphisms. We previously reported that the inactive mouse X chromosome has a strikingly different 3D configuration from the active X. Indeed, the inactive X comprises two condensed superdomains of frequent long-range intrachromosomal contacts separated by a hinge region, a configuration conserved in human. Genes that escape X inactivation are preferentially located at the periphery of the inactive X. Both in mouse and human the hinge region contains the conserved long noncoding RNA *Dxz4/DXZ4* locus that binds CTCF on the inactive X. In mouse, the hinge region also contains the minisatellite *Ds-TR* adjacent to a region with strong CTCF binding. To determine the role of the elements located in the hinge region in shaping the inactive X chromosome we have constructed allele-specific CRISPR/cas9 deletions and inversions within the hinge region. We report that, while deletion of *Ds-TR* alone or inversion of CTCF binding sites located near *Ds-TR* have no effect on the structure of the inactive X, a 127kb deletion that include *Dxz4* causes a drastic disruption of the superdomains. Both new contacts between superdomains and loss of contacts within superdomains were detected by Hi-C. Analyses of gene expression detected small changes in X inactivation and escape.

2156T

Identifying the functional domains of XIST and their role in X-chromosome inactivation. *T. Dixon-McDougall, C. Brown.* Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

Early in human embryonic development, the nearly 20kb long non-coding RNA, XIST, coats the X chromosome and triggers the stable inactivation of the nearly 1000 genes along its length. XIST was one of the first long non-coding RNAs identified, and similar to other regulatory long non-coding RNAs, acts as a modular scaffold, binding a range of factors that reorganize chromatin marks, silence gene expression and restructure its chromosome of origin. Many XIST interacting proteins have been identified, but without understanding the functional significance of the various XIST domains, how these factors interact with XIST to inactivate a chromosome is still a mystery. To develop a map of the functional domains of XIST and their contributions to the overall process of chromosome inactivation, the functionality of inducible full-length and partial XIST constructs were compared to each other to determine the effect of removing various domains of XIST. As the unique architecture of the X-chromosome itself contributes to X-chromosome inactivation, all of these XIST constructs were integrated into an autosomal FRT site located on chromosome 8p in a male cell line to avoid confounding variables. We used immunofluorescence to examine recruitment of heterochromatic marks; allele-specific pyrosequencing to measure silencing and RNA FISH to examine the ability to localize their chromosome of origin to the perinucleolar compartment. Initially, an assessment of 3-4 kb deletions revealed that the 3' region of XIST contributes to the recruitment of all heterochromatin marks analyzed, distal gene silencing and chromatin reorganization. An internal segment of XIST spanning two of the more strongly conserved repeat sequences was found to contribute to the recruitment of a subset of heterochromatin marks and the chromatin organization. These two domains possessed redundant systems necessary for localizing to their chromosome of origin and forming a unified XIST RNA coated domain. Subsequent finer-scale ~ 1 kb deletions were generated using CRISPR to specifically excise regions with a focus on the tandem repeat regions. These various constructs were measured using the same methods, creating a list of each segment of XIST's contribution to chromosome inactivation. This represents the first full length map of the functional domains of human XIST and an opportunity to identify novel long non-coding RNA functional domains and the factors with which they interact.

2157F

Human elements regulating escape from X-chromosome inactivation are recognized in mouse, and define new regions to interrogate for mechanism.

S. Peeters[1,2], A. Korecki[1,3], E. Simpson[1,3], C. Brown[1,2]. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Molecular Epigenetics Group, Life Sciences Institute, Vancouver, BC, Canada; 3) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada.

X-chromosome inactivation (XCI) epigenetically silences an X chromosome in mammalian females to provide dosage compensation between the sexes. However, a remarkable 15% of genes on the human inactive X chromosome are able to escape inactivation, with another 15% of genes that vary between individuals and tissues. Although genes escaping from XCI have been implicated in playing a role in sexual dimorphisms between men and women, as well as in manifestations of sex chromosome aneuploidies, no clear and complete mechanism behind this escape phenomenon has been identified and experimentally validated. Additionally, studies on human XCI have been limited due to the lack of a developmental model, as human embryonic stem cells have very unstable epigenetic regulation of XCI. As previous reports have described an intrinsic capacity of mouse gene *Kdm5c* to escape from XCI, we targeted a bacterial artificial chromosome (BAC) containing its human homologue *KDM5C* to the normally inactivated *Hprt* locus on the mouse X chromosome, to investigate the conservation of escape elements between mouse and human. Transgenic mice were bred to a strain carrying a deletion in *Xist* thus ensuring that our integrated BACs would always be on the inactive X. Brain, liver, and spleen from adult mice were analyzed for evidence of *KDM5C* escape from the inactive X by measuring promoter CpG island methylation of bisulphite converted DNA, as well as expression levels of RNA by RT-qPCR. Unexpectedly, human *KDM5C* appeared subject to XCI by expression, as well as showing DNA methylation at its promoter, leading us to hypothesize that either *Hprt* was an atypically strong silencing domain, or that human elements regulating escape from XCI are not recognized by mouse. To test these hypotheses we created two additional transgenic mouse strains, the first carrying an integration of mouse *Kdm5c* as a positive control for escape at *Hprt*, and the second carrying another human escape gene, *RPS4X*. Preliminary examination of tissues from these mice suggest that both of them are escaping from XCI, leading us to conclude that the elements controlling escape in humans are recognized by mouse, and that it was a missing regulatory element in the *KDM5C* integration that resulted in it being silenced. This work has added valuable support to using mouse as a model system for studying how human genes escape from XCI, and has highlighted new regions to interrogate in the search for elements regulating this process.

Attenuation of hedgehog signaling predisposes to nonalcoholic fatty liver disease. *A. Martinez[1], M. Guillen-Sacoto[1], R. Lipinski[2], Y. Abe[1], P. Kruszka[1], K. Weiss[1], J. Everson[3], R. Bataller[4], D. Kleiner[5], K. Sulik[3,6], B. Solomon[7,8], M. Muenke[1].* 1) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD; 2) Department of Comparative Biosciences, School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI; 3) Bowles Center for Alcohol Studies, University of North Carolina, Chapel Hill, NC; 4) Division of Gastroenterology and Hepatology, Department of Medicine, University of North Carolina, Chapel Hill, NC; 5) Laboratory of Pathology, National Cancer Institute, Bethesda, MD; 6) Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC; Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC; 7) Division of Medical Genomics, Inova Translational Medicine Institute, Falls Church, VA; 8) Department of Pediatrics, Inova Children's Hospital and Virginia Commonwealth University School of Medicine, Falls Church, VA.

Nonalcoholic fatty liver disease (NAFLD) is the most common form of liver disease and a leading cause of liver transplantation in the United States. While Hedgehog (Hh) signaling has been implicated in liver development and the progression of chronic liver injury, a role in liver lipid metabolism and the early stages of NAFLD has not been established. In this study we examined the prevalence of NAFLD in a cohort of patients with overt or microform holoprosencephaly (HPE), a disorder associated with germline mutations disrupting Hh signaling. Compared to the general population, the incidence of NAFLD was significantly higher in this cohort (54.50% of adults, $P < 0.001$; and 33.33% of children, $P = 0.002$), and affected individuals were younger (30.3 years, $P = 0.026$ in adults, 5.5 years, $P = 0.037$ in children). To test the hypothesis that Hh signaling disruption predisposes to liver steatosis, we used a *Gli2* heterozygous null (*Gli2+/-*) mouse model of diet-induced NAFLD. Gli2 is a vertebrate transcription factor necessary for Hh signal transduction. Compared to their wild-type littermates, mutant mice demonstrated increased weight gain when placed on a high-fat (HF) diet and increased liver steatosis induced by both a HF and a methionine- and choline-deficient (MCD) diet. Because MCD diets induce liver steatosis in the presence of weight loss, the increased susceptibility of mutant mice to accumulate hepatic fat is independent of the effects of systemic adipocity characteristic of obesity. In agreement with previous reports, the livers of mutant mice showed decreased hepatic expression of pro-fibrotic and pro-inflammatory genes. Interestingly, mutant mouse also revealed increased expression of PPAR-γ, a potent anti-fibrogenic and anti-inflammatory regulator. Our results demonstrate a direct involvement of Hh signaling in the early stages of NAFLD pathogenesis independent of obesity. We propose a disease mechanism that involves increased liver steatosis with reduced fibrosis, which may have important implications for the management of NAFLD and the development of new therapies targeting this pathway.

2159T

Interaction of saposin C with GCase mutations leads to mutation-dependent and tissue-specific disease phenotype in mice. *Y. Sun[1,3], H. Ran[1], B. Liou[1], B. Quinn[1], Y. Xu[1], G.A. Grabowski[1], W. Zhang[2].* 1) Div Human Gen, Cincinnati Children's Hosp, Cincinnati, OH; 2) Dept of Pathology, Cincinnati Children's Hosp, Cincinnati, OH; 3) Dept of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH.

The defective lysosomal hydrolysis of glucosylceramide (GC) in Gaucher disease is caused by mutations in *GBA1* that encodes acid beta-glucosidase (GCase). Saposin C activates GCase and has protective effects for GCase against proteolysis. To investigate the *in vivo* function of saposin C on *Gba1* mutants, variant Gaucher disease mouse models were generated by backcrossing point mutated GCase mice into saposin C deficient (C-/-) mice. The mutant GCase activities in the resultant mice were reduced by ~50%. The 9H;C* (D409H/D409H;C-/-) mice developed severe visceral GC accumulation and storage cells that were CD68 positive macrophage. In contrast, 4L;C* (V394L/V394L;C-/-) mice, a neuronopathic Gaucher disease model, accumulated GC and glucosylsphingosine (GS) primarily in the brain. Unlike D409V/D409V mice that developed normally for over a year, 9V;C* (D409V/D409V;C-/-) pups had a lethal skin defect. 0S;C* (N370S/N370S;C-/-) mice like N370S/N370S neonates had a lethal skin abnormality. In 9V;C* and 0S;C* pups, ultrastructural studies revealed irregular lamellar bodies in stratum corneum. Neonatal 9V;C* mice had moderate GC accumulation in the liver, brain and lung, whereas 0S;C* neonates showed slight GC accumulation in the lung. 4L;C* and 9H;C* brains showed GS accumulation, whereas 9V;C* and 0S;C* brains did not. These results suggest that lack of saposin C reduced the residual mutant GCase activity and potentiated substrate accumulation in selected tissues. GS appears to be a poor *in vivo* substrate for V394L and D409H GCases. These variant Gaucher disease mouse models provide insights into interaction of saposin C with specific mutant GCase and contribute to understanding the in vivo functional relationships between saposin C and GCase.

2160F

Studies of the functional role of *LYPLAL1* in Nonalcoholic Fatty Liver Disease (NAFLD). *E. Speliotes, Y. Chen, A. Wright, A. Wall, A. Tai, B. Halligan.* Dept of Internal Med, Gastroenterology & Dept of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI.

The prevalence of nonalcoholic fatty liver disease (NAFLD) has increased with the rise in obesity and is predicted to become the leading cause of liver disease globally by 2020. NAFLD is a spectrum of disease consisting of steatosis (fat, mostly triglycerides), steatohepatitis (NASH; fat and inflammation), and fibrosis/cirrhosis (scarring). The predisposition to develop NAFLD is partially genetic and in population genetic studies we have identified a genetic variant near the gene *LYPLAL1* that predisposes to human population based NAFLD. The protein encoded by the *LYPLAL1* gene, Lysophospholipase-like protein 1 (LYPLAL1) has strong homology to Lysophospholipase protein 1 (LYPLA1, Acyl-Protein Thioesterase APT1). LYPLAL1 and LYPLA1 are thought to be acyl-lysophospholipases which remove palmitate from s-palmitoylated proteins. To test the role of LYPLAL1 on NAFLD we created human cell line and mouse models of NAFLD. Knockdown and overexpression of *LYPLAL1* increased and decreased hepatic steatosis as measured by total cellular triglyceride accumulation respectively in both human HuH7 and HepG2 cell lines. We expressed and purified GST-LYPLAL1 fusion protein, and demonstrated that it can hydrolyze 4-nitrophenyl acetate and 4-nitrophenyl butyrin substrates consistent with its possible role as a thioesterase. Further, we stained wild type HuH7 and HepG2 cells with an anti-LYPLAL1 antibody and found that LYPLAL1 is localized to the perinuclear endoplasmic reticulum of human hepatocellular carcinoma cell lines, the site of protein palmitoylation/depalmitoylation suggesting a role for LYPLAL1 in the regulation of global protein localization. We have generated several Cas9/CRISPR *Lyplal1* knockout mouse mutants including early in frame stop codons and one large deletion leading to missense mutation. We are currently evaluating their phenotype on both normal and high fat/sugar (western) diets to determine the effect of *Lyplal1* knock out on NAFLD and other metabolic conditions. To test the involvement of LYPLAL1 protein palmitoylation we are using the acyl-biotinyl exchange (ABE) approach to exchange biotin groups for palmitate groups and analyze the results by blotting and MS proteomics. By comparing the spectrum of proteins palmitoylated in *LYPLAL1* normal, overexpression and knockdown cells lines and wild type and knockout mouse livers, we hope to identify the targets of LYPLAL1 and better understand its role in NAFLD. .

An Ashkenazi Jewish-predominant mutation in *CSF2RB* increases risk for Crohn's disease and attenuates GM-CSF signaling. *L. Chuang[1], N. Villaverde[1], K.Y. Hui[2,3], A. Mortha[4], A. Rahman[1], A.P. Levine[5], T. Haritunians[6], S. Ng[3], W. Zhang[3], N. Hsu[1], J. Facey[1], T. Luong[1], H. Fernandez-Hernandez[1], D. Li[6], M. Rivas[7], E.R. Schiff[5], L. Schumm[9], B.M. Bowen[3], Y. Sharma[1,3], K. Ning[1,3,10], C. Abraham[3], M. Daly[7,12], R.H. Duerr[11], A.W. Segal[5], M. Merad[4], D.P. McGovern[6], I. Peter[1], J.H. Cho[1,8].* 1) Genetics and Genomic sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 3) Section of Digestive Diseases, Department of Internal Medicine, Yale University School of Medicine, New Haven, CT; 4) Department of Oncological Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Centre for Molecular Medicine, Division of Medicine, University College, London, UK; 6) F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 7) Department of Medical and Population Genetics, Broad Institute, Cambridge, MA; 8) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 9) Department of Health Studies, University of Chicago, Chicago, IL; 10) Department of Molecular and Computational Biology, University of Southern California, Los Angeles, CA; 11) Division of Gastroenterology, Hepatology, and Nutrition, Department of Medicine, School of Medicine, University of Pittsburgh, Pittsburgh; 12) Department of Genetics, Harvard Medical School, Boston, MA.

Crohn's disease (CD) has the highest prevalence in Ashkenazi Jewish (AJ) populations. We sought to identify rare, CD-associated frameshift variants of high functional and statistical effects. We performed exome sequencing of AJ CD cases, and genotyped 224 frameshift variants using custom array genotyping in an AJ case-control cohort. Quantile-quantile (Q-Q) analysis of the 88 frameshift mutations was evaluated in order to assess the validity of the null distribution assumption. It revealed only two markers demonstrating significantly greater association evidence than predicted, namely the *NOD2* frameshift mutation and a frameshift mutation in the *CSF2RB* gene (P value 8.52 x 10^{-7}), which encodes for the colony stimulating factor 2 receptor, beta chain. The *CSF2RB* mutation involves deletion of a single guanine base, which is predicted to cause a frameshift at codon 708 of *CSF2RB* (colony-stimulating factor 2 receptor, beta chain). This would result in the expression of a 729-amino acid sequence, compared to 897 residues encoded by the canonical transcript. Exome-sequencing and array-based genotyping was performed in 1477 AJ CD cases and 2614 AJ controls. Replication genotyping of a *CSF2RB* (colony-stimulating factor 2, receptor beta) frameshift was performed in 1515 CD cases and 6980 controls. Intestinal *CSF2RB* gene expression and GM-CSF responsive cells were defined by CyTOF. Wild-type and mutant CSF2RB function was compared in cellular transfection and primary monocyte studies. We observed nominal evidence for CD association for the *CSF2RB* frameshift (P value 8.52x10^{-7}) in the discovery cohort, which was significantly replicated (combined P value 3.42x10^{-6}). In the intestine, robust GM-CSF induction of STAT5 phosphorylation is observed, with lesser induction of pERK and pAKT. Co-transfection of wild-type and mutant CSF2RB displayed decreased pSTAT5 with GM-CSF stimulation, consistent with a dominant negative effect. Monocytes from heterozygous frameshift carriers, present in 6% of AJ CD cases, demonstrated diminished GM-CSF responses, with markedly decreased aldehyde dehydrogenase enzyme activity associated with immune tolerance. Our findings define a primary role of diminished GM-CSF signaling and impaired innate immunity in CD pathogenesis.

Novel variants identified in Chinese ankylosing spondylitis families by whole-exome sequencing. *J. Liu[1], Z. Niu[1], Y. Li[1], Y. Wang[1], Y. Ma[1], H. Zhang[1], L. Jin[1], H. Zou[2], J. Wang[1].* 1) School of Life Science , Fudan University, Shanghai, China; 2) Division of Rheumatology, Huashan Hospital, Shanghai, China.

Ankylosing spondylitis (AS) is the main subtype and a main outcome of spondyloarthritis, the susceptibility to which is mainly determined by genetics. HLA-B27 shows the strongest reported association with AS, while it can only explain about a quarter of the overall genetic susceptibility to AS. On the other hand, previous studies reported that HLA-B27 positive individuals who had a first-degree relative infected with AS have more (6-16 times) susceptibility to developing AS themselves than those HLA-B27 positive ones but without AS family history. It indicated that some other genes have a strong effect on the development of AS in individuals with family history. Therefore, it is required to find high risk variants in patients with family history by next-generation sequencing.   Three unrelated AS Chinese families (6 patients were all HLA-B27 positive) were recruited in the first stage of the research. Additional 994 Chinese subjects with AS and 999 ethnically matched controls were recruited in the second stage. The diagnosis of AS was performed according to 1984 modified New York criteria of AS. After performing whole-exome sequencing in these AS families, we selected five gene variants (*TTN, ADAM2, RNF123, MGP,* and *LRR1*) to be validated in the second stage according to the following rules: (I) It was a functional nonsense mutation in coding region; (II) MAF in 1k genomes data <5%; (III) It was related to inflammation or bone information. Three of these selected variants (located in TTN, RNF123 and ADAM2) showed statistical significance between cases and controls. The odds ratio and chi square p-value of TTN variant were 5.04 and 0.02 respectively. As to RNF123 and ADAM2, their variants were not found in both the 1k genomes data base and all the controls. All individuals carrying the minor alleles were replicated by Sanger Sequencing. In conclusion, we performed a whole-exome sequencing to look for the rare variants from three AS families and validated five candidate variants in a 994 cases vs. 999 controls test. Three rare variants showed significant difference between AS and controls. In addition, all the three variants were nonsense in coding region and would play functional roles in AS.

BREATH: A web-accessible database of normal human and mouse lung development generated by the Molecular Atlas of Lung Development Program (LungMAP). *R. Clark[1], N.C. Gaddis[1], J.L. Levy[1], H. Pan[1], Y. Xu[2], M. Duparc[1], G.P. Page[1], J.A. Whitsett[2], S.M. Palmer[3], LungMAP Data Coordinating Center.* 1) RTI International, Research Triangle Park, NC; 2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Duke Clinical Research Institute, Duke University School of Medicine, Durham, NC.

The lung is a complex organ with high cellular heterogeneity, and research is needed to define the interactive gene networks and dynamic crosstalk among multiple cell types that coordinate normal lung development. Significant knowledge gaps exist in the understanding of lung development from late fetal to perinatal stages and through early childhood, a critical period when the diverse lung cells go through terminal differentiation and maturation and when alveoli form. Coordination and integration of information from disparate assays and experimental approaches is critically needed to help the pulmonary research community uncover the molecular determinants of lung development. The goal of LungMAP is to build an open-access resource providing a comprehensive molecular atlas of late-stage lung development in humans and mice, making otherwise dispersed data, reagents, and protocols freely available to the research community. We have created the Bioinformatics REsource ATlas for the Healthy lung (BREATH) database, applying novel data management and bioinformatics approaches to manage high-throughput multidimensional experimental data. BREATH is built on a triple store database backbone, integrated with anatomical ontologies for lung development, and provides access to novel web-based tools for the analysis and visualization of data generated by the four Research Centers and Human Tissue Core of the LungMAP Consortium. The current version of BREATH contains confocal immunofluorescence images, *in situ* hybridization images, histological images, and 3D confocal and uCT images of developing mouse and human lung at several time points, as well as single-cell RNAseq, proteomic, and lipidomic data from mouse and human lung cells. The LungMAP website (www.lungmap.net) provides an entry portal to the BREATH database and tools for exploring and interacting with the lung images and omics data. Future versions of BREATH will incorporate additional data types, including metabolomic and epigenetic data, and novel tools for cross-datatype analysis. A better understanding of the basic molecular pathways that regulate normal lung development will enable development of innovative treatments that successfully manipulate, enhance and improve lung injury repair and regeneration.

Pituitary hormone deficiency: Role of chromatin architecture in disease pathophysiology. *A. Daly, L.Y.M. Cheung, S.A. Camper.* Human Genetics, Michigan, Ann Arbor, MI.

Congenital hypopituitarism occurs in about 1/4000 births and can be life-threatening if not treated effectively. There are many genetic causes, including mutations in *PROP1* and *POU1F1*, but most patients have no molecular diagnosis. PROP1 induces POU1F1 expression, and POU1F1 organizes chromatin and drives the differentiation of cells that express thyrotropin, growth hormone or prolactin. To understand the mechanism of POU1F1 action, we utilized two POU1F1-expressing cell lines that represent sequential steps in pituitary development: hormone negative and hormone positive. We identified changes in chromatin architecture and factors that are exclusively associated with hormone expression using the Assay for Transposase Accessible Chromatin-Sequencing (ATAC-seq) and RNA-seq. There were numerous changes in chromatin architecture. *Nr5a1* encodes a transcription factor specific for the gonadotrope lineage, and it shifts to closed chromatin in more differentiated cells. This is consistent with the idea that competition between POU1F1 and NR5A1 establishes separate cell fates. *Rax* encodes the retinal and anterior neural fold homeobox transcription factor necessary for eye and hypothalamic development, and it also coverts to closed chromatin in the more differentiated cells. This may represent differentiation of a basic head placode towards pituitary gland fate instead of the eye fate and/or distinguishing hypothalamus from pituitary. This idea is supported by the discovery that *Prop1* deficiency permits ectopic expression of genes in the pituitary gland that are normally expressed in other head placodes and/or the hypothalamus. Application of Gene Set Enrichment Analyses (GSEA) to differentially accessible chromatin revealed that genes involved in cell proliferation and cell migration shift from open to closed chromatin as differentiation ensues. This suggests that the cell lines represent the *Pou1f1* expressing cells near the stem cell niche and those that have migrated into the parenchyma of the gland and differentiated to produce hormones. The RNA-Seq analysis will reveal candidate genes that work together with POU1F1 to alter chromatin architecture and promote differentiation and expression of the hormone genes. In conclusion, we have advanced our understanding of the mechanism of PROP1 and POU1F1 action and identified candidate genes for CPHD of unknown etiology.

2165T

The role of FREM/FRAS proteins in the development of diaphragmatic sac hernias. *V.K. Jordan[1], T.F. Beck[2,7], A. Hernandez-Garcia[2], P. Khundert[2], B.J. Kim[2], S.N. Jhangiani[2,3], T. Gambin[2], M. Starkovich[2,3], A.H. Li[4], D. Muzny[2,3], K. Lally[6], R. Gibbs[2,3], E. Boerwinkle[4], J.R. Lupski[2,3,5], D.A. Scott[1,2].* 1) Molecular Physiology and Biophysics, Baylor College of medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 4) Human Genetics Center, University of Texas Health Science Center, Houston, TX, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 6) Department of Pediatric Surgery, University of Texas Health Science Center, Houston, TX, USA; 7) Current affiliation: NHGRI, National Institutes of Health, Bethesda, MD, USA.

Congenital diaphragmatic hernia (CDH) occurs when the abdominal viscera—the liver, gallbladder, stomach, and/or intestines--enter into the thoracic cavity through an abnormal opening in the diaphragm. This life-threatening birth defect affects 1 in 3,000 newborns and accounts for ~8% of all major congenital anomalies. In ~20% of human CDH cases, the herniated viscera are encapsulated by a thin layer of membranous tissue referred to as a hernial sac. We have previously shown that isolated sac CDH in humans and mice can be caused by recessive pathogenic variants in *FREM1*, which encodes an extracellular matrix protein. In the extracellular matrix, FREM1 forms a self-stabilizing ternary complex with two related proteins—FREM2 and FRAS1—which plays an important role in cell adhesion and intercellular signaling. To determine if pathogenic variants in *FREM2* and *FRAS1* can also cause CDH, we performed exome sequencing on 69 patients with CDH. Four of these individuals (6%) carried rare, putatively deleterious compound and/or double heterozygous changes in these genes. Three of these individuals carried a c.4031G>A, p.Arg1344His change in *FREM2*. The frequency of this allele among Caucasians in our CDH cohort was statistically greater than that seen in ethnically matched control populations P < 0.0001. In support of *FREM2*'s role in the development of CDH, we also found sac hernias in 8.2% (5/61) of FREM2-deficient mice. We also found one rare FRAS1-deficient mouse with sac CDH (1/102, 1%). The sac hernias in these mice were indistinguishable from those seen in FREM1-deficient mice. In all cases, these hernias were located in the anterior region of the diaphragm and contained the gallbladder and a pedunculated mass of liver tissue. Further analysis revealed that these sac hernias form when the migrating muscular components of the diaphragm fail to meet at the midline behind the sternum. We went on to demonstrate that GATA4, a retinoic acid responsive transcription factor implicated in the development of sac CDH, modulates the transcriptional expression of *Fras1* in diaphragmatic mesothelial cells. We conclude that pathogenic variants in *FREM1*, *FREM2* and *FRAS1* may increase the risk of developing sac CDH in both humans and mice. Our data also suggests an important link between retinoic acid signaling and the maintenance of the extracellular matrix during diaphragm development.

2166F

Cushing's Disease associated with *USP8* mutations. *F.R. Faucz[1], A. Tirosh[1], A. Berthon[1], L.C. Hernández-Ramírez[1], N. Settas[1], A. Angelousi[1], R. Correa[1], P. Chittiboina[2], N. Pankratz[3], J. Lane[3], A. Dimopoulos[4], J. Mills[4], M. Lodish[1], C.A. Stratakis[1].* 1) Section on Endocrinology and Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA; 2) Surgical Neurology Branch, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, USA; 3) Department of Laboratory Medicine and Pathology, University of Minnesota Medical School, Minneapolis, MN, USA; 4) Epidemiology Branch, Division of Intramural Population Health Research, NIH, Rockville, MD, USA.

   Introduction: Somatic mutations in the ubiquitin-specific protease 8 gene (*USP8*), resulting in increased activity of the epidermal growth factor receptor (EGFR) signaling pathway, constitute the most common genetic alteration in patients with Cushing disease (CD). However, the occurrence and possible pathogenic role of germline *USP8* variants has not been assessed before. **Methods**: To examine the prevalence and clinical correlations of mutations in *USP8*, the complete *USP8*-coding and surrounding intronic regions were sequenced in 42 pediatric CD patients, followed up at the NIH, by Sanger sequencing of germline and tumor DNA. Clinical characteristics were compared among patients with a predicted by in silico as damaging germline variant of unknown significance (VUS) and/or somatic *USP8* mutations, vs. those without *USP8* changes (controls). **Results**: Mean age at diagnosis for the full cohort was 13.7±3.4 years (range, 6.1-18.7). Twenty one patients (50%) had *USP8* mutations, 8 with germline VUS and 13 had somatic mutations. All the somatic mutations that were not present at the germline level were located in the previously described hotspot region. Patients harboring a germline VUS had longer disease duration (3.1±1.6 vs. 1.8±1.6 years, p=0.02) and required treatment following operation more often (50% vs. 14.3%, p=0.045) compared with the controls. Patients with somatic mutations were predominantly females (84.6% vs. 47.6%, p=0.03). The biochemical profiles of somatic or germline mutations were similar to those of the controls. Adenoma parameters, including size and invasiveness were also similar. The time between disease onset and clinical diagnosis was longer for patients with germline *USP8* VUS (Breslow test, p=0.04). **Discussion**: Herein we report clinical data of pediatric CD patients seen in the NIH, according to presence and type of *USP8* mutations and/or germline VUS. We showed that patients harboring somatic *USP8* mutations were predominantly female. Moreover, patients with germline *USP8* VUS were diagnosed later. This may suggest that the disease is more indolent among CD patients with germline VUS of *USP8*. Further studies are needed to clarify how germline *USP8* VUS could affect EGFR signaling, and whether they could possibly contribute to pituitary tumorigenesis.

2167W

***Nr2e1* influences exploratory behavior but it is not necessary for the gonadotroph and somatotroph pituitary differentiation of zebrafish (*Danio rerio*).** *C. Caetano da Silva[1], P. S. Page-McCaw[2], W. Chen[2], L. R.S. Carvalho[1].* 1) Internal Medicine Department, Endocrinology Discipline, University of São Paulo Medical School, São Paulo, SP, Brazil; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, Tennessee, United States.

   Nr2e1, also known as *Tlx,* is an orphan nuclear hormone receptor that acts as a transcriptional repressor through physical association with transcriptional corepressors. Mutations in *Nr2e1* in mouse demonstrate that it is important for neural stem cell maintenance and proliferation. The loss of *Nr2e1* results in retinopathy, severe limbic defects, reduction in the volume of superficial cortical layers, also mice mutant for *Nr2e1* are aggressive and famously difficult to handle, previously being given the gene name *fierce*. Due to the fact that zebrafish is an animal model of easy handle, fast development and external reproduction, we used the genome editing tool, CRISPR/Cas9, to produce a permanent, heritable mutation in *nr2e1*. As seen in mice, *nr2e1* homozygous mutants are viable and both male and female mutants mate and produce viable offspring. In order to probe the behavioral phenotype of zebrafish, we have developed a novel assay to assess exploratory behaviors in this model. In the larval stages zebrafish are a non-aggressive and non-territorial species. However, aggressiveness is correlated with fearlessness, this fact prompted us to developed an assay that measures exploratory behavior. We observe that mutant animals are more exploratory than wildtype controls. Such as *Nr2e1*, *Sox2* is essential for neural stem cell maintenance and neogenesis in the mouse brain and it is well characterized stem cell marker in the pituitary. *nr2e1* is also expressed in the zebrafish pituitary, but its role in the pituitary development and terminal hormone expression has not been characterized. We analyzed Sox2 and Nr2e1 expression by immunofluorescence in the whole zebrafish brain at 10 dpf, 45 dpf, and in adults. While both proteins were present in the pituitary during development, surprisingly, they do not co-localize. We are currently investigating the role of *nr2e1* in zebrafish pituitary development.

2168T

Elevated testosterone levels in mice deficient for the chromatin modifying enzyme Kdm5c. *H. Weimar[1], K. Lewallen[1], Y. Shi[2], J. Xu[1].* 1) Dept. of Integrative Physiology and Neuroscience, Washington State University , Pullman, WA; 2) Boston Children's Hospital, Division of Newborn Medicine, Boston, MA.

The X-linked gene *Kdm5c* encodes a histone demethylase that is involved in epigenetic regulation of gene expression. By removing the methylation modifications from lysine 4 on histone H3, the Kdm5c enzyme suppresses the transcription of its targeted genes. When *Kdm5c* is mutated, its protein products are either absent or function poorly, resulting in up-regulation of genes normally repressed by this demethylase. Mutations of *KDM5C* cause many symptoms, including intellectual disability, aggression and disruptive behavior, as well as compromised male fertility. The goal of this ongoing project is to uncover the molecular basis for the disease phenotypes. We examined mice with a germline transmitted constitutive deletion mutation of *Kdm5c*, i.e. *Kdm5c* deficient mice (Kdm5c[Def]). They underwent behavioral testing, including a test of aggression. In comparison to wild type (WT) mice, Kdm5c[Def] mice displayed higher levels of aggression, reduced sociability, and memory deficits. Consistent with the finding of high aggression, the serum and testicular concentrations of testosterone were elevated in the Kdm5c[Def] mice, which in turn led to the up-regulated expression of androgen responsive genes in the brain, as shown by RNA-seq analysis. To investigate the cause for the increase of testosterone, expressions of steroidogenic genes were quantified in testes with RT-qPCR and found to be either *decreased* in the Kdm5c[Def] mice (e.g. *Hsd3b6*, *Hsd17b1,* and *Hsd17b3*) or similar between the two genotypes, making these genes less likely to be responsible for the increased levels of testosterone. Only one steroidogenic gene, *Srd5a1*, showed higher levels of mRNA expression in Kdm5c[Def] mice, which was concordant with the higher levels of H3K4 methylation at its promotor in the mutant mice. Histological examination revealed fewer testosterone producing Leydig cells in the Kdm5c[Def] mice as well as irregularities in spermatogenesis. The findings of this study help us to better understand the role of Kdm5c and epigenetic chromatin re-modeling in steroid production with direct relevance to spermatogenesis, male infertility, and behavior. Ultimately, this study might suggest chromatin targeted new treatments for male infertility as well as neuropsychiatric symptoms, such as aggression, that are related to abnormal testosterone levels. (Supported by an NIH R01 MH096066 to YS & JX).

2169F

Identification and characterization of a novel variant of human lysyl oxidase-like 3 (*LOXL3***).** *Y. Kim, A. Sharma-Bhandari, C. Li.* Dept Biochem, Wonkwang Univ Sch Med, Iksan, Jeonbuk, South Korea.

The human lysyl oxidase-like 3 (*LOXL3*) functions as a copper-dependent amine oxidase toward collagen and elastin. The LOXL3 protein contains four scavenger receptor cysteine-rich domains in the N-terminus in addition to the C-terminal characteristic domains of the lysyl oxidase (LOX) family, such as a copper-binding domain, a cytokine receptor-like domain and residues for the lysyl-tyrosyl quinone cofactor. Using BLASTN searches, we identified a novel variant of *LOXL3* (termed *LOXL3-sv2*), which lacked the sequences corresponding to exons 4 and 5 of *LOXL3*. The *LOXL3-sv2* mRNA is at least 2,398 bp in length, encoding a 608 amino acid-long polypeptide with a calculated molecular mass of 67.4 kDa. The deletion of exons 4 and 5 do not change the open-reading frame of LOXL3 but results in deletion of the SRCR domain 2. The recombinant LOXL3-sv2 protein showed a BAPN-inhibitable amine oxidase activity toward collagen type I. In RT-PCR analysis, *LOXL3-sv2* was detected in all human tissues tested, along with *LOXL3* and *LOXL3-sv1*, a previously identified variant of *LOXL3*. These findings indicate that the human *LOXL3* gene encodes at least three variants, LOXL3 LOXL3-sv1 and LOXL3-sv2, all of which function as amine oxidases.

2170W

Analysis of the interplay of lysosomal/autophagosomal pathways in osteoclasts towards correction of osteopetrosis. *C.E. Bauer[1,2], M. Pata[2], J. Vacher[1,2].* 1) Division of Experimental Medicine, McGill University, Montreal, Quebec, Canada; 2) Clinical Research Institute of Montreal, Department of Medicine, University of Montreal, Montreal, Quebec Canada.

Osteopetrosis is a disease characterized by the failure of osteoclasts (OCs) to resorb bone. As a consequence, bone mass is increased and bone marrow space is reduced; leading to premature death. The grey-lethal (*gl/gl*) Ostm1 null mouse model mimics severe human forms of osteopetrosis, and although the exact function of Ostm1 in osteoclasts is not fully understood, it appears to influence OC ruffled border (RB) formation. The RB is a platform for proton/protease excretion as well as bone material uptake and is formed through fusion of secretory lysosomes with the bone-apposed plasma membrane. Interestingly, our results implicate Ostm1 in autophagocytic clearance via the lysosomal pathway in neurons. Thus, it is imperative to assess Ostm1 role within the OC and the interplay of autophagy and lysosome biogenesis in OC RB formation. To assess these facets, we designed a transgene to stimulate the lysosomal/autophagy pathways in mature OCs. The expression of the Tfeb transcription factor, a master regulator of the autophagocytic/lysosomal pathways, was targeted to mature OCs with the Capthepsin K (Ctsk) promoter. To determine whether Ostm1's function is critical in the cellular clearance of autophagosomes, the expression of key autophagosomal/lysosomal trafficking and flux molecular regulators have been assessed in transgenic and non-transgenic wild-type (wt) mice. *In vitro* analyses of mature OC samples, cultured from transgenic wt mice, indicate that there is a significant upregulation of autophagosomal genes (*Atg5* and *Rab7*) when compared to non-transgenic controls. This correlates with the LC3II/I protein expression ratio, a marker of autophagy. Additionally, transgenic mice have higher levels of *Atp61v1*, a gene associated with OCs activity. Together, these data demonstrate that Tfeb upregulation can stimulate autophagy/lysosomal pathways in OCs, thereby furthering the understanding of Ostm1's role in RB function. Concomitantly, assessing correction of OC maturation/activation and the osteopetrotic phenotype is ongoing in Tfeb *gl/gl* transgenic mice, *in vivo*. Consequently, these studies will add to our understanding of the lysosomal/autophagocytic interplay in osteoclasts and could result in the development of new therapeutic treatments for osteopetrosis.

2171T

Loss of the lipid phosphatase Inpp4b in mature osteoblasts affects bone homeostasis. *W. Liu[1,2], L. Saad[1,2], M. Pata[2], J. Vacher[1,2].* 1) Division of Experimental Medicine, McGill University, Montreal, QC, Canada; 2) Department of Medicine, University of Montreal, Clinical Research Institute of Montreal, Montreal, QC, Canada.

Bone homeostasis relies on the tightly coordinated control of the bone-forming osteoblasts and the bone-resorbing osteoclasts. Disruption in the crosstalk between osteoblasts and osteoclasts can lead to different bone diseases such as osteoporosis and osteopetrosis, which affect over 1 million Canadians. Previous findings in our lab revealed a dysregulation in inositol-polyphosphate-4-phosphatase type II (Inpp4b) in the murine grey-lethal model of severe osteopetrosis. *Inpp4b*, expressed in both osteoblasts and osteoclasts, has been shown to be a negative regulator of osteoclastogenesis and a prognostic locus of osteoporosis. In order to elucidate the function of *Inpp4b* in mature osteoblasts and in bone homeostasis, we generated a floxed *Inpp4b* allele that would be deleted specifically in mature osteoblasts using human Osteocalcin-Cre in *Inpp4b*[lox/lox]; hOc-Cre (CKO) mice. Initial *in vivo* analyses of CKO mice show an increase in bone density at 8 weeks of age, reaching a control level by 4 months. *Ex vivo,* differentiated osteoblasts from calvaria of neonatal CKO mice display a decreased mineralization level compared to controls. Subsequent gene expression analyses reveal a downregulation of the mature osteoblast marker osteocalcin, concomitant with an increase in the mineralization inhibitor, osteopontin. These findings prompted us to determine the mechanism by which *Inpp4b* can regulate mineralization. Since autophagy has previously been described to be involved in mineralization, we examined the expression of the autophagy-related genes, *Atg5* and *Atg7*, in mature CKO osteoblasts. Interestingly, we observed a decrease in expression of these genes as well, suggesting an autophagy-related role for *Inpp4b* in mineralization. Taken together, these results demonstrate that the specific deletion of *Inpp4b* in mature osteoblasts can modulate bone homeostasis. In the future, we will characterize how *Inpp4b* can affect signalling pathways regulating osteoblast/osteoclast crosstalk. As a result, this study may yield future therapeutic targets in the prevention and treatment of different bone pathologies.

2172F

ERAP1 deficient mice phenocopy the major findings of humans with ankylosing spondylitis, including sacroiliitis, osteoporosis, bridging osteophytes, and sacral and vertebral fusions. *D.P.W. Rastall[1], S. Raehtz[2], Y. Pepelyayeva[1], F.L. Collins[2], P. O'Connell[1], S. Godbehere-Roosa[1], M. Henderson[3], L.R. McCabe[2,3], A. Amalfitano[1,4].* 1) Department of Microbiology and Molecular Genetics, College of Osteopathic Medicine, Michigan State University, East Lansing, MI 48824, USA; 2) Department of Physiology, Michigan State University, East Lansing, MI 48824, USA; 3) Department of Radiology, Michigan State University, East Lansing, MI 48824, USA; 4) Department of Pediatrics, College of Osteopathic Medicine, Michigan State University, East Lansing, MI 48824, USA.

In humans, several genome-wide association studies (GWAS) have identified variants in the endoplasmic reticulum aminopeptidase 1 (ERAP1) gene that alter the risk for development of ankylosing spondylitis (AS). We have demonstrated that high-risk AS ERAP1 variants directly stimulate human immune cells to cause secretion of IL-1β, IL-6, and TNF-α. Additionally ERAP1-/- mice had increased activation of NK and NK-T cells and increased production of IL-12 and MCP-1 in response to pathogen recognition and stimulation with TLR agonists. We also demonstrated a critical role for ERAP1 in adaptive immunity *in vivo* by demonstrating that ERAP1 could completely alter the immunodominant T-cell response, by creating and destroying peptides. Importantly, we also demonstrated that high-risk AS ERAP1 variants could over-trim peptide ligands resulting in decreased amounts of MHC-I on the surface of immune cells. As pro-inflammatory states have been linked with bone loss, we hypothesized that ERAP1 may also play a role in bone homeostasis. To test this hypothesis we investigated the role of ERAP1 in bone homeostasis using ERAP1-/- mice. Utilizing micro-CT based imaging, we demonstrate that aged ERAP1-/- mice (as compared to control mice) progressively develop many of the hallmark signs of human AS, including increased sacroiliitis, osteoporosis, erosions in the axial spine, bridging syndesmophytes (ankylosis), and bony fusion of the sacrum and vertebrae. These findings were confirmed with blinded scoring of both 2D radiographs, blinded scoring of 3D isosurface reconstructions, and quantitative measures of bone morphology. ERAP1-/- mice also accurately reproduce the global microscopic bone remodeling observed in AS patients including significantly decreased trabecular bone mineral content, decreased bone volume fraction, decreased trabecular thickness, and increased trabecular spacing in the sacrum, spine, and femur as confirmed by quantitative morphometry (utilizing GE Healthcare Micro View software). Together, these results demonstrate that ERAP1-/- mice can be used to pave the way to future studies exploring interventions that may prevent these bony pathologies from occurring. Furthermore, these results confirm the findings of GWAS that first identified the possible involvement of ERAP1 in AS, by identifying an animal model that demonstrates a role for ERAP1 in bone pathologies of the axial skeleton.

Osteogenesis imperfecta (OI) is a collagen-related heritable bone dysplasia. Dominant OI is caused by defects in type I collagen or *IFITM5*, while recessive forms result from deficiency of proteins that interact with collagen for modification, folding or crosslinking. We have identified the first X-linked form of OI caused by a defect in regulated intramembrane proteolysis (RIP). One type of RIP involves sequential cleavage of substrates by site-1 (S1P) and site-2 protease (S2P), encoded by *MBTPS1* and *MBTPS2*, respectively. S1P and S2P are Golgi membrane proteases that cleave regulatory proteins transported from the ER membrane in response to stress or decreased sterol metabolites, releasing mature N-terminal fragments that enter the nucleus to activate gene transcription. In two pedigrees with moderately severe OI, linkage analysis and next generation sequencing identified novel missense mutations in *MBTPS2*, predicting p.N459S and p.L505F substitutions located in or near the S2P NPDG metal-coordinating motif. Neither *MBTPS2* transcripts nor S2P protein were decreased in proband fibroblasts and osteoblasts. However, proband and *Mbtps2*-deficient CHO cells co-transfected with mutant *MBTPS2* and reporter constructs indicate deficient cleavage or activation of RIP substrates OASIS, ATF6 and SREBP. Consistent with diminished OASIS signalling, proband fibroblasts have significantly reduced type I collagen secretion (20-73% of normal control cells). Also, proband fibroblast matrix contains collagen with decreased mature crosslinks. Critically, Proband bone type I collagen contained less than half the normal level of hydroxylated Lys87, the residue crucial for crosslinking, and is associated with decreased Lysyl Hydroxylase 1 (LH1) levels in proband osteoblasts. In addition, proband urinary LP/HP crosslink ratios are increased. These findings suggest abnormal collagen crosslinking undermines bone strength in X-linked OI. S2P-deficient osteoblasts also demonstrated broadly defective differentiation with decreased expression of transcripts related to osteoblast maturation, including *ALPL*, when induced to differentiate in culture. Transcripts encoding OASIS and SMAD4, which together upregulate expression of matrix-associated genes, were also significantly reduced in proband versus normal control osteoblasts. These are the first human studies to demonstrate the fundamental role of RIP in bone development, in addition to its function in cholesterol metabolism.

2174T

Unraveling the *TBX5* regulatory landscape. *F. Petit[1,2], S. Manouvrier-Hanu[2], N. Ahituv[1,3].* 1) Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, CA, USA; 2) Univ. Lille, CHU Lille, EA 7364 - RADEME, F-59000 Lille, France; 3) Institute for Human Genetics, University of California San Francisco, CA, USA.

Human limb malformations are frequent congenital abnormalities with a prevalence of 1/500 births. So far, very few gene mutations leading to isolated (non-syndromic) limb malformations have been found. There is growing evidence that disruption of gene regulatory elements may play a major role in their pathogenesis. Discovering these elements and understanding their function still remains a major challenge. Here, we set out to characterize the role of *TBX5* regulatory elements in human limb malformations. *TBX5* encodes a transcription factor that plays a crucial role in forelimb bud initiation. Its inactivation in animal models abolishes forelimb skeletal formation. In humans, *TBX5* heterozygous mutations or rearrangements are responsible for the association of preaxial upper limb malformations and congenital heart disease called Holt-Oram Syndrome (HOS, MIM 142900). However, screening for *TBX5* coding mutations remains negative in 15-30% of typical HOS patients. Isolated bilateral amelia of the upper-limbs (MIM 601360) is a very rare condition reminding of the phenotype for *Tbx5* inactivation in animal models. Recurrent cases have been described in some families, suggesting a genetic component. We hypothesize that in these two conditions, disruption of *TBX5* regulatory element/s could cause these phenotypes. To gain insights into *TBX5* regulation, we used various genomic datasets (ChIP-seq, ChIA-PET, comparative genomics) coupled with mouse transgenic enhancer assays to identify and characterize novel *TBX5* regulatory elements. In addition, using *in situ* hybridization and CRISPR/Cas9 genome editing, we are characterizing the function of a *Tbx5* antisense non-coding RNA. To better understand how *Tbx5* regulates other genes, we are performing ChIP-seq for it on mouse E10.5 forelimbs. Finally, to translate our work to human limb malformations, we are screening patients with HOS that have no *TBX5* coding mutations and patients with amelia of the upper limbs using a candidate sequencing approach and whole-genome sequencing. Combined, our work will unravel the gene regulatory landscape of *TBX5* and how its alteration can lead to human disease. **Acknowledgments:** Sequencing was provided by the University of Washington - Center for Mendelian Genomics (UW-CMG) and was funded by the National Human Genome Research Institute and the National Heart, Lung and Blood Institute grant 2UM1HG006493 to Drs. Debbie Nickerson, Michael Bamshad, and Suzanne Leal.

Eyre[2].* 1) Department of Physiology & Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR; 2) Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA; 3) Department of Orthopaedic Surgery, Center for Orthopaedic Research, University of Arkansas for Medical Sciences, Little Rock, AR; 4) Department of Biochemistry & Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR; 5) Division of Genetics, University of Arkansas for Medical Sciences, Little Rock, AR.

Sc65 (Synaptoneal Complex 65) is an endoplasmic reticulum protein that belongs to the Leprecan family which include the prolyl 3-hydroxylases (P3H1, P3H2, P3H3) and cartilage associated protein (CRTAP). We and others have shown that mutations in both *CRTAP* and *LEPRE1* (encoding P3H1) cause recessive forms of Osteogenesis Imperfecta. Sc65 and CRTAP are both non-enzymatic proteins and share high homology suggesting Sc65 may also function in bone homeostasis. We have demonstrated in two different mouse genetic models that loss of Sc65 results in low bone mass. To study Sc65 function in bone, co-immunoprecipitation (co-IP) of Sc65 candidate interactors in mouse fibroblasts followed by mass spectrometry was performed. These experiments identified several fibrillar procollagen α-chains as likely substrates of Sc65 supporting the idea that Sc65 plays a role in collagen modification, similar to other Leprecans. At the biochemical level, mass spectrometry of type I collagen peptides showed severe under-hydroxylation at helical cross-linking sites K87 and K930/933 in collagen α1(I) and α2(I) chains both from bone and skin which are known LH1 preferred substrate residues but with no effect on sites of prolyl 3-hydroxylation. Direct co-IP assays showed Sc65 interaction with lysyl-hydroxylase 1 (LH1, Plod1), prolyl 3-hydroxylase 3 and cyclophilin B. Western blot revealed dramatic reduction of LH1 and P3H3 in primary osteoblasts and skin fibroblasts from *Sc65*-KO mice. Size exclusion chromatography confirmed that Sc65 and P3H3 form a stable complex in the ER that affects the activity of lysyl-hydroxylase 1 potentially through interactions with the enzyme and/or cyclophilin B. Further testing showed that *Sc65*-KO mice also have fragile skin with less tensile strength than control mice, consistent with a collagen cross-linking abnormality. Collectively, these results indicate that Sc65 is a novel adapter molecule that stabilizes a unique ER-resident complex that is essential for proper collagen lysyl-hydroxylation. Loss of Sc65 leads to complex instability and defective fibrillar collagen modifications which negatively impacts bone, skin and likely other connective tissues. This phenotype and the underlying collagen molecular defect resemble those seen in EDS type VIA patients carrying *PLOD1* mutations; therefore mutations in either *Sc65* or *LEPREL2* may be responsible for a similar or milder connective tissue disease that is yet uncharacterized.

Pigmented 3D skin models made from patient-specific iPS cell-derived melanocytes. *K.M. Eckl[1,2,3], D. Lima Cunha[2,3,4], T. Saric[5], H.C. Hennies[2,3,4,6].* 1) Dept. for Biology, Edge Hill University, Ormskirk, Lancashire, United Kingdom; 2) Center for Dermatogenetics, Div. of Human Genetics and Dept. for Dermatology, Medical Univ Innsbruck, Innsbruck, Austria; 3) Dept. of Biological Sciences, School of Applied Sciences, Univ. of Huddersfield, Huddersfield, UK; 4) Center for Dermatogenetics, Cologne Center for Genomics, Univ. of Cologne, Cologne, Germany; 5) Inst. for Neurophysiology, Univ. Hospital Cologne, Cologne, Germany; 6) CECAD, Univ. of Cologne, Cologne, Germany.

Skin model systems are reaching international acclaim to further patient-specific drug development and to minimize the use of animals in applied medical research. Lately we developed 3D skin models for various monogenic severe genodermatoses with and without changes in pigmentation. Up to date most 3D full-thickness skin models mimic the multi-layered epidermis and a simplified dermis, but are void of melanocytes, the body's first-line defense against UV-radiation induced skin cancer. Patient-derived, pigmented 3D skin models help us to understand disease mechanisms and allow safe and patient-directed drug development for genetic orphan diseases. Induced pluripotent stem cells (iPSC) generated from dermal fibroblast are an excellent source for fate-specific differentiation of cells into any desired tissue. Here we present first results from a new approach to differentiate human feeder-cultured iPSC into melanin expressing pure cultures of melanocytes. From roughly five iPSC colonies we have been able to cryopreserve more than 40 million cells per line within the first six passages. Melanocytes derived from iPSC underwent extensive characterization at the final end point and during all differentiation processes to compare and contrast similarities and differences between healthy and diseased cell lines, which encompass cells from a late infant patient with severe photosensitive trichothiodystrophy (TTD) with a homozygous mutation in *ERCC2* as well as cells from a patient diagnosed with congenital ichthyosis caused by a homozygous nonsense mutation in *TGM1*. To proof in-vitro functionality of the cells in regard to melanin-transfer and viability in a tissue environment, we used iPSC-derived melanocytes for patient-specific 3D skin modelling. With success we showed iPSC-derived melanocyte integration into the basal layers of the epidermal sheets as well as synthesis of melanin and darkening of 3D skin models after exposure to UV light. Most monogenic genodermatoses either with or without pigmentation changes are rare. Treatment is often only symptomatic and rarely sufficient. Individualized pigmented 3D full-thickness skin models allow academia and industry to identify those patient and disease specific drugs, which further melanocyte integrity allowing the skin to defend UV light caused skin damage.

Functional modeling of Bainbridge-Ropers syndrome (BRS) mutations suggests a dominant-negative mechanism of pathogenesis. *H. Nistala[1], J. Dronzek[1], J. McClain[2], D. Kajimura[3], S. Wolf[1], J. Overton[1], C. Shoenherr[2], B. Zambrowicz[3], J. Lupski[4], A.N. Economides[1,2].* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Genome Engineering Technologies, Regeneron Pharmaceuticals, Tarrytown, NY; 3) Velocigene Operations, Regeneron Pharmaceuticals, Tarrytown, NY; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Objective Heterozygous *de novo* truncating mutations in *ASXL3* are associated with BRS, characterized by neurologic abnormalities including intellectual disability, severe psychomotor retardation, and microcephaly. However, phenotype in affected individuals varies both in presentation and severity. Truncating mutations occurring in the 5' end of the penultimate exon are associated with more severe phenotype whereas truncating mutations upstream or at the extreme 3' end the gene result in benign phenotype. The goal of this study is to define molecularly the observed phenotypic polarity in BRS mutations. **Methods** Biallelic gene disruption at the *Asxl3* locus was achieved using CRISPR/Cas9-mediated gene editing in mES cells. Recombinants harboring truncating mutations either within the mutational hotspot (representing severe variants) or upstream (benign) were screened using Sanger sequencing and TOPO-PCR cloning. Targeted mES and parental mES (no editing detected) were differentiated into neuronal progenitors using established neural induction protocols. Transcript diversity and mRNA stability were compared between benign and severe variants using RT-PCR, PacBio sequencing and Northern-blot analyses. Furthermore, a recombinant chimeric splicing construct harboring *mAsxl3* locus (with or without the BRS mutations) flanked by constitutive splicing rat *Ins2* exon 2 and 3 was used to validate findings observed in the CRISPR-edited mES clones. **Results** Findings to date in CRISPR-edited mES and heterologous splicing reporter assays suggest that benign and pathogenic variants undergo nonsense-associated altered splicing (NAS). Consequently, mutant transcripts derived from the benign variant activated NMD whereas the stable truncated mRNA derived from pathogenic variants escape NMD with potential dominant-negative function. **Conclusion** Functional modeling of BRS mutations suggests that NAS and resulting activation or escape from NMD contributes to variable neurological phenotypes observed in patients with allelic truncating mutations in *ASXL3*. These observations are consistent with published clinical reports that truncating mutations occurring in the 5' end of Ex 11 or the novel splicing mutation abolishing splice donor site of Ex 11 result in severe BRS phenotype. Taken together, these findings crucially highlight how protein-truncating variants within the same gene can result in variable phenotypes depending on how the substrate transcript is post-transcriptionally processed.

2178F

Development of a screening platform to identify small molecules that modify mRNA splicing in familial dysautonomia. *M. Salani[1], A. Brenner[1], F. Urbina[2], E. Morini[1], E. Law[1], M. Nibratt[1], S.A. Slaugenhaupt[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) University of North Carolina, Chapel Hill, NC.

Familial Dysautonomia (FD) is an autonomic and sensory neuropathy caused by a mutation in the splice donor site of intron 20 of the *IKBKAP* gene. Variable skipping of exon 20 in the *IKBKAP* mRNA leads to a tissue-specific reduction in the level of IKAP protein. Patients produce normal mRNA and protein albeit at low leverls.Therefore, we hypothesized that we could increase cellular IKAP through splicing modification. We previously identified the plant cytokinin kinetin as an efficacious *IKBKAP* splicing modulator, able to restore normal levels of IKAP protein expression in patient cells as well as modify splicing *in vivo* in our transgenic mouse model of FD. Armed with a promising lead compound and unmet medical need, our FD project was chosen to be part of the NIH Blueprint Neurotherapeutics Network. Acting as a collaborative framework, Blueprint gives access to NIH-funded resources and consultants with expertise in various aspects of drug discovery. We developed a primary splicing assay by inserting Renilla (RLuc) and Firefly (FLuc) reporters into our previously well-characterized *IKBKAP* mini-gene constructs. Evaluation of FLuc/RLuc expression in 293T cells transfected with the construct enables a determination of the percent exon inclusion. Here we demonstrate the quality and reproducibility of our screening method. The 8-point dose-response curves generated in the primary assay have reproducible EC_{50} and efficacy values. To avoid false positives we also developed a counter screen in order to identify molecules that might interfere directly with the reporter. Further, we developed a secondary assay using human FD fibroblasts in which we quantify both IKBKAP expression and IKAP protein. After validation of our screening platform, we initiated medicinal chemistry and have tested 520 compounds using our primary assay, yielding 210 compounds that are more potent or efficacious than kinetin. Activity of a subset of these was verified in the secondary assay, and active compounds with favorable ADME and pharmacokinetic properties were evaluated in our transgenic mouse model of FD. *IKBKAP* splicing changes were observed *in vivo*, and detailed evaluation of tissue-specific activity is underway. Development and implementation of this moderately high throughput screening platform for splicing modification has greatly enhanced the likelihood of translating our findings into a new therapy that directly targets the molecular mechanism of disease in FD patients.

2179W

Dissection of the role of PARK9 (ATP13A2) in a clinical case with Kufor-Rakeb syndrome and implications for phenotype modification. *M. Kousi[1], J. Willer[1], V. La Bella[2], R. Spataro[2], N. Katsanis[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) ALS Clinical Research Center, University of Palermo, Palermo, Italy.

ATP13A2 is a member of the P5 ATPase family, recessive mutations in which have been reported to cause a recessive form of parkinsonism. The condition is termed Kufor-Rakeb syndrome and manifests juvenile-onset parkinsonism with associated spasticity, supranuclear gaze palsy, and dementia. Extensive inter- and intra-familial clinical variability have been reported. We recruited a family in which the 30-year-old proband presented with juvenile-onset amyotrophic lateral sclerosis (ALS) and dementia. The diagnosis was supported by the clinical observation of leg spasticity and extremity weakness with characteristic electromyography findings, as well as frontotemporal and cerebellar atrophy observed upon brain imaging evaluation. Subsequent to whole-exome sequencing, we identified a homozygous nonsense change that segregated with the phenotype and was absent from all control databases. *In vitro* studies in patient cells indicated that the mutant message is not subject to nonsense-mediated decay, thus indicating that this allele removes the last 567 amino acids of ATP13A2. To understand how the expression of mutant *ATP13A2* gives rise to an ALS pathology, we sought to establish the direction of effect of the allele identified in our proband and compare it to the effect of other previously published causative alleles, by generating an *in vivo* zebrafish surrogate model that recapitulates both the motor neuron deficits and cerebellar atrophy described. Armed with prior knowledge that supports that *ATP13A2* dysfunction is due to proteasomal defects, we complemented our studies by evaluating a range of components, including proteasomal agonists and genetic determinants such as *TFEB* that augment mitochondrial function and mediate misfolded a-synuclein aggregate exocytocis, as putative therapeutic approaches. Taken together, we expand the mutational spectrum of *ATP13A2* and highlight the importance of the *in vitro* and *in vivo* tools we generated towards the genetic and/or chemical amelioration of a core biological process that can be of putative therapeutic benefit to several other movement disorders that are due to proteasomal dysfunction, such as ALS and Parkinson disorder.

2180T

Expansion of the clinical phenotype of the distal 10q26.3 deletion syndrome to include ataxia and hyperemia of the hands and feet. *M. Lacaria[1], M. Srour[2,3], J. Michaud[4,5,6], A. Doja[7,8,9], E. Miller[10], J. Schwartzentruber[11], J. Majewski[11], K. Boycott[1,7,9] FORGE Canada Consortium.* 1) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 3) Department of Pediatrics, McGill University, Montreal, Quebec, Canada; 4) Research Center, Centre Hospitalier Universitaire Sainte-Justine, Montreal, Quebec, Canada; 5) Department of Pediatrics, Universite de Montreal, Montreal, Quebec, Canada; 6) Department of Neurosciences, Universite de Montreal, Montreal, Quebec, Canada; 7) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 8) Division of Neurology, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 9) Faculty of Medicine, University of Ottawa, Ottawa, Ontario, Canada; 10) Department of Medical Imaging, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 11) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

Distal deletion of the long arm of chromosome 10 is associated with a dysmorphic craniofacial appearance, microcephaly, behavioral issues, developmental delay, intellectual disability, and ocular, urogenital, and limb abnormalities. Herein, we present clinical, molecular and cytogenetic investigations of four patients, including two siblings, with nearly identical terminal deletions of 10q26.3, all of whom have an atypical presentation of this syndrome. Their prominent features include ataxia, mild-to-moderate intellectual disability, and hyperemia of the hands and feet, and they do not display many of the other features commonly associated with deletions of this region. These results point to a novel gene locus associated with ataxia and highlight the variability of the clinical presentation of patients with deletions of this region.

2181F

Impact of *SNX14* mutations on endocytic trafficking and autophagy. *P. Stanier[1], D. Bryant[1], E. Peskett[1], C. Demetriou[1], M. Ishida[1], M. Seda[1], J. Hurst[2], R. Scott[2], S. Sousa[3], D. Jenkins[1], M. Bitner-Glindzicz[1,2], G.E. Moore[1].* 1) University College London, Institute of Child Health, London, UK, United Kingdom; 2) Great Ormond Street Hospital, London, United Kingdom; 3) Hospital Pediátrico de Coimbra, Portugal.

Many conditions have been described where severe intellectual disability and ataxia are found in patients with cerebellar hypotrophy. Individually, most types are rare and without a known molecular pathology. Mutations in *SNX14* have recently been reported to cause a distinct autosomal-recessive cerebellar ataxia with moderate to severe intellectual disability, early-onset cerebellar atrophy, sensorineural hearing loss and coarsened facial features. The SNX14 protein contains a Phox (PX) domain and a regulator of G protein signalling (RGS) domain. Patient-derived fibroblasts were acquired from individuals of three unrelated consanguineous families in Turkey and Portugal. These cell lines have mutations that result in either truncation or loss of the SNX14 protein and in one patient, loss of a single exon (containing the PX-domain) alone was sufficient to result in the associated pathology. This suggests that the PX domain is critical for normal SNX14 function. *SNX14* mutations lead to the accumulation of vesicular inclusions in patient cells, indicating that there is a disturbance in protein metabolism and/or vesicle mediated transport. We show that cellular processes associated with autophagy provide additional evidence of this. However, the precise function of SNX14 remains unknown. We are investigating the role of SNX14 in subcellular trafficking by monitoring these processes in cell-based models of the disease. Loss of SNX14 appears to impact on cholesterol distribution and other lipids. Additionally, we are examining *snx14-/-* zebrafish to establish a research platform with which to explore the neurological deficits associated with the disease.

2182W

Relationship between *MAGEL2*, **a gene implicated in Prader-Willi syndrome, and RING-zinc finger-type E3 ubiquitin ligases.** *V. Carias, R. Wevrick. Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.*

Background: Prader-Willi syndrome (PWS) is a neurodevelopmental disorder characterized by developmental disabilities, obesity, excessive daytime sleepiness and night-time wakening, distinct facial features and autism spectrum disorder. PWS is a sporadic multigene chromosome deletion disorder involving the 15q11-q13 region. *MAGEL2* is one of several genes inactivated in children with PWS and is expressed throughout the brain during development. Mutations in *MAGEL2* alone cause Schaaf-Yang syndrome, a neurodevelopmental disorder associated with many clinical manifestations that are also common in PWS. Members of this family of proteins interact with and modify the function of RING-zinc finger-type E3 ubiquitin ligases (E3 ligases). E3 ligases are involved in ubiquitination, a posttranslational modification in which proteins are targeted for modification and degradation. Ubiquitination is involved in various cell processes such as cell cycle, regulation of transcription, circadian rhythm, and neuronal development. The specific protein function and proteome of MAGEL2 has yet to be elucidated. We investigated the relationship between MAGEL2 and various E3 ligases implicated in PWS. Specifically, we focussed on the E3 ligase TRIM32, which is implicated in Bardet-Biedl syndrome, another genetic neurodevelopmental obesity syndrome, and is also mutated in one form of limb girdle muscular dystrophy. Methods and Results: Using the Gateway Cloning vector system, various constructs were created for expression in mammalian cells (HA-MAGEL2, SF-MAGEL2, V5-TRIM32, V5-TRIM55, V5-RNF41, and V5-RBX1). Co-transfections of each E3 ligase and *MAGEL2* at various ratios were performed in U2OS cells to determine if there are effects on the abundance of either protein via western blot analysis. Co-expression of MAGEL2 modified the stability of several E3 ligases as determined by western blot analysis. Immunofluorescence was used to determine subcellular localization of MAGEL2 and various E3 ligases. Interestingly, MAGEL2 co-localizes with several E3 ligases in the perinuclear region in U2OS cells. Interactions between MAGEL2 and E3 ligases have also been detected. Conclusions: The identification of interactions between MAGEL2 and E3 ligases and their effects on their ubiquitination protein substrates will be useful in determining the underlying cellular mechanisms disrupted in children with PWS and related disorders.

2183T

Variants in *FAT2* **and** *FAT3* **are associated with autism and childhood apraxia of speech.** *S. Klein[1], S. Mullegama[2], U. C.L.A Clinical Genomics Center[2], J.A. Martinez-Agosto[1,3].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 3) Department of Pediatrics, Division of Medical Genetics, UCLA, Los Angeles, CA.

The genetic heterogeneity of autism spectrum disorders (ASDs) poses a challenge in identifying distinct developmental and cellular processes responsible for its etiology. Stratification of phenotypes within ASDs may help to identify distinct genetic subgroups, uncovering patterns of connectivity and signaling pathways responsible for its overall etiology. Amongst ASDs, the presence of specific comorbidities, such as childhood apraxia of speech (CAS), helps to define endophenotypes that may share common genetic etiologies. In this study we surveyed a cohort of ASD cases that had undergone clinical exome sequencing (CES) and focused on a subset that presented with CAS (5%). In 20% of cases we have identified variants in *CNTNAP2,* which is known to regulate speech development. Here we report novel variants in *FAT2* and *FAT3* identified in an additional 40% of ASD-CAS cases. *FAT* genes encode for transmembrane proteins that contain tandem cadherin-type repeats as well as epidermal growth factor (EGF)-like repeats. CES identified *de novo* rare heterozygous (c.85T>C) and compound heterozygous variants (c.[3475 C>A]+[5726C>T]) in *FAT2* and *FAT3* (c.[1868A>C] + [12863 A>C]+[12413 A>C]; c.[11332C>T]+[1081 G>C]). Variants in *FAT2* and *FAT3* were also associated with esotropia and seizures. The presence of distinct phenotypic findings further suggests the important role of FAT genes in brain function where they are highly expressed. Specifically, while *FAT3* is expressed in the cerebral cortex, *FAT2* is highly expressed in the cerebellum, reinforcing that connectivity between cortical and cerebellar function may be important in the pathogenesis of ASD and CAS. Pathway analysis of the FAT2 and FAT3 proteins identified genetic links to key regulators of speech development including FOXP1, FOXP2, FOXP4 and CNTNAP2, strengthening their potential role in language development. Our findings demonstrate a novel association for FAT2-3 with ASD-CAS. We propose that ASD-CAS represents a distinct genetic subgroup of ASD cases and provide novel insights into the genetic etiology of ASD-CAS.

2184F

X-linked histone demethylase Kdm6a regulates cerebellar development and motor coordination. *J. Xu[1], H. Weimar[1], T. Driessen[1], K. Ge[2].* 1) Dept. of Integrative Physiology and Neuroscience, Washington State University, Pullman , WA; 2) National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD 20814, USA.

Kdm6a is an X-linked histone demethylase that activates gene expression via removal of the repressive methylation mark at histone H3 lysine 27 (H3K27). In humans, *KDM6A* mutations cause Kabuki syndrome, a disorder characterized by intellectual disability and motor coordination deficits. To assess the role of Kdm6a in brain development and behavior, we generated a neuron-specific Kdm6a deficient mouse model (Kdm6a[Def]). The Kdm6a[Def] and wild type (WT) littermates have comparable body weight, reproductive behavior, and lifespan, different from the constitutive *Kdm6a* KO mice which die prenatally. The Kdm6a[Def] and WT mice also scored similarly in behavioral tests such as fear conditioning, locomotor activity, and grip strength. However, the mutant mice were impaired for motor coordination when tested with a rotarod. Gene expression analysis with RNA-seq and RT-qPCR identified mis-regulated genes, including up-regulated expression of cerebellar granule cell-specific genes (e.g. *Zic1*, *Etv1*, *Gabra6*, and *Grin2c*), in the Kdm6a[Def] mice. Some of these genes, *Zic1* and *Etv1* for instance, are known to be crucial to the proliferation and differentiation of granule cell precursors. We thus hypothesized that, in the Kdm6a[Def] granule precursors, gene mis-regulation leads to an altered cellular development and subsequently circuitry abnormality in terms of the inhibition-excitation balance, resulting in the behavioral manifestation of motor incoordination. Supportive evidence has been obtained from our ongoing studies including BrdU tracing of the newly born cerebellar granule cells. We believe that this series of analysis is shedding new light on the etiology of Kabuki syndrome as well as the epigenetic basis of brain development and motor behavior.

2185W

Novel role for the small GTPase Bardet-Biedl Syndrome protein 3 in the regulation of glucose transport in the brain. *S.C. Huang[1], C.S. Carter[2], N. Nuangchamnong[3], V. Buffard[2], C. Searby[2], Q. Zhang[2], V.C. Sheffield[2].* 1) Department of Molecular and Cellular Biology, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Department of Obstetrics and Gynecology, University of Iowa, Iowa City, IA.

Glucose is the obligate fuel source for the brain and is essential for normal neurological function. This nutrient depends on glucose transport protein type 1 (GLUT1) for its passage through the endothelial cells of the blood brain barrier. Dysregulation of such transport underlies GLUT1 Deficiency Syndrome [MIM: 606777], a debilitating neurological disease characterized by seizures and cognitive impairment. In spite of the importance of glucose delivery to the brain, little is known about the mechanisms that regulate its passage across the blood brain barrier. Therefore, the purpose of this study is to better understand glucose transport across the blood brain barrier and how glucose regulation affects brain function. Our approach to studying this problem was by using a genetic disease model. The blood brain barrier endothelial cells contain primary cilia to which transporter proteins and their downstream effectors often localize. Emerging evidence suggests that cilia play a central role in coordinating signaling pathways in development and cell homeostasis, with defects causing diseases called ciliopathies. One of the most studied ciliopathies is Bardet-Biedl Syndrome (BBS), a genetically heterogeneous and pleiotropic disorder with cardinal features that include cognitive impairment, obesity, retinal degeneration, and polydactyly. Proteins encoded by these BBS genes form a protein complex called the BBSome, which traffics cargo to and from cilia. Among these BBS-associated proteins is BBS3 [MIM: 600151], an ADP-ribosylation factor-like small GTPase. We have recently found that *Bbs3* knockout mice show diminished glucose levels in the brain with hallmarks of GLUT1 Deficiency Syndrome. We have identified low glucose levels in the cerebral spinal fluid in *Bbs3* knockout mice despite normal blood glucose. Through assessment of glucose uptake in the brain by fludeoxyglucose positron emission tomography, we have found that *Bbs3* knockout mice also have low glucose uptake in the brain, and this decreased uptake varies across different brain regions. Our findings indicate that BBS3 plays a role in regulating glucose transport across the blood brain barrier.

2186T

Impaired ER-Golgi trafficking as a novel therapeutic target for Pelizaeus-Merzbacher disease caused by PLP1 amino acid substitutions. *K. Inoue[1], H. Li[1], P.R. Mangalika[1], A. Nishizawa[1], H. Saya[2], Y. Goto[1].* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) Div Gene Regulation, Inst Advanced Medical Research, Keio Univ, Tokyo, Japan.

Pelizaeus-Merzbacher disease (PMD) is the most common, but incurable inherited hypomyelinating leukodystrophy caused by various mutations in the *PLP1* gene, which encodes a major myelin membrane lipoprotein. PLP1 amino acid substitutions often cause severe form of PMD. In addition to the well-recognized activation of the apoptotic pathway of unfolded protein response (UPR) as an underlying mechanism for oligodendrocyte cell death in PMD brains, we recently identified that mutant PLP1, which accumulates in ER, also interferes with intracellular transport of other normal membrane and secretary proteins, possibly affecting the cellular homeostasis. To explore this cellular pathology further at the molecular level, we employed temperature-sensitive VSVG-YFP system for real-time visualization of the secretary trafficking. We found that, while WT PLP1 has no effect, mutant PLP1 drastically delayed the processing time of VSVG-YFP coming out of ER. We have also explored if drugs that can enhance the transport of secretary and membrane proteins may rescue the cellular phenotype caused by mutant PLP1. To identify such drugs, we screened a library of 1400 existing medicine and identified 8 potential compounds by luciferase-based screening and immunostaining of KDEL receptor, which is normally present in Golgi apparatus but is mislocalized in ER when co-expressed with mutant PLP1. Current studies by treating PLP1 mutant mice (Msd) with these compounds may lead to a discovery of novel medicines for the treatment of PMD. We propose that impaired ER-Golgi trafficking by mutant PLP1 may serve as a novel therapeutic target for PMD caused by PLP1 amino acid substitutions.

2187F

Role of autophagy in the pathology of Snyder-Robinson Syndrome. *M.C. Malicdan[1,2], M. Goheen[1], J. Albert[1], C. Li[3], C.E. Schwartz[4], Y. Huang[1], J. Cassady[1], L. Wolfe[1,5], G. Zhai[3], P. Lee[1,5], D.R. Adams[1,2,5], W.A. Gahl[1,2,5].* 1) NIH Undiagnosed Diseases Program, NIH, National Human Genome Research Institute, NIH, Bethesda, MD; 2) MGB, NHGRI, National Institutes of Health, Bethesda, MD; 3) University of Miami, Medical School, Department of Molecular and Cellular Pharmacology, Miami, FL; 4) JC Self Research Institute, Greenwood Genetic Center, Greenwood, SC; 5) Office of the Clinical Director, National Human Genome Research Institute, NIH, Bethesda, MD.

Snyder-Robinson Syndrome (SRS) is an X-linked intellectual disability syndrome and results from loss of function mutations in the spermine synthase (*SMS*) gene. SMS is an enzyme involved in the polyamine biosynthesis pathway that catalyzes the conversion of spermidine to spermine. Two brothers presented to the NIH Undiagnosed Diseases Program (UDP) exhibiting SRS clinical features: facial asymmetry, hypotonia, intellectual disability, marfanoid habitus, muscular atrophy, and osteoporosis. Whole exome sequencing and follow-up Sanger sequencing revealed that both patients inherited an NM_004595.4:c.443A>G transition on chromosome X from their heterozygous mother, causing a missense Gln148Arg mutation in the SMS protein. Further analysis of patient cell lines showed a decrease in SMS protein levels, and a corresponding increase of spermidine and decrease of spermine, compared to control cells. Several studies have suggested that changes in polyamine levels can modulate autophagy and alterations of autophagy have been implicated in a number of neurodegenerative disorders as a major contributor to neurodegeneration. We hypothesized that modulation of autophagy in the two UDP SRS patients may be a contributor to their neurological phenotype. To investigate this connection, we designed a series of experiments to assess the macroautophagocytic process in the SMS mutant patient cell lines. Western blot analysis suggested increased steady-state levels of the autophagosome protein markers, LC3B-II and p62, in fibroblasts. Similarly, using immunofluorescence, increased autophagosome formation was detected in patients' cells. Our results indicate that macroautophagy is upregulated in SMS patient cells, suggesting that spermidine accumulating in cells due to spermine synthase deficiency may be targeted for autophagic degradation.

2188W

Phenytoin-responsive epileptic encephalopathy with a intragenic tandem duplication involving *FGF12.* A. Kikuchi[1], R. Shi[2], T. Kobayashi[1,3], R. Sato[1], M. Uematsu[1], K. An[4], S. Kure[1]. 1) Department of Pediatrics, Tohoku University Hospital, Sendai, Japan; 2) Department of Neonatology, First Affiliated Hospital, Medical College of Xi'an Jiaotong University, Xi'an, China; 3) Division of Genomic Medicine Support and Genetic Counseling, Department of Education and Training, Tohoku Medical Megabank Organization (ToMMo), Tohoku University, Sendai, Japan; 4) Clinical Technology Department, Tohoku University Hospital, Sendai, Japan.

Epileptic encephalopathies are heterogenous entity of epilepsies characterized by reccurent seizures with developmental slowing or regression. The genetic etiology of epileptic encephalopathies has gradually been revealed by the identification of causative genes, which include mutations in sodium channel subunits. Recently, non-secreting fibroblast growth factors (FGFs), sodium channel-binding proteins, have been associated with neurodevelopmental disorders including epileptic encephalopathy. Moreover, Siekierska et al. have reported a family of patients with epileptic encephalopathies with a *de novo* mutation in *FGF12*, which have a gain-of-function effect on sodium channel gating, predicting increased neuronal excitability (Neurology, 2016). Here, we report another case of *FGF12*-related epileptic encephalopathy. Contrast with the previous report, the phenotype was relatively mild. The patient had normal development prior to the onset of seizures at three years of age, and his seizure was respond to phenytoin, a sodium channel blocker. Genomic analysis revealed a intragenic tandem duplication involving the gene, probably thorough L1 family long interspersed nuclear elements-mediated nonallelic homologous recombination. cDNA analysis showed biallelic expression of FGF12 with abnormal transcripts. Although it remains unclear that how the products from the mutant allele work, the absence of loss-of-function mutations except in last exon or isoform-specific exon in ExAC database implicates that haploinsufficiency of FGF12 may be enough to invoke a disease phenotype as well as gain-of-function effect as described by Siekierska et al.. This report provides further evidence for as a causative gene for epileptic encephalopathy and expands the phenotypic spectrum of the *FGF12*-related epileptic encephalopathy. We also propose a therapeutic approach for *FGF12*-related epileptic encephalopathy by a sodium channel blocker.

Identification of muscle segment homeobox gene 1, *MSX1,* **as a candidate susceptibility gene for congenital heart disease in individuals with Wolf-Hirschhorn syndrome.** E.R. Harward[1], S. Venkatasubramanian[3], R.J. Vanzo[1], C.H. Hensel[1], M.R. Sdano[1], M.M. Martin[1], A. Lortz[4], J.C. Carey[2], E.R. Wassman[1], K.S. Ho[1,2]. 1) Lineagen, Inc, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah; 3) School of Computing, University of Utah; 4) 4p- Support Group.

Wolf-Hirschhorn syndrome (WHS) is a well-described contiguous gene deletion syndrome caused by varying sized deletions of the short arm of chromosome 4 with highly variable phenotypic features and disability. We used high-resolution genotype-phenotype correlation to define genetic loci within the 4p region that are likely causative for individual features and recently described a novel candidate gene associated with seizures in these individuals (Ho, et al, 2016). In the same cohort of thirty-four individuals with WHS, with deletions of 4p ranging from 1.3–32.5 MBp in size and containing 28-200 genes, we further correlated deletion breakpoints on a custom, ultra-high resolution chromosomal microarray with over 20 other specific phenotypic features of WHS. A novel statistical technique was used to analyze this dataset for non-obvious correlations between specific clinical features and genomic regions to identify candidate genes of likely pathogenicity. Congenital heart defects are highly prevalent in our WHS cohort (71%) and our statistical approach suggested muscle segment homeobox 1 (*MSX1*) as a relevant candidate gene within a 3 Mbp region associated with congenital heart defects (p=0.0048 Fisher's exact test, two-tailed). Within this region, *MSX1* is the likely candidate gene supported by its role in cardiac development. *MSX1* acts along with Wnt and BMP signaling in early vertebrate cardiac development (Rao et al, 2016), and dual disruption of both *Msx1* and its paralog *Msx2* in mice results in cardiac outflow tract abnormalities. *MSX1* appeared hyper-methylated in a human fetus with double outlet right ventricle, VSD, and hypoplasia of the ascending aorta (Serra-Juhe et al 2014). Aortic valve dysplasia was reported in a woman with a *de novo* duplication of a 3.8 Mbp containing the *MSX1* gene (Hitz, 2012). Two independent genome-wide association studies and one replication study identified SNPs in *MSX1* associated with atrial and ventricular septal defects. (Li et al 2015; Cordell et al 2013). *MSX1* had been proposed as a candidate gene involved in the oligodontia and cleft lip/palate associated with WHS. Our analysis did not support *MSX1* as the best candidate gene association for either, rather finding FGF pathway members involved in both. This computational approach will be applied to other traits associated with WHS as well as other genetic syndromes to search for the best predictive medical management.

2190F

Using zebrafish to model the role of *CLEC16A* in neurological disease. *M. Bakay[1], C. Seiler[2], S. Yoeu[1], C. Kao[1], R. Pandey[1], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Research Core Services, Children's Hospital of Philadelphia, Philadelphia, PA.

CLEC16A SNPs are associated with multiple autoimmune and inflammatory diseases, including type 1 diabetes, multiple sclerosis primary adrenal insufficiency, Crohn's disease, primary biliary cirrhosis, juvenile idiopathic arthritis, rheumatoid arthritis and alopecia areata; however, the primary function of this gene and the protein its encodes remains largely unknown. Recent studies in different model systems revealed that CLEC16A play an important role in autophagy/mitophagy. Zebrafish are now established as a valuable tool for disease modeling, especially for mitophagy and neurodegeneration. We hypothesize that using a CLEC16A specific morpholino (MO) mRNA knock down in zebrafish will reveal a neurological phenotype and help to understand the role of CLEC16A in nervous system.We designed a splice blocking MO which generates a frameshift mutation after exon 4 and introduced a STOP-codon soon after. RT-PCR was used to identify and quantify new transcripts. Introduction of the mutation was confirmed by sequencing. To perform MOs titration, three different concentrations (0.5, 0.75 and 1.0mM) of CLEC16A specific MOs were injected into the yolks of 1–8-cell-staged embryos. Since all of them had similar efficiency we decided to use 0.75mM MO for all further experiments. We confirmed stable CLEC16A KD as long as day 7 by CR-PCR. We studies 3, 5 and 7 day old zebrafish by microscopy. Loss of CLEC16A expression resulted in significantly reduced branching of motor neurons when compared to control MO injections.Our data suggest that CLEC16A may play an important role in motor neuron branching and development. We are currently investigating the effect of CLEC16A loss on disease pathogenesis in CLEC16A-mutant zebrafish focusing on neurogenesis, immune cell function and autophagy with preliminary results from those studies supporting an important role of CLEC16A in neuronal development.

2191W

Differential gene expression of sensory and motor neuron in embryonic spinal cord with single cell analysis. *J. Kim, M. Lin, T. Souaiaia, V. Wolseley, C. Walker, A. Camarena, J. Nguyen, J. Herstein, W. Mack, O. Evgrafov, R. Chow, J. Knowles.* Zilka Neurogenetic Institute, USC, 1501 San Pablo st. #401 Los Angeles, CA.

The gray matter in spinal cord is composed of dorsal and ventral horns. Dorsal horn contains sensory neurons and ventral horn contains motor neurons. Gradient of SHH protein expression determines the fate of these compartment during brain development. However, details of differentiation of these compartments of human embryo remains unclear. Our group has performed single-cell RNA sequencing of 17 interneurons, 34 sensory neurons and 226 motor neurons from human embryonic spinal cord of gestational age 9-16 weeks. Distinct sensory and motor neuron clusters were observed in PCA plot. 1,674 genes were found to be differentially expressed using DESeq2. This list includes several G protein coupled receptor genes, which are involved in pathways downstream of SHH (Sonic Hedgehog) gradient. We found some sensory markers such as POU4F1 on the list of overexpressed genes in sensory neurons. .

2192T

LGI1 mutations linked to lateral temporal epilepsy allow protein secretion and impair interaction with ADAM22/23 receptors. *C. Nobile[1], E. Dazzo[1], E. Leonardi[2], E. Belluzzi[3], E. Greggio[3], L. Vitiello[3], S. Malacrida[4], S. Tosatto[4].* 1) CNR-Neuroscience Institute, Padova, PD, Italy; 2) Woman and Child's Health Dept, University of Padua, Padova, Italy; 3) Biology Dept, University of Padua, Padova, Italy; 4) Biomedical Sciences Dept, University of Padua, Padova, Italy.

Autosomal dominant lateral temporal epilepsy (ADTLE) is a focal epilepsy syndrome caused by mutations in the LGI1 gene, which encodes a secreted protein. Most ADLTE-causing mutations inhibit LGI1 protein secretion, and only a few secretion-positive missense mutations have been reported. We describe the effects of four disease-causing nonsynonymous LGI1 mutations, T380A, R407C, S473L, and R474Q, on protein secretion and extracellular interactions. Expression of LGI1 mutant proteins in cultured cells shows that these mutations do not inhibit protein secretion. This likely results from the lack of effects of these mutations on LGI1 protein folding, as suggested by 3D protein modelling. In addition, immunofluorescence and co-immunoprecipitation experiments reveal that all four secretion-positive mutations significantly impair interaction of LGI1 with the ADAM22 and ADAM23 receptors on the cell surface. Thus, rather than inhibiting protein secretion, some ADLTE-causing LGI1 mutations reduce affinity of extracellular LGI1 for ADAM22 and ADAM23, which are both involved in the molecular mechanisms leading to ADLTE.

2193F

A combined approach of exome sequencing and genome editing identified *WDR62/MCPH2* mutations in patients with primary microcephaly. *T. Miyamoto[1], Y. Masatsuna[1], A. Fukumitsu[1], S.N. Akutsu[1], K. Hosoba[1], H. Morino[2], H. Kawakami[2], T. Yamamoto[3], K. Shimizu[4], H. Ohashi[4], S. Matsuura[1].* 1) Genetics & Cell Biol, RIRBM, Hiroshima University, Hiroshima, Japan; 2) Epidemiol, RIRBM, Hiroshima University, Hiroshima, Japan; 3) Math & Life Sci, Grad. Sch. Sci, Hiroshima University, Higashi-hiroshima, Japan; 4) Saitama Children's Medical Center, Saitama, Japan.

Primary microcephaly (MCPH) is an autosomal recessive neurodevelopmental disorder characterized by congenital reduction of head circumference. So far 13 causative genes have been identified. It was reported that *WDR62* gene, which encodes centrosomal protein to control mitotic spindle assembly, is responsible for *MCPH2* gene locus (Nature 2010, Nat Genet 2010). Here we identified compound heterozygous mutations c.731 C>T (p.Ser 244 Leu) and c.2413G>T (p.Glu 805 X) in the *WDR62/MCPH2* gene of the two siblings in a Japanese microcephalic family using whole exome sequencing. The molecular and cellular pathology of *WDR62/MCPH2* mutation-caused microcephaly remains unclear. Here we used CRISPR/Cas9 system-mediated genome editing technology and single strand oligonucleotide (ssODN) as a point-mutation targeting donor to generate human *WDR62/MCPH2* c.731 C>T (p.Ser 244 Leu) missense mutation knock-in cell lines in order to elucidate the physiological role of WDR62. *WDR62/MCPH2* mutated cells did not show aneuploidy, suggesting that WDR62 is dispensable for chromosomal stability. In the normal metaphase, mitotic spindle forms parallel to the substratum to ensure symmetric cell division. *WDR62/MCPH2* mutated cells exhibited randomized spindle orientation caused by the impaired microtubule assembly activity. During early neurodevelopment, neural stem cell expands its population by symmetric cell division, and the following asymmetric cell division produces neural stem cells and neurons to control the proper size of brain. Our results suggest that *WDR62/MCPH2* mutations disrupt symmetric cell division of neural stem cell to induce premature asymmetric cell division through the instability of spindle orientation to cause microcephaly.

2194W

Sequencing of exon 5 Chat gene in Iranian congenital myasthenic syndrome patients. *Z. Farjami[1,2], F. Shariatmadari[3], M. Houshmand[1].* 1) National Institute of Genetic Engineering and Biotechnology, Tehran,Iran, Tehran, Iran; 2) Department of Biology, Damghan Branch, Islamic Azad University, Damghan Iran; 3) Amir Kabir Hospital, Department of Pediatric Neurology, Faculty of Medicine, University of Medical science, Arak, Iran.

Congenital myasthenic syndrome (CMS) is a heterogeneous group of inherited disorders, which caused by handicapped signal transmission at the neuromuscular junction. Fatigable muscle weakness is a diagnosis symptom of syndrome. Phenotype analysis showed a uniform pattern of clinical features including mild to moderate fatigable weakness of ocular and bilateral ptosis, facial, bulbar, and limb muscles Mutations in several genes that encoding proteins expressed at the neuromuscular junction may cause CMS. Aim of present study is assessment of mutations in 5 exon of CHAT gene, which encodes choline acetyltransferas. The important Mutations in this gene cause congenital myasthenic syndromes. Utility of deletion/duplication analysis for this gene is unknown .The choline acetyltransferas CHAT gene might be frequent in European congenital myasthenic syndrome patients of Gypsy ethnic origin. Proportion of CMS Attributed to Mutations in CHAT Gene is 5%. We selected 23 Iranian patients with congenital myasthenic syndrome. DNA extracted from peripheral blood and polymerase chain reaction (PCR) and DNA cycle sequencing operated by automated sequencers ABI 3700 for exon 5 of CHAT gene. Our results in 23 Iranian patients with CMS, showed no missense mutation in 5 exon of CHAT Gene. It seems that Iranian CMS population has different genetic variations in compare with European population. Also different exons in CHAT or other genes could be hot spots in Iranian CMS population, which needs further studies.

2195T

Effectively modeling rare neurodevelopmental disorders: A pilot project identifying a novel chromatin remodelling disease. *S.C. Bell[1], H. Peng[1], I. Kolobova[1], C. Ernst[1,2,3].* 1) Neuroscience, McGill University, Montreal, Quebec, Canada; 2) Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Psychiatry, McGill University, Montreal, Quebec, Canada.

Developing effective models of rare neurodevelopmental disorders (NDDs) presents significant challenges due to the rarity of patients and the difficulties associated with acquiring human neuronal cells. This commonly forces researchers to rely on substandard models to study rare NDDs, which can obfuscate results. Therefore, developing a more effective methodology for modeling rare NDDs represents a key step towards improved therapeutics for these disorders. **Here we present our methodology for modeling rare NDDs, using a family with a rare mutation in a chromatin remodelling complex as a pilot study.** We recruited a family with two children suffering from severe seizures and developmental delay, with an unknown causative mutation. Exome sequencing of twenty-three family members identified a novel and potentially disease-causing variant in the gene *ACTL6B*, which encodes a key targeting component of an important regulator of neuronal development, the *SWI/SWF* chromatin remodeling complex. In order to model the disease present in the family, we converted fibroblasts from affected and healthy patients into induced pluripotent stem cells (iPSCs) and generated cortical neural progenitor cells. Using this disease model, patient cells were found to have a significantly reduced level of expression of *ACTL6B*, which correlated with a dysregulation of neuronal differentiation. The methodology utilized to investigate this variant in *ACTL6B* demonstrates how researchers can develop efficient and effective models of neural cells to model rare NDDs. The research shown here is also the first description of a disease-causing variant in the *ACTL6B* gene.

2196F

Interactions between the Prader-Willi syndrome candidate protein MAGEL2 and neuronal proteins. *M. Sanderson, H. Cortes, M. Zoeteman, R. Wevrick.* Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

   Inactivating mutations in the *MAGEL2* gene results in a neurodevelopmental disorder that causes intellectual disability called Schaaf-Yang syndrome. *MAGEL2* is one of the genes inactivated in Prader-Willi syndrome, which shares many clinical findings with Schaaf-Yang syndrome such as autism spectrum disorder. *MAGEL2* is predominantly expressed in brain and muscle, but is also seen in other tissues. The MAGEL2 protein contains a MAGE homology domain that is shared with ~40 other mammalian MAGE proteins. The MAGE protein necdin is encoded by *NDN*, which is co-deleted with *MAGEL2* in people with PWS. Both MAGEL2 and necdin interact with E3 ubiquitin ligases through their MAGE homology domain. In mice, loss of *Magel2* affects brain development and function, disrupts circadian cycles and causes other phenotypes that recapitulate symptoms of Schaaf-Yang and Prader-Willi syndromes. Mice lacking *Magel2* have decreased volume in specific regions of the brain and altered brain chemistry. However, little is known about the role that MAGEL2 plays in brain function and development. Identifying the proteins that interact with MAGEL2 in neuronal cells will allow us to connect the underlying molecular processes that MAGEL2 is involved in with the neurodevelopmental deficiencies in Prader-Willi syndrome and associated disorders. We used a combination of approaches to identify novel interactions between MAGEL2 and other proteins, including affinity purification-mass spectrometry, proximity-dependent biotin identification, yeast two hybrid analysis and candidate protein screening. We expressed recombinant epitope-tagged human MAGEL2 or mouse Magel2 in human or mouse cell lines that endogenously express MAGEL2/Magel2. We identified MAGEL2-interacting proteins involved in a variety of intracellular processes, including axon guidance, axonal transport, cellular responses to growth factor stimulus, nervous system development, protein ubiquitination and deubiquitination, retrograde transport, and autophagy. Expression of MAGEL2 affects the abundance of co-expressed proteins, suggesting that it plays an important role in protein stability through ubiquitin-mediated processes. This study provides additional insight into the normal cellular and developmental role of *MAGEL2*, and mechanisms through which the loss of *MAGEL2* in children with Schaaf-Yang or Prader-Willi syndromes impairs brain development and function.

2197W

Disruptions to the miRNA regulatory pathway may cause an increased rate of schizophrenia in individuals with 22q11.2 DS. *W. Manley, S. Siecinski, S. Ryan, V. Coulibaly, S. Buyske, L. Brzustowicz.* Genetics, Rutgers University, Piscataway, NJ.

   Schizophrenia is a complex and poorly understood disease caused by the interplay of many environmental and genetic factors. The 22q11.2 deletion syndrome (DS) is a disorder that is caused by the microdeletion of part of chromosome 22 leading to a 25-fold greater chance of developing schizophrenia in affected individuals versus the general population. The missing 22q11.2 region contains DGCR8, which is required for the initial step of miRNA biogenesis. However, the 22q11.2 deletion itself is not sufficient to cause schizophrenia, since 75% of individuals with this deletion do not develop the disease. We hypothesize that the 22q11.2 deletion increases the risk of schizophrenia through alterations in miRNA regulatory networks via depletion of several miRNAs. This network may serve as a protective buffer against the accumulation of deleterious mutations at other schizophrenia risk loci. We have expanded our sample of human neural stem cells (NSCs) from individuals with the 22q11.2 deletion and schizophrenia. The NSCs were generated from iPSCs using Neural Induction Media (Life Technologies). In order to ensure the presence of the 22q11.2 deletion, a FISH analysis was conducted (Cell Line Genetics) using a probe for 22q11.2 (TUPLE). Also, the levels of DGCR8 gene expression were quantified using the 7900HT Fast Real-Time PCR System (Applied Biosystems) along with Taqman Gene Expression Assays and Copy Number Assays to ensure DGCR8 reduction in 22q11.2 DS NSCs relative to otherwise healthy control NSCs. Unexpected chromosomal abnormalities associated with iPSC culture methods have made routine detection of the deletion essential. We have characterized disruptions to the miRNA regulatory network in the NSC lines using Taqman Array Human Microarray Cards Version 3.0 and Illumina Small RNA sequencing (RNA-Seq) using ten lines (5 control and 5 22q11.2 DS). Here we will present the miRNAs that we have identified to be differentially expressed in otherwise healthy control NSCs versus NSCs with 22q11.2 DS and schizophrenia. Our preliminary data shows that of the 377 tested miRNAs, nearly 30% have at least a 2 fold expression change in deletion samples. We predict that these miRNAs could be involved in the elevated risk of developing schizophrenia in individuals with 22q11.2 deletion syndrome versus the general population. Future studies will focus on determining the biological targets of these miRNAs using miRNA target prediction software.

2198T

Mouse models of human disease available from The Jackson Laboratory. *S. Rockwood, M. Sasner, The Genetic Resource Science Team.* The Jackson Laboratory, Bar Harbor, ME.

As our understanding of basic disease mechanisms grow, so does our appreciation for the complexities that stand as barriers to developing effective therapies. The advent of new genetic engineering technologies, tractable in the mouse, has spawned promising preclinical approaches to overcome these obstacles. To facilitate these developments, The Jackson Laboratory (JAX) Mouse Repository provides access to one of the largest sets of well-characterized genetically engineered mutant mouse strains available. Hundreds of new mouse lines generated by both the international scientific community and JAX researchers are added to the Repository each year. A growing selection of models with applications as hosts for cancer xenograft modeling, primarily on the NSG platform, is readily available. Strains have been optimized for specific purposes: support of human and murine hematopoietic cell engraftment, reduced xenogeneic graft-versus-host disease response, engraftment of human hematopoietic stem cells without irradiation and stable engraftment of primary human hepatocytes. Mouse strains that recapitulate aspects of specific diseases, such as Alzheimer's disease and Huntington's are available as well. To exploit the potential of CRISPR/Cas9 technology to generate precise models of disease, a large variety of Cas9-expressing lines are offered, including constitutive expressing and *cre*-inducible lines. Cas9 strains are available on multiple genetic backgrounds. In response to the threat posed by the spread of Zika virus, colonies of *Ifnar1*-deficient mice have been expanded. Several recent studies demonstrate that *Ifnar1* knockout mice represent a model that facilitates the study of Zika virus pathogenesis and should prove to be useful in the development of related therapies. In order to promote reproducibility in research, the Repository maintains a robust quality control and assurance program. Newly arriving strains are assayed to confirm the presence of expected genetically engineered mutations. Equally important, strains are also routinely screened for undesirable contaminating alleles and genetic backgrounds. Donating a strain to the Repository is an easy way to fulfill the NIH's requirements for sharing mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains: www.jax.org/donate-a-mouse. This work is supported by NIH, The Howard Hughes Medical Institute, and several private charitable foundations.

2199F

IImpaired transferrin receptor recycling in neurodegeneration with brain iron accumulation (NBIA). *A. Drecourt[1], M. Dussiot[1], J. Babdor[1], M. Garfa-Traoré[1], N. Goudin[1], F. Habarou[1], C. Bole-Feysot[1], P. Nitschké[1], C. Ottolenghi[1], V. Serre[3], I. Desguerre[2], N. Boddaert[2], O. Hermine[1], A. Munnich[1,2], A. Rotig[1].* 1) Institut IMAGINE, INSERM U1163, 24 Boulevard du Montparnasse, 75015 Paris, France; 2) Departments of Pediatrics, Radiology and Genetics, Hôpital Necker-Enfants Malades, 149 Rue de Sèvres, 75015 Paris, France; 3) Institut Jacques Monod, CNRS (UMR7592), 15 rue Hélène Brion, 75013 Paris, France.

Neurodegeneration with brain iron accumulation (NBIA) encompasses a group of rare neurogenerative disorders with different clinical, brain MRI and molecular features, underlined by progressive extrapyramidal dysfunction and iron accumulation in the brain. Eleven disease genes have been hitherto identified (*PANK2* [MIM 606157], *PLA2G6* [MIM 603604], *COASY* [MIM 609855], *FA2H* [MIM 611026], *ATP13A2* [MIM 610513], *C2orf37* [MIM 612515], *WDR45* [MIM 300526], *C19orf12* [MIMM 614297], *CP* [MIM 117700], *FTL* [MIM 134790] and *GTPBP2* [MIM 607434]). Few of these genes are known to be related to iron homeostasis. Exome sequencing in two independent families identified two novel genes for NBIA, *CRAT* [MIM 600184] and *REPS1* [MIM 614825]. *CRAT* encodes the carnitine acetyltransferase and b-oxidation of U-$^{13}C_{16}$ palmitate in cultured fibroblasts of the patient detected decreased levels of C_4 and C_2 suggesting a reduced β-oxidation that was rescued by overexpression of wt *CRAT* cDNA. REPS1 is involved in endocytosis and fibroblasts of the patient showed significant increase of iron content that was rescued by overexpression of wt *REPS1* cDNA. Internalization of transferrin (Tf)-bound iron by transferrin receptor 1 (TfR1) mediated endocytosis is the major route of iron uptake. Iron homeostasis is regulated by a post-transcriptional mechanism involving iron responsive proteins (IRPs) that represent the main iron regulators in vertebrates. This post-transcriptional regulation is the only known mechanism of iron homeostasis regulation. Interestingly, post-transcriptional regulation of TfR1 as well as ferritin was normal in fibroblasts of patients with *REPS1*, *CRAT*, *PANK2*, *PLA2G6*, *C19ORF12* and *FA2H* mutations, yet TfR1 and ferritins proteins were dramatically increased accounting for the abnormal iron uptake and major iron overload in NBIA . We also observed abnormal Tf and TfR1 recycling in NBIA fibroblasts, increased amount of TfR1 at cell surface and iron overload when cells were grown in high iron condition. Therefore, whatever the disease causing gene, NBIA fibroblasts are characterized by abnormal TfR1 recycling and iron overload. Moreover, the apparent escape of TfR1 and ferritin to IRPs regulation suggested alteration of an as yet unknown post-translational regulation in NBIA fibroblasts.

2200W

Immune cells emerging as major source of neurodegeneration in Parkinson's disease. *M.K. Pandey[1,2], D. Magnusen[1], M.M. McKay[1], M.A. Gurtler[1], M. Caballero[1], T.A. Burrow[1,2].* 1) Divisions of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH 45229; 2) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH 45229.

GBA1 mutations and increases of neuronal α-synulcein protein (α-syn) are the hallmark of Parkinson's disease (PD). Using *Gba1[D409/D409]* mouse model of PD, we have observed α-syn connection with brain recruitment of inflammatory subsets of dendritic cells (DCs) and T cells and their role in increased production of pro-inflammatory cytokines. These cytokines trigger neuronal loss and cognitive dysfunction in *Gba1[D409/D409]* mouse. However, the mechanism by which α-syn induces immune cells activation and increased generation of pro-inflammatory cytokines in PD is still not clear. To explore this, DCs and CD4[+]T cells were purified from brain of WT and *Gba1[D409/D409]* mouse and used for performing their ex-vivo stimulation with α-syn. These later cells were used for measurement of any alteration in phosphorylation of signaling cascades, (e.g., ERK1/2 and AKT), which are critical for generation of pro-inflammatory cytokines and induction of tissue inflammation. Our data showed that α-syn stimulated immune cells cause upregulation of pERK1/2 and pAKT and increased generation of pro - inflammatory cytokines (e.g., IFNg, TNFα, and IL6) in *Gba1[D409/D409]* mouse. Targeting indicated signaling could be potential therapy to discontinue inflammation and neurodegeneration in PD. .

2201T

The molecular phenotypes of *CHRNA7* copy number changes in human cells. *M.A. Gillentine[1], J.J. Kim[2], C.P. Schaaf[1,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Stem Cell Core, Baylor College of Medicine, Houston, TX; 3) Jan and Dan Duncan Neurological Research Institute, Houston, TX.

Chromosome 15q13 is one of the least stable regions in the genome due to low copy repeat (LCR) elements clustering into breakpoints (BP1-BP6), making the region vulnerable to non-allelic homologous recombination. At 15q13.3, recurrent copy number variants (CNVs) are observed in neuroaffected populations utilizing three sets of breakpoints, BP3-BP5, BP4-BP5, or the distal-*CHRNA7*-LCR (D-CHRNA7-LCR)-BP5. Deletions have been established as pathogenic, with probands presenting with autism spectrum disorder (ASD), epilepsy, and intellectual disability/developmental delay (ID/DD). 15q13.3 duplications, one of the most common CNVs identified in clinical microarray samples, have only been recently characterized, with probands presenting with ID/DD, ASD, and attention deficit hyperactivity disorder. Encoding for the α7 nicotinic acetylcholine receptor (nAChR) with high expression in the brain, *CHRNA7* has been suggested as a candidate gene for these CNVs. Additionally, the variable expressivity observed with these CNVs has been suggested to be a result of possible modifiers affecting the function of *CHRNA7*. One likely modifier is the human specific fusion gene, *CHRFAM7A*. In HEK293T cells, we have found that when overexpressed, α7 and CHRNA7-FAM7A colocalize and colocalize with the α7-specific antagonist α-bungarotoxin (α-bgtx), indicating that they form functional receptors. Additionally, when *CHRNA7* is coexpressed with *CHRFAM7A* or *CHRFAM7AΔ2bp*, we observe a decrease in α-bgtx fluorescence intensity, suggesting a possible dominant negative effect. In concert, utilizing patient derived human induced pluripotent stem cells (iPSCs) and iPSC-derived neurons, we are determining the molecular phenotypes and functional consequences of *CHRNA7* CNVs. In these iPSCs, mRNA levels of genes within 15q13.3 CNVs correlate to their genomic copy number. For smaller *CHRNA7* duplications spanning D-CHRNA7-LCR to BP5, mRNA overexpression suggests that the whole gene is duplicated. Additionally, duplications that may include part of *OTUD7A* do not appear to disrupt its expression. These changes in expression likely result in alterations of α7 protein expression and α7-nAChR specific calcium flux, which may be further impacted by the presence of *CHRFAM7A*. Overall, this suggests that changes in *CHRNA7* copy number and the presence of *CHRFAM7A* have functional consequences that are likely contributing to neurological phenotypes observed in patients.

2202F

Neurons derived from individuals with autism spectrum disorder show early impairments in synaptic functionality and network activity. *D.M. Dykxhoorn[1,3], C. Garcia_Serje[1], B.A. DeRosa[1,3], E. Artimovich[2], M.W. Nestor[2], D. Van Booven[1], K.C. Belle[1], H.N. Cukier[1], M.L. Cuccaro[1,4], J.M. Vance[1,3], M.A. Pericak-Vance[1,3].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Hussman Institute for Autism Research, Baltimore, MD; 3) John T. Macdonald Foundation Department of Human Gnenetics, University of Miami, Miami, FL; 4) Department of Neurology, University of Miami, Miami, FL.

Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental condition characterized by social-communicative difficulties and the presence of restricted repetitive behaviors and interests. Recent studies have shown that genes harboring ASD risk loci are highly enriched in genes expressed during early cortical development and genes that function in pathways involving the regulation of transcription, chromatin remodeling, cell adhesion, signaling complexes, and synapse function. However, the impact that these genetic variants have on ASD pathophysiology is still being revealed. This is due in part to a lack of genetically-relevant human disease models. Advances in human induced pluripotent stem cell (iPSC) technology and neural differentiation techniques have made it possible to study the molecular mechanisms that underlie ASD pathology in a model system that mimics the human genetics. To that end, we generated patient-specific iPSC lines from 6 unrelated, non-syndromic ASD individuals with rare variants identified through exome sequencing and 5 gender and ethnicity matched control lines. The ASD and control iPSCs were differentiated into cortical neurons and whole transcriptome analysis was performed. In addition, since the early establishment of functional cortical neural networks is an important step in overall brain development, and may be impaired in individuals with ASD, we examined the electrophysiological characteristics of these iPSC-derived neurons. Transcriptome analysis implicate disturbances in the regulation of transcription, WNT signaling, chromatin remodeling, cell adhesion and migration, and synapse development across all time points analyzed. Over the course of neuronal differentiation, we observe key changes in genes associated with neural development and synaptic functionality, including WNT/MET signaling ($p = 4.95 \times 10^{-36}$), cell migration ($p = 1.34 \times 10^{-6}$), GABAergic neuron signal transmission ($p = 2.86 \times 10^{-9}$), and WNT-mediated axon guidance ($p = 4.71 \times 10^{-5}$). Consistent with these patterns of gene expression, cortical neurons derived from ASD individuals demonstrated significantly decreased network spiking activity from MEA recordings ($p < 0.001$) as well as decreased numbers of calcium transients ($p < 0.05$). The results of this study suggest that there may be early deficits in network activity and morphology in ASD-specific iPSC-derived neurons that is detectable at both the transcriptomic and functional levels.

2203W

Metabolic consequences of dietary interventions in the Magel2-null mouse model of Prader-Willi syndrome. *J. Bischof, C. Smolarchuk, R. Wevrick.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada.

Children with Prader-Willi syndrome (PWS) or with Schaaf Yang syndrome and a deficiency of only one of the PWS genes, namely MAGEL2, have prenatal hypotonia, motor delays, and reduced muscle mass. Their myopathy contributes to the development of scoliosis, decreases caloric need, and impairs quality of life. Interventions that build muscle mass or improve exercise tolerance are key to controlling body weight in PWS. Our study focuses on dietary interventions and treatment with readily available compounds so that positive preclinical results can be readily translated into practice in the management of muscle tone and endurance in children with PWS. We found that *Magel2* is necessary for normal maintenance and function of skeletal muscle. Mice lacking *Magel2* have increased fat, decreased muscle, and reduced strength and endurance. We hypothesized that the muscle cells in mice lacking *Magel2* have a primary defect in their capacity to use carbohydrates vs. fat as fuel, and a reduced ability to reuse nutrients from the breakdown of cellular components. We tested whether dietary interventions ameliorate or worsen the muscle-related phenotypes in *Magel2*-null mice. Cohorts of 6-week old mice were fed diets that contained standard, high sucrose, high fat, or high fat then high fat-low carbohydrate (ketogenic) food. After treatment, we measured body composition and metabolic parameters in the mice and compared the findings between genotypes and among diets. These studies will inform us about the underlying bases for hypotonia and reduced muscle mass in PWS and Schaaf-Yang syndrome (MAGEL2 deficiency). These phenotypes have not yet been investigated at a genetic or molecular level. This study will also set the stage for future preclinical and clinical trials in PWS that repurpose drugs already in development for the treatment of other myopathies or forms of muscle atrophy.

2204T

Towards a complex genetic interaction model to explain phenotypic variability associated with rare copy-number variants. *M. Jensen, L. Pizzo, D.M. Singh, Q. Wang, S. Girirajan.* Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA.

Rare copy number variants (CNVs) have been associated with several complex neurodevelopmental disorders, including autism, schizophrenia, intellectual disability (ID), and epilepsy. One class of rare CNVs is characterized by phenotypic heterogeneity and the lack of known causative genes. For instance, the 16p11.2 deletion contributes to 1% of sporadic autism cases, and has also been linked to cases of ID, epilepsy, obesity, and congenital malformations. We hypothesize that interactions between genes within the CNV (in *cis*) and at second sites outside the CNV (in *trans*) determine the neurodevelopmental phenotypes associated with these CNVs, instead of only one causative gene within the CNV. In order to identify important interactions and underlying molecular pathways related to these CNVs, we performed RNA sequencing of 13 *Drosophila* knockdown models of rare CNV orthologs: *CDIPT, CORO1A, DOC2A, KCTD13, MAPK3,* and *PAGR1* in the 16p11.2 deletion; *C16orf52, CDR2,* and *UQCRC2* in the 16p12.1 deletion; and *DLG1, NCBP2, PAK2* and *PIGZ* in the 3q29 deletion. We analyzed the lists of differentially-expressed genes in each knockdown model for enrichment of gene ontology and KEGG Pathway annotations, functional relevance to neurodevelopment, and identified disease-associated genes. Among the 16p11.2 ortholog knockdowns, we found four knockdown models that resulted in a large number of differentially-expressed genes (1,084 genes in *CDIPT*, 527 in *KCTD13*, 457 in *CORO1A*, and 327 in *MAPK3*). Similarly high disruption of expression was observed in the 16p12.1 and 3q29 knockdown models. The differentially expressed genes in the four 16p11.2 knockdown models are enriched for gene ontology terms related to core cellular processes, such as amino acid metabolism and oxidoreductase activity, as well as immune response. In addition, each set of differentially expressed genes contains genes involved in embryonic development, post-synaptic density, and FMRP-binding targets, all functions important to normal neurodevelopment. The top genes in each of the four knockdown models generally show a high degree of connectivity based on protein-protein interaction and co-expression data. We will use these results to generate an interaction-based genetic network that connects genes within CNVs to known disease-associated genes in relevant pathways.

2205F

Brain effects of APOE in Down syndrome revealed by MRI. *L. Dai[1], J. Anderson[2], M. Burback[1], J.R. Korenberg[1].* 1) Department of Pediatrics, Brain Institute, University of Utah, Salt Lake City, UT; 2) Department of Radiology, University of Utah, Salt Lake City, UT.

The most significant genetic risk factor for Alzheimer's disease (AD) is the presence of allelic variants, ε4 and ε2, of APOE. It is known that about 25-70% of people with Down syndrome (DS) will develop features of AD by 60 y/o. However, it is unclear whether APOE variation is associated with developmental alterations of the brain in DS that may predispose to AD or may significantly increase the risk of AD in DS beyond trisomy 21. Previous reports of APOE phenotype-genotype in DS are conflicting. Here we report the APOE genotype and associated structural MRI (FreeSurfer) in a young age adult cohort of 17 subjects with DS and 11 controls (age 14-33), two identical twins discordant for DS and two subjects with DS caused by partial trisomy 21, one that includes, and the other that excludes APP located on HSA21. The results indicate that, whereas the APOE allele frequencies are similar in DS and controls, there is strong association of a subset of brain regions with the ε4 vs ε2 genotypes. These include ε4 associated with decreased volumes of total cortical white matter (WM), area of the medial anterior cingulum WM, and dorsal anterior cingulum WM and similar to findings in AD. The MRI data from the identical twins (22 yo, ε3/ε3), provide a unique test of the APOE-brain associations found in the population based DS cohort. The WM volumes of the normal twin is at the mean of the control cohort, and of the twin with DS is at the mean of the ε3/ε3 DS cohort. These findings strongly suggest that APOE ε4 affects brainwide WM development, particularly the WM circuitry of the medial frontal region of the left hemisphere, the anterior cingulate gyrus. We note that these results suggest a prenatal effect of APOE, ε2 and ε4 on brain development that may or not affect cognition in DS but may significantly increase the risk for AD in DS. The well-established roles of the medial anterior cingulate in error detection, conflict monitoring, emotional modulation and attention reflect a close correspondence with the cognitive and behavioral deficits of DS. Disturbed connectivity of the ACG, its association with APOE4 and its possible relationship to Von Economo neurons provide testable human cellular and organismal models and a truly fresh look at Alzheimer's disease.

2206W

Parsing the genetic brain connectome using rare identical twins discordant for Down syndrome. *J.R. Korenberg[1], J. Anderson[2], M. Burback[1], J. Edgin[3], G. Gerig[4], L. Dai[1].* 1) Department of Pediatrics, University of Utah, Salt Lake City, UT; 2) Department of Radiology, University of Utah, Salt Lake City, UT; 3) Department of Psychology, University of Arizona, Tucson, AZ; 4) New York University Tandon School of Engineering, Brooklyn, NY.

Down syndrome (DS) is a major cause of mental retardation and congenital anomalies. Understanding the genetic or neurocognitive effects of trisomy 21 has always been severely limited by the heterogeneity of genes located on chromosome 21 and by the enormous variations in the remainder of the 30,000 genes located on the other chromosomes. Identical twins are therefore nature's unique opportunity to see the dramatic effects of identical genes on phenotype. Here we report the structural and functional MRI, DTI, and extensive cognitive and genetic measures of a pair of identical twins discordant for DS and compared them to the typical DS and TC cohort. We determined chromosomal features of DS in one, >96% trisomy 21 in cord blood, blood and fibroblasts, and in the other a normalized phenotype, >92% normal karyotype in these tissues. Structural MRI showed distinguishable patterns in most but not all regions between the identical twins. Normalized volumes of the 96% mosaic twin were very close to the DS group, and the 8% mosaic twin volumes were similar to controls. An exception was DS-like volume in the 8% mosaic twin of the right fusiform gyrus, involved in visual memory and language. Only the 96% mosaic twin demonstrated increased internetwork synchrony across networks seen in typical DS during functional MRI. The twins are a graphic vision of how a simply trisomy for 21 disturbs brain wiring and the results implicate the hippocampal and fusiform gyrus formation in the neural systems responsible for visual-spatial and linguistic deficits of DS. .

2207T

Role of a circadian-relevant gene, *NR1D1*, in brain development: Possible involvement in the pathophysiology of autism spectrum disorder. *M. Goto[1], M. Mizuno[2], A. Matsumoto[1], Z. Yang[1], E. Jimbo[1], H. Tabata[2], H. Osaka[1], K. Nagata[2,3], T. Yamagata[1].* 1) Pediatrics, Dept, Jichi Medical University, Shimotsuke, Tochigi, Japan; 2) Molecular Neurobiology Dept, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan; 3) Neurochemistry Dept, Nagoya University Graduate School of Medicine, Nagoya, Japan.

Autism spectrum disorder (ASD) is frequently accompanied by comorbid conditions, and associated with problems in the early developmental period including hyperactivity, panic, self-injury, and sleep disturbance. Among them, sleep disruption (such as insomnia or a short sleep cycle) is one of the most common and distressed problems. In our previous study (Yang *et al*. 2015), we screened ASD patients with and without sleep disorders for mutations in the coding regions of circadian-relevant genes, and detected mutations in several clock genes including *NR1D1*. Thus, circadian-relevant genes likely represent impaired molecular clock mechanisms that potentially contribute to the etiology of ASD. Here, we further screened ASD patients for *NR1D1* mutations and identified three new mutations, including a *de novo* heterozygous mutation, c.1499G>A (p.R500H). We then examined the role of NR1D1 in development of the mouse cerebral cortex. Acute knockdown of mouse *NR1D1* by *in utero* electroporation caused abnormal positioning of cortical neurons during corticogenesis. This aberrant phenotype was rescued by wild type NR1D1, but not by the c.1499G>A mutant. Moreover, knockdown of *NR1D1* also suppressed axon extension, while proliferation of neuronal progenitors and stem cells at the ventricular zone was not affected. Taken together, NR1D1 plays a pivotal role in corticogenesis via regulation of excitatory neuron migration and synaptic network formation. Consequently, functional defects in NR1D1 may relate to ASD pathophysiology.

2208F

Effects of altered 7q11.23 copy number on neural stem cell physiology and cortical organization during murine embryonic development. *H.M. Oh[1], F. Miller[1,2,3], L. Osborne[1,2].* 1) Institute of Medical Sciences, University of Toronto, Toronto, Ontario, M5S 1A8; 2) Department of Molecular Genetics, University of Toronto, Toronto, ON, M5S 1A8; 3) Developmental and Stem Cell Biology, Hospital for Sick Children, ON, M5G 1X8.

Williams Syndrome (WS) and 7q11.23 Duplication Syndrome (Dup7) are two rare neurodevelopment disorders caused by deletion and duplication respectively, of 25 genes on chromosome 7q11.23. Individuals with WS or Dup7 present with an array of cognitive and behavioural phenotypes, including anxiety, autism, speech and language delay, and intellectual disability, but the biological basis for these neuropsychiatric symptoms remain unknown. Structural and functional abnormalities of the cortex have been identified in both WS and Dup7, suggesting that cortical development is perturbed in these disorders. Our lab has generated mouse models with altered gene dosage of two candidate genes from the WS commonly deleted region, General Transcription Factor 2 I (*Gtf2i*) and GTF2I Repeat Domain containing protein 1 (*Gtf2ird1*). These models include mice with hemizygous deletion of both genes (*Gtf2i/Gtf2ird1*[+/-]) and mice with duplication of *Gtf2i* (*Gtf2i*[+/Dup]). We have used these mice to determine whether altered expression of *Gtf2i* and/or *Gtf2ird1* affects neural stem cell growths and cell-fate, and potentially contributes to the neurological features of WS and Dup7. Our results showed that *Gtf2i/Gtf2ird1*[+/-] mice with a hemizygous deletion had an overall reduction in the number of neuronal precursors and neurogenesis with an increase in astrogenesis whereas mice with an additional copy of *Gtf2i* had an increase in the number of precursors and neurogenesis along with a decrease in astrogenesis. These early changes in neural development translated into perturbed cortical organization with changes in cortical thickness and cell packing density in mid-gestation developing brain. These data will help us understand how the developing brain is perturbed in people with WS and Dup7 and may give insight into an answer the pathological causes and possibly help identify therapeutic interventions to treat the cognitive disorders involving autism and social dysfunction.   .

2209W

***ARID1B* disorders of intellectual development: Expanding the phenotype and insights from** *in vitro* **and** *in vivo* **models.** *C. Dias[1,2], M. Levitin[1], G. Sanchez-Andrade[1], S.S. Gerety[1], P.H. Tate[1], F. Guillemot[2], W.C. Skarnes[1], M.E. Hurles[1], D.D.D. Study[1], D.W. Logan[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) The Francis Crick Institute, Mill Hill Laboratories, London, United Kingdom.

Whole exome and genome sequencing of large cohorts of individuals with intellectual and developmental disability (IDD) have revealed that heterozygous mutations in *ARID1B*, of the BAF swi/snf chromatin-remodeling complex, are associated with IDD. Originally identified in individuals with Coffin-Siris Syndrome (CSS), *ARID1B* mutations are associated with both syndromic and non-syndromic IDD. We show that in a cohort of individuals ascertained for developmental disorders, *ARID1B* mutations are identified in individuals with variable clinical features, most commonly with intellectual, developmental or speech and language delay. De novo mutations in *ARID1B* are a leading cause of IDD. We explore the phenotypic spectrum of ARID1B-IDD, identifying inconstant but highly discriminatory features, such as agenesis of the corpus callosum and laryngeal anomalies. To further investigate the role of *ARID1B* in development and cognition, we examined the effect of heterozygous loss of function in mouse models. We show that heterozygote mutant mice recapitulate morphological and behavioral features seen in patients, namely growth delay and long-term memory defects. To examine the effect of *Arid1b* haploinsufficiency on transcriptional regulation, we performed genome-wide RNASeq in cellular and *in vivo* models of *Arid1b* haploinsufficiency. Heterozygous loss of *Arid1b* does not significantly affect transcription in mouse ES cells, but induces significant gene expression deregulation during neural stem cell differentiation. Likewise, haploinsufficient embryonic mouse brain at E14.5 shows an altered transcriptional profile suggestive of a role for *Arid1b* in axonal guidance and cell-cell interaction. Mutant adult hippocampus shows an abnormal gene expression profile: it implicates axon guidance pathways previously identified in another model of BAF complex-associated-IDD, and genes involved in synaptogenesis and long-term potentiation. Dysregulation of genes associated with other neurodevelopmental disorders are over-represented in post-natal mutant hippocampus. Hence, we demonstrate a crucial role for *ARID1B* in brain development and long-term memory. In the mouse model, we identify pathways affected by *Arid1b*-dependent BAF complex disruption at different developmental stages. Our study underscores the relevance of mammalian models to further elucidate IDD and related disorders.

2210T

Reciprocal brain size defects and intellectual disability in patients with activating mutations in the mTOR pathway. *M.R.F. Reijnders[1,8], M. Kousi[2,8], G.M. van Woerden[3,8], J. Bralten[1], G.M. Mancini[4], T. van Essen[5], C.M. Marcelis[1], M. Proietti-Onori[3], E. Smeets[6], M. van Gastel[7], A.P.A. Stegman[6], S.J.C. Stevens[6], C. Gilissen[1], R. Pfundt[1], P.L. Tan[2], T. Kleefstra[1], Y. Elgersma[3,8], N. Katsanis[2,8], H.G. Brunner[1,6,8].* 1) Human Genetics, Radboudumc, Nijmegen, The Netherlands; 2) Center for Human Disease Modeling, Duke University, Durham, North Carolina, USA; 3) Department of Neuroscience and ENCORE Expertise Center for Neurodevelopmental Disorders, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) Department of Clinical Genetics, Erasmus MC, Sophia Children's Hospital, Rotterdam, The Netherlands; 5) University of Groningen, University Medical Center of Groningen, Department of Genetics, Groningen, The Netherlands; 6) Department of Clinical Genetics, Maastricht University Medical Center, Maastricht, The Netherlands; 7) Department of medical care, SWZ zorg, Son, The Netherlands; 8) These authors contributed equally.

Activating *de novo* or somatic mutations in the mTOR signaling pathway have been associated with a host of neurodevelopmental traits, hallmarked by megalencephaly and intellectual disability (ID). To test systematically the contribution of this pathway to sporadic ID, we evaluated 102 genes from the mTOR pathway in 820 ID patients. We identified 14 *de novo* mutations within 9 different genes: 4 known ID genes (*PIK3R1; PIK3R2; RAF1; PPP2R5D*) and 5 candidate ID genes (*RHEB; RAC1; PPP2R5E; PPP2CA; ERK1*). Aberrant brain size was present in the majority of patients (67%) and this percentage was significantly increased compared to patients with mutations in known ID genes that are not involved in the mTOR pathway (28%). We focused further on the pathomechanism of 4 germline missense mutations in 2 candidate ID genes: *RHEB*, an mTORC1 component, and *RAC1*, that signals through mTORC2 and the MAPK cascade. Whereas patients with *RHEB* mutations show severe ID, hypotonia, epilepsy and macrocephaly, patients with *RAC1* mutations have ID, epilepsy and microcephaly. Functional modeling of the discovered mutations in zebrafish and mouse embryos, as well as in primary neuronal cultures, showed all alleles to be hyperactivating and to induce defects in neuronal migration, proliferation and soma size. A direct opposite effect to overall brain size for *RAC1* and *RHEB* mutants, concordant to the human phenotype, was present and could be ameliorated by the administration of rapamycin *in vivo*. Motivated by the high frequency of aberrant brain size in ID syndromes within the mTOR pathway, we queried the Discovery cohort of the ENIGMA brain volume genome-wide association dataset; we found a significant association of mTOR signaling components with brain volume in the population ($p_{self-contained} = 0.003447$ and $p_{competitive} = 0.041912$). Taken together, our data measure and expand the contribution of mTOR signaling components to syndromic ID. They also suggest the presence of a continuum of effect in this pathway, wherein highly deleterious *de novo* alleles drive pathological conditions whereas likely milder effects contribute to normal variation in brain volume.

2211F

Genomic and functional studies provide evidence for two-hit model for neurodevelopmental disorders. *L. Pizzo, A. Polyak, M. Jensen, E. Huber, J. Yoon, A. Kubina, D. Mayanglambam, S. Girirajan.* Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.

We present detailed phenotypic, genomic, and functional analysis of the 16p12.1 deletion, provide evidence for causality of specific genes within 16p12.1, and assess their genetic interactions within specific cellular and developmental pathways. We performed deep phenotyping of 100 families with the deletion and CNV and exome sequencing analysis in 30 families, and identified several loss-of-function variants within functional gene classes associated with various developmental pathways (*SETD5, LAMC3, MIER2, MAPK4* and *CEP135*), and large disease-associated CNVs including 3q29 deletion, 15q13.3 deletion, and 22q11.2 duplication. Clinical data suggested increased severity of phenotypes in probands with additional hits affecting various domains of development and behavior, compared to those with single hits. We further performed functional evaluation by decreasing the expression of the four (*UQCRC2, C16ORF52, POLR3E*, and *CDR2*) 16p12.1 orthologs in *Drosophila melanogaster*. Using a series of tissue-specific promoters and RNA-interference transgenic lines, we assessed dosage sensitivity of the orthologs by testing developmental and molecular phenotypes. Neuronal-specific knockdown led to increased head sizes for *CDR2* (6.5 SD, p<0.0010) and *POLR3E* (5.2 SD, p<0.0010), and a severe morphological eye defects for *POLR3E* and *C16orf52* (p<0.05). Ubiquitous knockdown resulted in early lethality for *POLR3E* and *UQCRC2* fly lines, and neuron-specific knockdown of *POLR3E* resulted in severe motor defects and early adult lethality. To further map specific pathways associated with these phenotypes, we performed RNA sequencing of *Drosophila* brain samples with neuron-specific knockdown and identified several genes belonging to core biological pathways. To fully characterize the contribution of 16p12.1 orthologs to developmental phenotypes, we performed interaction studies using pair-wise knockdown of genes within the CNV. Variable phenotypes were detected for all interactions containing *POLR3E*, suggesting a major role for *POLR3E* for the observed phenotypes, while other genes in the region potentially modify the phenotype. We also tested *trans* interactions of 16p12.1 orthologs with second hits identified in patient cohorts, and found several enhancers and suppressors of the phenotype. Our results provide functional support for the proposed two-hit model and potentially identify novel interacting genes that modulate the 16p12.1 phenotype.

2212W

A human-specific duplicated gene in the *1q21* **locus has a potential function in brain development.** *G.A. Lodewijk[1], F.M.J. Jacobs[1], A.D. Ewing[5], A.M. Novak[2,4], S. Katzman[2], S.R. Salama[2,3], D. Haussler[2,3].* 1) Swammerdam Institute for Life Sciences, University of Amsterdam, The Netherlands; 2) UC Santa Cruz Genomics Institute, University of California, Santa Cruz, CA, United States of America; 3) Howard Hughes Medical Institute, Bethesda, MD, United States of America; 4) Biomolecular Engineering, University of California, Santa Cruz, CA, United States of America; 5) Mater Research Institute, University of Queensland, Brisbane, Australia.

The human brain is characterized by a remarkable expansion over the last million years. However, the underlying genetic events related to specifying human brain development remain largely unknown. We hypothesize that gene duplication events have contributed significantly in changing gene regulatory pathways of the brain. In previous work (Jacobs *et al.*, submitted) we cultured human and rhesus monkey embryonic stem cells (ESCs). Under defined conditions, these ESCs were grown into cortical organoids, representing the early embryonic neocortex *in vitro*. At different time points during differentiation, cortical organoids were profiled by RNA-sequencing. In these data we found a human-specific duplicated gene (*HUSD1*) that was differentially expressed between human and rhesus monkey cortical organoids. The *HUSD1* gene cluster consists of several duplications located in the *1q21* locus. The instability of the *1q21* locus has led to many genomic rearrangements of this locus in recent evolutionary history. Specifically in the human genome the *1q21* locus harbors many copy number variations (CNVs) related to brain disorders. To test the significance of *HUSD1* in brain development, we have done two key experiments: 1) Ectopic expression of *HUSD1* in the neocortex of embryonic mice via *in utero* electroporation, revealing it can modulate brain development. 2) RNA-sequencing of mouse cortical organoids, derived from mouse ESCs stably expressing *HUSD1*, which show enhanced expression of early forebrain markers. These data indicate that *HUSD1* is a novel human factor regulating brain development. Our future efforts will largely focus on unraveling the molecular mechanisms of *HUSD1* in human brain development, as well as its potential involvement in *1q21* CNV related brain disorders.

2213T

Exome sequencing of 311 trios confirms the importance of *de novo* **mutations in intellectual disability.** *T. Schwarzmayr[1], H.J. Luedecke[2], A.M. Zink[3], E. Graf[1], N.C. Bramswig[2], T. Wieland[1], J. Becker[3], R. Berutti[1], J.C. Czeschik[2], K. Cremer[3], T. Meitinger[1,5], H. Engels[3], D. Wieczorek[2,4], T.M. Strom[1,5].* 1) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 2) Institute of Human Genetics, Universitätsklinikum Essen, Universität Duisburg-Essen, Essen, Germany; 3) Institute of Human Genetics, Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany; 4) Institute of Human Genetics, Heinrich-Heine-University, Medical Faculty, Düsseldorf, Germany; 5) Institute of Human Genetics; Technische Universität München, Munich, Germany.

Intellectual disability (ID) has an estimated prevalence of 1-2%. Recently, exome sequencing of parent-child trios has shown that a large proportion of ID are caused by de novo mutations. We sequenced exomes of 311 children with ID and their parents to an average read depth of 114. CNVs have previously been excluded in most patients. Variant data was generated through an automated pipeline using multiple variant and CNV callers and stored in a custom database. Variants were annotated in a cooperative way through a Web-based frontend and confirmed by Sanger sequencing. We identified 556 de novo variants (116 synonymous, 330 missense, 9 in-frame indels, 101 loss-of-function), with an exomic mutation rate of 1.83 per individual per generation. 52 patients (17%) had at least one protein altering de novo variant in a gene already associated with a developmental disease by monoallellic mutations (291 genes from the DDG2P database version July 2015). 60 patients (19%) had no de novo variant. These variants in combination with data from collaborating groups were instrumental in identifying two genes not yet associated with ID, HIVEP2 and CHAMP1. Additionally, we extended the phenotypic spectrum of protein altering variants in seven genes: ASXL3, KCNH1, SETD5, CTNNB1, ECHS1, IQSEC2 and TCF20.

individuals	de novo	synonymous	missense	indel	LoF
311 cases	556	116 (0.21)	330 (0.59)	9 (0.02)	101 (0.18)
50 controls	58	22 (0.38)	31 (0.53)	0	5 (0.09)

We compared these de novo variants to a set of 58 de novo variants identified in 50 healthy control trios, corresponding to an exomic mutation rate of 1.16 per individual per generation. 17 controls (34%) had no de novo variant. Interestingly, the difference in the synonymous mutation rate was not significant (p=0.51; Mann-Whitney-Wilcoxon test, two-sided), however the difference in the protein altering mutation rate was highly significant (p=2.37×10^{-5}). When comparing only the 253 cases, excluding cases with de novo variants in genes already associated with developmental disorders or in one of the nine genes described above, to the 50 controls, the difference between protein altering mutation rates remains highly significant (p=7.11×10^{-4}). In summary, we show that exome sequencing in a multicenter setting with an appropriate IT environment can efficiently be used to generate clinical grade diagnoses by integrating the advantage of standardized central sequencing and distributed evaluation and annotation of the resulting data in the clinical context.

2214F

Discovery of Vimentin as a novel target under the dynamic regulation of FMRP. *H. Gong[1], G.M. Gafford[1], F. Zhang[1], S.T. Warren[1,2].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Biochemistry and Pediatrics, Emory University School of Medicine, Atlanta, GA.

Fragile X syndrome (MIM 309550) is the most common cause of intellectual disability and a well-known cause of autism spectrum disorder. Fragile X syndrome is caused by the absence or dysfunction of fragile X mental retardation protein (FMRP), a RNA-binding and translation regulation protein. There are several comprehensive RNA studies that have identified putative FMRP bound sequences and genes through various methods. However, no studies have particularly focused on the identification of the nascent peptides that are stalled by FMRP on the ribosomes. We applied the puromycin-associated nascent chain proteomics (PUNCH-P) method to post-runoff hippocampal slices. By comparing wildtype (WT) and *Fmr1* knockout (KO) mice with and without DHPG stimulation, we discovered Vimentin as the DHPG inducible translation suppression target of FMRP. We also found that in the absence of FMRP, the mRNA and protein levels of Vimentin are elevated both *in vivo* and *in vitro*. Additionally, further experiments indicated that FMRP interacts with Vimentin mRNA and affects its stability. These results together reveal that Vimentin is under the dynamic regulation of FMRP. Identification of the FMRP binding site on Vimentin mRNA is currently ongoing.

2215W

Identification of alternative *FMRP* translation start sites by non-ATG codons. *Y. Wen[1], S.T. Warren[1,2].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Biochemistry and Pediatrics, Emory University School of Medicine, Atlanta, GA.

Mutations in *FMR1* gene cause Fragile X syndrome (MIM 309550), a frequent cause of inherited intellectual disability. A trinucleotide $(CGG)_n$ repeat expansion in the 5'-untranslated region of *FMR1* gene is the most common mutation, which results in the epigenetic silencing of the gene and the absence of the encoded protein FMRP. The aim of this project is to identify non-ATG-initiated translation of FMRP that could be directed by the hairpin-forming trinucleotide repeats. In our study, we have demonstrated that there are several novel non-canonical translation initiation codons located upstream of the main open reading frame (ORF) of the *FMR1* gene. We also confirmed the existence of these non-ATG start sites for FMRP synthesis in the mouse hippocampus by immunoprecipitation. Our functional analysis for two possible non-ATG start codons (-219ACG & -69CTG), located before and right after the $(CGG)_n$ repeats, showed that in addition to initiating the expression of FMRP at alternative start sites, these potential non-canonical start codons can also affect FMRP expression initiated from classic ATG start. Interestingly, removing the $(CGG)_n$ repeats increased the expression of the alternative FMRP products but decreased the total amount of FMRP. Taken together, our results identify alternative FMRP translation start sites by non-ATG codons in both human and mouse *in vitro* and *in vivo*, providing new evidence of non-ATG initiated translation.

Driver genes for 2p15p16.1 microdeletion syndrome identified using clinical, genomic and functional analysis. *E. Rajcan-Separovic[1], H. Bagheri[1], C. Badduke[1], Y. Qiao[1], R. Colnaghi[2], D. Alcantara[2], I. Abramowicz[2], C. Dunham[3], J. Wen[1], R. Wildin[4], M. Nowaczyk[5], J. Eichmeyer[6], A. Lehman[3], B. Maranda[7], S. Martell[1], X. Shan[8], S. Lewis[3,9], M. O'Driscoll[2], C. Gregory-Evans[8].* 1) Dept Pathology (Cytogenetics), University of British Columbia, Vancouver, Canada; 2) Human DNA Damage Response Disorders Group, Genome Damage & Stability Centre, University of Sussex, Brighton, United Kingdom; 3) BC Children's Hospital, Vancouver, Canada; 4) National Human Genome Research Institute, Bethesda, Maryland, United States; 5) Department of Pathology and Molecular Medicine, McMaster University Medical Centre, Hamilton, ON, Canada; 6) St. Luke's Children's Hospital, Boise, ID, United States; 7) Medical Genetics, Universite de Sherbrooke, Sherbrooke,Canada; 8) Department of Ophthalmology, University of British Columbia, Vancouver, Canada; 9) Department of Medical Genetics, University of British Columbia, Vancouver, Canada.

   Introduction: The 2p15p16.1 microdeletion syndrome has a core phenotype consisting of intellectual disability, microcephaly, hypotonia, delayed growth, common craniofacial features, and digital anomalies. So far, more than 30 cases with this syndrome have been reported in literature; however, the size of the deletions and their breakpoints vary making the identification of candidate genes challenging. Recent reports pointed to four genes (*XPO1*, *USP34*, *BCL11A* and *REL*) which were included, alone or in combination, in the smallest deletions causing the syndrome.   **Results**: Herein, we describe 8 new cases with 2p15p16.1 deletion and review all published cases. We demonstrate functional deficits for the above4 candidate genes using patient lymphoblast cell lines (LCLs) and knockdown of their orthologs in zebrafish. All genes were dosage sensitive based on reduced protein expression in LCLs. In addition, deletion of XPO1, a nuclear exporter, co-segregated with nuclear accumulation of one of itscargo molecules (rpS5) in patient LCLs. Other pathways associated with these genes (e.g. NF-kB and Wnt signaling as well as DNA damage response) were not impaired in patient LCLs. Knockdown of *xpo1a*, *rel* , *bcl11aa* and *bcl11ab* resulted in abnormal zebrafish embryonic developmentincluding microcephaly, dysmorphic body, hindered growth, small fins as well as structural brain abnormalities. **Conclusions**: Our multifaceted analysis strongly implicates *XPO1*, *REL*, and *BCL11A* as candidate genes for the 2p15p16.1 microdeletion syndrome. It also demonstrates the benefits of using zebrafish for identification of driver genes for genomic disorders. Our current work includes overexpression of the candidate genes in zebrafish, to determine if they cause mirror image phenotypes (e.g. macrocephaly).

2217F

Defects of adult hippocampal neurogenesis unify genetically distinct causes of Kabuki syndrome. *G. Carosso[1,2], J. Weissman[4], J. Fahrner[1,3], L. Zhang[1], H.T. Bjornsson[1,3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD, USA; 2) Predoctoral Training Program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD, USA; 3) Department of Pediatrics at the Johns Hopkins University School of Medicine, Baltimore, MD, USA; 4) Kennedy Krieger Institute, Baltimore, MD, USA.

   Kabuki syndrome (KS) is a genetically determined cause of intellectual disability resulting from loss-of-function (LOF) mutations in two histone-modifying enzymes, lysine-specific methyltransferase 2D (KMT2D) and lysine-specific demethylase 6A (KDM6A/UTX). These enzymes alter methylation states on histone tails at H3K4 and H3K27, respectively, and promote transcriptionally permissive open chromatin states despite opposing enzymatic activities. However, it remains poorly understood how these distinct genetic causes produce overlapping neurobehavioral phenotypes in KS. Previously, we demonstrated a reversible deficiency of adult hippocampal neurogenesis in the subgranular zone (SGZ) of the dentate gyrus (DG) in a *Kmt2d* LOF mouse model, suggesting that intellectual disability in KS may be amenable to postnatal therapy. We now show reduced cellular proliferation in the SGZ, visualized by EdU incorporation, in a second, genetically distinct mouse model of KS with *Kdm6a* LOF. This points to deficient adult neurogenesis as a unifying pathogenic feature of KS, leading us to hypothesize that heterozygous LOF mutations in both KS genes perturb chromatin accessibility and alter transcription of shared neurogenic gene expression programs. Using confocal microscopy, we see reduced activation of radial glia-like (RGL) neural stem cells (NSCs) in SGZ (25% decrease, p<0.05), indicating disruption of the first discrete neurogenic step. Similar reduction is seen in migrating neuroblasts expressing doublecortin (DCX) in the SGZ (22% decrease, p<0.01), culminating in fewer mature neurons (NeuN+ cells) in the DG granule cell layer (9% decrease). Interestingly, neuroblast deficiency is associated with reduced fluorescence intensity for the open chromatin mark H3K4me3 within DCX+ cells (p<0.05), supporting a mechanistic link between altered histone modifications and neurobehavioral phenotypes. To identify target genes dysregulated secondarily to KS mutations, we are performing next-generation RNA sequencing and genome-wide chromatin profiling in hippocampal NSCs harboring *Kmt2d* and *Kdm6a* LOF mutations. Our results demonstrate that genetically distinct KS types lead to common defects of an ongoing, postnatal neurogenic process accompanied by cell type-specific histone methylation alterations. Targeting this unified pathogenic mechanism at precise stages may enable a generalized rescue strategy for intellectual disability in genetically distinct forms of KS and related disorders.

2218W

Rapid *in vitro* evaluation of variants of uncertain significance from patients with developmental delay and/or intellectual disability. *K.L. Engel[1], J.N. Cochran[1], A.A. Hardigan[1], M.D. Amaral[1], K.M. Bowling[1], C.R. Finila[1], S.M. Hiatt[1], M.L. Thompson[1], D.E. Gray[1], J.S. Whittle[1], W.V. Kelley[1], M.E. Cochran[1], K.M. East[1], N.E. Lamb[1], C.A. Rich[1], K.B. Brothers[1], E.J. Lose[1], S.B. Simmons[2], E.M. Bebin[2], G.S. Barsh[1], G.M. Cooper[1], R.M. Myers[1].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) University of Alabama at Birmingham, Birmingham, AL.

Developmental delay and intellectual disabilities (DD/ID) include devastating phenotypes and comprise a large fraction of rare undiagnosed conditions in children. Unfortunately, little is known about the cellular mechanisms that lead to disease, and as a consequence, therapeutic advancements have suffered. Previous studies have indicated a strong genetic component to these phenotypes, and successful identification of causal genetic variants through exome or whole genome sequencing sometimes leads to clinical diagnoses, revision of treatment strategies, community and support network building, and increased quality of life. However, sequencing-based diagnostic efforts typically solve only a subset of cases; while precise numbers vary according to ascertainment and study enrollment criteria, large fractions of children cannot be given a precise genetic diagnosis even after whole genome sequencing. In our own work as part of the Clinical Sequencing Exploratory Research (CSER) consortium, we have found diagnostic genetic variants in ~27% of children with conditions refractory to standard diagnostic tests. Rigorous experimental evaluation of variants and genes implicated in DD/ID is needed to increase diagnostic rate, particularly for the subset of the undiagnosed cases where a potential genetic cause is identified but not confirmed, termed to be variants of uncertain significance (VUSs). VUSs typically arise as a result of a lack of information about the relevance (or lack thereof) of a given gene to disease, the impact (or lack thereof) of a given variant on gene function, or both. In our studies to date, ~15% of affected children harbor a VUS. Introduction of these VUSs, a portion of which are in gene expression regulators, into human neurons derived from neural precursor cells through gene editing technology will provide evidence for or against the association of these sequence variants on key molecular and cellular phenotypes including global gene expression at the levels of both transcription and translation, neuronal excitability, and synapse and/or ion channel composition profile. The studies proposed here will provide critical insights regarding the biological roles of genes and variants associated with DD/ID and establish a framework for future mechanistic interrogation of genetic variation. Furthermore, the insights gained from this work will inform future studies aimed at therapeutic intervention for under– and undiagnosed DD/ID disorders.

2219T

Functional investigation of Early B-Cell Factor 3 (*EBF3*) haplo-insufficiency as a novel genetic cause of developmental delay and intellectual disability. *A. Hardigan[1,2], D. Savic[2], B. Roberts[2], J. Prokop[2], R. Ramaker[2], K. Bowling[2], S. Hiatt[2], C. Holden[2], G. Cooper[2], R. Myers[2].* 1) University of Alabama at Birmingham, Department of Genetics, Birmingham, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Developmental delay and intellectual disability (DD/ID) is characterized by limitations in cognitive and adaptive behavior and represents a heterogeneous group of syndromic and non-syndromic disorders. DD/ID is estimated to have a worldwide prevalence of 1-3% and can occur in combination with congenital malformations and other neurologic disorders such as epilepsy. Genetic mutations represent a major cause of established DD/ID cases and over 700 genes have been linked to various forms of DD/ID. The identification and functional characterization of new genes involved in DD/ID has important implications for diagnosis and clinical management. As part of the Clinical Sequencing Exploratory Research (CSER) program, our lab has employed trio-based whole-exome and whole-genome sequencing (WES/WGS) of almost 250 patients and unaffected parents to identify the potential underlying genetic causes of their respective DD/ID conditions. We have identified two DD/ID patients with different VUS in the atypical helix-loop-helix (HLH) transcription factor (TF), early B-cell factor 3 (*EBF3*). Both *EBF3* VUS are SNVs, causing a p.P177L missense mutation in the DNA-binding domain and an IVS11+1G>T mutation disrupting a D-1 splice site in the HLH dimerization domain, respectively. Although not a previously documented DD/ID gene, *EBF3* is a member of the EBF TF family that has been shown to control migration of Cajal-Retzius cells from the cortical hem and drive expression of genes critical for neuronal differentiation, making it a prime candidate. However, relatively little is known about how *EBF3* fits into the intricate gene regulatory circuitry underlying neural development In order to identify a causal mechanistic basis for the identified *EBF3* mutations in DD/ID etiology, we have comprehensively assessed the role of each VUS on DNA binding affinity and global genome-wide occupancy using ChIP-seq, and determined alterations in the gene expression programs regulated by *EBF3* with RNA-seq. These experiments demonstrate that the VUS disrupt *EBF3* function via reducing DNA-binding activity and disrupt critical neurodevelopmental gene expression networks. In conjunction with *EBF3* VUS patient data, this work supports the establishment of *EBF3* as a new DD/ID gene and serves as a framework for its further functional validation.

2220F

Zebrafish models of Marinesco-Sjögren syndrome. *G. Kawahara, Y. Hayashi.* Pathophysiology, Tokyo Medical School, Tokyo, Japan.

Marinesco-Sjögren syndrome (MSS) is an autosomal recessive disease characterized by progressive myopathy, cerebellar ataxia, mental retardation, and congenital cataracta. MSS is caused by mutations in the *SIL1* gene. SIL1 is known as a nucleotide exchange factor for the endoplasmic reticulum chaperone BiP. Zebrafish disease models are useful to analyze the mechanism of various diseases, including neuromuscular disorders. We analyzed zebrafish sil1 function using antisense morpholino oligos. To create MSS model fish, we have started to create MSS knocked-out fish by CRISPR-Cas9 system. Two different morpholinos were injected at 1-2 cell stage. At 4 days post-fertilization (dpf), thirty percent of fish injected with morpholino 1 and 2 showed reduced birefringence. Morphants had small diameter of eyes and reduction of purkinje cells in cerebellar area. Co-injection of zebrafish *sil1* mRNA along with the morpholino restored normal development the morphants. Additionally, BiP (a ER stress marker protein), LC3 (an autophagy marker protein) and activated caspase 3 (an apoptosis marker) were increased in these morphants. With CRISPR/Cas9 system, we successfully identified founders that could pass mutations in the *sil1* gene through the germline. Their offspring carried indel mutations, suggesting that these founders carrying heritable mutations. These findings suggest that it will be feasible to create a MSS model fish for a therapeutic chemical screening.

2221W

Aberrant splicing of *ACADM* exon 5: A balance between enhancers and silencers. *L.L. Christensen, G.H. Bruun, M.R. Larsen, B.S. Andresen.* Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense M, Denmark.

Correct splicing of vulnerable constitutive exons is dependent on exonic splicing enhancers (ESE) and exonic splicing silencers (ESS). Therefore sequence variations that create or disrupt ESS/ESEs may cause missplicing and disease, irrespective of the predicted consequences according to the genetic code. Sequence variants in *ACADM* may cause MCAD deficiency (MCADD). Because MCADD is frequent, newborns are screened by MS/MS and diagnosis is confirmed by mutation analysis. Therefore, the potential deleterious effect of identified variants needs to be correctly assessed. We previously identified a frequent missense variation, c.362C>T in exon 5, which abolishes a fundamental ESE, causing exon skipping, loss of functional protein and consequently MCADD. The c.362ESE functions both by antagonizing a juxtaposed c.351ESS, and it is required to define the weak exon 5 3' splice site. Notably, a silent polymorphic variation, c.351A>C inactivates the c.351ESS, and makes splicing immune to the deleterious c.362C>T. We speculated that *ACADM* exon 5 is vulnerable, and investigated presumed silent and missense variants identified in different parts of exon 5 in newborns with MCADD. Minigene studies revealed that several of the variants cause exon skipping by abolishing different ESEs. Employing siRNA/overexpression of splicing regulatory factors (SRFs) and RNA pull-down, we characterized new ESEs and ESSs and the binding SRFs. We show that the ESEs and ESSs need to be in a finely tuned balance to allow exon 5 inclusion. This balance is not only dependent on steric competition of SRFs for binding to juxtaposed ESE/ESSs, as previously demonstrated for the c.362ESE and c.351ESS. Instead the overall balance between ESEs/ESSs located throughout the exon needs to be maintained. In line with this we show that a c.331G>A missense variation abolishes an ESE to cause complete exon skipping. Remarkably, the polymorphic c.351A>C, which inactivates the distant c.351ESS, also makes splicing immune to the deleterious effect of c.331G>A. Moreover, inactivation of an ESS at pos. c.325, abolishes the splicing defect of the distant c.362C>T variant as well as that of the juxtaposed c.331G>A. We conclude that splicing of weak exons can be disrupted by several different missense/silent variations. Moreover, weak exons are critically dependent on the overall balance between ESE/ESSs located throughout the exon. It is thus essential to evaluate effects on splicing in the context of the haplotype.

2222T

lincRNA gene expression in the mammalian inner ear. *K. Ushakov[1], T. Koffler-Brill[1], A. Rom[2], I. Ulitsky[2], K.B. Avraham[1].* 1) Human Molecular Genetics and Biochemistry, Tel Aviv University, Tel Aviv, Israel; 2) Department of Biological Regulation, Weizmann Institute of Science, Rehovot, Israel.

Mammalian genomes are highly complex and regulated at multiple levels. A novel class of RNA molecules, the long intervening non-coding RNAs (lincRNAs), imposes one of these levels of regulation. lincRNAs are transcripts of >200nt in length and similarly to messenger RNA (mRNA), they are capped, polyadenylated and spliced. However, unlike mRNAs, they are less abundant and possess a higher tissue specificity. lincRNAs are versatile and exert their regulation at several cellular levels and have been linked to development and disease. The mammalian inner ear is a complex organ comprised of the cochlea, responsible for hearing and the vestibule, responsible for balance. To reach such tissue intricacy, several levels of regulation are required and thus the development of these organs involves complex genetic programs, orchestrated by genetic and epigenetic factors. Though largely unexplored, we hypothesize that lincRNAs play a significant role in the inner ear as well. As a result, our goal is to build a complete inventory of the lincRNAs that are expressed throughout mouse inner ear development and to understand their impact on gene regulation. We generated RNA-seq data by high-throughput sequencing of sensory epithelia containing hair and supporting cells at two developmental stages. The reads were subjected to a pipeline for lincRNA profiling. We identified 1920 lncRNA genes, of these 403 are novel unannotated lincRNAs. Based on a number of criteria we chose several lincRNAs for further investigation, which included profiling in the whole animal and tissue and developmental stage expression. Next we focused on studying lincRNAs that are in close proximity to genes important for hearing and deafness in order to identify whether there are any cis-regulatory mechanisms operating between these gene pairs. This characterization of lincRNAs will aid us to comprehend the auditory and vestibular neurosensory systems, towards understanding mechanisms of hearing and balance disorders. .

2223F

Pax2/Pax2a **regulates** *Cyp1b1/cyp1b1* **expression in mice and zebrafish.** *L.A. Schimmenti[1], P.R. Preorius[2], M. McGrail[3], S.L. Solin[3], M.D. Gearhart[4], S.L. Lerach[5].* 1) Otorhinolaryngology, Mayo Clinic, Rochester, MN; 2) Department of Biology, Hanover College, Hanover, IN; 3) Department of Genetics, Cell Biology and Development, Iowa State University, Ames, IA; 4) Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 5) Pediatrics, University of Minnesota, Minneapolis, MN.

Purpose: Autosomal dominant pathogenic variants in *PAX2* cause Renal Coloboma syndrome (OMIM 120330), a condition characterized by optic nerve dysplasia/coloboma and renal hypodysplasia. To date, transcriptional targets of *PAX2* remain largely unidentified. We hypothesize that *PAX2* regulated genes may explain phenotypic overlap between optic nerve findings of Renal Coloboma Syndrome and other conditions, specifically glaucoma. The purpose of this study is to identify genes regulated by *Pax2/pax2a* during mouse and zebrafish eye development and to generate alleles of zebrafish *pax2a* to evaluate target gene expression. **Methods**: RNAseq was performed from biological replicates of E11.5 wildtype and *Pax2-/-*mouse eye tissue. qPCR confirmed differential target expression in embryonic mice and zebrafish. TALEN generated variants within the paired domain of zebrafish *pax2a* and were used for *in situ* hybridization to evaluate *cyp1b1* expression patterns. Bioinformatic analysis of *Cyp1b1* genomic sequence was performed to identify putative Pax2 binding sites. **Results**: RNAseq identified fifty differentially expressed eye genes in E11.5 *Pax2-/-* mouse eye tissue compared to wildtype; *Cyp1b1* expression was significantly reduced. *Cyp1b1/cyp1b1* differential expression was confirmed by qPCR in both mouse and zebrafish embryos. *cyp1b1* expression by *in situ* hybridization was present in the wildtype zebrafish eye at 30hpf. A restricted expression pattern was observed in *pax2a-/-* hypomorphs with greater restriction in *pax2a-/-* null alleles. Identification of Pax2/pax2a binding sites upstream of the *Cyp1b1/cyp1b1* ATG start site supports possible direct transcriptional regulation by Pax2/pax2a. **Conclusions**: We determined that *Cyp1b1* expression by RNAseq is reduced in mouse and confirmed by qPCR in both *Pax2a/pax2a-/-* mouse and zebrafish. *cyp1b1* expression in *pax2a-/-* zebrafish eyes is restricted in an allele specific manner with the greatest restriction occurring in null alleles compared to hypomorphic and wildtype alleles. It is important to note that in humans, autosomal recessive *CYP1B1* pathogenic variants cause congenital glaucoma as well as chorioretinal colobomas suggesting that phenotypic overlap in human patients with Renal Coloboma Syndrome may have a functional basis. Our results support that Pax2/pax2a regulates *Cyp1b1/cyp1b1* expression during vertebrate eye development and provides mechanistic insight into the optic nerve phenotypes observed in Renal Coloboma Syndrome.

2224W

Identification of *SPECC1L* mutations in patients with non-syndromic cleft lip and palate. *I. Saadi[1], E.G. Hall[1], N.R. Wilson[1], S. Undurty[2], J. Standley[2], E.A. Augustine-Akpan[3], Y. Kousa[4], D.S. Acevedo[1], L. Pitstick[5], N. Natsume[6], S. Yousaf[1], T. Busch[2], E. Kosa[1], C. Nguyen[7], M. Nguyen[7], W.L. Adeyemo[8], M.A. Eshete[9], A. Czirok[1], B.C. Bjork[5], B.C. Schutte[4], S. Suzuki[2,6], J.C. Murray[2], A. Butali[3].* 1) Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS; 2) Department of Pediatrics, Craniofacial Anomalies Research Center, University of Iowa, Iowa City, IA; 3) Department of Oral Pathology, Radiology and Medicine/Dow Institute for Dental Research, College of Dentistry, University of Iowa, Iowa City, IA; 4) Department of Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI; 5) Department of Biochemistry, Midwestern University, Downers Grove, IL; 6) Division of Research and Treatment for Oral and Maxillofacial Congenital Anomalies, School of Dentistry, Aichi-Gakuin University, Nagoya, Japan; 7) Odonto Maxillo Facial Hospital, 263-265 Tran Hung Dao Street, District 1, Ho Chi Minh City, Vietnam; 8) Department of Oral and Maxillofacial Surgery, College of Medicine, University of Lagos, Lagos, P.M.B. 12003, Nigeria; 9) Department of Plastic and Reconstructive Surgery, Addis Ababa University, Addis Ababa, P.O. Box: 26493, Ethiopia.

SPECC1L mutations have been identified in patients with rare atypical clefts, and in patients with syndromic cleft lip and palate. These mutations cluster in the second coiled coil and calponin homology domains of SPECC1L, and severely affect the ability of SPECC1L to associate with acetylated microtubules. We wanted to determine if *SPECC1L* mutations also contributed to non-syndromic orofacial clefting. We sequenced 62 Caucasian, 89 Filipino, 90 Ethiopian, 90 Nigerian and 95 Japanese patients with nsCL/P. We identified four rare coding variants (A86T, M91I, T299A, R546Q). Interestingly, all of these variants reside outside of SPECC1L coiled coil domains, and appear to mildly affect the ability of SPECC1L to associate with acetylated microtubules, which is evident upon quantitative fluorescent activated cell-sorting analysis following transfection into mammalian cells of GFP-fusion constructs carrying these variants. Thus, these *SPECC1L* variants associated with nsCLP result in milder functional defects than variants associated with atypical or syndromic clefting. We previously showed that severe deficiency of *Specc1l* in a mouse model results in early embryonic lethality. To validate that moderate *Specc1l* deficiency in mouse affects palatogenesis, we generated a hypomorphic allele, *Specc1l[del200]*, which shows perinatal lethality. Indeed, *Specc1l[del200/del200]* homozygous mutants show rare occurrence of cleft palate. Consistently, *Specc1l[severe/del200]* compound mutants show higher penetrance of cleft palate phenotype. Live-imaging analyses indicate that primary mouse embryonic palatal mesenchyme cells from *Specc1l[severe/del200]* mutants are impaired in collective cell migration. We further show that SPECC1L is broadly expressed in the palate epithelium and mesenchyme, and that this SPECC1L expression is drastically reduced in *Irf6* mutant palates. Together, our data indicate that palatogenesis is specifically sensitive to deficiency of SPECC1L dosage and function in both mouse and human. *SPECC1L* represents a novel gene that functions downstream of *IRF6* in the etiology of nsCL/P.

2225T

Loss-of-function mutations in the X linked gene *STAG2* cause a novel cohesinopathy. *M.W. Wessels[1], W.K. Chung[2], J. Demmers[3], I.M. Frohn-Mulder[4], R. Willemsen[1], J. Saris[1], P.J. Willems[5], S. Sharaeian[6], K.S. Wendt[6].* 1) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 2) Departments of Pediatrics and Medicine, Columbia University Medical Center, New York, New York, 10032; 3) Proteomics Center, Erasmus University Medical Center, Rotterdam, The Netherlands; 4) Department of Pediatric Cardiology, Erasmus Medical Center, Rotterdam, The Netherlands; 5) GENDIA, GENetic DIAgnostic Network, Antwerp, Belgium; 6) Department of Cell Biology, Erasmus Medical Center, Rotterdam, The Netherlands.

Background Defects of the cohesin complex or cohesin regulators, commonly referred to as "Cohesinopathies", are associated with developmental syndromes. The most prominent cohesinopathy is Cornelia de Lange Syndrome (CdLS). Cohesin is important for genome stability, sister chromatid cohesion, DNA damage repair, chromatin looping as well as overall transcriptional regulation, and the complex consists of the core subunits SMC1A, SMC3, RAD21 and the orthologs STAG1 or STAG2. The *STAG2* gene localizes on the X chromosome and undergoes X inactivation. So far, only patients with duplications of the *STAG2* gene have been reported. **Methods and Results** Here we describe two female patients, one with a *de novo* heterozygous 160 kb deletion in Xq25, encompassing the 5' and a large part of the *STAG2* gene, and one with a *de novo* truncating *STAG2* mutation that presumably leads to loss of function. Clinical features in these patients include intellectual disability, microcephaly, mild dysmorphic features, short stature, scoliosis, hypertrophic cardiomyopathy, coarctation of the aorta and congenital diaphragmatic hernia. The dysmorphic features were not suggestive of Cornelia de Lange syndrome. X inactivation studies showed different patterns of X inactivation in different tissues, with skewed X inactivation in blood and reversal skewed X inactivation in fibroblasts in one of the two girls. Sister-chromatid cohesion and cell susceptibility to DNA damage and radiation was normal. Patient-derived cells without expression of STAG2 and cell-line based model systems were used to study the effect of the mutation for the different cohesin functions. **Conclusion** Heterozygous inactivating mutations of *STAG2* lead to a new human cohesinopathy and further confirms a role for the involvement of the Scc3/STAG subunits of cohesin in human disease. .

2226F

Identification of novel candidate genes for Disorders/Differences of Sex Development (DSD) by investigation of variants of uncertain significance identified in 46,XY DSD using the C57BL/6J-Y[POS] mouse model.
H. Barseghyan[1], M. Zadikyan[1], S. Kamsut[1], M. Almalvez[1], M. Bramble[1], M. Larson[1], R. Baxter[1], V. Arboleda[1], A. Eskin[1], S. Nelson[1], E. Delot[1,2], E. Vilain[1,2]. 1) Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California; 2) Pediatrics, David Geffen School of Medicine, University of California, Los Angeles, California.

Disorders of Sex Development (DSD) are defined as "congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical." These conditions have an approximate frequency of 0.5-1% of live births and encompass a wide variety of urogenital abnormalities ranging from mild hypospadias to sex reversal. We have performed exome sequencing (ES) to identify the underlying genetic cause in patients diagnosed with 46,XY DSD. In the majority of cases a specific genetic diagnosis was not found, nevertheless ES yielded large numbers of variants of uncertain significance (VUS). To investigate the relevance of these VUS in regards to the patient's phenotype, we utilized a powerful mouse model for studying undervirilization in 46,XY individuals, in which the presence of a Y chromosome originating from a *M. domesticus poschiavinus* strain (Y[POS]) on C57BL/6J (B6) background results in XY undervirilization and sex reversal. We hypothesized that abnormal gonadal expression of specific genes in B6-Y[POS] males during gonadal development would correlate with VUS in genes of 46,XY DSD patients identified through ES. We isolated gonadal tissue from wild type (WT) B6 and undervirilized B6-Y[POS] males at embryonic day 11.5 (21ts) a time point when the surge of *Sry* gene was compete and performed RNA sequencing in order to assess differential gene expression. We identified 310 genes that were differentially expressed in B6-Y[POS] gonads compared to WT gonads with a fold change (FC) greater than 1.5. A missense variant with a minor allele frequency of less than 1% was present in 187 differentially expressed genes from mouse model and were classified as VUS in our unexplained 46,XY DSD cases. We performed further filtering of these variants by restricting the MAF to 0.1%, increasing expression difference to 2 fold and relying on *in silico* tools for prediction of damaging variants. Using these filtering criteria we identified 19 novel candidate genes involved in 46,XY DSD pathogenesis. Among these genes, several were chosen for further follow up validation using *in vitro* tools such as cell lines and assays. This method allowed identification of novel candidate genes, mutations in which were associated with 46,XY DSD.

2227W

Development of antisense oligonucleotide therapy for Fibrodysplasia Ossificans Progressiva. *R. Maruyama[1], J. Elliott[1], Y. Echigoya[1], T. Yokota[1,2], O. Caluseriu[1].* 1) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Muscular Dystrophy Canada Research Chair, University of Alberta, Edmonton, AB, Canada.

Fibrodysplasia Ossificans Progressiva (FOP) is a rare autosomal-dominant (AD) disorder characterized by progressive heterotopic ossification. The worldwide prevalence is approximately 1 case in 2 million individuals. The median lifespan of the patients is approximately 40 years of age. Currently, there is no effective treatment available. More than 95% of cases are caused by a recurrent mutation of (617G>A; R206H) in *ACVR1*, a bone morphogenetic protein (BMP) type I receptor. The mutation renders ACVR1 responsive to Activin A, by which WT ACVR1 is not activated. The ectopic activation of ACVR1[R206H] by Activin A induces heterotopic ossification. Because ACVR1[R206H] is a hyperactive receptor, a promising therapeutic strategy is to decrease the activity of ACVR1 in patients. To accomplish this goal, we developed new therapies utilizing antisense Locked Nucleic Acid Gapmers (LNA Gapmers). LNA Gapmers are DNA oligonucleotides with fully modified phosphorothioated backbones and have locked nucleic acid (LNA) modification at both ends; they hybridize to a target sequence of mRNA, which induces the mRNA degradation by RNase H. We designed and screened LNA Gapmers specific to *ACVR1* to identify the ones that efficiently reduce the expression of *ACVR1* in FOP patient fibroblasts. Several of our custom designed LNA Gapmers successfully reduced the expression of ACVR1 both in RNA and protein level in the FOP patient fibroblasts. The *in vivo* efficacies of the LNA Gapmers will be tested by FOP mouse and xenograft models. Successful completion of this study will provide a proof of principle for applying antisense oligonucleotide therapy for FOP, and possibly for the treatment of other AD disorders with toxic gain of function mutations.

2228T

Aberrant splicing induced by the most common EPG5 mutation in an individual with Vici syndrome. *M.S. Kane[1], T. Vilboux[1], L.A. Wolfe[2,3], P.R. Lee[2], Y. Wang[1], K.C. Huddleston[1], J.G. Vockley[1,4], J.E. Niederhuber[1,5], B.D. Solomon[1,4,6].* 1) Inova Translational Medicine Institute, Falls Church, VA; 2) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director and the National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Office of the Clinical Director, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Department of Pediatrics, Virginia Commonwealth University School of Medicine, Richmond, VA; 5) Adjunct Professor Oncology, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Inova Children's Hospital, Inova Health System, Falls Church, VA.

Vici syndrome is a severe autosomal recessive condition recently found to be caused by mutations in the *EPG5* gene (NG_042838.1) (Cullup et al, 2013.). The most common disease causing variant identified in Vici syndrome patients is *EPG5* NM_020964.2: c.1007A>G p.Gln336Arg. It has been suggested that this variant may affect splicing via *in silico* prediction models. However, multiple prediction tools yield discordant results regarding the impact on both mRNA splicing and pathogenicity of the amino acid change caused by this variant. Therefore, we have sought to characterize *EPG5* mRNA (expression level and splice isoforms) in fibroblasts from an individual with prototypical features of Vici syndrome who is homozygous for the *EPG5* c.1007A>G variant. We find that *EPG5* transcripts are reduced by 50% in the affected cells compared to control cells. By targeted amplification, cloning and sequencing of the residual transcripts, we observe both normal and abnormal splice products in the context of this Vici syndrome variant. While most of the abnormal splice isoforms encode a premature stop codon due to inclusion of *EPG5* IVS2, approximately 25% of the residual mRNA encodes the missense mutation. These results show the impact of this variant on the mRNA and may reveal that Vici syndrome may only be due to potential null allele variants in *EPG5*. Our results suggest the importance of performance of mRNA analyses in other patients carrying other rare missense variants associated with this disorder. Utilization of RNA sequencing for future analyses will yield a broader picture of all possible abnormal splice isoforms occurring in the context of *EPG5* deleterious variants.

2229F

Exome sequencing in patients with Acrocallosal syndrome like features and functional studies suggest disturbed ciliar Sonic Hedgehog signalling caused by mutations in either *KIF7*, *C5orf42* or *SHH* as underlying cause. *A. Rauch[1], R. Asadollahi[1], J.E. Strauss[2], M. Zenker[3], O. Beuing[4], S. Edvardson[5], O. Elpeleg[6], T.M. Strom[7], P. Joset[1], D. Niedrist[1], C. Otte[1], B. Oneda[1], P. Boonsawat[1], S. Azzarello-Burri[1], D. Bartholdi[1], M. Papik[1], M. Zweier[1], C. Haas[8], A.B. Ekici[9], A. Baumer[1], E. Boltshauser[10], K. Steindl[1], M. Nothnagel[11], A. Schinzel[1], E. Stoeckli[2].* 1) Inst Medizinische Genetik, Univ Zurich, Schlieren-Zurich, Switzerland; 2) Institute of Molecular Life Sciences and Neuroscience Center Zurich, University of Zurich, Zurich, Switzerland; 3) Institute of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany; 4) Institute of Neuroradiology, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany; 5) Pediatric Neurology Unit, Hadassah University Hospital, Mount Scopus, Jerusalem, Israel; 6) Monique and Jacques Roboh Department of Genetic Research, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 7) Institute of Human Genetics, Technische Universität München, Munich, Germany; 8) Zurich Institute of Forensic Medicine, University of Zurich, Zurich, Switzerland; 9) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany; 10) Department of Pediatric Neurology, University Children's Hospital, Zurich, Switzerland; 11) Cologne Center for Genomics, Department of Statistical Genetics and Bioinformatics, University of Cologne, Cologne, Germany.

Acrocallosal syndrome (ACLS) is an autosomal recessive neurodevelopmental ciliopathy which is known to be caused by mutations in *KIF7*. It is recognizable by macrocephaly and facial dysmorphism amongst other overlapping ciliopathies summarized as Joubert syndrome related disorders, for which 30 genes have been identified so far. In order to evaluate the specificity and aetiology of ACLS-like features, we performed genetic and functional analyses in patients with consistent craniofacial appearance and variable other features out of the Joubert syndrome related disorders spectrum. We analysed 13 patients from 9 families including the original two patients by whole-exome or targeted Sanger-sequencing of *KIF7*. Surprisingly, while 7 patients including the original ACLS cases harboured biallelic *KIF7* mutations, 4 patients showed biallelic mutations in the known Jourbert syndrome gene *C5orf42,* and one patient showed a novel de novo truncating mutation in *SHH,* which was known to cause holoprosencephaly, only. While all our patients shared the common minimal diagnostic criteria of cognitive deficits, ACLS-like craniofacial features and abnormal corpus callosum or MTS or vermis hypoplasia, *KIF7* mutated patients had more severe facial dysmorphism and in general had moderate to severe intellectual disability. Long-term follow-up of the patients allowed us to delineate that patients with *C5orf42* mutation usually caught up and remained only mildly to moderately retarded after initial severe developmental delay. However, one patient with homozygosity for a *KIF7* splice site mutation at position -3 also caught up and remained only mildly retarded, which may indicate some leakiness of this mutation. We also estimated the most recent common ancestors for two Swiss *KIF7* founder mutations to 1000-4000 years ago. While KIF7 and SHH were known proteins in ciliary Sonic Hedgehog (Shh) signaling, we showed for the first time abnormal primary cilia in fibroblasts of *C5orf42*-mutated patients. Additionally, *C5orf42* knock-down in chicken embryos revealed axonal pathfinding errors similar to those observed after perturbation of Shh signalling, abnormal neural circuit formation and aberrant craniofacial features consistent with facial widening in the patients. Our findings therefore suggest that ACLS-like craniofacial features are a more general sign of disturbed Shh signaling and can be caused by mutations in *KIF7*, *C5orf42* or *SHH*.

2230W

***IRF6* missense mutations decrease the transactivation ability without affecting the homodimer forming ability.** *K. Imaki, T. Sae, H. Soushi, A. Itsuro, T. Inamine, K. Tsukamoto, K. Shinji.* Dpt of Pharmacotherapeutics Nagasaki Univ Grad Sch, Nagasaki, Japan.

I. Kouta, T. Sae, H. soushi, A. Itsuro, T. Inamine, K. Tsukamoto, K. Shinji Dpt of Pharmacotherapeutics, Nagasaki Univ Grad Sch, Nagasaki, Japan [;Background and Objectives]; *Interferon regulatory factor 6 (IRF6)* mutations are involved in the development of Van der Woude syndrome (VWS) and popliteal pterygium syndrome (PPS). We selected seven VWS mutations, such as V321M, G325E, L345P, C347F, F369S, C374F, and K388E, and one PPS mutation S424L. To elucidate the pathogenic mechanism of VWS and PPS, we investigated whether these mutations that cause VWS or PPS affect the transactivation ability and the homodimer forming ability of *IRF6* in cell culture assays. [;Method]; Eight variant types of *IRF6* expression vectors we generated were transfected into HEK293T, MCF-7, and MDA-MB-231 cells and we compared the transactivation activity by means of a dual-luciferase assay. In addition, after a plasmid expressing AcGFP-mutant IRF6 fusion proteins and a plasmid expressing ProLabel-wild type IRF6 fusion protein were co-transfected into HEK293T cells, we performed a co-immunoprecipitation assay with anti-GFP antibody and compared the homodimer forming ability by measuring the ProLabel activity. Statistical analyses were performed with Dunnett's test after the ANOVA using the SPSS software package. A P value of less than 0.05 was considered to be statistically significant. [;Results]; The transactivation activities of V321M, G325E, L345P, C347F, C374W, K388E, and S424L were significantly reduced, compared with those of the wild-type. In contrast, the ProLabel activities showed no significant differences in the homodimer forming ability between the wild-type and the mutants. In addition, the stimulation with WNT-5A significantly increased the ProLabel activity in wild-type IRF6. [;Discussion □Conclusion]; In this study, we demonstrated that missense mutations of *IRF6* found among the patients with either VWS or PPS reduce the transactivation level statistically without affecting the IRF6 homodimer formation in cell culture assays. Moreover, we suggest that WNT-5A is involved in the IRF6 homodimer formation. Missense mutations may inhibit IRF6 from either translocating into the nucleus or binding to the elements of target genes. We propose that the decrease of transactivation and the change of the expression levels in the target genes by *IRF6* mutations may cause VWS and PPS, through the IRF6-mediated signaling pathway.

2231T

Altered ribosomes in the recessive ribosomopathy, Shwachman-Diamond syndrome. *M.E. Tourlakis[1], H. Liu[2,3], R. Gandhi[2], P. Hu[4], A.D. Paterson[2,5], J.M. Rommens[2,3].* 1) Life Sciences Division, Quest University Canada, Squamish, British Columbia, Canada; 2) Program in Genetics & Genome Biology, Research Institute, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 4) Department of Biochemistry & Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 5) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada.

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disease characterized by growth retardation, exocrine pancreatic dysfunction, skeletal dysplasia, cognitive impairment and bone marrow failure. SDS is caused by mutations in *SBDS*. Recent studies indicate that Sbds functions together with Efl1to release Eif6 from the pre-60S complex, enabling ribosomal subunit joining for translation initiation. To assess the protein synthesis deficiencies that have been detected in culture and *in vivo* models of SDS, ribosomal profiles of SDS murine fetal organs were examined and found to lead to reduced 80S monosome peaks and polysomes with increased number and amplitude of sub-peaks. Ribosomal subunit level ratios (60S/40S) were not altered. To understand these observations and to learn how the SDS translatome is altered, total and polysomal mRNAs of mutant and control fetal liver samples were studied using cDNA microarray analyses. By comparing individual polysomal-bound probe level to respective steady state probe level, 1,089 probe sets (of 25,914 analyzed) exhibited altered polysome loading in mutant fetal livers, with 817 being increased (fold change ≥ 2; FDR adjusted P-value ≤ 0.05). These groups corresponded to a total of 799 RefSeq genes, but did not reveal specific biological pathways or point to alerted stress response pathways detected in other organs exhibiting SDS phenotypes. Further, the changes in polysome loading did not correspond to changes in steady state protein levels, as indicated by label-free mass spectrometry or immunoblotting. Rather, these changes reflected physical features of the transcripts, including 5' untranslated region composition as well as the nucleotide composition of the open reading frame and the 3' untranslated regions. Increased binding was consistent with low GC content and longer untranslated regions, features suggestive of bound ribosomes that are not functioning. In additional investigations, Eif6 was found to be present in profile fractions containing either the 60S subunit and 80S monoribosome complexes in mutants, in contrast to only 60S subunits in controls. Together, we conclude that the untimely release of Eif6 due to Sbds deficiency results in ribosomes with compromised translation and that SDS phenotypes reflect protein synthesis insufficiency due to the loss of translation initiation and the formation of sub-populations of 'SDS ribosomes' with non- or poor- translating capability.

OFD1 cooperates with Bicc1 to regulate protein synthesis at the centrosome. *B. Franco[1,6], D. Iaconis[1], M. Monti[2], M. Renda[1], A. van Koppen[3], M. Chiaravalli[4], F. Cozzolino[2], P. Pignata[1], C. Crina[1], P. Pucci[2], A. Boletta[4], V. Belcastro[1], R.H. Giles[3], E.M. Surace[1], M. Pende[5], R. Tammaro[1].* 1) 1.Telethon Institute of Genetics and Medicine (TIGEM), Via Campi Flegrei, 34, 80078, Pozzuoli, Naples, Italy; 2) 2.Dipartimento di Scienze Chimiche and CEINGE Biotecnologie Avanzate, Università di Napoli Federico II, Via Gaetano Salvatore 482, 80145 Napoli, Italy; 3) 3.Department of Nephrology and Hypertension, University Medical Center Utrecht, Heidelberglaan 100, 3584CX Utrecht, the Netherlands; 4) 4.Division of Genetics and Cell Biology, Dibit, San Raffaele Scientific Institute, Via Olgettina, 58 – 20132, Milan, Italy; 5) 5.Institut National de la Santé et de la Recherche Médicale (INSERM) U1151, Institut Necker Enfants Malades, Université Paris Descartes, Sorbonne Paris Cité, Paris, France; 6) 6.Department of Translational Medicine, University of Naples "Federico II", Via Sergio Pansini, 80131, Naples, Italy.

Protein synthesis is traditionally associated with specific cytoplasmic compartments. We now show that OFD1, a centrosomal/basal body protein, interacts with components of the Preinitiation complex of translation (PIC) and of the Eukaryotic Initiation Factor (eIF)4F complex and modulates the translation of specific mRNA targets in the kidney. We demonstrate that OFD1 cooperates with the mRNA binding protein Bicc1 to functionally control the protein synthesis machinery at the centrosome where also the PIC and eIF4F components were shown to localize in mammalian cells. Interestingly, Ofd1 and Bicc1 are both involved in renal cystogenesis and selected targets were shown to accumulate in two models of inherited renal cystic disease (i.e. a murine model of Oral-facial-digital (OFD) type I syndrome and a murine model of autosomal dominant polycistic kidney disease (PKD1). Our results highlight a possible role for the centrosome as a specialized station to locally modulate translation for specific functions of the nearby ciliary structures and may provide functional clues for the understanding of renal cystic disease.

2233W

Mutations in *DHH*, *WWOX* and *FLNB* cause 46,XY DSD through disruption of the MAP kinase pathway. *J. Loke, M. Syeda, K. Upadhyay, A. Pearlman, H. Ostrer.* Pathology, Albert Einstein Sch Med, Bronx, NY.

Introduction. Disorders of sex development (DSDs) affect up to 1:1000 individuals and may account for 7.5% of all birth defects. 46,XY DSD may occur when testes determination has failed or is incomplete. Previously, we showed that mutations in *MAP3K1* are a common, if not the most common, cause of 46,XY DSD (Loke et al. Hum Mol Genet 23:1073-83, 2014). These mutations decrease SOX9 expression and increase β-catenin activity, tilting the balance away from testis determination in the interacting male and female sex-determining pathways. Here, these genetic pathways have been extended to individuals with 46,XY DSD who have mutations in other genes. **Materials and methods.** Mutations in *DHH, WWOX* and *FLNB* were observed in individuals with 46,XY DSD. Notably, the individual with the biallelic mutations in *FLNB* also had Larsen syndrome, as did her father. These mutations were recreated in NT2/D1 cells, then assessed for expression of SRY, SOX9, FOXL2, WNT4, phospho p38, phospho ERK1/2 by qPCR and/or digital cell Western. The activity of β-catenin was assessed by the TOPFLASH luciferase assay. **Results.** The mutations in *DHH, WWOX* and *FLNB* caused deceased expression of SRY and SOX9, increased expression of FOXL2 and WNT4 and increased phosphorylation of p38 and ERK1/2, thus accounting for the phenotypes. **Conclusion.** Mutations in genes for signaling molecules (DHH), structural molecules (FLNB) and transcription factors (WWOX) can all disrupt sex determination by modifying the activities of genes in the MAP kinase-transcription factor signal transduction pathway. The NT2/D1 functional assay system can be adapted readily to understanding the effects of mutation in any candidate sex determining gene and to screen for new sex determining genes. Overlap in developmental pathways between Sertoli cells and chrondrocytes can cause co-occurring DSDs and skeletal dysplasias, as has been observed for campomelic dysplasia and now for Larsen syndrome.

2234T

SOX11 is necessary for development of the bony labyrinth. *E.D. Sperry[1,3], R. Hojjati[2], D.L. Swiderski[4], G. Wan[4], S. Brewer[4], V. Popov[4], W.M. King[4], G. Corfas[4], Y. Raphael[4], D.M. Martin[1,3,5].* 1) Medical Scientist Training Program, University of Michigan, Ann Arbor, MI; 2) College of Literature, Science, and the Arts, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Otolaryngology - Head and Neck Surgery, University of Michigan, Ann Arbor, MI; 5) Department of Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI.

The transcription factor SOX11 is of increasing interest as a mediator of inner ear development. Heterozygous mutations in *SOX11* cause Coffin-Siris (CS) syndrome, a heterogeneous disorder resulting in craniofacial anomalies and sensory impairments, including sensorineural hearing loss. Interestingly, *Sox11* expression is regulated by the chromatin remodeler CHD7, altered in CHARGE syndrome, which presents with complex inner ear malformations. A recent report suggests that SOX11 is necessary for proper development of utricular hair cells. Here, we sought to further explore roles for SOX11 in common genetic pathways with CHD7 during inner ear development. By paintfill analysis, we observed lateral semicircular canal abnormalities in one-third of *Sox11*[+/-] (*N*=10/26) and all *Sox11*[-/-] (*N*=12/12) E14.5 ears. Examination of *Sox11*[-/-] E11.5 and E12.5 embryos revealed a failure of lateral semicircular canal fusion plate formation. *Sox11*[+/-] mice exhibited mild high-frequency hearing loss by auditory brainstem response (ABR) testing and a significant reduction in P1 latencies by vestibular sensory evoked potential (VsEP) testing. Quantitative RT-PCR, *in situ* hybridization, and immunofluorescence on E10.5 and E12.5 *Sox11* and *Chd7* mutant ears showed spatiotemporal misregulation of several genes critical for ear morphogenesis, including *Bmp4*, *Otx1*, and *Shh*. Further, dosage-dependent reductions in *Sox11* mRNA were detected at E10.5 and E12.5 in *Chd7*[Gt/+] and *Chd7*[Gt/Gt] mutant ears relative to *Chd7*[+/+] controls. SOX11 immunofluorescence was reduced in *Chd7*[Gt/+] and absent in *Chd7*[Gt/Gt] inner ears. *Chd7;Sox11* double heterozygous mutant inner ears exhibited the same morphologic changes in semicircular canal structure as *Chd7*[Gt/+] mice. Taken together, our studies demonstrate that loss of *Sox11* in mice results in lateral and posterior semicircular canal dysplasia, concurrent with spatiotemporal misregulation of genes critical for development of the bony labyrinth. Further, we observe a possible role for SOX11 in adult mouse auditory and vestibular function. Finally, *Sox11* may mediate some of the effects of CHD7 during mouse inner ear development. These studies help clarify molecular relationships between *Sox11* and *Chd7* in inner ear development and provide insights about the pathogenic mechanisms involved in CS and CHARGE syndromes.

2235F

Fetal neuronal migration defects and severe cardiac abnormalities associated with a *de novo* **pathogenic mutation in the** *PIK3R2* **gene.** *G. Nimmo[1,2], A. Staines[2], P. Shannon[3], S. Keating[3], G. Mirzaa[4], D. Chitayat[1,2].* 1) Department of Paediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, The University of Toronto, Toronto, Ontario, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Dept. of Obstetrics and Gynaecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) The Prenatal Diagnosis and Medical Genetics Program, Dept. of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Department of Pediatrics and Center for Integrative Brain Research , Seattle Children's Research Institute, The University of Washington, Seattle, WA, USA.

The Megalencephaly-polymicrogyria-polydactyly-hydrocephalus (MPPH) syndrome is known to be associated with mutations in three PI3K-AKT-MTOR pathway genes: *PIK3R2, AKT3* and *CCND2*. So far all reported human cases were in liveborn individuals and the fetal findings have not well been delineated. Further, none of the mutation-positive MPPH individuals had non-CNS abnormalities, with the exception of postaxial polydactyly. Here, we report the first fetus with a *de novo* mutation in the most commonly seen MPPH gene, *PIK3R2*, who had severe CNS and cardiac defects, further expanding the clinical spectrum of *PIK3R2*-related disorders. The mother was a 32 year old G1P0 woman of Anglo-British descent and the father was 38 years old and of Anglo-Saxon descent. Both parents were healthy and non-consanguineous. Initial prenatal ultrasound done at 13 weeks showed NT of 1.6 mm and a detailed fetal ultrasound at 20 weeks gestation showed hypoplastic left heart with coarctation of the aorta. The couple was counseled and decided to interrupt the pregnancy. A fetal autopsy confirmed the cardiac abnormalities and also showed cerebral abnormalities including aberrant cortical lamination predominantly involving the temporal lobes, as well as numerous leptomeningeal and subcortical heterotopias. Whole-exome sequencing revealed a previously unreported *de novo* apparently constitutional mutation in the *PIK3R2* gene. Although only a handful of variants have been reported in patients with MPPH, all but one describe variants affecting the SH2 domain of PIK3R2 (p.G373R). Herein, we documented a non-synonymous amino acid substitution affecting a highly conserved residue outside the SH2 domain and in a region proposed to interact with the catalytic subunit of PI3K and expand the role of this gene to include cardiogenesis.

2236W

Gene discovery in Mabry syndrome (OMIM 239300): Disruption of the gly-cophosphatydylinositol (GPI) anchor biosynthesis pathway associated with a metabolic disorder causing profound mental retardation, seizures and other neurologic deficits. *M. Thompson[1], C.C. Mabry[2].* 1) Laboratory Medicine and Pathobiology, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) Pediatrics, University of Kentucky, Lexington, KY, USA.

Mabry syndrome (OMIM 239300), an autosomal recessives syndrome of hyperphosphatasia (elevated circulating alkaline phosphatase (AP), seizures and neurologic deficits) was first described in 1970. Over the ensuing four decades, few cases were reported. In 2010, however, new families were identified and the syndromic nature of the disorder confirmed. This enabled the use of exome sequencing to identify the causative defects in the glycosyl phosphatidylinositol (GPI) biosynthetic pathway. Genetic variants of the phosphatidylinositol glycan (PIG) biosynthesis gene products (active in the endoplasmic reticulum) and the Post-GPI Attachment to Proteins (PGAP) gene products (active in the Golgi) have been identified. We continue our work of gene discovery in Mabry syndrome using exome sequencing of original index cases. This work will identify novel genes and/or mutations associated with the form of this autosomal recessive disorder as it was first described in 1970. Since these patients exhibit lysosomal storage, we will have the opportunity to identify the role this material may play in the etiology of seizures and cognitive defects seen in Mabry syndrome. While the contribution of hyperphosphata-sia to the pathogenesis of the syndrome is not known, since there are more than 250 other proteins dependent on GPI for their anchoring to the plasma membrane, the present study of Mabry syndrome may provide a new window on AP function in growth and development.

2237T

Cross-species comprehensive phenotyping to reveal the genetic basis of disease: Informatics for the International Mouse Phenotyping Consor-tium. *T. Meehan[1], A. Mallon[2], H. Parkinson[1], D. Smedley[3], MPI2 Consortium.* 1) EMBL-EBI, Hinxton, Cambridge, United Kingdom; 2) MRC Harwell, Oxford, UK; 3) Genomics England, Queen Mary University of London, London, UK.

Correlating phenotypic aspects of disease with causal genetic variants are often confounded by a lack of functional gene knowledge. The Interna-tional Mouse Phenotyping Consortium (IMPC) is addressing this challenge by building a functional catalog of a mammalian genome by producing and characterizing a knockout mouse strain for every protein-coding gene. This G7 recognized global research infrastructure carefully coordinates activities across a dozen international partners to generate strains for the biomedical re-search community. Data from a standardized, broad-based phenotyping pipe-line is collected, quality controlled, archived and analyzed by the IMPC-Data Coordinating Center. Annotation with biomedical ontologies allows biologists and clinicians to easily find mouse strains with phenotypic traits relevant to their research and facilitates integration with other resources. With phenotype data available for over 3000 knockout strains at mousephenotype.org, new gene-phenotype correlations are providing novel insights into development, fertility, disease and sexual dimorphism. We will present our informatics ap-proach for identifying and characterizing hundreds of new rare disease models and demonstrate how clinical researchers can benefit from IMPC resources. .

IGF2 and its network partners: Key factors in the etiology of Russell-Silver syndrome. *T. Eggermann, L. Soellner, M. Begemann.* Dept Human Gen, Univ Hosp, Aachen, Germany.

With the identification of 11p15.5 disturbances in Russell-Silver syndrome (RSS/Silver-Russell syndrome) ten years ago, the central role of at least the telomeric imprinted region ICR1 in 11p15.5 for the etiology of the disease became obvious. Two of the genes regulated by the ICR1 are IGF2 and H19. Due to its physiological function and its imprinting status, IGF2 had been suggested as the causative gene for RSS, but the final clue was still missing. With the recent identification of a paternally inherited IGF2 mutation in a family with growth retardation and RSS, we could confirm the hypothesis that IGF2 is the key factor for the growth retardation and other features in RSS. In the last decade it has emerged that IGF2 and other imprinted genes belong to common functional networks, either because of their physiological function or because they belong to the imprinted genes network (IGN), and molecular alterations of genes of IGF2 interaction partners also contribute to growth retardation. Comprehensive studies in our patient cohort (n>500) referred for RSS diagnostic testing helped us to identify further molecular alterations in the 11p15.5 region itself, but also in other genes and chromosomes (e.g. GRB10 in 7p13, MEST in 7q31, IGF1R in 15q26). Our data and those from animal and cellular models indicate that IGF2 and the coregulated H19 gene as well as further imprinted and/or functionally related factors belong to the IGN and the IGFII-IGF1R signaling cascade by cis and trans acting mechanisms. These findings contribute to a better understanding of human growth and its disturbances. The translational use of this knowledge has significantly improved molecular diagnostics of RSS and will have an impact on personalized patient management.

2239W

Identification of the first causative missense mutation of the *GPSM2*-gene in a patient with Chudley-McCullough syndrome (CMS). *P.M. Kroisel[1], G. Schaller[2], T. Kau[3], R. Birnbacher[4], M.R. Speicher[1], C. Windpassinger[1], K. Wagner[1], T. Schwarzbraun[1].* 1) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 2) Pediatrician, Villach, Austria; 3) Department of Pediatrics, Pediatric Radiology, Hospital Klagenfurt, Klagenfurt, Austria; 4) Department of Pediatrics, Regional Hospital Villach, Villach, Austria.

In the second child of a consanguineous couple of Turkish origin typical symptoms of Chudley-McCullough syndrome (CMS [MIM 604213]) are present. Both parents are healthy first degree cousins. The patient is now 4 years old and shows characteristic MRI findings of his brain including dysgenesis of corpus callosum and asymmetry of ventricles and complex microgyria although brain anomalies in CMS can show a considerable variability. Congenital deafness and a developmental delay of his expressive speech were also diagnosed. Initially he did also show a delay of his motor development but this is not present anymore. By autozygosity mapping a homozygosity of several larger genomic segments also including the *GPSM2*-gene was confirmed and subsequent TruSight One gene panel analysis revealed the homozygous missense mutation g.128G>A, p.Gly43Asp of the *GPSM2*-gene. Interestingly up to now according to the literature and HGMD professional just 10 causative mutations of the *GPSM2*-gene in CMS and non syndromic hearing loss have been reported and all of these mutations are loss of function mutations. These are either homozygous or compound heterozygous nonsense mutations, one splicing mutation or two one base pair deletions. Our CMS patient is therefore the first reported with a causative missense mutation of the *GPSM2*-gene. Analysis of the identified missense mutation on function of the G protein signaling modulator 2 could provide a better understanding of the relevant domains of this gene product. It will be interesting to follow up the further development of our patient and compare it with other described cases to learn more on the impact of this new mutation of the *GPSM2*-gene on prognosis with detailed characterization of the genotype-phenotype relationship in CMS patients.

2240T

In vitro modelling Richieri-Costa-Pereira syndrome with iPSC-derived neural crest cells. *C.M. Musso[1], G.S. Kobayashi[1], F.A.A Ishiy[1], L.C.J. Caires[1], E. Goulart[1], L. Alvizi[1], A.G. Morales[1], K. Grisei-Oliveira[2], M.R. Passos-Bueno[1].* 1) Institute of Biosciences, University of São Paulo, São Paulo, Brazil; 2) Hospital Israelita Albert Einstein, São Paulo, Brazil.

Richieri-Costa-Pereira syndrome (RCPS) is a rare acrofacial dysostosis likely caused by disturbances in cranial neural crest development. RCPS is characterised by Robin sequence, cleft mandible and limb defects and is caused by non-coding expansions in the 5'UTR of *EIF4A3,* which are involved in many aspects of RNA metabolism (mRNA splicing and nonsense-mediated decay); nevertheless, the pathogenetic mechanism needs to be elucidated. The 5'UTR of the EIF4A3 is characterized by multiple allelic patterns, varying in size and organization of repeats, and RCPS patients present an increased number of motifs in this region. Here, we have demonstrated by Luciferase assay, *in vitro,* that the increased alleles are directly associated to a decreased gene expression; however, the impact of the *EIF4A3* deficiency in human development remains unknown. These results indicated a regulatory role for this region, which may be due a differences in the transcription factor binding sites between control and mutant alleles, evidenced by *in silico* analysis. Further, in order to investigate the eatiology of this syndrome, we have successfully established iPSC-derived neural crest cells (iNCCs) and iNCC-derived mesenchymal cells (nMSCs) from RCPS subjects and controls. All the cells were characterised by RT-qPCR, flow cytometry and immunofluorescence analysis and we have evaluated the migration potential, apoptosis and mesenchymal differentiation of these cells. We showed that RCPS cells possess increased osteogenic potential in comparison to controls, evidenced by increased expression of *RUNX2*, *ALP* and *BGLAP,* increased alkaline phosphatase activity and mineralized matrix deposition. We have demonstrated that this altered osteogenic differentiation is due to transcriptional dysregulation of osteogenesis-associated genes and such dysregulation was also observed in RCPS knockdown cells, supporting the relationship between reduced *EIF4A3* expression and osteogenic potential. This work indicates a possible pathogenetic mechanism for RCPS and shows the relevance of iPSCs to study craniofacial disorders. CAPES, FAPESP, CNPq.

Regulation of colonic proinflammatory cytokines and chemokines by the Ankylosing spondylitis-associated, GWAS-identified ERAP1 gene. *Y.A. Aldhamen[1], F.S. Alyaqoub[1], Y. Pepelyayeva[1], D.P Rastall[1], A. Raedy[1], P. O'Connell[1], C. Pereira-Hicks[1], S. Godbehere[1], L.R. McCabe[1,2], A. Amalfitano[3].* 1) Microbiology and Molecular Genetics, Michigan State University , East Lansing , MI; 2) Department of Pediatrics, College of Osteopathic Medicine, Michigan State University, East Lansing, MI 48824; 3) Department of Physiology, Biomedical Imaging Research Center, Michigan State University, East Lansing, Michigan, USA.

Endoplasmic reticulum aminopeptidase 1 (*ERAP1*) gene polymorphisms have been linked to several autoimmune diseases that are characterized by chronic inflammation such as Ankylosing spondylitis (AS), type I diabetes, multiple sclerosis, and Behcet's disease; however, a role for *ERAP1* in colitis has not been described. Notably, gut inflammation was found in 49% of AS patients and AS patients are also known to develop colitis. However, the exact molecular mechanism that predisposes AS patients to intestinal inflammation has not been defined. We previously demonstrated that *Erap1* deficiency alters innate and adaptive immune responses during pathogen recognition. In addition, we also demonstrated that autoimmune disease-linked variants of *ERAP1* activate the NLRP3/caspase-1 inflammasome pathway. Previous reports showed that mice deficient for NLRP3 inflammasome components are highly susceptible to dextran sodium sulfate (DSS)-induced colitis. Here, we hypothesized that *Erap1* may modulate the susceptibility of animals to DSS challenge, due to *Erap1*'s impact on innate immune responses. We show that mice deficient for *Erap1* (*Erap1*-/-) are highly susceptible to DSS-induced colitis, as compared to WT mice. We also identified exaggerated colon proinflammatory cytokine and chemokine responses in the DSS treated *Erap1*-/- mice, as compared to WT mice, resulting in increased mortality rates and severe intestinal inflammation. In addition, decreased production of the protective cytokine, IL-18, was also noted in *Erap1*-/- mice. Assessment of the intestinal inflammation marker lipocalin-2 (Lcn-2), reveled potent increases in Lcn-2 in DSS-treated *Erap1*-/- mice. Moreover, utilization of *Erap1*/β2m double knockout mice suggested that these responses are mediated in part by a mechanism that was independent of antigen presentation functions, that is also mediated by *Erap1*. These results demonstrate that *Erap1* mediates a protective function during colitis, a function that we correlated with its ability to regulate the production of intestinal proinflammatory cytokines and chemokines. These results are highly relevant to humans as *ERAP1* polymorphisms are associated with autoimmune diseases that are also associated with higher risks for development of colitis.

Dental arch dimensions and tooth eruption are under genetic influence. Since 1972, the dentist visits of Danish school children are recorded in a central database. Apart from the eruption status of primary/permanent teeth and their caries status, additional traits of malocclusion and crowding are reported. Analyzing genome-wide data of more than 13,000 individuals, we identified a genetic variant, rs17563, associated with mandibular crowding (OR 1.19, $P=4\times10^{-11}$). The risk allele frequency was significantly decreased in individuals with excessive spacing and also in cases with diastema. The variant in bone morphogenetic protein 4 (*BMP4*) has previously been described in the context of primary and permanent tooth eruption, with the risk allele for crowding associated with later eruption, which could be a consequence of the limited space in the jaw. Furthermore, *BMP4* plays an important role in embryonic development and can cause eye, brain, and digit anomalies. Previous studies showed that *BMP4* is expressed early in tooth development and our findings underline a central role of *BMP4* in multiple dental traits.

Analysis of matrix metalloproteinase expression in pressure ulcer healing.
A. Bhagat[1], M. Dwivedi[1], R. Srivastava[1], A. Chandra[2], S. Raj[1]. 1) Orthopaedic Surgery, King George's Medical University, Lucknow, India; 2) Surgical Gastroenterology, King George's Medical University, Lucknow, India.

Introduction: Matrix metalloproteinases (MMPs) play a major role in wound healing: they can degrade all components of the extracellular matrix. In pressure ulcers there is an excess of MMPs and a decrease of the tissue inhibitors of MMPs (TIMPs). This imbalance is probably one cause of impaired healing. However, little is known about changes in MMPs during wound healing. This study was planned to evaluate the levels of MMPs at different follow-up.**Material & Methods:** 22 subjects with pressure ulcers were enrolled in the study. Wound tissue was collected regularly during the 9 week follow-up period, for measurement of MMP-8, MMP-9 and TIMP-1. Results were analyzed by the degree of wound healing: good healers (defined by a reduction of 65% wound surface area at 5 weeks) and bad healers (reduction of less than 65% in wound surface area at 5 weeks). Levels of MMPs were analyzed by ELISA.**Results:** Levels of MMP-8 and 9 decreased earlier in good healer group. The initial levels of MMP-8 were similar in good and poor healers ($P = 0.1$) but the level increased significantly at week 2 in good healers ($P = 0.03$). This was continued in successive weeks. There was a significant correlation between a high ratio of MMP-8/TIMP-1 and good healing ($r = 0.65$, $P = 0.008$). Pierson correlation analysis showed that an MMP-8/TIMP-1 ratio of 0.39 best predicted wound healing (sensitivity = 71%, specificity = 87.5%).**Conclusion:** A low level of MMP-8 seems essential to wound healing, while an excess of MMP-8 and -9 is deleterious, and could be a target for new topical treatments. The MMP-8/TIMP-1 ratio is a predictor of healing in pressure ulcers.

2244F

An ENU mutagenesis screen using inbred mice identifies mutations in the collagen-modifying enzymes *Colgalt1* **and** *Plod3***, which result in nearly identical phenotypes.** *K.A. Geister, A.E. Timms, S. Ha, D.R. Beier.* Center for Developmental Biology and Regenerative Medicine, Seattle Children's Research Institute, Seattle, WA.

The discovery of modifier genes in human and mouse has seen slow progress. In mice, this is largely due to the reliance on inherent variability among inbred strains, which makes identifying the causal variant, even in highly resolved mapped loci, quite challenging. We have developed a fast and cost-effective method for genetic mapping of causal ENU-induced mutations using Next Generation Sequencing that combines single nucleotide polymorphism (SNP) discovery, mutation localization, and identification of causal sequence variants. This approach precludes the need for an outcross to facilitate mapping, as we use the ENU-induced variants as SNP markers. This strategy allows us to perform both primary screens and modifier screens on fully inbred lines. We have successfully mapped causal mutations using this approach, and we are currently testing the efficacy of this strategy with regard to modifier discovery using two C57BL/6 congenic strains as our sensitized lines. We anticipate that we may ascertain more complex genetic interactions as well as new ENU-induced mutant phenotypes that model human birth defects. In our first screen we discovered two ENU-induced mutations in genes that encode collagen-modifying enzymes that result in a nearly identical phenotype. One mutation is in *Colgalt1* (collagen (beta 1-O) galactosyltransferase type 1), which is required for proper galactosylation of hydroxylysine residues in a number of collagens. The other mutation is in *Plod3*, which can catalyze the formation of hydroxylysine, and results in a number of disruptions in the vasculature, skin, and other organs when mutated in human patients. *COLGALT1* mutations, in contrast, have yet to be documented in humans. *Colgalt1* mutant embryos exhibit skeletal, skin, and muscular defects, and we hypothesize that the *Colgalt1* mutant could serve as a model of a human connective tissue disorder and/or congenital muscular dystrophy or myopathy. The mutants also show variable expressivity of cleft palate and exencephaly. Examination of the sequencing data appears to exclude the likelihood that these are due to an unlinked ENU-induced variant, illustrating that stochastic effects remain an important source of variation in developmental phenotypes. The effect of *VDR* **knockdown on T Cell Apoptosis.** *Z. Shirvani-Farsani[1], M. Behmanesh[2].* 1) Department of Genetics, Faculty of Biological Sciences, Shahid Beheshti University, Tehran, Iran, PhD; 2) Department of Genetics, Faculty of Biological Sciences, Tarbiat Modares University, Tehran, Iran, PhD.

BACKGROUND: Vitamin D receptor (VDR) is a member of the nuclear receptor family of transcription factors. VDR play an essential role in immun cells apoptosis. However, the molecular mechanisms underneath this effect remain unclear. Therefore, We evaluated the effect of vitamin D receptor (VDR) knockdown on T cell apoptosis. **METHODS:** Jurkat T cells lines were cultured under controlled conditions. Then we used shRNAs targeting the human VDR and a scrambled non-targeting control. The efficiency of VDR down-regulation in the cells was determined using real-time RT-PCR. Next, apoptosis was assessed using the Flow Cytometery and Annexin V FITC apoptosis detection kit. Statistical analysis of the data was performed using two-way ANOVA test. **RESULTS:** These results demonestrated that VDR knockdown statistically significantly increased apoptosis in Jurkat T up to ~13%. **CONCLUSIONS:** In conclusion, shRNA study suggests that the VDR may be a novel target in apoptosis investigations. Therefore, identifiable markers related to VDR may allow for a use of those in different diseases. **Keywords:** VDR, T cells, Apoptosis, Flowcytometery. .

Global loss of BBS proteins is associated with increased levels of reactive astrocytes and pro-inflammatory cytokines, IL1b, IL6, IL15 and TNFa in brains of mouse models of Bardet Biedl Syndrome. *M. Singh, V. Sheffield.* University of Iowa, Iowa City, IA.

Bardet Biedel Syndrome (BBS) is a rare human cilioopathic genetic disorder. Principally it is characterized by obesity, retinitis pigmentosa, polydactyly, hypogonadism, and renal failure. Proteins in primary cilia and basal bodies mediate numerous signaling pathways including Notch signaling and inflammation. It has been shown that loss of BBS1 and BBS4 lead to increased notch signaling due to defective Notch receptor trafficking with notch receptor accumulating in late endosomes. The Notch-STAT3 signaling axis is reported to control reactive astrocyte proliferation and the JAK/STAT3 signaling pathway is a common inducer of reactive astrocytes. Increased reactive astrocytes secrete molecules that promote neuro-inflammation leading to neurodegeneration. Reactive astrocytes are associated with patients with brain injury and diverse central nervous tissue disorders. Therefore, understanding the signaling network that regulates reactive astrocytes has the potential to provide therapeutic targets to treat many central nervous disorders. In this study it was hypothesized that loss of BBS proteins in mouse models of BBS syndrome promotes astrocyte reactivity in brains of BBS mice. We examined RNA and protein samples by RT-PCR and western blot analysis and performed confocal immunofluorescence imaging from brains of wild type littermates and BBS null mice for molecular markers of reactive astrocytes including GFAP, Vimentin, and Serpina3n. We find that expression of GFAP, Vimentin, and snerpinA-3n are significantly increased in brains of BBS mice when compared to their wild type littermates. In addition, we also find several pro-inflammatory molecular markers of IL15, IL1b, TNFa, and IL6 are significantly increased without any alteration in microglia markers of reactivity in brains of BBS mice when compared to their wild type littermates. All together these results suggest that BBS proteins plays an important role in regulating astrocyte function and that increased pro-inflammatory molecules indicate the presence of neuro-inflammation in brains of BBS mice. .

Gene coexpression network analysis reveals thymic sexual dimorphism in human infants. *C.A. Moreira-Filho[1], S.Y. Bando[1], F.B. Bertonha[1], L.R. Ferreira[1], A. Coutinho[2], M. Carneiro-Sampaio[1].* 1) Pediatrics, University of Sao Paulo, Sao Paulo, Sao Paulo, Brazil; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal.

It is widely known that in human populations females are more susceptible to autoimmune diseases than males. Recently, Dragin et al. [J Clin Invest. 2016 126:1525] shown that estrogen-mediated downregulation of AIRE influences sexual dimorphism in autoimmune diseases. Here we studied whole mRNA and microRNA expression in human thymus explants obtained from infants aged 3-17 months (11 males and 11 females) undergoing corrective cardiovascular surgery. In the male (M) versus female (F) comparison, 775 GO annotated differentially expressed (DE) genes (out of 12,469 valid transcripts) were found to be upregulated and two were downregulated in the M group. The *AIRE* gene has essentially the same expression level in M and F groups. Gene coexpression networks (GCNs) were inferred for M and F groups considering the DE genes. High hierarchy genes were identified for M and F groups revealing noteworthy features: genes related to autoimmune diseases, as *STAT3* and *TYK2*, are high-hubs respectively in F and M networks. Community detection analysis was accomplished and coarse-grained community structure revealed the interconnections between gene communities, showing that F communities are, in general, more interconnected. MicroRNA target analysis indicated a minor role for epigenetic mechanisms in the maintenance of GCNs topological dimorphism. These data suggest that genetic mechanisms and prenatal hormonal influences probably act synergistically in establishing thymic sexual dimorphism.

Investigating the roles of miRNAs in the differentiation of human induced pluripotent stem cells into kidney. *L. Li, H.H. Cheung, K.K. Miu, D.D. Cao, J.J. Tu, W.N. Law, W.Y. Chan.* School of Biomedical Sciences, Chinese University of Hong Kong, Hong Kong, Hong Kong.

Studying human embryogenesis *in vivo* is still impeded by the impracticality of obtaining embryo samples. Therefore, human induced pluripotent stem cells (hiPSCs), which are capable to different into any somatic cell types, offer an ideal model system to study human embryogenesis *in vitro*. Previous studies suggested that microRNA (miRNAs) are the key regulators of lineage specification. However, whether miRNAs are key regulators in renal formation and associated diseases remains obscure. To investigate the roles of miRNAs in renal differentiation, we recapitulate the early stage of embryonic kidney development (KD) *in vitro* by synchronously inducing both nephron progenitors and ureteric bud from hiPSCs. During the first 10 days of induction, we chose four time-points to perform miRNA microarray analyses. By integrating the array data and bioinformatics analysis, we found one novel downregualted miRNA – *miR-105-5p* whichwas predicted to target *PKD1* and *PKD2*. Normal expression of polycystin-1 and polycystin-2, encoded by *PKD1* and *PKD2*, contribute to, while their dysregulation perturb, the maintenance of normal epithelial structure in developing kidney. The luciferase reporter assay confirmed the interaction between *miR-105-5p* and *PKD1*/*PKD2*. Interestingly, both the expression of *PKD2* mRNA and Polycytin-1/2 were reversely correlated with that of *miR-105-5p*, whereas the expression of *PKD1* did not change during KD. Therefore, it is possible that *miR-105-5-5p* inhibit *PKD1* via translational repression while suppress *PKD2* via transcript degradation. Furthermore, the gain- and loss- of function assay from KD 0 to KD 3 revealed that *miR-105-5p* might contribute to mesoderm formation by regulating Wnt signaling pathway. Thus, we provided the evidence that *miR-105-5p* is an important regulator in the early stage of embryonic kidney development.

Early embryo stride over the mountain in regulatory gene networks to achieve differentiation - The morula is the turning point of the embryonic development. *X. Kong, Y. Zhang, M. Jiang, Y. Zhu.* Molec Gen, Inst Hlth Sci, Shanghai, Shanghai, China.

Background/Objective: Early embryonic development is a complex process that involves a cascade of morphologic changes that transform an oocyte into a zygote, morula, and blastocyst and finally into an embryo implanted in the uterus. Changes in genes promote the development from one stage to the next. But how these genes are activated and how the gene regulatory relationship changes are still unclear. It is worthy to study the changes in gene regulatory network during early embryonic development. **Method:** We examined single-cell RNA sequencing data of preimplantation embryos to define gene regulatory network for each stage. K-core scoring was used to simply depict the structure of network and identify the core regulatory genes. Genes were grouped into co-expression modules to examine the preservation of gene relationships between stages. The critical transition of gene relationships were identified by the dynamical network biomarker (DNB) analysis. The changes of connection number and connecting targets were considered to identify the different connection genes. **Results:** We found that the extent of regulatory connection rapidly increased from the 4-cell to the morula, after which the number of connections suddenly decreased. We identified the core regulatory genes in the each stage and found gene networks were different between stages. We further confirmed the morula is a critical transition stage of gene connections. The morula can be compared to the mountain where one side is non-differentiated cells and the other side is differentiated cells. We discovered that the genes showing significant connection changes between before and after morula became the core regulatory genes after morula and we found these genes were prone to be up-regulated in the morula. The core regulatory genes of morula seemed to be the main triggers to actuate striding across the morula mountain. These results have potential ramifications for the mechanisms controlling early embryonic development, for central regulatory factors that might be good candidates for further analysis of cell differentiation.

Opposing effects of FGF2 and TGF-β/Activin/Nodal signalling inhibition on BMP4-mediated trophoblast differentiation of hESCs. *M. Koel[1,2], U. Võsa[3], K. Krjutškov[1,4,5], E. Einarsdottir[4,5], J. Kere[4,5], J. Tapanainen[6], S. Katayama[4], S. Ingerpuu[2], V. Jaks[2,7], U.-H. Stenman[8], K. Lundin[6], T. Tuuri[6], A. Salumets[1,9,10].* 1) Competence Centre on Health Technologies, Tartu, Estonia; 2) Department of Cell Biology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 3) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 4) Department of Biosciences and Nutrition, and Center for Innovative Medicine, Karolinska Institutet, Huddinge, Sweden; 5) Molecular Neurology Research Program, University of Helsinki and Folkhälsan Institute of Genetics, Helsinki, Finland; 6) Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; 7) Department of Biosciences, Karolinska Institutet, Huddinge, Sweden; 8) Department of Clinical Chemistry, University of Helsinki, Helsinki, Finland; 9) Department of Obstetrics and Gynaecology, University of Tartu, Tartu, Estonia; 10) Institute of Biomedicine and Translational Medicine, University of Tartu, Tartu, Estonia.

Several studies have demonstrated that human embryonic stem cells (hESC) can be differentiated into trophoblast-like cells if exposed to morphogenic protein 4 (BMP4) and/or inhibitors of fibroblast growth factor 2 (FGF2) and the transforming growth factor beta (TGF-b)/Activin/Nodal signalling pathways. The goal of this study was to investigate how much the inhibitors of these pathways can individually improve the efficiency of hESC differentiation when compared to basic BMP4 treatment. RNA sequencing was used to analyse the effects of all possible inhibitor combinations on the differentiation of the hESCs into trophoblast-like cells over 12 days. Genes differentially expressed compared to untreated cells were identified in seven time points. Additionally, expression of total chorionic gonadotropin (hCG) and its hyperglycosylated form (hCG-H) were determined by immunoassay from cell culture media. We showed that sole FGF2 inhibition up-regulates syncytiotrophoblast-specific genes (*CGA*, *CGB* and *LGALS16*), induces several molecular pathways involved in embryo implantation and triggers hCG-H production. In contrast, inhibition of the TGF-β/Activin/Nodal pathway decreases the ability of hESCs to form trophoblast-like cells. This information about the conditions needed for hESCs differentiation toward trophoblast-like cells helps us to find an optimal model for studying the early development of human trophoblasts in normal and complicated pregnancy.

2251W

Partial characterization of the content of extracellular microvesicles released by cultured murine chondrocytes. *L.R. Aguiar, R. Pogue.* Universidade Católica de Brasília, Brazil.

Chondrocytes are the constituent cells of cartilage, residing within an extracellular matrix made up principally of collagens and sulfated proteoglycans. These cells constantly send and receive signals, employing various signaling pathways such as TGF-b, BMP, hedgehog, WNT and FGF. These signals result in various cellular activities such as alterations in gene expression, differentiation and apoptosis. Recently, a new player has been identified in the paracrine signaling processes occurring in all tissues. Extracellular microvesicles are membrane-encapsulated structures that are released by all cell types so far tested, and are present in all bodily fluids. They are commonly classified based on their mechanism of biogenesis (exosomes, microvesicles, apoptotic bodies), and have been widely shown to contain lipids, proteins and different nucleic acids, which may reflect their cell-type of origin. The objective of the current study was to collect the microvesicular fraction released into culture media by murine chondrocytes, and to test for the presence of well-known chondrocyte-associated transcripts within that fraction. We detected the presence of mRNA representing Col2a1, Aggrecan, WDR5, FGFR2, FGFR3, IHH, BMP4 and GAPDH, as well as miR16, miR100, miR125, miR140 and miR328. The RNA content of the microvesicles reflects their chondrocytic origin and gives insight into their possible roles in inter-cellular communication within cartilage.

Role of the apico-basal polarity gene *SCRIBBLE1* in the pathogenesis of neural tube defects. *F. Kharfallah[1], A. El Hassan[1], M.C.G. Guyot[1], E. Merello[2], P. De Marco[2], G. Di Cristo[1], V. Capra[2], Z. Kibar[1].* 1) Chu Sainte-Justine. Montreal University, Montreal, Quebec, Canada; 2) U.O. Neurochirurgia, Instituto G. Gaslini, Genova, Italy.

Scribble (*Scrib*) is a key regulator of apicobasal (AB) polarity of epithelial cells and has long been studied as a tumor suppressor gene in mammals. *Scrib1* was also implicated in another form of polarity called planar cell polarity (PCP) where epithelial cells become polarized along the plane of the epithelium. In vertebrates, PCP, also called the non-canonical Frizzled/Dishevelled (Fz/Dvl) pathway, mediates a morphogenetic process called convergent extension (CE) during gastrulation and neural tube formation. *SCRIB1* encodes a large, 195-kDa cytoplasmic scaffolding protein that comprises a large leucine-rich repeat (LRR) region and 4 PDZ domains that regulate protein-protein interactions, including the PCP protein *VANGL2*. *Scrib1* physically and genetically interacts with *Vangl2* and plays a direct role in its asymmetric targeting during PCP signaling in the cochlea. In mouse Circletail (Crc), homozygous mutations at *Scrib1* cause a lethal form of neural tube defects (NTDs) called craniorachischisis whereby the neural tube remains open throughout the spinal cord. In humans, rare variants in SCRIB1 were associated with NTDs in a small fraction of patients. This project aims at investigating the role of *SCRIB1* as a gene involved in both ABP and PCP in a large cohort of human NTD patients and in the mouse mutant Crc. We identified 5 rare missense mutations in 6 NTD patients that were absent in 400 controls analyzed and predicted to be pathogenic using bioinformatics. Using the yeast two hybrid system, we identified two mutations that affect the well- established interaction between SCRIB1 and VANGL2. We also identified two NTD-associated mutations that affect protein localization of SCRIB1 in MDCK cells. In parallel, we used the Crc mouse to look at the expression pattern of Scrib1, Vangl2 and other polarity markers. Our study will help us better understand the role of *SCRIB1* as a molecular link between ABP and PCP during normal and abnormal neural tube development.

Investigating the role of SOX6 during the development of the peripheral nervous system. *C. Gopinath[1], W.D. Law[2], J.F. Rodríguez-Molina[3], A.B. Prasad[4], L. Song[5], G.E. Crawford[5,6], J.C. Mullikin[4], J. Svaren[7,8], A. Antonellis[1,2].* 1) Cellular and Molecular Biology Program, University of Michigan Medical School, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI; 3) Cellular and Molecular Pathology Program,University of Wisconsin-Madison, Madison, WI; 4) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 5) Center for Genomic and Computational Biology,Duke University Medical Center, Durham, NC; 6) Department of Pediatrics, Duke University Medical Center, Durham, NC; 7) Waisman Center,University of Wisconsin-Madison, Madison, WI; 8) Department of Comparative Biosciences, University of Wisconsin-Madison, Madison, WI.

Myelinating Schwann cells insulate motor and sensory axons in the peripheral nervous system (PNS) to allow rapid saltatory conduction along peripheral nerves. The transcription factor SOX10 is essential for all stages of Schwann cell development and activates the expression of key myelin genes in the PNS. Thus, identifying and characterizing SOX10 target genes will improve our understanding of Schwann cell function. Toward this, we performed computational and functional analyses that revealed highly conserved, intronic SOX10 response elements including one at the *SOX6* locus. Interestingly, SOX6 competes with SOX10 for DNA binding at myelin-related loci in oligodendrocytes, the glial cells of the central nervous system. This results in inhibition of premature myelination during oligodendrocyte development. It is possible that a similar mechanism occurs in the PNS; however, the function of SOX6 has not been studied in the PNS and SOX10 has not been shown to regulate *SOX6* transcription in any cells. Our hypothesis is that SOX10 activates *SOX6* expression during Schwann cell development. Subsequently, SOX6 inhibits the expression of a subset of SOX10 target genes to maintain a premyelinating state. Our data demonstrate that *SOX6* is expressed in Schwann cells and that the enhancer identified in the initial screen acts as an alternative promoter. To determine if SOX10 regulates *SOX6* via this alternative promoter, we deleted the SOX10 consensus sequences, which resulted in reduced promoter activity in cultured Schwann cells. Additionally, expressing SOX10 in SOX10-negative motor neurons induced the activity of this promoter and enacts transcription of endogenous *SOX6* mRNA expressed from this promoter. Combined, these data indicate that SOX10 regulates the expression of *SOX6* via an alternative promoter. The SOX10 site within this promoter is conserved to zebrafish, therefore we are deleting this promoter and the associated first exon in zebrafish using CRISPR-Cas9 technology. Future work will focus on determining if *SOX6* represses SOX10 function in myelinating Schwann cells and to test this we will overexpress SOX6 in myelinating Schwann cells and perform RNA-seq to identify target loci that may be regulated by SOX6. In sum, we have identified SOX6 as a target gene of SOX10 in Schwann cells. Our future efforts will reveal the role of SOX6 in the peripheral nerve and improve our understanding of the regulatory pathways important for Schwann cell development.

Expression quantitative trait and allele specific analyses identify tissue-specific associations in a non-human primate model. *I. Zelaya[1,2], S. Service[1], A. Jasinska[1], M.J. Jorgensen[4], J. Kaplan[4], W. Warren[5], R. Woods[3], G. Coppola[1,3], N. Freimer[1].* 1) Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, Los Angeles, CA; 2) Bioinformatics Interdepartmental PhD Program, University of California, Los Angeles, Los Angeles, CA; 3) Department of Neurology, University of California, Los Angeles, Los Angeles, CA; 4) Department of Pathology, Section on Comparative of Medicine, Winston-Salem, NC; 5) McDonnell Genome Institute, Washington University School of Medicine, 4444 Forest Park Avenue, St Louis, MO 63108, USA.

Genome-wide association studies over the past decade have identified numerous variants associated to disease, most of them located in non-coding regions of the genome. Expression quantitative trait locus (eQTL) analysis is a powerful approach to identify associations between genotypes and gene expression, however systematic eQTL studies relevant to humans are limited by either sample availability (for human tissues) or evolutionary distance (rodent and invertebrate tissues). The vervet monkey (*Chlorocebus aethiops sabaeus*) constitutes an attractive model for these studies, as considerable tissue resources have already been collected and the genome sequenced. We obtained RNA-seq data from six different tissue types from 58 animals at developmental stages ranging between birth and adulthood, and performed an eQTL analysis. We used 500k SNPs with a MAF >= 0.10 as mapping set. To test for association of genotypes to gene expression we used the Efficient Mixed-Model Association eXpedited (EMMAX) statistical test, including age and sex as covariates. We identified hundreds of genes with local tissue-specific associations and a handful of genes with distant tissue-specific associations. The number of associations shared among all six tissues, both local and distant, was much smaller, reinforcing the idea that genetic variation plays different roles across tissues. We also completed allele specific expression analyses. The identified loci significantly overlapped with our local eQTL results (p= 6.7e-09), and a handful of genes were identified as having only allele-specific expression differences, occurring possibly at the isoform level, and not detectable by our eQTL analysis. This work was supported by the NIH grants R01RR016300/R01OD010980, R37MH060233-09S1, U54HG003079 and P40OD010965.

The use of large neutral amino acids (LNAAs) as a dietary supplement is not effective in reducing plasma Phe levels but improves neuropsychological performances in Phenylketonuria. *I. Scala[1], M. Marino[2], M.P. Riccio[2], C. Bravaccio[2], G. Parenti[1], P. Strisciuglio[1].* 1) Department of Pediatrics, Clinical Genetic Unit, Federico II University Hospital, Naples, Italy; 2) Department of Pediatrics, Child Neuropsychiatric Unit, Federico II University Hospital, Naples, Italy.

Introduction: Phenylketonuria (PKU) is a metabolic disorder caused by phenylalanine hydroxylase deficiency. The treatment is based on a low-Phe diet. The diet begins at birth and continues for a lifetime, with regular monitoring of phenylalanine (Phe) concentrations. Large neutral amino acids (LNAA) therapy has been developed as an alternative to dietary restriction: LNAAs compete with Phe at the level of the brain and intestinal transporters, and may be useful in reducing Phe blood concentrations. Studies showed a possible 20 to 50% reduction of plasma Phe levels in subsets of PKU subjects, while others showed improvements of neurocognitive performances. However, data are still inconclusive. Objectives: To evaluate the effectiveness of LNAAs in reducing plasma Phe levels and improve neuropsychological performances in adult PKU subjects. Patients and methods: 9 subjects with PKU (4F/5M; 7 cPKU, 2 mPKU; mean age: 24 +/- 4,4 years) were supplemented for 9 months with LNAA (Moviscom, 0.5-1 g/kg) divided in 3 daily doses at main meals, with complete replacement of the previous non-LNAA formula. Each patient underwent to Phe, Tyr, Phe/Tyr ratio monitoring; neuropsychological assessment at T0 and T + 3 months by using the American Psychological General Well-Being Index (PGWBI), the Wisconsin Card Sorting Test (WCST), TAP tests and HPG test. Results: LNAA supplementation was ineffective in reducing plasma Phe levels (p>0.05), while tyr levels increased in all patients (mean±DS: 49.1 ± 15.27 *vs* 104.02 ± 23.41; p <0.01). Post-treatment Phe/Tyr ratio decreased up to 59% in all patients. Neuropsychological assessment showed: significant increase in all areas of the WCST test in 9/9 patients (45-65° centile at T0 vs 75-85° centile at T+3); improvements of anxiety, positivity, wellness, vitality and self-control areas at the PGWBI tests; improved performance in the dominant hand in 2/9 patients at the 9-HPG; decreased reaction times of alertness in all the analysed patients; improvement of the reaction time in 6/9 subjects at the sustained attention test. Conclusions: LNAA therapy was not effective in reducing plasma Phe levels, but was effective in increasing plasma levels of Tyr. The neuropsychological evaluation showed a global improvement of sustained attention, alertness, planning, problem solving, an improvement of anxiety, self-control and vitality and this improvement was independent of Phe metabolic control.

Stable isotope breath testing as a measure of methylmalonyl-coa mutase (MUT) activity in methylmalonic acidemia. *J. Gagné[1], I. Manoli[1], E. Harrington[1], S. Smyth[2], J. Hattenbach[2], J.L. Sloan[1], K.Y. Chen[2], C.P. Venditti[1].* 1) National Human Genome Research Institute, Bethesda, MD; 2) National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD.

Isolated methylmalonic acidemia (MMA) is a grave autosomal recessive inborn error of metabolism, caused by a defect in methylmalonyl-CoA mutase (MUT). In some severe patients, liver (LT), kidney (KT), or combined liver and kidney (LKT) transplantation has been used as a surgical treatment for MMA. Previous studies have shown that $1\text{-}^{13}C$-propionate oxidation can be used to measure whole body MUT activity in gene therapy treated and transgenic MMA mice and have encouraged translation to patients, with the aim of using this approach as an outcome measure for therapeutic interventions such as gene therapy. We therefore investigated $1\text{-}^{13}C$-propionate oxidation in 31 patients with isolated MMA (*mut[0]* N=19, *mut[-]* N=6, *cblA* N=6, age range: 4-41 years), including 3 KT, 1 LT, and 4 LKT recipients, as well as one patient who received a heterotopic liver allograft post KT (hLKT). In addition, 7 healthy volunteers (3 males, 4 females, age range: 21-44 years) and 8 heterozygote controls (age range: 35-62 years) were tested to establish test reproducibility. Baseline CO_2 production of the participants was measured using an indirect calorimetry cart before sodium $1\text{-}^{13}C$-propionate was administered as an oral or G-tube bolus, and breath samples were collected serially over 2 hours via disposable breath collection kits to measure $^{13}CO_2$ enrichment. Propionate oxidation was decreased in all non-transplanted MMA patients compared with controls (*p*<0.0001). Both LT and LKT recipients demonstrated oxidation rates similar to control levels (*p*=NS), as did KT recipients responsive to vitamin B-12 supplementation (N=2) with *cblA* MMA. However, the remaining KT recipient, a severely affected mut[0] patient carrying two stop mutations, showed almost no metabolism of label. Repeat testing conducted on healthy volunteers and 9 MMA patients (7 *mut*, 2 *cblA*) supported excellent reproducibility. Notably, similar oxidation rates were observed in 2 patients despite markedly different plasma methylmalonic acid concentrations between one assessment and the next. This suggests that measured $1\text{-}^{13}C$-propionate oxidation may be a more consistent and reproducible clinical biomarker than plasma metabolites that depend, in part, on protein intake and kidney function. This safe and minimally invasive method therefore has great potential as an outcome measure for enzyme replacement strategies in MMA, such as transplantation, and gene or cell therapy.

Disease symptoms and impacts as reported by patients with acid sphingomyelinase deficiency (ASMD) and caregivers. *R. Avetisyan[1], A. Hareendran[2], S. Stringer[3], S. Tan[1], B.J. Sanson[1], S. Hass[1].* 1) Sanofi Genzyme, Cambridge, MA, United States; 2) Evidera, London, United Kingdom; 3) Evidera, Bethesda, MD, United States.

Acid sphingomyelinase deficiency (ASMD), also called Niemann-Pick Disease Types A and B (NPD A and B), is a rare, progressive, life-threatening genetic disorder with an estimated incidence of 0.4-0.6 per 100,000. The metabolic defect, deficiency of the enzyme acid sphingomyelinase, leads to abnormal accumulation of sphingomyelin resulting in multiple organ damage and dysfunction. ASMD represents a spectrum of phenotypes; the most severe form (infantile neurovisceral ASMD, NPD A) is characterized by early onset of disease and rapid progression of psychomotor degeneration, leading to death, usually by 3 years of age from respiratory failure. An intermediate, chronic neurovisceral form has later symptom onset and slower disease progression. Patients with chronic visceral ASMD (NPD B), lack neurological symptoms but have significant hepatosplenomegaly, respiratory, gastrointestinal, musculoskeletal, and hematological manifestations. The primary objective of this qualitative research study was to obtain information directly from patients and caregivers about the disease symptoms and impact on patient's lives. Interviews were conducted with 11 adult and 9 pediatric patients with chronic ASMD and/or their caregivers. The interviews included both open-ended and structured questions; structured questions were developed based on literature review and clinical expert interviews. Questionnaires were also administered to evaluate demographic and clinical characteristics of the patients. The mean age of patients was 37 (SD 15.5) years and 10 (SD 4.7) years for adults and children, respectively, and 64% of adult and 45% of pediatric patients were female. The most commonly reported symptoms were enlarged abdomen (due to hepatosplenomegaly), breathing difficulties, frequent respiratory infections (including pneumonia), abdominal pain, bleeding/bruising, back and limb pain, and fatigue. Specific symptoms reported by patients to be most bothersome/ important to them included: fatigue, shortness of breath, bruising/ bleeding, lower limb/ joint pain, sleep disturbances, headaches, and diarrhea. ASMD was found to substantially impact physical, social, and emotional functioning in both adults and children. This study describes symptoms experienced by patients with chronic ASMD and the significant impact of the disease on patients' lives. The findings also offer a framework for the development of an ASMD disease-specific patient-reported outcome measure. Supported by Sanofi Genzyme.

Diverse clinical manifestations and heterogeneous natural history of acid sphingomyelinase deficiency. *M. McGovern[1], R. Avetisyan[2], B.J. Sanson[2], O. Lidove[3].* 1) Dept Pediatrics, Stony Brook Univ, Stony Brook, NY; 2) Sanofi Genzyme, Cambridge, MA; 3) Hôpital de la Croix Saint Simon, Paris, France.

Acid sphingomyelinase (ASM) deficiency (ASMD), historically known as Niemann-Pick disease (NPD) type A and B, is a rare autosomal recessive lysosomal storage disorder caused by different *SMPD1* mutations. ASMD pathogenesis is characterized by the abnormal accumulation of the primary ASM substrate, sphingomyelin, in cells of the monocyte-macrophage system in various organs. Current treatment options are limited to symptom management and supportive care. An enzyme replacement therapy is in clinical development. Early disease recognition and timely diagnosis of ASMD is important, but often hampered by the rarity and phenotypical heterogeneity of the disease. The following review of the published literature and the synthesis of the evidence is intended to facilitate a better understanding of ASMD manifestations and natural history. The natural history of patients with NPD A is almost uniformly characterized by onset in early infancy and rapidly progressing psychomotor degeneration, which typically results in death by age 3 years from respiratory failure. In contrast, patients with NPD B have a widely heterogeneous natural history. NPD B is a chronic progressive disease that may affect multiple organs, with typical manifestations including hepatosplenomegaly, progressive infiltrative lung disease, liver dysfunction, heart disease, growth delay, osteopenia/osteoporosis, atherogenic lipid profile, and cytopenias. Bleeding, shortness of breath, joint/limb pain, abdominal pain, and bruising are common symptoms and may result in chronic fatigue, limited physical activity, inability to work, and social isolation. Patients with a variant form of NPD B may also have neurologic symptoms, which range from mild hypotonia to cognitive disability or progressive motor degeneration. Most patients with NPD B succumb to disease complications before or in early adulthood; common causes include pneumonia, respiratory failure, bleeding, and liver failure. ASMD is a rare, multi-systemic, and heterogeneous disease, and these features contribute to low disease awareness and delays in diagnosis. Despite recent progress in the characterization of ASMD, more information on disease progression, subpopulations, genotype-phenotype relationships, prognostic factors, and impact on quality of life is needed. A better characterization of ASMD subpopulations and their natural histories may facilitate earlier disease recognition in this rare patient population. Supported by Sanofi Genzyme.

Two sibling cases of aspartate-glutamate carrier 2 (Citrin) deficiency: Does diet affect prognosis? *Y. Watanabe[1,2], K. Fukui[1], N. Harada[1], K. Tashiro[2], T. Inokuchi[2], S. Yano[1,3], Y. Yamashita[1], Watanabe.* 1) Dept Pediatrics, Kurume Univ, Kurume, Japan; 2) Research Inst GC/MS, Kurume Univ, Kurume, Japan; 3) Genetics/Pediatrics, USC, Los Angeles, CA, United States.

   Background: Citrullinemia Type 2 (CTLN2) is due to the defective mitochondrial aspartate-glutamate carrier isoform 2 (AGC2 or citrin). Citrin is a component of the malate-aspartate shuttle, which transfers reducing equivalents from NADH from the cytosol to the mitochondria and is expressed in the liver. Patients with CTLN2 develop sudden onset hyperammonemia with neuropsychiatric symptoms in adulthood. Mutations in citrin are also known to cause neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD). Patients with citrin deficiency often have characteristic food preference for high protein and high fat diet, and aversion to carbohydrate rich diet. Treatment with sodium pyruvate has been shown to have beneficial effects in lowering lactate/pyruvate ratio and ureogenesis in the liver-perfusion system in citrin-deficient mice, possibly by lowering cytosolic NADH/NAD ratio. **Case Study**: Two Japanese full siblings (62y male and 59y female) with citrin deficiency showed significantly different clinical courses, possibly due to their diet. The elder brother is an owner chef of a "Tempura" restaurant for more than 30 years. He had been well until age 19y when he developed recurrent pancreatitis. Liver biopsy at age 56y due to chronic liver disease, showed the findings suggestive of Hemochromatosis and fatty liver. At age 62y, he developed hepatic coma with hyperammonemia (312uM). Plasma amino acid analysis showed high citrulline, suggestive of CTLN2. Plasma lipid and lipoprotein analysis showed normal total cholesterol, low HDL, and low apoA1 and apoB concentrations. Lipoprotein fractionation showed a midband between the LDL and VLDL bands. He has been on protein rich diet; however, he cannot tolerate high fat diet due to chronic pancreatic dysfunction. His sister has been well without any specific citrin deficiency related symptoms. She likes high protein food and "Tenkasu", crunchy surface of Tempura, and avoids high carbohydrate diet. **Results:** Compound heterozygous mutations in *SLC25A13*[g.IVS13+1G>A/g.IVS16ins3kb] were identified, confirming the diagnosis of citrin deficiency in the two siblings. Implementation of MCT oil in the brother improved the liver function including total bile acid metabolism. **Discussion**: Sodium pyruvate has been used to treat Citrin deficiency. Supplementing fatty acids including MCT oil may also have beneficial effects, possibly due to increasing mitochondrial matrix NADH/NAD ratio leading to ATP synthesis.

2260W

C26-ceramide is a new and sensitive biomarker for Farber disease. *P. Bauer[1], C. Cozma[1], M.I. Iurascu[1], S. Zielke[1,2], A. Rolfs[1,2].* 1) Centogene AG, Rostock, Germany; 2) Albrecht-Kossel-Institute for Neuroregeneration, University of Rostock, Germany.

   Background: Farber disease (Farber's lipogranulomatosis, ceramidase deficiency), is an autosomal recessive, extremely rare disease caused and characterized by a deficient acid ceramidase activity encoded by ASAH1 gene. Low ceramidase activity is resulting in accumulation of fatty substances, mainly ceramides. At clinical level, Farber disease is manifesting through hallmark symptoms such as: periarticular nodules, lipogranulomas, swollen and painful joints and a hoarse voice or a weak cry; in addition to these, also hepatosplenomegaly, rapid neurological deterioration or developmental delay are reported. Seven different Farber types were described, with phenotypes varying from mild cases with a longer life expectancy to very severe cases, where the patients do not survive past their first year of life. Methods: The screening through over 40 different ceramide-like molecule show that only C26 is specifically increased in samples from Farber patients. Results: We present here a new method of diagnosis of Farber disease by determining the concentration of C26 ceramide isoforms using LC/MRM-MS and C25 ceramide as internal standard. Moreover, we found that cis-isomer of the C26 ceramide is a specific biomarker for Farber disease, with pathological values in a range of 39.2-150.0 nmol/L blood (normal range 13.6-23.4 nmol/L blood, N=192, healthy individuals). The current study based on dried blood pots samples from 11 Farber patients and 11 Farber carriers – the highest number of Farber patients enrolled in one study to present. The new biomarker can be determined directly in the dried blood spot extract with low sample consumption, easy sample preparation, high reproducibility and it presents the possibility of to be used in high throughput screenings. Conclusion: Cis-C26 ceramide is a specific biomarker for Farber Disease.

2261T

Lyso-sulfatide is a specific and sensitive biomarker for the early diagnosis of metachromatic leukodystrophy. *S. Eichler[1], C. Cozma[1], G. Kramp[1], M.I. Iurascu[1], L. Demuth[1], S. Oppermann[1], S. Zielke[2], A. Rolfs[1,2].* 1) Centogene AG, Rostock, Germany; 2) Albrecht-Kossel-Institute for Neuroregeneration, University of Rostock, Germany.

   Background: Metachromatic leukodystrophy (MLD) is a lysosomal storage disease caused by mutations in ARSA gene, inherited in autosomal recessive manner. MLD is characterized by a low aryl sulfatase A (ARSA) activity which leads to the accumulation of sulfatides (sulfated glycocerebrosides) in tissues, destroying the myelin sheath of the nervous system with serious consequences manifested in clinical symptoms such as: weakness, muscle rigidity, developmental delay, blindness, convulsions, paralysis, and dementia. A recent studies suggested that lyso-sultatides (sulfatide without an acyl group or sphingosine-glycoside-sulfate) are the toxic species responsible for the development of MLD. Recently developed enzyme replacement therapy and the steep progression of the disease in ARSA patients make the development of high throughput screening diagnosis of high importance. **Methods:** We report here the development of biochemical screening method for ARSA patients using a combination of two techniques: (i.) arylsulphatase enzymatic activity in leucocytes pellet by fluorimetry and (ii.) quantification of ARSA specific biomarker lyso-sulfatide by multiple reaction monitoring mass spectrometry (LC/MRM-MS). **Results:** 29 subjects with reduced ARSA enzymatic activity enrolled in the study (27 ARSA clinically and genetically confirmed ARSA patients; 2 patients with ARSA pseudodeficiency clinically confirmed) were involved in the current study. ARSA gene was sequenced for all patients enrolled in the study and MLD diagnosis was genetically confirmed. Arylsulfatase A activity was investigated in leukocytes extract and lyso-sulfatide was investigated in plasma of MLD patients, pseudo-ARSA patients and normal controls. Lyso-sulfatide was found to be 0.54 ± 0.29 ng/mL for MLD patients and below limit of quantification for normal controls and pseudo-arylsulfatase A deficiency patients. The results were subjected to ROC analysis and show a specificity and sensitivity of over 99% for the analyzed samples. **Conclusion:** Lyso-sulfatide is a sensitive biomarker for MLD **Keywords**: ARSA deficiency, AS enzymatic activity, ARSA biomarkers .

2262F

Lyso-SM-509 is an easy-measurable and sensitive biomarker for Niemann-Pick disease: A one-year study. *A. Rolfs[1,2], C. Cozma[1], G. Kramp[1], G. Oprea[1], S. Eichler[1], A. Giese[2].* 1) Centogene AG , Rostock, Germany; 2) Albrecht-Kossel-Institute for Neuroregeneration, University of Rostock, Germany.

   Niemann Pick Type C (NPC) disease is an autosomal recessive disease caused by mutations in NPC1 or NPC2 genes translated in defects of the lysosomes transport system (namely cholesterol transporters) leading to abnormal accumulation of cholesterol and glycolipids in the lysosome. Although other organs may be affected (e.g. hepatosplenomegaly), NPC is characterized mainly by progressive neurological deterioration manifested through symptoms e.g. cerebellar ataxia, epilepsy, cataplexy, dystonia, spasticity, hypotonia, ptosis, microcephaly, psychosis, progressive dementia. Recently developed treatment renders the NPC diagnosis of high importance. We present here our experience regarding the NPC diagnosis using lyso-SM-509 biomarker concentration determination, followed by genetic analysis of NPC1 and NPC2 genes. The levels of lyso-SM-509 in blood reflect the burden of the NP disease and it can be used for the easy diagnosis of NP patients and for the monitoring of the disease progression. Determination of lyso-SM-509 is performed by multiple reaction monitoring mass spectrometry (LC/MRM-MS), an analytical method proven to be reliable and reproducible in plasma, serum, EDTA blood and dried blood spots (DBS). Moreover, by combining the results with the levels of lyso-SM-465 the type A/B and type C patients can clearly be distinguished. We validated the lyso-SM-509 biomarker for clinical diagnostic in samples of patients suspected of NP in our laboratories sent by customers from all over the world. We identified 186 NPC patients and 110 NP A/B patients using lyso-SM-509 and the diagnosis was directly confirmed by sequencing of the NPC1/NPC2 or SMPD1 genes. Lyso-SM-509 has a sensitivity of 100 % and specificity of 99.15 % for the diagnosis of NP. Most of the NPC cases were diagnosed at an age of 3 to 10 years (30.65 %). The gender distribution was even between the two sexes. We have identified a total of 426 pathological alleles in the different NPC cases. 75 unique variants (44.6%) were previously published, and 94 (56.4%) are described in CentoMD® exclusively. From the 169 unique NPC1 and NPC2 variants, 87% are located within the coding genetic regions, and 13% have non-coding location. All cases identified lyso-SM-509 biomarker were genetically confirmed proving its specificity. The ease of DBS based lyso-SM-509 makes the marker an ideal parameter for the simple and confident diagnosis of NP as well as the monitoring of the diagnosed NP patients.

2263W

Recessively inherited *LRBA* mutations cause neonatal diabetes. *M.B. Johnson[1], E. De Franco[1], A. Al Senani[2], N. Elbarbary[3], Z. Siklar[4], M. Berberoglu[4], Z. Imane[5], M. Blud[6], A. Haghighi[7], I. Ullah[8], D. Gardner[9], A.T. Hattersley[1], S. Ellard[1,10], S.E. Flanagan[1].* 1) Institute of Biomedical and Clinical Science, University of Exeter Medical School, Exeter, England, United Kingdom; 2) The Royal Hospital, Muscat, Oman; 3) Department of Paediatrics, Ain Shams University, Cairo, Egypt; 4) Ankara University School of Medicine, Turkey; 5) Childrens Hospital, Rabat, Morocco; 6) Beasat Hospital, Hamedan, Iran; 7) Harvard Medical School, Boston, USA; 8) Sultan Qaboos University Hospital, Sultanate of Oman; 9) Academia Endocrinology Department, Singapore General Hospital, Singapore; 10) Royal Devon and Exeter Hospital, Exeter, UK.

   Background and Aims Trio analysis of exome sequencing data is an effective approach for detecting causative *de novo* mutations. Compound heterozygous mutations are the next most likely aetiological cause in outbred pedigrees and their identification may lead to the characterisation of novel recessive disorders or expand the phenotype associated with mutations in known genes. We sought to identify the genetic cause of neonatal diabetes (NDM) in a patient in whom no mutation had been detected in the known aetiological genes.   **Materials and Methods** We performed exome sequencing in a patient with NDM diagnosed at 7 weeks and autoimmune lymphoproliferative disease (diagnosed at 3 years) and his unrelated, unaffected parents. A targeted next generation sequencing (NGS) panel of all known/candidate NDM genes, including *LRBA*, was used to screen 66 probands with infancy onset diabetes (diagnosed before 1 year) who were either the result of a consanguineous union and SNP typing had identified homozygosity for the *LRBA* genomic region or who had features suggestive of an immunodysregulatory disorder. Mutations identified were confirmed by Sanger sequencing or droplet digital PCR.   **Results** No pathogenic *de novo* mutation was identified in the index patient with NDM and autoimmune lymphoproliferative disease. Further analysis identified compound heterozygous *LRBA* mutations (p.S2659X/c.3156del). *LRBA* mutations were previously described in patients with chronic variable immunodysregulation 8 (CVID-8), but NDM was not reported as a feature of this condition.   Targeted next generation sequencing of *LRBA* identified homozygous *LRBA* mutations in an additional 7 patients from 6 families. All mutations are predicted to be functionally null. Diabetes was diagnosed between 6 weeks and 15 months. Other common features in the patients included autoimmune haematological disorders (5/8 patients) and enteropathy (4/8 patients). Effective personalised therapy is available for these patients in the form of Abatacept, a mimetic for the suppressive receptor that is post-translationally regulated by *LRBA*.   **Conclusion** Our study confirms the role of *LRBA* as an NDM gene and expands the disease phenotype associated with *LRBA* mutations. A combined strategy based on both genetic prior probability and likely phenotype is an effective method of identifying patients with CVID-8. A genetic diagnosis is clinically important for these patients as it predicts prognosis and will guide medical management.

2264T

Reclassifying the most common *HNF4A* MODY mutation as an example of a rare low penetrance variant. *T.W. Laver[1], K. Colclough[1,2], M. Shepherd[1], K. Patel[1], J.A.L. Houghton[1,2], P. Dusatkova[3], S. Pruhova[3], A.D. Morris[4], C.N. Palmer[4], M.I. McCarthy[5,6,7], S. Ellard[1,2], A.T. Hattersley[1], M.N. Weedon[1].* 1) Institute of Biomedical and Clinical Science, University of Exeter, Exeter, UK; 2) Department of Molecular Genetics, Royal Devon & Exeter NHS Foundation Trust, Exeter, UK; 3) Department of Paediatrics, 2nd Faculty of Medicine, Charles University in Prague and University Hospital Motol, Prague, Czech Republic; 4) Medical Research Institute, Ninewells Hospital and Medical School, University of Dundee, Dundee, U.K; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, U.K; 6) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, U.K; 7) National Institute for Health Research Oxford Biomedical Research Centre, Churchill Hospital, Oxford, U.K.

   Genetic variants encompass rare, pathogenic variants causing monogenic disease and common variants that predispose to polygenic conditions. However there is third category: rare, low penetrance variants which cause disease in only a subset of individuals. Dominantly acting *HNF4A* mutations cause maturity onset diabetes of the young (MODY), a young-onset (<25yrs), sulfonylurea-sensitive form of diabetes and are associated with increased birth weight and transient neonatal hypoglycaemia. Here, we reclassify the most common *HNF4A* MODY variant, p.R114W, as an example of a rare variant which causes monogenic disease with low penetrance. Despite being the most frequently reported *HNF4A* mutation there were question marks over the pathogenicity of p.R114W: functional studies reported inconsistent results, there was a lack of co-segregation in some pedigrees, and an unexpectedly high frequency in ExAC. We sequenced *HNF4A* in 2289 MODY patients and compared the frequency of p.R114W to that in 12890 controls and 9185 patients with type 2 diabetes. We confirm that p.R114W is a pathogenic variant with an odds ratio of 30.4 (95% CI: 9.79 – 125, $P=2\times10^{-21}$) for diabetes in our MODY cohort compared to controls. However p.R114W has reduced penetrance; only 54% of heterozygotes developed diabetes by age 30 compared to 71% for other *HNF4A* variants. p.R114W heterozygotes do not have the increased birth weight characteristic of patients with other *HNF4A* variants (3476g vs. 4147g, $P=0.0004$). Additionally fewer patients responded to sulfonylurea treatment (48% vs. 73%, $P=0.038$). In conclusion, we reclassify the most common *HNF4A* MODY variant, p.R114W, as an example of a rare variant which causes monogenic disease with low penetrance. It causes a distinct clinical subtype of *HNF4A* MODY with reduced sensitivity to sulfonylurea treatment and no effect on birth weight. This has implications for diabetes treatment, management of pregnancy and predictive testing of at-risk relatives and highlights the increasing difficulties of assigning pathogenicity to low penetrance variants in monogenic disease.

2265F

A case of non-autoimmune normal weight diabetes in association with multiple congenital anomalies overlapping with CHARGE syndrome. *M. Sanyoura[1], A. Bindal[1], D. Del Guadio[2], D. Waggnner[2], R. Naylor[1], S. Greeley[1], L. Philipson[1]. 1) Section of Adult and Pediatric Endocrinology, Diabetes & Metabolism, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.*

　CHARGE syndrome is a rare multisystem autosomal dominant or sporadic disorder consisting of eye coloboma, heart defects, choanal atresia, retardation of growth and development, genito-urinary anomalies, and ear abnormalities. Many of these features, including genital hypoplasia, cleft palate, and heart defects, overlap with other multiple anomaly syndromes such as 22q11.2 deletion, Kallmann, and Kabuki Syndrome.　Here we describe an atypical case who presented with characteristic features of CHARGE syndrome and developed adult-onset diabetes.　EH is a 22 year old female with a history of multiple congenital anomalies that include right iris coloboma, choanal atresia, congenital deafness, absent ribs, dental hypoplasia, bilateral 2nd branchial cleft sinus tracts, aplasia of the posterior semicircular canals, and a history of chronic otitis. She also has amastia and athelia with hypogonadotropic hypogonadism and primary amenorrhea, but is able to have menses with estradiol replacement. In addition, she has been noted to have osteopenia and hyperlipidemia with mildly high total LDL, HDL, and triglyceride levels. Family history is only significant for one brother who has ventricular septal defect and developmental issues. Diabetes was diagnosed at age 18 with blood sugars as high as 800 mg/dL with HbA1c at 14%. BMI is 17.5 kg/m2. Antibody testing was negative with easily detectable C-peptide levels that have persisted for more than 4 years after diagnosis. She has had stable good glycemic control on low dose insulin therapy (0.2U/kg/day of mostly glargine). Recent addition of a DPPiv-inhibitor resulted in improvement of HbA1c from 7.5% to 6.7%.　Sequence analysis of all 37 coding exons and flanking intronic sequences of *CHD7* revealed no causative mutation. Large deletions or duplications were excluded by CGH. Next generation targeted sequencing panels for hypogonadotropic hypogonadism and diabetes were also negative. Trio exome sequencing revealed a de-novo mutation in *KMT2D* responsible for Kabuki Syndrome. This mutation, c.10784A>G p.Tyr3595Cys, has never been reported and is predicted to be damaging.　Our study expands on the clinical phenotype of Kabuki Syndrome and proposes an association between it and antibody negative insulin dependent diabetes. Advances in molecular genetic testing can help establish the correct diagnosis and Kabuki Syndrome should be considered in future patients with features of CHARGE syndrome without a *CHD7* mutation.

2266W

Genotype-first approach for identifying maturity-onset diabetes of the young in a clinical population. *A.H. Wardeh[1], U.L. Mirshahi[1], J. Goehringer[1], J.L. Williams[1], C.B. Manney[1], J.B. Leader[1], T.I. Pollin[3], A.R. Shuldiner[2], D.J. Carey[1], Geisinger-Regeneron DiscovEHR Collaboration. 1) Geisinger Health System, Danville, PA, USA; 2) Regeneron Genetics Center, Tarrytown, NY, USA; 3) University of Maryland School of Medicine, Baltimore, MD, USA.*

　Maturity Onset Diabetes of the Young (MODY) is a monogenic (autosomal dominant) form of diabetes that is estimated to account for 1-2% of all diabetes cases. It is usually misdiagnosed as type-1 or type-2 diabetes due to phenotypic overlap. Traditionally, MODY is defined as non-insulin dependent diabetes before the age of 25 in lean individuals, but many affected individuals do not fit this definition. Accurate diagnosis of MODY can alter treatment recommendations, often enabling the replacement of insulin with oral medication or no treatment, and better risk assessment for related individuals. There are fourteen known MODY types defined by genetic etiology. Mutations in *HNF4A*, *GCK*, and *HNF1A* account for ~90% of known MODY cases.　We used a genotype-first approach to identify individuals with potential MODY variants. Within the DiscovEHR Cohort exome sequence database we identified rare variants (<0.05% MAF) in *HNF4A*, *GCK*, and *HNF1A*. These were further classified as loss-of-function (LOF)—frameshift, stop-gain, indel, splicing, and initiation codon variants—and missense variants. The latter were classified as potential MODY variants based on data in the Leiden Open Variant Database. Diabetes phenotype was determined by the presence in the electronic health record (EHR) of diabetes ICD9, medications, and/or lab values.　In 50,791 whole exome sequences, 60 variants matched the criteria for potential MODY variants listed above (20 variants in *HNF4A*, 12 in *GCK*, and 28 in *HNF4A*). There were 180 heterozygous carriers for these variants, of which 75 were excluded based on insufficient EHR data. The remaining individuals included 34 *HNF4A*, 19 *GCK*, and 52 *HNF1A* carriers.　Seventy-eight percent of putative MODY variant carriers met criteria for diabetes (p = 0.0001, OR = 3.20, 95% CI [1.75, 5.84] compared to age, sex, and BMI matched non-carriers). These results strongly support a pathogenic role for the majority of the MODY variants identified. Based on these findings, we estimate the prevalence of MODY in this clinical population to be approximately 1 in 500.　Current efforts are focused on refining the diabetes phenotype assessment and analysis of pedigrees to further improve the identification of pathogenic variants as implemented in the ACMG/AMP standards. Identified variants will be confirmed in a CLIA/CAP-accredited laboratory, enabling disclosure of variants to patients and providers and potentially more individualized and effective and less invasive treatment.

2267T

Single *NPHS2* mutation identifies 27% of steroid resistance in Black South African Children with nephrotic syndrome: Implications for precision medicine. *C.A Winkler[1], K. Asharam[2], R. Bhimma[2], H.M. Coovadia[3], W.P. Wenkosi[2], T. Naicker[2], J.B. Kopp[4], R. Johnson[1], S. Limou[1], G.W. Nelson[1].* 1) Leidos Biomedical Research Inc./National Cancer Institute, Frederick, MD; 2) Nelson R. Mendela School of Medicine, University of KwaZulu-Natal, Durban, SA; 3) School of Public Health, University of Witwatersrand, Johannesburg, SA; 4) 6Kidney Disease Branch, National Institute of Diabetes and Digestive Diseases, Bethesda, MD, USA.

   NPHS2 mutations are a common cause of childhood steroid resistant nephrotic syndrome (SRNS), which frequently progresses to end stage kidney disease. Among children in South Africa with nephrotic syndrome, Black children are more likely to have SRNS than Indian children. We investigated whether *NPHS2* variants contributed to this disparity. Unrelated Indian and Black children in ZuluNatal Province with nephrotic syndrome (n=78) were enrolled; children with SRNS underwent kidney biopsy. *NPHS2* was sequenced for 64 NS cases and 107 ethnicity-matched controls. A replication group comprised 20 Black SR-FSGS cases and 19 controls. Children were analyzed for consanguineous inheritance and for response to immunosuppressive therapy. 55% of Indian and 97% of Black children with NS were steroid resistant ($p<10^{-5}$); 8/30 (27%) of SRNS Black children with FSGS were homozygous for *NPHS2* V260E. V260E homozygosity was replicated in 6/20 (30%) Black children with SR-focal and segmental glomeroloslcerosis (FSGS). The mutation was not observed in Indian cases or controls although one Black blood donor was heterozygous for V260E. Black children homozygous for V260E developed SRNS at an earlier age than non-carriers (34 vs 78 months, p=0.009) and none achieved either partial or complete proteinuric remission (0% vs. 47%, p=0.002). SRNS among unrelated Black children is partially explained by homozygosity for the V260E pathogenic mutation, present in 32% of SR-FSGS cases, which is not due to cryptic consanguinity among affected children. Genotyping a single *NPHS2* mutation in Black African children with NS will identify many with SR-FSGS making it possible to avoid kidney biopsy and ineffective steroid treatment. This study highlights the need for genetic studies in diverse populations. Identification of this mutation as a part of differential diagnosis would be a cost-effective alternative to kidney biopsy in homozygous carriers, and identify a large subset of patients who are unresponsive to immunosuppressive agents (specifically, oral steroid treatment and cyclophosphamide). This would spare these children the potential severe and life threatening adverse effects of these agents while at the same time reducing health care costs for an overburdened health care system.

2268F

Severe adverse reactions in 3 Mexican brothers with MPS-II to Idursulfase. *F. Campos - Romero[1], J.I. Navarrete -Martinez[2], I. Godoy - Escobar[3], G.H. Wakida -Kusonoki[3], A.E. Limon - Rojas[4], D.E. Cervantes - Barragan[2].* 1) Allergy and Clinical Immunology, Hospital Central Sur Alta Especialidad Pemex, Mexico, Mexico, Mexico; 2) Genetics, Hospital Central Sur Alta Especialidad Pemex, Mexico, Mexico, Mexico; 3) Pediatrics Hospital Central Sur Alta Especialidad Pemex, Mexico, Mexico, Mexico; 4) General Dictatorate , Hospital Central Sur Alta Especialidad Pemex, Mexico, Mexico, Mexico.

   MPS-II is a X linked lysosomal storage disease, caused by *I2S* gene mutations leading to deficit of the iduronate-2-sulfatase enzyme that results in the degradation of glycosaminoglycans pathway blockage. The disease has an extensive multiorgan involvement. Enzyme replacement therapy (ERT), is one of the few therapeutic options for the disease. The infusion is applied IV 0.5 mg/kg each week. Common adverse reaction (AR) include headache, itching, fever, hypertension, urticaria in 75% approximately. We report a series of 3 Mexican brothers with MPS-II with severe adverse reactions in the HSCAE PEMEX. Case 1:The propositus is a 3y male, product of a monocigotic twin pregnancy, from Veracruz. Repeat upper way infections and developmental delay were noticed, the diagnosis of MPS-II was stablished; with IDS/IDSP1 inversion mutation genotype. ERT began in 2008. At the 3rd, and 39th infusion presents fever 39°C, general malaise and headache. In 2011 ERT was suspended by thrombocytopenia. After 15 days he developed severe sepsis and died in 2011. Case 2: In the second twin the IDS/IDSP1 inversion genotype was confirmed. Sinubronquial chronic syndrome and allergy to rice was present. ERT began 2008, with erythema, urticaria, angioedema, respiratory distress in replacements 2,3,4 and 5. Before the 6th infusion wheezing and fever starts leading to ERT withdrawal. Two weeks after developed infusion, bleeding gums, plaquetopenia and haemolytic crises leading to treatment with gamma globulin and steroids, platelet apheresis and splenectomy. He dies in 2010.Case 3:The youngest brother has the same genotype and whole egg and rice allergy.ERT began at 2008. Adverse reactions include fever and erythema at 3rd infusion. Before 5 years of ERT he starts with fever, diaphoresis, tachycardia,erythema, respiratory distress and wheezing.We performed in February 2016 SPT with idursulfase (2mg/ml), and ID skin test (0.02,0.2 and 2 mg/ml) all results were negative, ruled out type I hypersensitivity.We re-start ERT with a 1/10 (0.0012mg/ml) dilution at 4 ml/hr, increasing every 15 minutes until tolerate 32 ml/hr with total time of 6 hours without adverse event. So far continues his ERT at doses 1:1 without AR. Idursulfase adverse reactions are common, but thrombocytopenia is a rare one. It is important in suspected AR perform SPT and IDT to make a timely diagnosis, and prevent fatal outcomes.

The eliglustat ENCORE trial: Outcomes after 4 years of treatment in adults with Gaucher disease type 1 who were previously stabilized on enzyme replacement therapy. *T.A. Burrow[1], T.M. Cox[2], G. Drelichman[3], R. Cravo[4], M. Balwani[5], A.M. Martins[6], E. Lukina[7], B. Rosenbloom[8], O. Goker-Alpan[9], N. Watman[10], A. El-Beshlawy[11], P.S. Kishnani[12], M.L. Pedroso[13], S.J.M. Gaemers[14], R. Tayag[15], M.J. Peterschmitt[14].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 2) University of Cambridge, Addenbrooke's Hospital, Cambridge, UK; 3) Hospital de Niños Ricardo Gutiérrez, Buenos Aires, Argentina; 4) State Institute of Haematology 'Arthur de Siqueira Cavalcanti', Rio de Janeiro, Brazil; 5) Mount Sinai Hospital, New York, NY, USA; 6) Universidade Federal de São Paulo, São Paulo, SP, Brazil; 7) National Research Center for Hematology, Moscow, Russia; 8) Cedars-Sinai/Tower Hematology Oncology, Beverly Hills, CA, USA; 9) Lysosomal Disorders Unit, O&O Alpan, LLC, Fairfax, VA, USA; 10) Hospital Ramos Mejia, Buenos Aires, Argentina; 11) Pediatric Hematology, Cairo University, Egypt; 12) Duke University School of Medicine, Department of Pediatrics, Durham, NC, USA; 13) Hospital de Clinicas, Universidade Federal do Paraná, Curitiba, PR, Brazil; 14) Sanofi Genzyme, Cambridge, MA, USA; 15) Prometrika, Cambridge, MA, USA.

Background: Gaucher disease type 1 (GD1) is caused by acid β-glucosidase deficiency leading to accumulation of glucosylceramide in lysosomes. Enzyme replacement therapy (ERT) augments a patient's own residual enzyme activity and breaks down accumulated glucosylceramide. Substrate reduction therapy (SRT) partially inhibits glucosylceramide synthase and slows down production of glucosylceramide. Eliglustat, an oral SRT, is approved in the US and Europe as first-line treatment for adults with GD1 with compatible CYP2D6 metabolizer phenotypes (>90% of patients). In the ENCORE (NCT00943111, Sanofi Genzyme) primary analysis of GD1 adults (N=159) previously stabilized on ERT, eliglustat was non-inferior to imiglucerase in maintaining stability after 12 months (Cox. *Lancet.* 2015). **Methods:** During the ENCORE trial, patients could receive eliglustat for 2 to 4+ years, depending on time of enrollment (which spanned 2 years), trial randomization, and geographic location (51 US patients were switched to commercial therapy when it became available as per the trial protocol). We report on long-term safety and efficacy with respect to years on eliglustat therapy for all 157 eliglustat-treated patients in ENCORE, 46 of whom were followed for ≥4 years. Repeated Measures ANOVA methods were used to analyze hemoglobin, platelet count, and spleen and liver volume data. **Results:** Mean values for hemoglobin, platelets, and spleen and liver volumes remained stable over 4 years. Year to year, all 4 measures also remained stable collectively (composite endpoint relative to baseline values) in ≥85% of patients, and individually in ≥91%. Year to year, all 4 therapeutic goals for hemoglobin concentration, platelet count, spleen and liver volumes for patients on ERT (Pastores. *Semin Hematol.* 2004) were maintained collectively in ≥92% of patients; each individual goal was maintained in ≥94% of patients. Mean bone mineral density Z-scores (lumbar spine and femur) remained stable and within healthy reference ranges throughout the trial. Eliglustat was well-tolerated over 4 years during the primary and extension phases; 4 patients (2.5%) withdrew due to adverse events considered related to eliglustat. No new or long-term safety concerns were identified. **Conclusions:** Adults with GD1 treated with eliglustat for up to 4 years in the ENCORE trial maintained clinical stability by both composite and individual measures.

2270T

A natural history study of patients with acid sphingomyelinase deficiency (ASMD). *L. Clarke[1], G.F. Cox[2], R. Giugliani[3], M.M. McGovern[4].* 1) Dept Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Sanofi Genzyme, Cambridge, MA, USA; 3) Department of Genetics, UFRGS, Medical Genetics Service, HCPA, Porto Alegre, Brazil; 4) Department of Pediatrics, Stony Brook University School of Medicine, Stony Brook, New York, USA.

Acid sphingomyelinase deficiency (ASMD), historically referred to as Niemann-Pick disease type A (NPD A) and B (NPD B), is a rare, autosomal recessive, lysosomal storage disorder. ASMD presents as a spectrum of severity, and is fatal by 3 years of age in its most severe, infantile neurovisceral form (NPD A). Two chronic forms of the disease also exist, an intermediate form with neurovisceral involvement (NPD B variant) and a less severe, chronic visceral form (NPD B) with no neurologic involvement but considerable disease-related morbidity and mortality. To assess the burden of disease in patients with ASMD, clinical and healthcare use data were abstracted from the medical records of 100 patients with infantile neurovisceral (13%), chronic neurovisceral (6%), and chronic visceral (81%) disease. Most patients were female (62%) and/or Caucasian (68%). Nearly half of the patients were from either the Brazil (46%) or US (41%) site. The majority of patients (98%) were diagnosed with ASMD via enzyme assay at a median age of 0.6 years (range 0.6-1.7), 2.9 years (range 0.4-42.8), and 6.0 years (range 0.5-40.1) for infantile neurovisceral, chronic neurovisceral, and chronic visceral ASMD, respectively. Height/length and weight Z-scores decreased markedly over the first 5 years of life for all three forms. After age 5, mean Z-scores continued to decrease but remained within normal limits in patients with chronic forms of the disease. Developmental delay (92%, 33%, 15%) and regression (54%, 33%, 1%) were more common in the infantile and chronic neurovisceral forms than in the chronic visceral form, respectively. Overall, the majority of patients (54%) underwent at least one surgical procedure. Annual hospitalization rates (2.23, 0.42, 0.41/yr) and emergency room visits (0.72, 0.07, 0/yr) were higher for patients with infantile neurovisceral disease than those with chronic neurovisceral or visceral ASMD. Platelet and WBC counts decreased over time in patients with chronic ASMD. Hepatic and respiratory disorders were the most common morbidities across patients. For patients with chronic visceral ASMD, earlier age at diagnosis was associated with greater morbidity. Analgesics, antibiotics, and respiratory drugs were the most commonly used medications. This chart review demonstrates significant disease burden and healthcare use in patients with ASMD. Diagnosis is often significantly delayed in patients with chronic ASMD. Funded by Sanofi Genzyme.

Generating a Drosophila model of Mucopolysaccharidosis IIIB as a testbed for chaperone therapy. *F.T.C. Silva[1,2], S.T. Sweeney[2].* 1) University of Brasília, Brasília, Brazil; 2) University of York, York, United Kingdom.

Mucopolysaccharidosis (MPS) IIIB is a lysosomal storage disorder caused by N-Acetyl-a-glucosaminidase (NAGLU) enzyme deficiency resulting in accumulation of glycosaminoglycan heparan sulfate. Patients present in childhood with neurodegeneration, aberrant behaviour, skeletal problems and reduced life span. We developed a Drosophila model for MPSIIIB with a view to identifying therapies. We generated an allelic series of mutants in NAGLU and assessed their phenotypes, totalizing 4 mutant genotypes and 1 control wild type (n=100 for each genotype). Longevity and behavioural responses (climbing and vortex recovery) were assessed. Wild type life span averaged 27.5 ± 5.2 days, while mild mutant alleles had an average of 20.6 ± 4.6 and 16.5 ± 4.8 days. Null alleles with larger genomic deletions averaged 11.7 ± 3.4 days and 12.8 ± 4.1 days. Behavioural responses for climbing showed hyperactivity in young mutants while vortex recovery failed to differentiate between genotypes. These results recapitulate longevity and hyperactivity behavior that is characteristic of affected children with MPSIIIB. We initiated experiments to test potential 'chaperone therapy'. Mutants in NAGLU patients are often mis-sense and resulting proteins could potentially produce function if the protein quality surveillance machinery did not degrade them first. We wish to rescue function by the feeding substrate mimics (chaperones) to encourage proper protein folding of NAGLU. We therefore designed transgenes encoding *NAGLU* with clinical mutations to be expressed in the *NAGLU* null background. Using a new NAGLU substrate for enzyme visualization in stained tissues of 3rd instar larvae, we can then assess protein activity and test for rescue phenotypes. *NAGLU* and mutant *NAGLU* were cloned into pUAST-AttB vector, allowing insertion in a known genomic site to ensure equal protein expression. We are now in a position to rescue *NAGLU* mutants to assess rescue by physiology, histology and enzyme activity. Developing animal models is an essential tool to test and generate new therapies for genetic disorders like MPS IIIB, and open new perspectives to improve patients' life quality and longevity.

Lyso-Gb1 correlates with Gaucher disease parameters in clinical trials using velaglucerase alfa and is a Gaucher-specific biomarker. *A. Zimran[1], D. Elstein[2], B. Mellgard[2], Q. Dinh[3], P. Chang[4], Y. Qiu[5], Y. Qin[4], C. Cozma[6], S. Eichler[6], A. Rolfs[6,7].* 1) Gaucher Clinic, Shaare Zedek Medical Center, affiliated with the Hebrew University-Hadassah Medical School, Jerusalem, Israel; 2) Shire Global Medical Affairs, Shire, Zug, Switzerland; 3) Shire Global Medical Affairs, Shire, Lexington, MA, USA; 4) Biostatistics and Statistical Programming Department, Shire, Lexington, MA, USA; 5) Bioanalytical and Biomarker Development, Shire, Lexington, MA, USA; 6) Centogene AG, Rostock, Germany; 7) Albrecht-Kossel-Institute for Neuroregeneration, University of Rostock, Rostock, Germany.

BACKGROUND Gaucher disease (GD) is an autosomal recessive disorder, in which glucosylceramide accumulates in macrophages, due to deficient lysosomal β-glucosidase activity. Although biomarkers have been described, none are specific to GD. Based on studies in heterogeneous populations, deacylated glucosylceramide (glucosylsphingosine; lyso-Gb1) has been identified as a potential GD-specific biomarker. METHODS Lyso-Gb1, chitotriosidase and CCL18 were quantified in patients (pts) enrolled in velaglucerase alfa (vela) clinical trials, and correlations with clinical GD parameters investigated. Pts naïve to enzyme replacement therapy (ERT-naïve) and those treated previously with imiglucerase (imi; Switch) were included. Age at baseline and genotype were considered as independent variables with respect to response. RESULTS 164 blood samples from 22 ERT-naïve pts (age 6–62 y; 7 N370S/N370S genotype) and 141 samples from 22 switch pts (6–69 y; 6 N370S/N370S) were analyzed.

Lyso-Gb1 concentrations (ng/mL)			
Visit during vela treatment	ERT-naïve (45/60 U/kg vela EoW)	Switch (15–60 U/kg vela EoW)	P value#
Week 0 (baseline)	323.2±140.5 [n=22]	91.8±84.8 [n=22]	p<0.0001
Week 53 (ERT-naïve) or 51 (switch)	117.8±78.1* [22]	82.5±85.9 [21]	p=0.0005
Week 209	60.4±39.1*† [12]	42.3±37.9 [4]	

*p<0.0001 for the change from baseline within the group; †p=0.0012 for the change from Week 53 within the group; # between groups. EoW – every other week In all ERT-naïve pts, baseline lyso-Gb1 concentrations (range 146–563 ng/mL) were higher than reported previously in untreated N370S/N370S pts (Rolfs et al. Plos One 2013). In 21/22 switch pts, baseline lyso-Gb1 concentrations were elevated (16–302 ng/mL), despite ≥22 months of prior imi. Lyso-Gb1 concentrations correlated with platelet counts (p<0.0001 for ERT-naïve pts; p=0.0109 for switch pts) and normalized spleen volumes (p<0.0001 and p=0.0008, respectively) over time in a repeated measures linear mixed-effect model, despite interpatient variation in these clinical parameters. Between weeks 25–209, lyso-Gb1 correlated with chitotriosidase and CCL18 in ERT-naïve (*r*≥0.38 and *r*≥0.44) and switch pts (*r*≥0.89 and *r*≥0.86). CONCLUSIONS For the first time, we show correlations between a GD-specific biomarker, lyso-Gb1, and clinical GD parameters and established non-specific biomarkers. Treatment with vela resulted in significant decreases in lyso-Gb1 in ERT-naïve pts and in those switched from imi, among whom only 1/22 had near-normal baseline lyso-Gb1 concentrations.

2273T

Argininosuccinate lyase deficiency: A hepatic glycogen storage disorder? *L. Burrage[1], S. Madan[1], X. Li[1], M. Jiang[1], R. Cela[1], M. Finegold[2], S. Nagamani[1], D. Bali[3], B. Lee[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pathology, Baylor College of Medicine, Houston, TX; 3) Department of Pediatrics, Duke University Medical Center, Durham, NC.

Urea cycle disorders (UCDs) are among the most common inborn errors of metabolism. Since the introduction of expanded newborn screening, every infant born in the United States is screened for several UCDs at birth allowing for early diagnosis and initiation of treatment to prevent hyperammonemia. However, natural history studies have demonstrated that the pathophysiology of UCDs cannot be completely explained by hyperammonemia. Thus, other metabolic mechanisms must explain many UCD complications. Liver dysfunction is one complication that may occur independently of hyperammonemia. Although various forms of liver dysfunction may occur in UCDs, patients with argininosuccinate lyase deficiency (ASLD) have higher plasma AST and ALT as compared to patients with more proximal disorders. Liver disease in ASLD ranges from evidence of hepatocellular injury to fibrosis and cirrhosis requiring liver transplantation. By light microscopy, one unique feature of the hepatic pathology of UCDs is increased hepatic glycogen deposition which is similar to that observed in glycogen storage disorders. The ASL-deficient ($Asl^{neo/neo}$) mouse which has hepatomegaly, evidence of hepatocellular injury, and increased hepatic glycogen deposition, serves as a model for studying the hepatocellular injury and hepatic glycogen accumulation observed in patients with UCDs. Quantification of hepatic glycogen after 3-hour, 12-hour, and 24-hour fasts in $Asl^{neo/neo}$ mice revealed significantly increased hepatic glycogen content compared to wild type (WT) mice at all time points with larger differences observed at the 12-hour and 24-hour time points. These results suggest that hepatic glycogen catabolism is altered in $Asl^{neo/neo}$ mice. Investigations of the activity of hepatic glycogenolytic enzymes revealed that the activity of glycogen phosphorylase is significantly reduced in $Asl^{neo/neo}$ mice compared to WT mice. The hepatocellular injury and hepatic glycogen accumulation are rescued by a helper dependent adenovirus expressing ASL using a liver specific (ApoE) promoter suggesting that the phenotype is intrinsic to hepatocytes. Studies investigating the mechanism underlying this reduction in glycogen phosphorylase activity are ongoing. Overall, our studies of hepatic glycogen storage in ASLD will provide novel insights into the relationship between the urea cycle and glycogen metabolism and may provide new avenues for research aimed at understanding long-term hepatic complications of UCDs.

2274F

Next-generation sequencing analysis of 53 patients diagnosed with *mut* methylmalonic aciduria. *J. Chu[1], M. Pupavac[1], D. Watkins[1], X. Tian[2], Y. Feng[2], S. Chen[2], R. Fenter[2], V.W. Zhang[2], J. Wang[2], L.J. Wong[2], D.S. Rosenblatt[1].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, United States.

Isolated methylmalonic aciduria (MMA-uria) is caused by a deficiency in either the mitochondrial methylmalonyl-CoA mutase (MCM) enzyme or the synthesis of its cofactor, adenosylcobalamin. Biallelic mutations in the *MUT* gene, which encodes MCM, are responsible for the *mut* form of MMA-uria. Patients with this disorder present symptoms of metabolic acidosis, failure to thrive, recurrent vomiting, hypotonia, lethargy, and dehydration in the newborn period. Nearly 250 different disease-causing mutations in the *MUT* gene are known. In this study, a next-generation sequencing (NGS) based gene panel, recently developed at Baylor Miraca Genetics Laboratories, was used to analyze 53 patients that had been diagnosed with *mut* MMA-uria by somatic cell complementation analysis. Two mutations in the *MUT* gene and a total of 53 different mutations were identified in 48 of 53 patients (91%). As the clinical and biochemical findings of these patients are consistent with the *mut* phenotype, it is predicted that all of the identified mutations are pathogenic. Of these, 16 mutations were novel, including the largest insertion mutation in the *MUT* gene to date. Phenotypic rescue and analysis of cDNA were used to confirm that the major insertion was responsible for the MCM deficiency observed in the patient's fibroblasts. No *MUT* gene mutations were detected in 5 of 53 (9%) patients. Review of the cellular complementation data used to initially diagnosis these 5 patients showed the results to be equivocal, putting the initial diagnosis into question. No diagnosis was possible in four of the patients. One patient was found to carry two novel mutations in the *SUCLG1* gene which are likely causal for the patient's phenotype. Combination of the NGS panel and functional analyses provided optimal diagnoses for this cohort of patients.

2275W

Tackling the Duarte galactosemia problem. *J.L. Fridovich-Keil[1], M.E. Lynch[2], N. Potter[3], C. Coles[2], J.G. Mulle[4], G. Howard[1], C.E. Barrett[2], S. Edwards[2], E.H. Wilson[3], K. Johnstone[2], J. Kable[2], M.P. Epstein[1].* 1) Dept Human Gen, Emory Univ Sch Med, Atlanta, GA; 2) Psychiatry and Behavioral Sciences, Emory Univ Sch Med, Atlanta, GA; 3) Speech and Hearing Sciences, Washington State Univ, Spokane, WA; 4) Epidemiology, Rollins Sch of Public Health, Emory Univ, Atlanta, GA.

Duarte galactosemia (DG) is one of the most common metabolic disorders identified by newborn screening in the US; it results from partial deficiency of galactose-1P uridylyltransferase. Newborns with DG display a compromised ability to metabolize galactose, a sugar abundant in milk, and manifest elevated galactose metabolites in blood and urine while drinking milk. Reports about long-term developmental outcomes in DG are mixed and healthcare providers disagree about whether intervention is warranted. Specifically, some healthcare providers advise dietary restriction of milk for their patients with DG, at least for the first year of life, while others do not. Those who recommend intervention argue that the galactose metabolites that otherwise accumulate might be deleterious. Those who do not recommend intervention argue that the documented benefits of breastfeeding outweigh any possible negative consequences of the accumulated metabolites. The ongoing disagreement leaves parents in a quandary and infants at potential risk. We are conducting a 3-year multi-state study to clarify: (1) whether children with DG, ages 6-12 years old, are at increased risk for developmental problems, and if so, (2) whether patient exposure to milk in early childhood shows an association with developmental outcomes. To conduct this study we are recruiting nearly 300 children, half with DG (cases) representing a spectrum of milk exposures, and half unaffected controls. To assess child developmental outcomes we are using validated tests of cognitive skills (especially memory, executive function, and auditory processing), communication (speech and language), physical development (including motor skills, coordination, and occurrence of tremors), social-emotional development, and auditory sensation all administered by trained professionals. We are collecting information about child diet and possible covariates using a parent/guardian response survey. We will analyze the final data set using stepwise linear regression with generalized estimating equations to determine significant predictors of outcome while controlling for relevant covariates (e.g. child age, gender, SES, sib relationships). The results will provide a foundation of shared knowledge enabling healthcare providers and the families they serve to make evidence-based decisions about what to feed their baby with DG. Depending on the outcome of the study, there also may be implications for newborn screening.

2276T

Triple therapy (arginine fortification + lysine restricted diet + pyridoxine) for pyridoxine dependent epilepsy. *S. Jaggumantri[1], C.R. Coughlin[2], W. Al-Hertani[3], A. Shuen[3], R.M. Jack[4], C. Burns[2], D. Mirsky[5], R. Gallagher[2], C. van Karnebeek[1], J. Van Hove[2].* 1) Paediatrics, University of British Columbia, Vancouver, BC, Canada; 2) Section of Clinical Genetics and Metabolism, Department of Pediatrics, University of Colorado, Aurora, CO, United States; 3) Department of Medical Genetics, Montreal Children's Hospital, McGill University of Health Centre, Montreal, QC, Canada; 4) Department of Laboratory Medicine, Seattle Children's Hospital Laboratory, Seattle, WA, United States; 5) Department of Radiology, University of Colorado, Aurora, CO, United States.

Pyridoxine dependent epilepsy (PDE) is an epileptic encephalopathy caused by mutation in *ALDH7A1* gene resulting in impaired cerebral lysine catabolism and accumulation of neurotoxic metabolites. Despite adequate seizure control with pyridoxine, 75% of individuals with PDE have significant developmental delay and intellectual disability. We describe a new combined therapeutic approach to reduce putative toxic metabolites from impaired lysine metabolism. This approach utilizes pyridoxine, a lysine-restricted diet to limit the substrate that leads to neurotoxic metabolite accumulation and l-arginine to compete for brain lysine influx and liver mitochondrial import. We conducted an open label observational cohort study in 6 PDE patients on triple therapy (Arginine fortification -150mg/kg/day, Lysine restricted diet – as per PDE consortium guidelines and pyridoxine -15-30mg/kg/day) for 6-12 months. Neurodevelopmental outcome was measured using, standard scales along with level of plasma, urine and cerebrospinal fluid (CSF) biomarkers as biochemical outcomes. Triple therapy was well tolerated and safe. Patients on triple therapy showed near normalization of urine α-aminoadiphic semialdehyde and plasma pipecolic acid. Level of biomarkers in CSF further decreased after arginine fortification in patients already on lysine restricted diet. All patients showed improvement in developmental and cognitive domains, specifically in motor skills and speech; younger patients seemed to benefit most. Furthermore, a decrease in calculated brain lysine influx was noted. Decreasing brain lysine flux via dietary restriction and arginine supplementation (competitive inhibition over the blood-brain-barrier) is effective in decreasing neurotoxic metabolite production and improving cognitive function. Residual disease symptoms could be related to early injury suggested by initial MR imaging prior to initiation of treatment or from severe epilepsy prior to diagnosis. Further studies are needed to generate more robust evidence and elucidate optimal treatment. Early diagnosis via newborn and neonatal screening allow for early intervention and potentially improved cognitive outcomes.

2277F

IEMBASE: Community-based expert knowledgebase and mini-expert platform for inborn errors of metabolism. *J. Lee[1,2], C. van Karnebeek[1,3], W. Wasserman[1,4], G. Hoffmann[5], N. Blau[6,7].* 1) Centre for Molecular Medicine and Therapeutics, BC Children's Hospital, Vancouver, BC, Canada; 2) Genome Science and Technology Graduate Program, University of British Columbia, Vancouver, BC, Canada; 3) Division of Biochemical Diseases, Department of Pediatrics, BC Children's Hospital, Vancouver, BC, Canada; 4) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 5) Department of Pediatrics, University Children's Hospital, Heidelberg, Germany; 6) Dietmar-Hopp Metabolic Center, University Children's Hospital, Heidelberg, Germany; 7) Division of Metabolism, University Children's Hospital, Zürich, Switzerland.

Objectives: Inborn errors of metabolism (IEMs) represent a large class of 500+ rare genetic disorders. The flourishing number of identified disorders can be attributed to a century-long history of research and diverse community of investigators and clinicians. Given the treatments and therapies which have become available for many IEMs, timely and accurate diagnosis is essential. Yet, it is often challenging due to their clinical heterogeneity and required knowledge on hundreds of IEMs. Such a challenge can be relieved by the rich community knowledgebase that the IEM community has established. However, access to this knowledgebase has been limited as much of the knowledge expanded before modern data systems. To address this gap, we have now developed an online platform, which combines a comprehensive community knowledgebase with a basic diagnosis support system. **Design and Methods:** We extracted disease-characterizing profiles of clinical symptoms and biochemical markers (n=2324) from an expert-generated database of 530 IEMs. The extracted IEM profiles were transferred to the nascent knowledgebase to populate. The knowledgebase was then mapped to the Human Phenotype Ontology in order to ensure interoperability with external rare disease databases, as well as exploitability by our diagnosis support system. Using this knowledgebase, we developed an algorithm which combines semantic similarity and cosine similarity in order to provide a tiered list of possible IEMs matching the user-provided disease profile. The disease-matching algorithm has undergone preliminary evaluation using 88 retrospective cases contributed by different metabolic centers. **Results:** IEMBASE (www.iembase.org) accepts an array of biochemical markers and clinical symptoms from a user and returns a ranked list of possible IEM disorders that match the input profile. In addition, the system curates expert-contributed information on IEMs, provides differential diagnoses, lists possible treatment options, and provides access to external resources. The disease-matching algorithm was able to retrieve the exact diagnosis (100% fit) in 66% of retrospective cases using a combination of clinical and biochemical information. 88% of cases had a correct diagnosis within the top 5 suggested diagnoses. **Conclusions:** We expect that this unique system dedicated to IEMs will significantly improve practice to benefit patients and families suffering these rare diseases.

Prospective treatment of argininosuccinate lyase deficiency with sodium phenylbutyrate does not prevent development of hepatic disease or recurrent hyperammonemia. *A. Yu[1], P. Chakraborty[2], M.T. Geraghty[2].* 1) Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Pediatrics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Argininosuccinate lyase (ASL) deficiency is a urea cycle defect with clinical features that include hyperammonemia, neurocognitive deficiencies, hepatic disease, trichorrhexis nodosa and hypertension. Long-term management typically involves a protein-restricted diet, arginine supplementation, oral nitrogen scavenging therapy and possibly orthotopic liver transplantation. While arginine supplementation alone has been used, the addition of sodium phenylbutyrate may prevent recurrent hyperammonemia and improve hepatitis. There are 2 reported cases of prospective arginine therapy for ASL deficiency but there have been no reported cases which include the prospective use of sodium phenylbutyrate. We report a 4 year old boy who was ascertained on the basis of an affected older sister. His sister was rescued from a neonatal hyperammonemic coma and had significant global developmental delay, seizures, and liver disease. She died during an episode of hyperammonemia and status epilepticus at 4 years old. Our patient was treated prospectively with low dose arginine, sodium phenylbutyrate, and dietary restriction of protein. He did not develop neonatal hyperammonemia but despite therapy, he had ongoing hepatic disease and had 3 episodes of hyperammonemia (maximum = 435umol/L). At 2 years old, he was treated with a liver transplant. Post-transplant, he has not had any subsequent hyperammonemic events and his argininosuccinic acid level has declined. Prospective treatment of ASL deficiency with low dose arginine and sodium phenylbutyrate does not prevent hepatic disease or recurrent hyperammonemia and a liver transplant may still be required.

2279T

The natural history of HARS deficiency: Precipitous clinical deteriorations represent a critical feature. *L. Badalato[1,2], C.A. Rupar[3,4], V.M. Siu[3,4].* 1) Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) University of Ottawa, Ottawa, Ontario Canada; 3) London Health Sciences Centre, London, Ontario, Canada; 4) University of Western Ontario, London, Ontario, Canada.

Histidyl-tRNA synthetase (HARS) deficiency, previously described as Usher Syndrome type 3B (USH3B MIM [614504]), is a rare autosomal recessive condition that has been exclusively observed in the Old Order Amish populations of Pennsylvania and Ontario. The causative founder mutation in *HARS* (c.1361A>C) was initially reported in 2012, and the condition was primarily characterized by progressive vision and hearing loss, ataxia, and visual hallucinations during infectious illnesses. Since then, we have identified the largest known population of patients with HARS deficiency, including 15 molecularly confirmed and 4 suspected cases in Southwestern Ontario. A striking distinction arose between our patients and the two reported in Pennsylvania: we observed a high frequency of catastrophic clinical deteriorations in response to febrile illness, which were previously described as rare. 8 of our 19 patients have died secondary to complications from febrile illnesses between the ages of 0 to 11. Three of our patients have survived similar life threatening clinical deteriorations, and none of our cohort has yet survived to adulthood. Autopsy reports from 2 of our patients suggested acute respiratory distress syndrome (ARDS), which is consistent with the clinical presentation we observed in others. Hypotension, encephalopathy, visual hallucinations, elevated CK, and gastrointestinal bleeding have also been observed with febrile illnesses. Acute vision/hearing loss and ataxia can also occur, typically with partial or full recovery once the illness resolves. Aside from these episodes, most of our population shared similar features with the Pennsylvania patients. Some were too young to manifest certain features or undergo complete ophthalmologic and audiologic exams, but where data was available, 10/11 patients had progressive vision loss (average age of onset 4.3y), and 9/11 had ataxia. 12/14 had progressive hearing loss; age of onset was <3 years in all cases, and 6 required cochlear implants. Variable developmental delays were seen in 4/12, and leukodystrophy was noted in 4/5 where brain imaging or pathology was available. In summary, here we provide the first comprehensive report of the natural history of HARS deficiency, based on the largest population of such patients reported to date. We highlight the precipitous nature of the acute clinical deteriorations that can occur in these patients, an understanding of which is crucial to optimize their care.

2280F

Rescue of neonatal lethality in a *cblC* mouse model by AAV gene therapy and hydroxocobalamin treatment enables examination of disease-associated retinal degeneration. *M.L. Arnold[1], J.L. Sloan[1], N.P Achilly[1], G. Elliot[2], I.F. Onojafe[3], B.P. Brooks[3], H. Qian[4], C.P Venditti[1].* 1) Organic Acid Research Section, Genetics and Molecular Biology Branch, NHGRI, Bethesda, MD; 2) Genomics Core, NHGRI, Bethesda, MD; 3) Pediatric, Developmental, and Genetic Ophthalmology Section, NEI, Bethesda, MD; 4) Visual Function Core, NEI, Bethesda, MD.

Combined methylmalonic acidemia and homocysteinemia, *cblC* type (*cblC*), is the most common inborn error of cobalamin (vitamin B12) metabolism and is caused by mutations in the *MMACHC* gene. MMACHC transports and processes intracellular cobalamin into its two active cofactors, 5'-adenosyl-cobalamin and methylcobalamin, necessary for the enzymatic reactions of methylmalonyl-CoA mutase and methionine synthase, respectively. Disease manifestations include growth failure, anemia, heart defects, developmental delay, neurocognitive impairment and a progressive retinopathy that causes blindness, usually by the end of the first decade. Treatment with cobalamin and other supplements improves the metabolic abnormalities but fails to improve the retinal disease. To explore pathophysiology and develop more effective therapies for *cblC*, we created a mouse model using TALENs and focused our studies on one allele: *Mmachc* c.162_164delCAC p.S54_T55delinsR (Δ3). *Mmachc*[Δ3/Δ3] homozygous mutant mice displayed early juvenile lethality (n=42, median=6 days, p<0.0001) and body weight (n=15, p<0.0001), and massive metabolic perturbations (elevated plasma methylmalonic acid, homocysteine, cystathionine and decreased methionine, p<0.05 for all metabolites). To assess the potential for gene therapy as a treatment for *cblC*, we generated two AAV vectors: rAAVrh10-CBA-m*Mmachc* and rAAV9-CBA-h*MMACHC* and compared a single intrahepatic dose (1 x 10[11] GC) of AAV in neonatal mice with biweekly injections of OH-cobalamin, the standard therapy. *Mmachc*[Δ3/Δ3] mice in all treatment groups (AAVrh10 n=11, AAV9 n=5, OH-Cbl n=8) displayed improved growth and increased survival with the majority surviving greater than 6 months (p<0.0005 for all treatments). We examined the ocular pathology in AAV and OH-Cbl treated *Mmachc*[Δ3/Δ3] mice which showed thinning of the outer nuclear layer and shortening of photoreceptor outer segments, consistent with the pathology described in treated patients. Furthermore, electroretinography (ERG) confirmed impaired retinal function *in vivo*: the a and b waves of dark-adapted *Mmachc*[Δ3/Δ3] mice were significantly reduced, indicating rod photoreceptor involvement (p<0.02). Successful treatment of *Mmachc*[Δ3/Δ3] mice enabled us to model, for the first time, *cblC* associated ocular pathology and will provide a translational platform for the development of new therapies, including gene therapy.

2281W

Lipoprotein lipase deficiency in a Mexican child homozygote for the Gly-188Glu mutation. *A. Colima[1,2], M.T. Magañn[2], T. Hernández[1,2], A. Vázquez[3], J.R González[2], N. Solís[4].* 1) CENTRO UNIVERSITARIO DE CIENCIAS DE LA SALUD, UNIVERSIDAD DE GUADALAJARA,GUADALAJARA, JALISCO,MÉXICO; 2) CENTRO DE INVESTIGACIÓN BIOMEDICA DE OCCIDENTE,IMSS, GUADALAJARA, JALISCO, MÉXICO; 3) UNIVERSIDAD AUTÓNOMA DE GUADALAJARA, GUADALAJARA, JALISCO, MÉXICO; 4) HOSPITAL GENERAL DE LEÓN, LEÓN, GUANAJUATO, MÉXICO.

Lipoprotein lipase (LPL) deficiency (MIM 238600) is an autosomal recessive inherited disorder characterized by a severe hypertriglyceridemia due to an impaired catabolism of triglycerides and an accumulation of triglyceride-rich lipoproteins. LPL deficiency is caused by mutations in *LPL* gene; to date more than 180 LPL-deficiency mutations have been reported. We studied a 6-years old girl from Guanajuato, México with biochemical and clinical characteristics of severe hypertriglyceridemia. The patient has handled very high triglyceride levels which range from 1937mg/dl to 5987mg/dl, biochemical analyses also showed low levels of LDL and HDL (30mg/dl and 10mg/dl respectively). Physical examination of the patient showed the presence of eruptive xanthomas on dorsal hands, she also referred to had anemia, nosebleeds, abdominal pain, and pancreatitis which are characteristic of LPL deficiency. The patient is under pharmacological treatment with 200 mg of bezafibrato per day and a fat-restricted diet. Her mother showed slightly elevated triglycerides levels (209 mg/dl) while her father showed high triglycerides levels (356mg/dl) and low HDL levels (31mg/dl). DNA was obtained with the CTAB-DTAB method for a molecular analysis. The primer pairs to PCR were design using the Oligo 6 software. Mutational screening of *LPL* gene was performed by direct sequencing using an ABI PRISM310 genetic analyzer. The patient was homozygous for the missense mutation in exon 5 which produces an amino acid substitution of glycine for glutamic acid in the codon 188 (c.563G>A, P.Gly188Glu, rs118204057) which has been previously reported to cause LPL deficiency. Her parents, who are second cousins, were carriers of this mutation. No other variants were identified in the other exons. Molecular analyses was performed in other 16 family members, of which eleven were adults and five were minors, nine of them were carriers of the mutation (seven adults and two minors). Biochemical analyses showed that only one of them had elevated triglyceride levels (259mg/dl), the rest of them were normal. To our knowledge this is the first case of LPL deficiency reported in Mexico.

2282T

A deletion mutation of the *POLD1* gene in a Japanese woman with congenital partial lipodystrophy, mandibular hypoplasia, sensorineural deafness and short stature identified by whole-exome sequencing analysis. *K. Yanagi[1], H. Sasaki[2], K. Ohokubo[3], K. Kobayashi[4], Y. Tajiri[5], M. Iso[1], Y. Matsui[1], Y. Kuroki[1], H. Ogata[6], K. Nakabayashi[8], K. Okamura[7], K. Hata[6], Y. Matsubara[8], T. Kaname[1], Initiative on Rare and Undiagnosed Diseases in Pediatrics (IRUD-P).* 1) Dept. of Genome Medicine, Center for National Research Institute for Child Health and Development; 2) Counseling and Health Center, Kyushu University; 3) Dept. of Laboratory Medicine, Fukuoka University School of Medicine; 4) Dept. of Endocrinology and Diabetes Mellitus, Fukuoka University Chikushi Hospital; 5) Dev. of Endocrinology and Metabolism, Kurume University School of Medicine; 6) Department of Maternal–Fetal Biology, Center for National Research Institute for Child Health and Development; 7) Department of Systems Biomedicine, Center for National Research Institute for Child Health and Development; 8) Center for National Research Institute for Child Health and Development.

A 44-year-old Japanese female has been described with congenital partial lipodystrophy (CPL), mandibular hypoplasia, sensorineural deafness, and short stature including the progeroid features of unknown genetic origin. She was born to non-consanguineous parents at full term gestation (43 weeks) with birth weight of 3650 g. Fat-loss on the limbs and growth retardation were noticed around the age of 12 month by her parents. At the age of 14 years, she was admitted to the Fukuoka University Hospital due to short stature and muscle cramp of her lower extremities several occasions. She had progeroid feature with symmetrical fat loss (predominantly her face and extremities, but excessive accumulation of visceral fat), skin atrophy, and short stature (between -2SD and -3DS). Sparse hair, mandibular hypoplasia with crowded teeth and bilateral hearing loss were presented. Tissue calcification of Achilles tendon and juvenile cataract, however, were not observed. She was also affected with impaired glucose tolerance (IGT) or diabetic pattern on O-GTT with hyperinsulinemia and severe insulin resistance. Low plasma leptin and adiponectin were observed. Pituitary-adrenal axis including GH and IGF-1 was within normal. Whole exome sequencing (WES) analysis was performed in herself and family members using Human All Exon V6 kit (Agilent) and HiSeq 2500 (illumina). Then, a de novo mutation in the *POLD1* gene (NM_001256849: c.1812_1814delCTC, p.Ser605del, affecting the polymerase active site) was found in this patient, which was also confirmed by Sanger sequencing. The mutation was not found in in-house data of exome sequencing in Japanese individuals. No pathogenic mutations were noted in this case as known to the lipodystorophy-related genes, such as *AGPAT2, BSCL2, CAV1, CIDEC, FBN1, LIPE, LMNA, NK, PIK3R1, PLIN1, PPARG, PSMB8, RTRF, ZMPSTE24* and *WRN*. Thus, according to the both unique clinical manifestations and the results of WES analysis, this case was diagnosed so-called "MDPL syndrome (MIM#15381)" associated with mandibular hypoplasia, deafness, progeroid features and lipodystrophy, which was recently described as a novel subtype or new causative syndrome of CPL or progeroid syndrome. MDPL syndrome has been reported as autosomal dominant disorder with 13 various ethnic patients to date. The mutation, p.Ser605del, found in our Japanese case is also found in 11 cases out of these patients. The mutation might be a hotspot of MDPL syndrome in worldwide without ethnicity.

2283F

Familial hypercholesterolemia-associated genetic variants among a cohort of 50,726 patients within a single healthcare provider organization. *N.S. Abul-Husn[1], K. Manickam[2], L.K. Jones[2], E.A. Wright[2], D.N. Hartzel[2], C. Gonzaga-Jauregui[1], C. O'Dushlaine[1], J.B. Leader[2], H.L. Kirchner[2], D.M. Lindbuchler[2], M.L. Barr[2], M.A. Giovanni[2], J.D. Overton[1], J.G. Reid[1], R.P.R. Metpally[2], A.H. Wardeh[2], I.B. Borecki[1], A. Baras[1], A.R. Shuldiner[1], O. Gottesman[1], D.H. Ledbetter[2], D.J. Carey[2], F.E. Dewey[1], M.F. Murray[2], Geisinger-Regeneron DiscovEHR Collaboration.* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Geisinger Health Center, Danville, PA.

Familial hypercholesterolemia (FH) is a public health genomics priority, but remains under-diagnosed and under-treated despite widespread cholesterol screening. This represents a missed opportunity to prevent FH-associated cardiovascular morbidity and mortality. Pathogenic variants in three genes (*LDLR*, *APOB*, and *PCSK9*) account for the majority of FH cases. We assessed the prevalence and clinical impact of FH variants in 50,726 individuals from the MyCode® Community Health Initiative at Geisinger Health System who underwent exome sequencing as part of the DiscovEHR human genetics collaboration with the Regeneron Genetics Center. This is the first large-scale study utilizing exome sequencing for the evaluation of FH in a U.S. Healthcare Provider Organization. Thirty-five known and predicted pathogenic variants in *LDLR*, *APOB*, and *PCSK9* were identified in 229 individuals, corresponding to a carrier frequency of 1:222. Surprisingly, FH variants were found to explain only 2.5% of severe hypercholesterolemia (LDL-C ≥ 190 mg/dl) in the cohort. Applying Dutch Lipid Clinic Network diagnostic criteria to electronic health record (EHR) data, we found criteria supporting a clinical diagnosis of FH in 62% of FH variant carriers. We estimated that 14 of the 35 FH variants might have reduced penetrance, as not all carriers of these variants met pre-sequencing diagnostic criteria for FH despite having LDL-C data available in their EHRs. Active statin use was identified in 57% of FH variant carriers; however, only 33% had a most recent LDL cholesterol level below 100 mg/dl. FH variant carriers had significantly increased odds of general and premature coronary artery disease (CAD; OR = 2.62, p = 4.3x10^{-11}, and OR = 3.72, p = 5.5x10^{-14}, respectively). The increased odds of premature CAD was greatest in carriers of *LDLR* predicted loss-of-function variants (OR = 10.29, p = 9.8x10^{-19}) and smallest in carriers of *APOB* variants (OR = 1.74, p = 0.12), demonstrating the potential value of molecular sub-classification of disease. In summary, we show that large-scale genomic screening in patients with longitudinal EHR data has the ability to detect FH, uncover and characterize novel pathogenic variants, determine disease prevalence, and enhance overall knowledge of clinical impact and outcomes. Our findings highlight the under-treatment of FH, and demonstrate a potential clinical benefit for the large-scale sequencing planned by the national Precision Medicine Initiative.

2284W

Expanding the spectrum of novel and founder mutation(s) in children affected with Tay-Sachs disease from India. *M.A. Mistri[1], P.M. Tamhankar[2], C. Datar[3], M. Kamate[4], S. Idicula-Thomas[5], S. Nampoothiri[6], M. Kabra[7], R. Puri[8], K.M. Girisha[9], S. Mehta[10], D. Solanki[11], F. Sheth[1], S. Gupta[12], J. Sheth[1].* 1) Biochemical and Molecular Genetics, FRIGE's Institute of Human Genetics, Ahmedabad, Gujarat-India, India; 2) ICMR Genetic Research Center, National Institute for Research in Reproductive Health, Mumbai, Maharashtra, India; 3) Department of Genetics, Clinical Geneticist, Sahyadri Medical Genetics and Tissue Engineering Facility (SMGTEF), Pune, India; 4) Department of Pediatric Neurology, KLES Prabhakar Kore Hospital, Belgaum, Karnataka, India; 5) Biomedical Informatics Center, National Institute for Research in Reproductive Health, Mumbai, Maharashtra, India; 6) Department of Pediatric Genetics, Amrita Institute of Medical Science & Research Centre, AIMS Ponekkara PO, Cochin, Kerala, India; 7) Genetics Unit, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India; 8) Center of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, India; 9) Department of Medical Genetics, Kasturba Medical College, Manipal University, Manipal, Karnataka, India; 10) Usha-deep Hospital, Naranpura, Ahmedabad, Gujarat, India; 11) Mantra Child Neurology & Epilepsy Clinic, Bhavnagar, Gujarat, India; 12) Department of Biochemistry, M.S. University, Vadodara, Gujarat, India.

Tay-Sachs disease (TSD) is an autosomal recessive neurodegenerative disorder caused by impaired activity of the lysosomal enzyme β-Hexosaminidase-A (EC 3.2.1.52) due to the mutation in *HEXA* gene. Although, the mutation spectrum for TSD in India has been partly addressed by us, present study is to further understand the molecular heterogeneity of the disease in Indian population. Present study report the molecular characterization performed on 21 unrelated affected patients with classical TSD. Complete sequencing followed by MLPA analysis revealed 17 variants, 9 of which were novel, including 3 missense variants [V206L, Y213H, G454R], 1 nonsense variant R420X, 1 splice site variant c.460-1G>A, 1 small deletion c.1349delC (A450VfsX3), 2 large deletion [Exon 2-3 deletion & Exon 1 deletion] and 1 heterozygous duplication of exon-1 with unknown second allele. Previously known 5 missense variants [M1T, R170Q, D322N, E462V, R499C], 2 splice site variants [c.459+4A>C, c.1073+1G>A] and 4bp insertion [c.1278insTATC (Y427IfsX5)] were also identified. In 2 cases with clinically suspected TSD; due to normal enzyme level activator protein deficiency was suspected. Molecular analysis of *GM2A* gene was also carried out in 2 patients and has revealed 2 novel homozygous variants including 1 nonsense E158X and 1 splice site c.243-2A>T variants. All novel missense variants of *HEXA* & *GM2A* gene were shown to be pathogenic by SIFT, Polyphen2 and Mutation taster algorithms while splice site variants were confirmed by Mutation taster and NNSplice 0.9 algorithms. Protein homology modeling study was carried out to further establish the effect of novel variants. The sequence alignment of *HEXA* & *GM2A* genes from various species reveals that all residues are highly conserved. The E462V variant was present either in homozygosity or as compound heterozygote, in 5 (~25%) unrelated patients further reconfirm this as a founder mutation in our population. We have also demonstrated that all *HEXA* mutations for Indian patients are associated with severe phenotypes and pseudo-deficient or adult onset alleles are highly unlikely in patients from India. Moreover, 2 cases have also shown deficiency in GM2 activator protein which is very rare and only 9 cases so far reported in the world literature. It can be concluded from these cases that children clinically suspected with TSD having normal β-Hexosaminidase (Hex-A & total-Hex) study should be further investigated for GM2 activator protein deficiency.

2285T

A very rare complication of sitosterolemia. *E.E. Conboy[1], F. Bazerbachi[2], K.D. Watt[3], P.S. Kamath[3], D. Babovic-Vuksanovic[1].* 1) Clinical Genomics, Mayo Clinic, Rochester, MN; 2) Gastroenterology, Mayo Clinic, Rochester, MN; 3) Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN.

Sitosterolemia is a rare autosomal recessive metabolic disease that was first described in 1974 by Bhattacharyya and Connor who reported on two intellectually normal sisters with tendinous and tuberous xanthomas and elevation of blood levels of β-sitosterol, campesterol and stigmasterol. The STSL locus was mapped to chromosome 2p21 in 1998. Soon afterward, mutations in *ABCG5* and *ABCG8* were found to be genetic cause of sitosterolemia. These two genes encode for (ATP)-binding cassette (ABC) transporters sterolin-1 and sterolin-2, which are sterol transporters that normally cooperate to limit intestinal absorption by resecreting plant sterols back into the glut lumen and to promote biliary excretion of plant sterols. In healthy individuals, almost all of the small percent of absorbed plant sterols are quickly secreted into the bile so that they are left with only trace amounts of these phytosterols in the blood. Altered forms of these transporters predispose to sterol accumulation, allowing patients to absorb a much larger percentage of ingested sterols, and the transporter dysfunction in the liver allows these patients to only secrete a fraction of these absorbed sterols back into the bile. This results in various complications of increased phytosterol levels, including premature coronary artery disease, tendon xanthomas, hematologic abnormalities including hemolytic anemia and macrothrombocytopenia, as well as a less well-known complication of liver cirrhosis. We review a case of a 21 year old man who presents with bicytopenia, liver failure and premature atherosclerosis and evaluation for liver and heart transplant. The underlying cause for his organ dysfunction was undiagnosed until futher workup revealed a sitosterol level of 174.5 (normal 0-5 mg/L). Genetic testing was sent and he was found to have a homozygous pathogenic mutation in ABCG5, c.1336C>T and p.Arg446*. Prior to this case, there has only been one other known case of a patient with sitosterolemia suffering from liver cirrhosis. It is estimated that there are around 100 reports of patients with sitosterolemia worldwide, however, given that the usual test for plasma cholesterol concentration does not measure phytosterols it is likely an under-recognized entity.

2286F

Molecular follow-up of a newborn screening (NBS)-positive case of medium-chain acyl-coenzyme A dehydrogenase deficiency (MCADD) identified two *ACADM* variants: Are they clinically pathogenic? *Y. Ho, C. Morgan, B. Johnson.* Clinical Genomics, Invitae Corp, San Francisco, CA.

MCADD is one of the most common recessively inherited metabolic diseases. It is caused by pathogenic mutations in the ACADM gene that affect the β-oxidation of fatty acids 6–12 carbons long. Affected individuals generate insufficient ketones for energy during periods of glucose and glycogen depletion and can experience extreme hypoglycemia. Untreated episodes can lead to coma and death. Adverse outcomes can be prevented by avoiding metabolic stress and following simple dietary interventions.We report an NBS-positive infant with confirmatory testing results revealing continued elevation of C6, C8, C10, C10:1, and elevated C8/C10 ratio. Next-generation sequencing identified two ACADM variants: c.985A>G (p.Lys329Glu) and c.797A>G (p.Asp266Gly). The pathogenic p.Lys329Glu mutation—most prevalent in patients with clinically symptomatic MCADD— is reportedly as high as 80% homozygous but is considerably less frequently observed in individuals identified through NBS (63%/47% homozygous). The p.Asp266Gly variant, currently classified as a variant of uncertain significance, has been previously reported in newborns with biochemical markers consistent with MCADD and shown to cause partial enzymatic deficiency; however, it has not been reported in clinically symptomatic patients.The highly prevalent pathogenic p.Lys329Glu variant confers high risk for metabolic decompensation, although unaffected homozygous adults have been reported. Conversely, whereas the p.Asp266Gly variant has been identified in MCADD-positive NBS, it causes only partial deficiency of the enzyme and, to the best of our knowledge, has not been reported in clinically symptomatic patients. In addition, although this genotype has been previously described in one NBS-positive MCADD case, the long-term outcome is unknown.Our patient showcases the uncertain reality patients and clinicians often face when dealing with a rare disease like MCADD for which NBS positivity with confirmatory results does not necessarily predict clinical consequences. Emerging evidence supports an MCADD genotype–phenotype correlation, although further substantiation of this relationship is needed. We share this report with the goal of contributing to MCADD genotype and phenotype data collection, which is essential for understanding the natural history and more accurately projecting the long-term clinical consequences of MCADD.

2287W

Regulation of HDL-c levels via ABCA1: A role for *LRP1.* *F. Oldoni[1], J. van Capelleveen[2], N. Dalila[3], M.M. Motazacker[2], J. Heeren[4], R.J. Sinke[5], G. Dall-inga-Thie[2], D. Hui[6], R. Frikke-Schmidt[3,7], A. Tybjærg-Hansen[3,7,8], K. Hovingh[2], J.A. Kuivenhoven[1].* 1) Department of Molecular Genetics, University Medical Centre Groningen, Groningen, The Netherlands; 2) Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands; 3) Department of Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital and Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 4) Department of Biochemistry and Molecular Cell Biology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; 5) Department of Genetics, University Medical Centre Groningen, Groningen, The Netherlands; 6) Department of Pathology and Laboratory Medicine, Metabolic Diseases Institute, University of Cincinnati College of Medicine, Cincinnati, Ohio; 7) Copenhagen General Population Study, Herlev Hospital, Copenhagen University Hospital and Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 8) Copenhagen City Heart Study, Frederiksberg Hospital, Copenhagen University Hospital and Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark.

Background: The genetic architecture of HDL-c deficiencies (HDLD) is well-acknowledged through rare mutations in *ABCA1* (MIM 600046)*, APOA1* (MIM 107680) and *LCAT* (MIM 606967). However, recent studies in liver-specific *Lrp1* (LDL receptor related protein 1) knock-out mice have indicated that Lrp1 also modulates plasma HDL-c (high-density lipoprotein cholesterol) levels. So far, a role for LRP1 in human HDL metabolism has not yet been elucidated. This study focuses on the molecular mechanism underlying a low HDL cholesterol phenotype in heterozygotes for *LRP1* mutations. **Methods:** Targeted-sequencing efforts in individuals with extremely low HDL-c levels (<0.6mmol/L or 23.2mg/dL) identified the first two missense mutations in *LRP1*, c.9730G>A (p.Val3244Ile) and c.11949G>T (p.Glu3983Asp). The *LRP1* locus was found to be strongly associated with HDL-c and ApoA1 levels in a large Danish population cohort (The Copenhagen City Heart Study) suggesting its potential involvement in HDL metabolism. Both *in-vitro* (overexpression and CRISPR-Cas9 deficient cell lines) and *ex-vivo* (patient-derived fibroblasts) approaches have been employed to evaluate the mutations functional consequences and study the molecular mechanisms regulating ABCA1 plasma membrane localization. **Results and Conclusions:** Mutant LRP1 proteins are significantly reduced by 40-60% and less stable when compared to wild-type (WT). Notably, ABCA1 cell surface localization has been shown to be significantly decreased by 60-70% in carrier fibroblasts and LRP1-deficient cells. Molecular evidence supports the notion that alteration of both lysosomal enzyme Cathepsin D and Prosaposin levels affect ABCA1 plasma membrane presence. In addition, phenotype rescue studies in knock-out cells enabled the full recovery of ABCA1 cell surface expression upon introduction of the WT form of LRP1 but not the mutant. The use of extreme genetics has led to the identification of the first LRP1 deficient individuals featuring with extremely low HDL-c levels. Our data suggest that in humans as in mice, LRP1 affects intracellular trafficking of ABCA1 to the plasma membrane, which could explain low HDL-c in our study subjects.

2288T

Niemann-Pick disease type C1: A case with an unreported mutation.
R.J. Sandoval-Muñiz[1], A. Cordero[2], R. Cruz[2], E. López[2], E. Rivera[2], A. Rea[3], J. Hernández[3], Y. Nakashima[3], R. Nieto[3], E. Zapata[3], G. González[2], J.R. Corona[1,3], L. Arnaud-López[1,3]. 1) Doctorado en Genética Humana, Universidad de Guadalajara, Genetics Service, Pediatric Division of Hospital de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, Mexico; 2) Hospital Civil de Guadalajara "Dr. Fray Antonio Alcalde", Hospital No. 278, Col. El Retiro, Guadalajara, Jalisco, México; 3) Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, Salvador de Quevedo y Zubieta No. 750, Col. La Perla, Zip Code 44340.

Niemann-Pick disease type C1 (NPDC1; MIM 257220) is an autosomal recessive lysosomal storage disease. According to its pathophysiology it is classified into types A, B, C and D. NPDC1 despite a highly variable clinical spectrum, spleen, liver and brain are affected. Mutations in gene *NPC1* mapped on chromosome 18q11.2, that predicts a protein of 1278 amino acids trigger the disease. This protein acts as a transmembrane efflux pump apparently causing inadequate exogenous cholesterol esterification. Case report:A 28 months-old boy, young parents with no consanguinity or know medical problems. He started his conditions at 5 months of age with delayed acquisition of skills and regression after 8 months, at 27 months presented spasticity and arthralgia. Physical examination: W: 11.4 kg (-1.65 SD), H: 90 cm (+0.28 SD), CC: 47.9 cm (-1.07 SD). Irritable, clinical dystonia, spasticity generalized, hyperreflexia, muscular atrophy, *pectus excavatum*, bloating by hepatosplenomegaly, no ascites. Index of diagnostic suspicion: 88. Hypochromic-microcytic anemia (HG 10.3 g/dL, HTO 35%), thrombocytopenia (95.1 miles/µL), impaired lipid metabolism (TGL 203, LDL 30.4 and VLDL 41 mg/dL) and increased liver enzymes (TGO 93.8 IU/L). Peripheral blood smear showed microcytosis, poikilocytosis, hypochromia, normal platelets. Bone marrow aspirate: increased red and megakaryocytic series, white series with large, round, eccentric nucleus and foam cells. Radiology: PA thoracolumbar presented hepatosplenomegaly. Abdominal ultrasonography and liver elastography exhibited hepatosplenomegaly that suggesting storage disease. Mechanics swallowing: absent suction and trachea-esophageal reflux. Cranium NMR: cortico-subcortical atrophy. Molecular study: homozygous mutation of the gene *NPC1*, c.3734C>T(p.P1245L). NPC-509 1.7 ng/mL and chitotriosidase 2500 nmol/h/mL. Conclusions: NPDC1 is a lysosomal hoarding, characterized by storage of sphingosine, glycosphingolipids and cholesterol with a decreased of lysosomal calcium wich leads to neurovisceral damage and innate inmune dysfunction. Index suspicion helps to identify patients with visceral, neurological and psychiatric clinical data. Presence of foam cells are no considered pathognomonic diagnosis and may be required skin biopsy as a complement diagnostic with inmunohistochemical staining. *NPC1* gene homozygous mutation c.3734C>T (p.P1245L) previously unreported and correspondsto the classification 1 of the American College of Medical Genetics.

2289F

Phenotypic characterization of cell lines from patients with spondylometaphyseal dysplasia with cone-rod dystrophy (SMD-CRD). *J. Jurgens, N. Sobreira, A. Franca, J. Hoover-Fong, D. Valle.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

   SMD-CRD is a rare, autosomal recessive disorder caused by partial or complete loss-of-function variants in *PCYT1A* [Hoover-Fong et al., 2014; Yamamoto et al, 2014]. Clinical characteristics include progressive, early-onset photoreceptor degeneration as well as short stature, bowing of the long bones, metaphyseal flaring, rhizomelic shortening, platyspondyly, and scoliosis. *PCYT1A* encodes CTP:phosphocholine cytidylyltransferase α (CCTα), an enzyme which catalyzes the rate-limiting step in *de novo* synthesis of phosphatidylcholine (PC), the predominant membrane phospholipid in mammalian cells. Here we describe the phenotypic characterization of cultured skin fibroblasts from SMD-CRD patients. Western blot analysis of CCTα expression in cultured fibroblasts of 5 SMD-CRD patients (4 probands and an affected sib) showed variable levels of CCTα. When compared to controls, Ala99Val homozygotes had a 30% reduction in protein levels; Glu129Lys homozygotes had a 70% reduction; and patients homozygous for a 1-bp frameshifting insertion (Ser323Argfs*38) had no detectable CCTα. To assess PC synthesis, we measured incorporation of [³H]-choline into PC in intact fibroblasts over time. As compared to controls, fibroblasts homozygous for the Ser323Argfs*38 allele were severely deficient in their ability to convert [³H]-choline into PC. This defect was exacerbated by pre-incubation (10 min at 400 µM) of cells with oleate, a known activator of CCTα. Oleate pre-incubation promoted an ~ 4-fold increase in PC synthesis in control cells with no effect on SMD-CRD patient cells (Ser323Argfs*38 homozygote). Using cells from Drosophila and mice, Guo et al. (2008) and Krahmer et al. (2011) demonstrated that CCTα-deficient cells formed fewer and larger lipid droplets than did control cells after oleate exposure. We hypothesized that SMD-CRD patient fibroblast cells would also exhibit abnormal lipid droplet accumulation in response to oleate. Interesting, we found that SMD-CRD fibroblasts (Ser323Argfs*38 homozygote) failed to show significant differences in lipid droplet numbers or sizes as compared to control fibroblasts. We conclude that SMD-CRD patient fibroblasts display variable levels of reduction in PC synthesis and CCTα protein but, surprisingly, have no accompanying lipid droplet abnormalities.

Mutations in the tyrosine-protein kinase *Lyn* cause an early-onset neutrophilic vasculitis syndrome: Report of two unrelated cases. *A. Almeida de Jesus[1], G. Montealegre[1], H. Freeman[2], N. Martin[3], E. Omoyinmi[4], B. Marrero[1], K. Calvo[5], R. Chyi-Chia Lee[6], A. Brundidge[7], D. Kleiner[8], S. Hewitt[6], D. Chapelle[7], Y. Huang[1], S. Brooks[7], S. Moir[8], E. Maffre[9], P. Brogan[4], M. Merchant[6], Z. Deng[7], R. Goldbach-Mansky[1].* 1) Translational Autoinflammatory Disease Section, NIAID, NIH, Bethesda, MD, USA; 2) Raigmore Hospital, Inverness, Scotland; 3) Royal Hospital for Children, Glasgow, Scotland; 4) University College London Institute of Child Health, London, UK; 5) Hematology Service, Department of Laboratory Medicine, NIH, Bethesda, MD, USA; 6) National Cancer Institute (NCI), NIH, Bethesda; 7) National Institute of Arthritis Musculoskeletal and Skin Diseases (NIAMS), Bethesda, MD, USA;; 8) Immunopathogenesis Section, NIAID, NIH; 9) Yale University, New Haven, CT.

   Statement of purpose: Tyrosine-protein kinase Lyn is a Src-family tyrosine kinase. Lyn[up/up] mice have a gain-of-function mutation at the tyrosine position 508 (p.Y508F) and present with severe anemia, autoimmune glomerulonephritis and positive ANA. We describe two patients with a *de novo* germline mutation in *LYN*, a gene not previously associated with a Mendelian human disease. **Methods** WES was performed using human exome capture Agilent V5 enrichment kit and Illumina HiSeq2000 platform. **Case Reports:** Patient 1 is a 5 year-old Caucasian male born at 31 weeks' gestation who presented with hydrops fetalis and post partum developed a purpuric skin rash, hepatosplenomegaly, periorbital erythema and testicular pain. Laboratory exams showed increased C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), anemia, thrombocytopenia and increased liver enzymes. At 9 months of age a splenectomy was performed and he developed leukocytosis and thrombocytosis while the anemia persisted. A liver biopsy showed a periportal lymphocytic infiltrate and vanishing bile duct disease. He had vasculitis on a skin biopsy and circulating autoantibodies. We identified a *de novo* mutation in a candidate gene (*LYN*) by WES that was confirmed by Sanger sequencing. The mutation *LYN* NM_002350 c.1524C>G leads to a premature stop-codon at p.Y508*. B-lymphocytes showed a constitutive phosphorylation of Lyn and a diminished frequency of immature B cell populations in peripheral blood and in bone marrow. The tyrosine kinase inhibitor dasatinib was initiated and patient responded with reduction of steroid dose, lower frequency of disease flares, resolution of anemia, reduction in total lymphocyte count and normalization in liver enzymes. Patient 2 is 14 year-old Scottish male who presented with an erythematous skin rash on the second day of life. At the age of 3 months, he developed a purpuric skin rash and fevers, abdominal and testicular pain, diarrhea, periorbital erythema and increased CRP and ESR. The recurrent symptoms have responded to oral steroids. He was recently started on etanercept with a good preliminary clinical response. Targeted gene-panel sequencing revealed a *LYN* NM_002350 c.1523A>T, p.Y508F mutation in *LYN*, which was confirmed to be de novo by Sanger sequencing. **Conclusion:** We have used WES and targeted deep sequencing to identify activating mutations in Lyn kinase gene (*LYN*) in two patients with neonatal-onset of fever, small vessel vasculitis and systemic inflammation.   .

2291T

Effect of alpha-lipoic acid and curcumin against tumor necrosis factor-alpha levels in lymphocytes cultured from Fanconi Anemia. *E. Torres-Anguiano[2,3], A. Corona-Rivera[1,2], R. Silva-Cruz[2], U. Santana-Bejarano[2,3], A. Vázquez-Reyes[2,3], J. Roman-Corona[4], L. Bobadilla-Morales[1,2].* 1) Unidad de Citogenética, Servicio de Hemato-Oncología Pediátrica, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jal., México.

Fanconi anemia (FA) is an autosomal recessive genetic disorder characterized by chromosomal fragility, progressive bone marrow failure, somatic abnormalities and susceptibility to cancer. FA is caused by the disruption of FA-BRCA pathway, 19 human genes have been implicated in the causation of disease. The patients with FA are often found overproducing TNFα, which may directly affect hematopoietic stem cell (HSC) function by impairing HSC survival and proliferation, or indirectly change the bone marrow microenvironment critical for HSC homeostasis and function, therefore contributing to disease progression in FA. The aim of the present work is to evaluate the effect of curcumin and alpha lipoic acid on the TNFα levels in lymphocyte cultures from Fanconi anemia patient, with exons 12 to 18 deletions mutation of the *FANCA* gene. From FA patient 6 ml peripheral blood were collected, and then lymphocytes were isolated by Lymphoprep density gradients and cultured in RPMI 1640 medium containing 15% fetal calf serum, antibiotics (10,000 units/ml of penicillin and 10,000 µg/ml of streptomycin) and L-glutamine. Incubate at 37°C with 5% CO2 atmosphere, for 72 h. After 24 h incubation, the cells were treated with α-lipoic acid (80µM) and curcumin (25µM). TNFα levels were determined using Human TNFα ELISA Kit; all measurements were made in triplicate. Statistical comparison among groups was estimated using one-way ANOVA. Lymphocyte cultures without antioxidant treatment the TNFα level was 91.1pg / ml, cultures treatment with curcumin was 52.1 pg/ml TNFα, the cultures with treatment alpha lipoic acid was 81.4 pg / ml TNFα and cultures treatment with the combined α-lipoic acid plus curcumin was 70.5 pg/ml TNFα. The lymphocyte cultures treatment with curcumin and the combined α-lipoic acid plus curcumin showed a significant reduction in the TNFα levels compared to Lymphocyte cultures without antioxidant treatment (p<0.05). Globally, the percentage of reduction the TNFα in lymphocyte cultures treated with curcumin was 42% (p<0.05) and with the combined α-lipoic acid plus curcumin was 22.6% (p<0.05). The bone marrow failure and development of cancer in Fanconi anemia is associated with inflammation, experimental and clinical studies focus future prospects of therapies to finding compounds capable of reducing these characteristics. The results suggest that curcumin can be an effective antioxidant prophylactic and reduces the inflammatory process present in Fanconi anemia.

2292F

Glanzmann thrombasthenia in South Asia: Molecular analysis and identification of novel mutations. *A. Haghighi[1], M. Borhany[2], A. Ghazi[3], N. Edwards[4], A. Tabaksert[4], A. Haghighi[5], N. Fatima[2], T.S. Shamsi[2], J.A. Sayer[4].* 1) Harvard Medical School, Boston, MA; 2) Department of Hematology, Hemostasis & Thrombosis of National Institute of Blood Disease & Bone Marrow Transplantation, Karachi, Pakistan; 3) Chronic Pain Clinic, Wilderman Medicine Professional Corporation, Toronto, Canada; 4) Institute of Genetic Medicine, Newcastle University, Newcastle, UK; 5) Toronto General Hospital, University of Toronto, Toronto, Canada.

Glanzmann thrombasthenia (GT) is an inherited genetic disorder affecting platelets, which is characterized by spontaneous mucocutaneous bleeding and abnormally prolonged bleeding in response to injury or trauma. The underlying defect is failure of platelet aggregation due to qualitative and/or quantitative deficiency of platelet integrin αIIbβ3 resulting from molecular genetic defects in either ITGA2B or ITGB3. Here, we examine a Pakistani cohort of 20 patients with clinical symptoms of GT who underwent laboratory and molecular genetic analysis. In patients with a broad range of disease severity and age of presentation, we identified pathogenic mutations in ITGA2B in 14 patients from 9 different families, including 2 novel homozygous mutations and 1 novel heterozygous mutation. Mutations in ITGB3 were identified in 6 patients from 4 families, two of which were novel homozygous truncating mutations. A molecular genetic diagnosis was established in 11 families with GT, including 5 novel mutations extending the spectrum of mutations in this disease within a region of the world where little is known about the incidence of GT. Mutational analysis is a key component of a complete diagnosis of GT and allows appropriate management and screening of other family members to be performed.

2293W

Sweet's syndrome in a patient with compound heterozygous mutations in the Mediterranean fever gene (*MEFV*). *M. Michelson-Kerman[1,2], C. Vinkler[1,2], D. Lev[1,2].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Maccabi Health Service, Tel-Aviv, Israel.

Sweet's syndrome (SS) or acute febrile neutrophilic dermatosis is a rare disorder that often occurs in association with other systemic diseases. The disorder is characterized by development of nonpruritic, painful erythematous plaques with pseudovesicles, occasional pustules and rare bullae. SS consists of a triad of erythematous plaques infiltrated by neutrophils in association with fever and leukocytosis. The pathological features of SS involve the dermis. The condition presents in three clinical settings: classic (or idiopathic) SS, malignancy-associated SS and drug-induced SS syndrome. The treatment of choice for SS are systemic corticosteroids, although colchicine and potassium iodide are also considered to be effective for SS. We present an unusual recurrent course of SS in a 38 year old man who carries compound heterogous mutations in the MEFV gene. A 38 year old, generally healthy man from Sephardic Jewish ancestry, had suddenly developed fever, malaise, artralgia and painful erythematous plaques with pustules and bullae on the anterior aspects of the upper extremities. Diagnostic evaluation included moderate leucocytosis, elevated erythrocyte sedimentation and C-reactive protein rate and normal liver functions. antistreptolysin O-titer. Blood cultures and tuberculosis test were negative. Chest radiography was normal. The symptoms exacerbated despite treatment with systemic corticosterids. Clinical improvement appeared after administration of colchicine . Mutational analysis of the MEFV gene revealed compound heterozygous M694V and V726A mutations. Familial Mediterranean fever (FMF) is an autosomal recessive disease characterized by recurrent attacks of fever with serosal inflammation. The FMF gene (MEFV) encodes the protein pyrin that plays an important role in modulating the innate immune response. MEFV mutations have been identified primarily in patients from Mediterranean populations and in Israel the carrier state is as high as1: 5. Sweet's syndrome has been described in a patient with classical FMF as a possible new cutaneous feature and has never been described as a presenting sign of FMF. Although various skin lesions have been described with FMF, erysipelas-like erythema (ELE) has been reported the only pathognomonic cutaneous manifestation. Our patient, carrying compound heterozygous mutations in MEFV presented with Sweet's syndrome. We suggest that SS skin lesions might be an only cutaneous presentation of FMF. .

Genomic characterization of Diamond-Blackfan anemia reveals known and novel ribosomal causes. *S.A. Savage[1], P. Khincha[1], S.R. Ellis[2], N. Giri[1], S. Brodie[3], S. Chandrasekharappa[4], W. Zhou[3], B.D. Hicks[3], J.F. Boland[3], M. Yeager[3], K. Jones[3], B. Zhu[3], M. Wang[3], B.P. Alter[1], L. Mirabello[1].* 1) Div Cancer Epidemiology & Genetics, Natl Cancer Inst, Bethesda, MD; 2) Department of Biochemistry and Molecular Biology, University of Louisville, Louisville, KY; 3) Cancer Genomics Research Laboratory, Leidos Biomedical Research, Frederick National Laboratory for Cancer Research, Frederick, MD; 4) Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, Bethesda, MD.

Diamond-Blackfan anemia (DBA) is a rare inherited bone marrow failure syndrome (IBMFS) characterized by erythroid hypoplasia typically presenting with macrocytic anemia in infancy, often with normal white blood cell and platelet counts. It is associated with a spectrum of congenital anomalies, including flat nasal bridge, high arched or cleft palate, short stature, abnormal thumbs, genitourinary and cardiac defects, and webbed neck. DBA patients are at high risk of AML, MDS, colon adenocarcinoma and osteosarcoma. Many patients with DBA have autosomal dominant germline pathogenic variants or deletions in genes affecting ribosomal biogenesis. Associated genes are part of the small (*RPS19, RPS24, RPS17, RPS7, RPS10, RPS26, RPS27, RPS28, RPS29*) and large (*RPL35A, RPL5, RPL11, RPL26, RPL15, RPL27*) ribosomal subunits. Pathogenic variants in two X-linked genes, *GATA1* and *TSR2,* cause DBA in a minority of patients. However, about 45% of DBA families are yet to have a pathogenic variant in a disease-causing gene identified. 87 DBA families have enrolled in the National Cancer Institute's IBMFS study (NCT00027274) to date. Study participants completed detailed questionnaires, medical records were reviewed, and a subset of families underwent evaluations at the NIH Clinical Center. Clinical testing performed prior to 2014 identified the genetic cause in 26 families. Genetic testing information or DNA samples were not available on 26 families. Blood or buccal cell DNA from 35 families was subjected to whole exome sequencing (WES), targeted deletion analysis and genome-wide assessment of copy number variation to identify the pathogenic variant. The causative genetic change was discovered in 17 of the 35 gene unknown families. Pathogenic variants in known DBA-associated ribosomal genes were present in 15 (43%) families. We discovered 2 novel genes with pathogenic variants in 2 families: *RPL35* (p.K77N) and *RPL18* (p.L51S). These variants were proven to be deleterious by functional assays showing characteristic pre-rRNA processing defects and differential gene expression when compared with wild-type. The genetic cause was identified in 43 (71%) of the 61 families available for testing. The combination of WES and deletion analyses was efficient and led to the discovery of 2 novel causes of DBA, in addition to the 17 known causes. Studies are ongoing to identify the etiology in the families with a yet unknown genetic cause of DBA.

2295F

Identification of the molecular causes of hereditary spherocytosis. *L.J. Drury[1], S. Butchart[2], M. Fantauzzi[2], J. Baker[3], M. Kirby-Allen[3], V. Blanchette[3], J. Pugi[3], J. Langer[4], M. Carcao[3].* 1) PreventionGenetics, Marshfield, WI; 2) Department of Nursing, Hospital for Sick Kids, Toronto, Canada; 3) Division of Haematology/Oncology, Hospital for Sick Kids, Toronto, Canada; 4) Division of General Surgery, Hospital for Sick Kids, Toronto, Canada.

Hereditary spherocytosis (HS) is form of hemolytic anemia that affects 1 in 3,000 individuals. The *ANK1, SPTB, SLC4A1, SPTA1,* and *EPB42* genes encode proteins important for maintaining the membrane cytoskeleton allowing normal red blood cells to adopt a biconcave disk morphology. Mutations in these genes lead to HS which can be inherited in both autosomal dominant and recessive manners. Despite HS being a common form of hemolytic anemia, the mutations resulting in HS are incompletely defined. Here we present genetic findings, including genotype and presumed inheritance patterns, from 80 patients with HS. In collaboration with Sick Kids Hospital (Toronto, Canada), we conducted Next Generation sequencing for the *ANK1, SPTB, SLC4A1, SPTA1,* and *EPB42* gene and characterized variants based on ACMG guidelines. All pathogenic, likely pathogenic, and variants of uncertain significance were verified by Sanger sequencing. Potential molecular causes of HS were identified in 70 of 80 patients with 65 mutations being novel. The majority of mutations characterized were private truncating (nonsense, frameshift, or splicing) defects within the *ANK1* and *SPTB* genes resulting in autosomal dominant forms of the disease. In one case we were able to identify a deletion encompassing exons 18-26 in the *ANK1* gene using Next Generation sequencing data. This deletion was confirmed using end point PCR to characterize the precise breakpoints for the deletion. Interestingly, there were 12 cases where mutations were identified in two genes. With these genes participating in the spectrin membrane anchoring complex, it is possible that corresponding mutations both contribute to disease. In all, understanding the genetic etiology for HS families is important for determining modes of inheritance and aiding in the genetic counseling for prospective parents. Importantly, our results are one of the most comprehensive genetic analyses for an HS cohort to date and will add to the growing mutation databases for these genes.

2296W

An update on the diagnostics, phenotype and treatment of deficiency of ADA2 (DADA2). *N. Deuitch, Q. Zhou, A. Ombrello, D. Stone, T. Romeo, A. Jones, D.I. Kastner, I. Aksentijevich.* Inflammatory Disease Section, National Human Genome Institute, Bethesda, MD.

DADA2 is a recessively inherited disease caused by loss-of-function mutations in the *CECR1* gene, which encodes adenosine deaminase 2 (ADA2). Patients present with fevers, rashes, polyarteritis nodosa (PAN) and/or recurrent ischemic strokes leading to neurological impairment. Although the precise molecular mechanism of this disease is not clear, it appears that in addition to its deaminase activity, ADA2 plays an important role in the development of hematopoietic cells. We performed Sanger sequencing of all 9 exons of *CECR1* in the patients and unaffected family members. RT-PCR and cDNA sequencing was done in patients who carry only one coding mutation in the gene to evaluate the presence of both alleles. We tested serum ADA2 enzyme activity in patients using a modified kit from Diazyme. Since our initial publication we have expanded our cohort to include 39 patients, 33 of whom carry bi-allelic homozygous or compound heterozygous mutations in *CECR1*. The remaining patients carry only a single detectable pathogenic mutation suggesting the presence of non-coding and genomic deletion disease-causing variants. We identified 26 mutations, 16 of which had not previously been associated with DADA2. All variants were rare and reported at low frequencies (<.001) in the ExAC, dbSNP, 1000 Genomes, and ClinSeq databases, consistent with the recessive inheritance. All variants were predicted to be damaging by bioinformatics tools and likely affect catalytic activity and protein stability. The 15 patients tested for ADA2 activity were found to have significantly decreased protein activity compared to healthy age-matched controls and unaffected family members. This biochemical test could be used to support the clinical diagnosis of DADA2, particularly in cases of patients with only one demonstrable disease-causing variant. We have also expanded the spectrum of phenotypes associated with DADA2 to include skin nodules diagnosed as erythema nodosum, digital osteolysis, medium vessel vasculitis, hematuria, ischemic bowel disease and immunodeficiency. Treatment with TNF inhibitors efficiently reduced inflammation. 12 patients had experienced at least one ischemic stroke. Over a collective 1,064 patient months before treatment these 12 patients had a total of 46 strokes. In the 323 post-treatment patient months there have been no strokes. We have established the use of anti-TNF medications as the standard of care for all DADA2 patients in our clinic. .

2297T

Inherited hemoglobin disorders are associated with high serum hepcidin concentrations in Cambodian women of reproductive age. *C.D. Karakochuk[1,2], M.K. Barker[1,2], K. Naguib[1,2], R. Devenish[3], C. Oberkanins[4], H. Puhringer[4], R.E. Aleliunas[2,5], A.M. Devlin[2,5], T.J. Green[6,7].* 1) Human Nutrition, University of British Columbia, Vancouver, British Columbia, Canada; 2) Child and Family Research Institute, Vancouver, British Columbia, Canada; 3) National Pediatric Hospital, Phnom Penh, Cambodia; 4) ViennaLab Diagnostics GmbH, Vienna, Austria; 5) Pediatrics, University of British Columbia, Vancouver, British Columbia, Canada; 6) Pediatrics and Reproductive Health, University of Adelaide, Adelaide, Australia; 7) Division of Healthy Mothers, Babies and Children, South Australian Health and Medical Research Institute, Adelaide, Australia.

   Background: Certain inherited hemoglobin (Hb) disorders are associated with altered iron metabolism. Our aims were to assess the frequency of deletions and/or mutations in the 4 α-genes (*HBA1*, *HBA2*) and 2 β-genes (*HBB*) encoding Hb, and to compare hepcidin (a peptide that regulates iron metabolism) concentrations among women with normal and abnormal Hb genotypes in Cambodia. **Methods:** This analysis includes 263 randomly chosen women of 809 who were participating in a larger trial investigating the causes of anemia from Kampong Chhnang province, Cambodia. To be eligible for the trial, women had to be non-pregnant, between 18-45 y, and have a Hb <117 g/L based on a portable hemoglobinometer. Hb (g/L) was measured on a fasting venous blood sample using an automated hematology analyser (Sysmex XN-1000). Serum hepcidin (nmol/L) was measured using an immunoassay kit (DRG International, USA). Hb typing for Hb variants was assessed using capillary Hb electrophoresis using a MINICAP analyser (Sebia, France). DNA extracted from buffy coat was assessed for 21 α-globin gene deletions and point mutations using a StripAssay® SEA kit (ViennaLab Diagnostics, Austria). **Results:** Mean ± SD age of women was 30 ± 8 y, 66% of women had 1-2 children. Overall, mean ± SD Hb was 118 ± 13 g/L, anemia prevalence (Hb <120 g/L) was 47% (*n*=124/262), and median (IQR) hepcidin was 6.1 (1.7, 11.4) nmol/L. A total of 72% (*n*=189/263) of women had some type of abnormal Hb, with 4 variant Hb types identified by Hb electrophoresis (Hb E, CS, H and F) and 7 α-gene deletions/mutations identified by the α-globin Strip Assay® (-3.7, -4.2, --SEA, Hb CS, Hb QS, Hb PS, and anti -3.7). The Hb E trait (β^{E}β) and α-3.7 trait (-3.7α/αα) were most common (24% and 13%, respectively). Median (IQR) hepcidin concentrations were over twice as high among women with an abnormal Hb genotype (6.7 [2.9, 12.7] nmol/L), as compared to women with a normal Hb (3.1 [0.4, 8.9] nmol/L; p<0.0001). **Interpretation:** We highlight the high frequency and diverse heterogeneity of Hb disorders among Cambodian women. Serum hepcidin concentrations were significantly higher among Cambodian women with an abnormal Hb genotype, as compared to women with normal Hb. When hepcidin levels are high, iron becomes trapped in cells and dietary iron absorption is reduced, which may alter iron utilization and iron availability in the body. This has implications for the accurate measurement and interpretation of iron biomarkers in this population.

2298F

Genetic features of myelodysplastic syndrome and aplastic anemia in pediatric and young adult patients. *S.B. Keel[1], A. Scott[2,3,4], M. Sanchez-Bonilla[5], P.A. Ho[2,3,4], S. Gulsuner[6], C.C. Pritchard[7], J.A. Abkowitz[1], M.C. King[6], T. Walsh[6], A. Shimamura[5].* 1) Medicine, Division of Hematology, University of Washington, Seattle, WA; 2) Clinical Research Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Pediatric Hematology/Oncology, Seattle Children's Hospital, Seattle, WA; 4) Pediatrics, University of Washington, Seattle, WA; 5) Boston Children's Hospital, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA; 6) Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 7) Laboratory Medicine, University of Washington, Seattle, WA.

   Clinical and histopathological distinction between the inherited versus acquired bone marrow failure (BMF) or myelodysplastic syndromes (MDS) is challenging. To determine whether a subset of pediatric and young adults undergoing hematopoietic stem cell transplantation for aplastic anemia (AA) or MDS have germline mutations in BMF/MDS genes, we performed a targeted next-generation genetic screen of peripheral blood DNA samples from children and young adults with AA or MDS obtained from a biorepository of patients transplanted at the Fred Hutchinson Cancer Research Center and retrospective chart review. Pathogenic variants were validated by Sanger sequencing and confirmed as constitutional by sequencing DNA isolated from a second tissue or by chromosome fragility testing of patient-derived lymphoblasts. Compound heterozygous variants were confirmed to be in trans by subcloning and Sanger sequencing. Mutations in inherited BMF/MDS genes were found in 5.1%(5/98) of AA patients and 13.6%(15/110) of MDS patients. While the majority of mutations were constitutional, a *RUNX1* mutation present in the blood at a fifty-percent variant allele fraction was confirmed to be somatically acquired in one MDS patient, highlighting the importance of distinguishing germline versus somatic mutations by sequencing DNA from a second tissue or from parents. Pathologic mutations were present in *DKC1, MPL,* and *TP53* among the AA cohort, and in *FANCA, GATA2, MPL, RTEL1, RUNX1, SBDS, TERT, TINF2,* and *TP53* among the MDS cohort. Family history or physical exam failed to reliably predict the presence of germline mutations. Only 2 of the 5 AA patients with mutations had a physical anomaly and only 1 patient had a family history of cancer or a related phenotype. Among the MDS cohort, only 3 of the 14 patients with mutations had a physical anomaly and while patients with mutations were more likely to have a positive family history of cancer or a related phenotype than those patients without mutations [71%(10/14) vs. 49%(47/96)], the absence of a family history did not exclude the possibility of a mutation. The identification of these inherited disorders can inform donor selection, family counseling, transplant preparatory regiment selection, and surveillance for disease-specific extrahematopoietic complications. Our work suggests that genetic screening to evaluate inherited BMF/MDS genes collectively should be considered in pediatric and young adults presenting with AA and MDS.   .

Genetic susceptibility to neonatal group B streptococcal disease. *A. Borghesi[1,2,3], S. Asgari[1,2], C.W. Thorball[1,2], N. Chaturvedi[1,2], I. Mazzucchelli[3], M. Stronati[3], L. Schlapbach[4], J. Fellay[1,2].* 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, Lausanne, Vaud, Select a Country; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Neonatal Intensive Care Unit, San Matteo Hospital, Pavia, Italy; 4) Paediatric Critical Care Research Group, Mater Children's Hospital, Brisbane, Australia.

   Background: group B streptococcus (GBS) or *Streptococcus agalactiae* is the most frequently isolated microorganism in neonatal sepsis. Clinical observation demonstrates that only a small proportion of infants exposed to GBS develops overt disease, suggesting that host determinants play a major role in individual susceptibility. Monogenic disorders causing inborn errors of the innate immune responses to microorganisms are thought to give an important contribution to susceptibility to infectious diseases early in life. **Statement of purpose**: we aim to test the hypothesis that rare or novel genetic variants causing single-gene inborn errors of the protective immunity to GBS account for the individual susceptibility in a subset of patients with neonatal GBS disease. **Methods**: We enrolled otherwise healthy, full-term newborn infants who suffered from life-threatening, late-onset (after 6 days of life) neonatal GBS infection. We performed exome sequencing in 30 patients and their parents when available. After read alignment and variant calling, we ran single variant and gene-based case-control tests, comparing our GBS cases to an in-house control population of 120 individuals. We also prioritized variants by filtering against the ExAC database (keeping only variants with a minor allele frequency < 0.01) and by genetic and functional annotation (keeping only missense or predicted loss-of-function (LOF) variants observed in homozygous or hemizygous state). **Summary of results**: The percentage of the bait regions covered 20x or more was higher than 95% for more than 90% of the samples. Five genes were significantly enriched for potentially deleterious variants in the GBS cohort: *SLC35E2B, OR9G1, MAP2K3, CDK11B, MUC3*. By variant prioritization, we identified 168 LOF or missense variants, including 19 in genes predicted to be involved in primary immunodeficiency by the human gene connectome. Further analysis is needed to explore the *de novo* autosomal dominant and compound heterozygous autosomal recessive genetic models.

Exome sequencing of 200 patients with primary immunodeficiencies: Translational genomics with direct clinical implications. *P. Arts[1], A. Simons[1], E. Yilmaz[1,2], A.R. Mensenkamp[1], W.A. van Zelst-Stams[1], M. van Deuren[3], A.K. Simon[3], J.A. Veltman[1], F.L. van de Veerdonk[3], M.G. Netea[3], A. Hoischen[1].* 1) Department of Human Genetics, Radboud University Medical Center, Nijmegen, Netherlands; 2) Department of Medical Biology, Faculty of Medicine, Akdeniz University, Antalya, Turkey; 3) Department of Internal Medicine and Radboud Center for Infectious Diseases, Radboud University Medical Center, Nijmegen, Netherlands.

   Introduction: Primary immunodeficiencies (PIDs) are severe medical conditions caused by non-redundant defects of innate or adaptive immune responses, leading to recurrent, severe infections. Severely affected PID patients with an unknown genetic defect were referred for diagnostic exome-sequencing. Methods: Exome data of 200 PID cases have been analyzed following these criteria: As a first tier, variation in 301 genes known to cause PIDs are studied using an *in silico* filter during data-analysis. In addition, 131 patients without a genetic diagnosis after step 1 gave permission for exome-wide analysis of the data. In selected cases *in vitro* stimulations of mononuclear blood cells identified cytokine production capacity defects and provided additional functional evidence for the diagnosis. Results: Diagnostic exome analysis revealed (likely) pathogenic mutations in known PID genes in 32 cases (19%). Exome-wide analysis led to identification of additional causative mutations in 9 patients, for which underlying genes have a known role in specific immunological sub-pathways. One example with direct clinical implication of this approach was the characterization of a genetic, and IFNγ production defects in a patient with recurrent mucocutaneous HSV infections. For this patient IFNγ replacement therapy successfully prevented infections. Conclusion: Exome sequencing can provide a genetic diagnosis in a significant number of patients with PIDs. It is important to perform exome-wide analyses after an analysis of the known PID genes because many new PID genes are only just being discovered. The molecular diagnosis provided novel insight in therapeutic options for a subset of our patients.

2301F

Mutational spectrum of a series of mexican patients with hereditary angioedema: Report of three novel mutations in *SERPING1* **gene.** *D.E. Cervantes-Barragan[1], M.J. Gaytan Garcia[1], J.I. Navarrete Martinez[1], A. Limón Rojas[2], A. Lupian Sanchez[2], F. Campos Romero[3].* 1) Genetics, Hospital Central Sur de Alta Especialidad, Mexico city, Mexico city, Mexico; 2) General Dictatorate, Hospital Central Sur de Alta Especialidad, Mexico city, Mexico city, Mexico; 3) Allergy, Hospital Central Sur de Alta Especialidad, Mexico city, Mexico city, Mexico.

Hereditary angioedema (HAE) is an autosomal dominant inheritance disease with a worldwide prevalence of 1:50.000, to date there are over 300 known mutations in C1- inhibitor (*SERPING1*) gene that means a decreased levels or funtion in the first component of the complement pathway, increased production of bradikinin and restrict the action of factor XII an Kallikrein. The phenotype is characterized by recurrent attacks of severe swelling of limbs, face, intestinal tract, genitals and airway, tipically without hives, 89 % have prodromal symptons like a non itchy rash, called *erythema marginatum*, flu-like, nausea, fatigue, rumbling, and tingling caused by minor trauma, infections, drugs but often with out an specific trigger. The aim of the study is to report 3 novel mutations in 5 patients with hereditary angioedema. Sequencing and MLPA was performed in the 5 patients. The molecular analysis revealed, two novel deletions c.116delA (p.Asp39Alafs*40) in exon 3, c.773delA(p. Asn258Thrfs*21) in exon 5, and a missense variant c.1328A>C (p.Hys443Pro) in exon 8. This three reports are added to the previous *SERPING1* mutations. Genotype-phenotype correlations are important for prognosis and treatment for these patients. .

2302W

Identification of novel candidate genes for susceptibility to tuberculosis by identifying disease-causing mutations in individuals with PIDs. *E.G. Hoal[1], N. Schlechter[1], M. Möller[1], P.D. van Helden[1], M. Schoeman[1], M. Urban[1], M. Esser[2], A. Franke[3], C.J. Kinnear[1].* 1) Mol Biol & Hum Genetics, Stellenbosch Univ, Tygerberg, Western Cape, South Africa; 2) Pathology, Stellenbosch Univ, Tygerberg, Western Cape, South Africa; 3) Institute for Clinical Molecular Biology, Christian-Albrechts University, Germany.

Although approximately 33% of the world's population is infected with *M.tuberculosis*, the causative agent of tuberculosis (TB), only 10% of infected individuals will develop active disease. While the genotype of invading strain and environmental factors are crucial in disease outcome, host genetic factors can be decisive. Several investigations have successfully identified genes involved in TB susceptibility. Nevertheless, it is certain that more susceptibility genes exist, but identifying them in a complex disease such as TB is challenging. Answers may lie in the genomes of individuals suffering from a group of inherited primary immunodeficiency disorders (PIDs) for which multiple *M.tuberculosis* infections is a common feature. We hypothesize that the genes involved in these PIDs could be candidate genes for increased TB susceptibility in the general population. We aimed to identify novel TB susceptibility genes by finding gene mutations in patients suffering from PIDs characterized by increased TB susceptibility. The exomes of three PID patients as well as their healthy parents, where possible, were sequenced using the Illumina HiSeq. Bioinformatic techniques were used to identify a large number of variations from the reference human genome for each patient. We prioritized the genes based on OMIM and HGMD database entries which resulted in the identification of three novel putative disease-causing variants, one per patient, situated in two novel susceptibility genes namely Mitogen-activated protein kinase kinase kinase 14 (*MAP3K14* [MIM 604655]) and Transporter associated with antigen presentation (*TAP1* [MIM 170260]). Functional studies are currently being done to investigate their involvement in disease, after which case-control association studies will be conducted in a cohort of TB patients and healthy controls. The identification of these disease-causing mutations can provide us with novel candidate genes to screen for TB susceptibility in the general population.

2303T

Mendelian genetic studies of immune disorders to identify novel targets for therapeutic intervention. *J. McElwee[1], J. Maranville[1], J. Hughes[2], Y. Huang[1], M. Jordan[4], S. Snapper[5], W. Dunn[5], J. Ouahed[5], M. Lenardo[7], Y. Zhang[7], H. Su[7], J. Milner[7], J. Cohen[7], H. Matthews[7], J. Lyons[7], G. Sun[7], X. Yu[7], R. Goldbach-Mansky[3], A. Almeida de Jesus[3], Z. Deng[3], Y. Liuv[3], R. Geha[6], J. Chou[6], H. Runz[1].* 1) Genetics and Pharmacogenomics, Merck Research Labs, Boston, MA; 2) Computational Genomics & Genetics, Merck Informatics IT, Boston, MA; 3) National Institute of Arthritis and Musculoskeletal and Skin Diseases, NIH, Bethesda, MD; 4) Divisions of Immunobiology and bone marrow transplant and immune deficiency, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) Inflammatory Bowel Disease Center, Boston Children's Hospital, Boston, MA; 6) Division of Immunology, Boston Children's Hospital, Boston, MA; 7) National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD.

Mendelian disorders that selectively affect the immune system provide a means to identify and understand new genes and pathways involved in human immunology which could represent new routes for therapeutic intervention for human disease. As part of a collaborative effort to identify novel therapeutic opportunities in immunobiology, Merck Research Labs and a network of investigators from the NIH Clinical Center, Boston Children's Hospital, and Cincinnati Children's Hospital Medical Center, have undertaken focused studies of Mendelian forms of primary immunodeficiencies, syndromic atopic disease, very-early onset inflammatory bowel disease, and severe auto-inflammatory conditions using whole-exome (WES) and/or whole-genome (WGS) sequencing approaches. Thus far, we have sequenced 1445 subjects representing 520 independent kindreds exhibiting a range of suspected Mendelian immune diseases. As part of these studies, we have sequenced 208 samples from 42 kindreds using both WES and WGS. While WGS provides clear technical superiority in a number of areas, we find that it did not lead to substantial improvements in the discovery of causal genes in our cohort for unsolved kindreds previously sequenced using WES. Within our cohort, we have used Mendelian filtering techniques, further supported by extensive molecular and cellular validation studies, to successfully identify causal mutations in known and novel immune genes for over 20% of kindreds that have been analyzed to date. From these studies, we have identified and characterized a number of new genes important for immune function and causal for human immune disease, such as LRBA, CTLA4, PIK3R1, and STAT3. Additional novel causal genes and high-quality candidates in several families are currently being functionally validated, and several novel mechanisms are being explored as therapeutic targets for autoimmune disease. We will present an overview of our recent novel discoveries, a comparison of WES and WGS approaches, and our experience of Mendelian genetic studies in this unique discovery cohort.

2304F

Biallelic missense mutations in *NSMCE3,* **encoding a subunit of the SMC5/6 complex, cause a chromosome breakage syndrome with severe lung disease.** *G. van Haaften[1], S.N. van der Crabben[1], M.P. Wheeler[3,4], J.J. Palecek[7], A.R. Lehmann[2], A.W. Oliver[2], L.H. Pearl[2], S.E. Plon[3,4,5,6], J.M. Murray[2].* 1) University Medical Center Utrecht, Utrecht, the Netherlands; 2) Genome Damage and Stability Centre, School of Life Sciences, University of Sussex, Falmer, Brighton, United Kingdom; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston TX, USA; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston TX, USA; 6) Texas Children's Hospital, Houston TX, USA; 7) Central European Institute of Technology and Faculty of Science, Masaryk University, Brno, Czech Republic.

We describe a new chromosome breakage syndrome associated with severe lung disease in early childhood. Four children from two unrelated kindreds died during infancy of severe pulmonary disease following viral pneumonia with evidence of combined T- and B-cell immunodeficiency. Whole exome sequencing revealed biallelic missense mutations in the *NSMCE3* gene encoding a subunit of the SMC5/6 complex, essential for DNA damage response and chromosome segregation. The *NSMCE3* mutations disrupt interactions within the SMC5/6 complex, leading to destabilization of the complex. Patient cells showed chromosome rearrangements, micronuclei, sensitivity to replication stress and DNA damage, and defective homologous recombination. This study is an example of the power of genematcher.org in uniting researchers studying rare genetic diseases.

2305W

Somatic mosaicism of an intragenic duplication in X-linked *FANCB* observed in a Fanconi anemia patient and his mother, leads to an unusual phenotype. *S.C. Chandrasekharappa[1], A.D. Auerbach[2], F.P. Lach[2], D.C. Kimble[1], F.X. Donovan[1], J. Thomas[1], M. Park[1], P. Chines[1], A. Vlachos[3], A. Smogorzewska[2], R.S. Asur[1].* 1) National Institutes of Health, Bethesda, MD; 2) The Rockefeller University, New York, NY; 3) Hofstra Northwell School of Medicine, New Hyde Park, NY.

Fanconi anemia (FA) is a rare, mostly recessive, disorder characterized by congenital malformations, progressive bone marrow failure, and predisposition to cancer. FA is a genetically and phenotypically heterogeneous disorder, with 19 known FA genes. Patients harboring X-linked *FANCB* mutations usually present with a severe clinical phenotype, resembling VACTERL syndrome with hydrocephalus. We describe here a patient determined to be complementation group FA-B by rescue of crosslink hypersensitivity of patient fibroblasts by expression of *FANCB*, with much milder phenotype (cafe-au-lait spots, failure to thrive, hypopigmented skin patches, tracheomalacia, no hematologic manifestations at age 12 yrs.). The patient exhibited mosaicism detected during the DEB test, a diagnostic for FA, where patient LCLs were resistant to DEB while fibroblasts were sensitive. Employing aCGH and targeted next-gen sequencing, we identified an intragenic duplication in *FANCB*. The 9154 bp duplication included the first coding exon, exon 3, and the flanking intronic regions (chrX:14877976-14887129). Presence of a 4 bp homology (GTAG) at both ends of the breakpoint appears to indicate the duplication may have been mediated via the alt-EJ mechanism. A ddPCR assay was developed for the junction region to evaluate the extent of the duplication. The duplication was present in 90% of the patient fibroblast cell line but in only 5% of the patient LCL. This is consistent with the DEB test, indicating that the allele with duplication has reverted back to wild-type (WT) in LCL and, to a lesser extent, in fibroblast cells. The assay also detected the duplication in DNA from the mother, which also exhibited a similar mosaic reversion in which only 22% of DNA carried the duplication. RT-PCR of RNA from patient fibroblast cells showed the WT transcript, along with an aberrant transcript, 1 kb larger. PacBio sequencing of the larger transcript revealed the aberrant transcript had insertion of the entire exon 3, predicted to introduce a stop codon at the junction. Unlike sequence variants, duplications are difficult to define precisely and quantitate accurately. We demonstrate that detailed characterization of the disease-causing variant is critical for better understanding the patient phenotype.

2306T

Modeling dyskeratosis congenita in the mouse. *C. Keegan[1], K. Bisht[2], J. White[1], J. Chase[3], G. Balbin-Cuesta[3], S. Savage[4], J. Nandakumar[2], I. Maillard[3].* 1) Dept. of Pediatric Genetics, Univ Michigan, Ann Arbor, MI; 2) Dept. of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI; 3) Dept. of Internal Medicine, University of Michigan, Ann Arbor MI; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD.

Dyskeratosis congenita (DC [MIM 127550]) is a telomere biology disorder characterized by hematopoietic failure and classically associated with the clinical triad of oral leukoplakia, dysplastic nails, and pigmentary skin changes. Classic DC is caused by mutations in telomerase genes (*TERC* and *TERT*) and associated proteins (*DKC1*). In recent years, the clinical spectrum of DC has expanded to include rare, severe variants such as Hoyeraal Hreidarsson (HH) syndrome, and more common variants such as aplastic anemia and pulmonary fibrosis that can present during adulthood. Likewise, the genetic spectrum has expanded to include proteins that regulate telomerase trafficking, replication, stability and telomere length. Shelterin is a six-protein complex that regulates access of telomerase to telomeres and protects chromosome ends from unregulated DNA repair. Mutations in two shelterin components, *TINF2* and *ACD*, have been identified in individuals with DC. Although the basic mechanisms by which shelterin protects telomeres have been identified, the pathogenic mechanisms that lead to DC phenotypes remain largely unidentified. The goal of this project is to dissect the in vivo mechanisms leading to expression of the DC phenotype by modeling human DC mutations in the mouse, both by studying the function of hematopoietic stem and progenitor cells expressing specific shelterin protein variants and by engineering these variants into the mouse genome. Our group previously identified biallelic mutations in *ACD* in a family with HH syndrome, c.508_510delAAG (p.K170del) and c.1471A>C (p.P491T), which affect recruitment of telomerase and binding to TIN2, respectively. Using CRISPR/Cas9 genome editing, we have generated a mouse line with a mutation in the orthologous residue (K82) in mice, and we are in the process of generating P491T (P365T) in mice. Homozygous K82del mice are viable and exhibit no identifiable external phenotype. Because mice have longer telomeres than humans, we predict that we will observe a DC-like phenotype in successive generations, and these crosses are in progress. We have also followed the growth of K82del/+ intercross mice and have found that homozygous K82del mice exhibit increased weight gain compared to K82del/+ and +/+ mice beginning at age 2-3 months. Modeling specific human mutations in the mouse will provide a better understanding of the in vivo mechanisms that lead to phenotypes within the DC spectrum. Supported by R01-AG050509.

2307F

Assessment of risk of developing pancreatic risk with ATM gene mutation based on the genetics of hereditary pancreatitis by using saliva: A multi-center evaluation. *S. Singh[1], S. Ghavimi[2], H. Azimi[4,5,8], J. Brown[3,4], A. Razavi[5,7], P. Sealy[2], A. Afsari[2], S. Emmamian[6], A. Asghar Kolahi[9].* 1) Internal Medicine , University of Illinois at Chicago , Chicago , IL; 2) Howard University Hospital, Department of Medicine, Washington, DC; 3) Carleton University, Division of Human Science, Ottawa, Ontario, CA; 4) PsychoGenom, Ottawa, Ontario, CA; 5) Genomics On Call, Washington DC; 6) University of Indiana, Department of Health Sciences and Physics, Bloomingdale, IN; 7) Islamic Azad University of Tehran, Tehran, Iran; 8) University of Ottawa, Ottawa, Ontario, CA; 9) Shaheed Beheshti School of Medicine, Genetic statistician, Tehran, Iran.

   Objective: To evaluate the genetics of hereditary pancreatitis (HP) in adult patients with Chronic pancreatitis, and heterozygous mutations of ATM gene. **Methods:** This outpatient study was conducted on 200 Patients, of whom (n=100) from Psychogenome, Canada, and (n=100) came from Tajrish's Hospital, which wore diagnosed with Chronic Pancreatitis. We examined the patients and their parents for Hereditary Pancreatitis. HP defined as those with trypsinogen gene (PRSS1) mutation on the long arm of chromosome seven (7q35), and Heterozygous ATM mutation was defined with those with 1 or more mutations in our panel [(8 variants) 5762ins137, 5762-1050A>G, E1978*, Q1970*, R2506Tfs*3, R35*, c.3576G>A, c.7638_7646del9, p.H1082Lfs*14). Patients were also categorized in groups of having mutation in their ATM gene DNA was extracted from peripheral blood leukocytes, and exons 2 and 3 of the gene of PSSR2 and exon 2-6 of ATM were individually amplified by polymerase chain reaction and sequenced by NGS. **Results:** Of 200 adult patients with pancreatitis (median age 55), 64 (32%) were diagnosed with adult onset of HP. From the 64 patient with positive mutation on the trypsinogen (PRSS1) gene, 34 of them had one parent with mutation of the trypsinogen gene (PRSS1). The route of inheritance is Autosomal Dominant. From the 34 adult patients who had parents with the mutations of the trypsinogen gene (PRSS1), and 37 (19%) were heteroz, for ATM gene mutation, 39 (61%) recalled of their babies or young children, with having been diagnosed with epigastric pain, severe vomiting and nausea both after birth and during early childhood. From the 37 patients who wore diagnosed with having the mutations in the ATM, (PRSS1) gene and HP, 11 (30%) indicated that one of their parents has been deceased or currently diagnosed with Pancreatic Cancer. From this 37 patients with (HP) and genetic mutations of ATM and PRSS1 gene 14 (38%) also had Type 1 Diabetes Mellitus, 7 (19%) had a sibling or family member which was diagnosed with breast cancer and 4 (11%) had colorectal cancer. **Conclusions:** Patients with HP who have a heterozygous mutation of the ATM gene have a higher incident of developing Pancreatic Cancer. We suggest GI-Fellows and physicians to work closely with genetic counselors for families with history of HP or pancreatitis and cancer . Better risk models and Genetic panel screening will help for a precise diagnostic and preventive interventions early in the life of individual patients.

2308W

Hypomorphic autosomal dominant polycystic kidney disease (ADPKD): A rare case of lethal biallelic ADPKD and asymptomatic heterozygotes. *A.L. Goetsch[1], B. Angle[2], S. Peters[3], M.J. Hussey[4], J.C. Lane[5].* 1) Genetics, Birth Defects & Metabolism, Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL; 2) Pediatric Genetics, Advocate Lutheran General Hospital, Park RIdge, IL; 3) Genetic Medicine, Northwestern Medicine, Winfield, IL; 4) Maternal Fetal Medicine, Northwestern Medicine, Winfield, IL; 5) Nephrology, Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL.

   Autosomal Dominant Polycystic Kidney Disease (ADPKD) is one of the most common genetic conditions with prevalence of 1:400 to 1:1000. The disease is considered nearly 100% penetrant. Typically, adults over 30 years of age known to have pathogenic variants in *PKD1* and *PKD2* are found to have bilateral renal cysts. It has been established in the literature that rare *biallelic* inheritance of *PKD1* pathogenic variants mimic Autosomal Recessive Polycystic Kidney Disease (ARPKD) within families characterized by otherwise typical ADPKD. To our knowledge, individuals reported with *biallelic* ADPKD have at least one affected parent. We describe an infant with lethal *biallelic* ADPKD and two unaffected heterozygote parents, thus supporting the theory of *hypomorphic* alleles in ADPKD.   Prenatal ultrasound was significant for enlarged, echogenic kidneys with oligohydramnios and hydrops fetalis, findings typically consistent with ARPKD. Prenatal testing was inconclusive, as a single paternally inherited variant of uncertain clinical significance in *PKHD1* was identified (c.275G>A, p.Arg92Gln). The infant was born at 30 2/7 weeks gestation due to premature labor. His health was complicated by kidney failure, respiratory failure due to pulmonary hypoplasia, and congenital heart defects. The infant died on day of life four. His autopsy was significant for large kidney size (493g) with presence of glomerulocystic disease (GKD). These findings were suggestive of either ADPKD or isolated GKD in the absence of specific syndromic features. Additional genetic testing revealed two novel likely pathogenic variants in *PKD1* (c.5480G>A, p.Gly1872Glu; c.6542A>G, p.Tyr2181Cys). Parental studies confirmed the infant inherited the *PKD1* variants in *trans*. At this time, both parents are in good health with no evidence of renal cysts on ultrasound imaging. Their two living children and current pregnancy are known to carry the *PKD1* c.6542A>G (p.Tyr2181Cys) likely pathogenic variant. All family members are currently undergoing appropriate ADPKD surveillance given the lack of data on *hypomorphic* alleles in ADPKD.   In summary, this case supports the possibility of *hypomorphic* alleles in ADPKD, such that *PKD1* variants with reduced or incomplete penetrance in heterozygotes can present as lethal disease in compound heterozygotes. It raises the need for additional research to determine appropriate medical management guidelines and genetic counseling for seemingly asymptomatic heterozygotes.

2309T

Molecular characterization of Peruvian families with Fabry Disease. *G. Manassero-Morales, K. Franco-Bustamante.* Genetics, Instituto Nacional de Salud del Niño San Borja, Lima, Lima, Peru.

  Introduction: Fabry disease [MIM 301500], is a progressive, X-chromosomal inherited lysosomal storage disorder, of the catabolism of glycosphingolipids produced by a deficit of lisosomal enzyme α-galactosidase A (α-GAL A). The Human Gene Mutation Database, Fabry mutation database, and Clin Var database have hundreds of mutations of GLA gene encoding α-GAL A registered. The estimated incidence of Fabry disease is □1 in 50,000 males in the world; although the incidence or prevalence in Perú has not been estimated. **Objective:** To present the molecular characterization of fourteen Peruvian families with Fabry disease. **Methods:** A screening program using α-GAL A activity in Blood Spot was performed in patients undergoing hemodialysis at the largest hospitals in the country; sixteen patients had reduced enzyme activity confirmed in leukocytes. Complete molecular analysis of the GLA gene showed mutations in fourteen patients. A family tree was built for each proband including all members of at least four generations; enzymatic and molecular familial mutation targeted testing was performed in all available at risk family members. **Results:** Of the fourteen mutant alleles found in these families, eleven different mutations were identified; three families shared mutations (p.D109G, p.K130 and p.R363H). Four novel mutations were detected, (p.G35A, p.I64F, p.K130T and p.G171S). Of the 364 at risk members tested for their specific familial mutation, 128 (35.16%) heterozygous cases were detected, from which, 44 (34.37%) were male patients and 84 (65.63%) female. Twenty male patients and one symptomatic woman are actually undergoing Enzyme Replacement Therapy (ERT). Results are summarized in table 1. **Conclusions:** The molecular GLA full gene analysis in fourteen Peruvian families showed eleven different genotypes; four novel mutations were found. Results confirm the importance of pedigree analysis as a useful tool to determine at risk family members in order to identify symptomatic patients and recommend early replacement treatment. **Disclosure:** This study was sponsored by Sanofi-Genzyme.

Table 1: Genotype characterization in Peruvian Families with Fabry Disease						
Family	Genotype	Members at risk tested	Heterozygous mutation detected	Male	Female	ERT
1	M1T	78	19	10	9	12
2	R363H	52	22	9	13	1
3	G171S	5	3	1	2	1
4	M1K	18	4	1	3	2
5	D109G	21	10	5	5	3

Identification and molecular modeling of novel mutations in Congenital Adrenal Hyperplasia patients (*CYP21A2* **gene).** *R. Prasad[1], R. Khajuria[1], R. Walia[2], A. Bhansali[2].* 1) Biochemistry, PGIMER, Chandigarh, Chandigarh, India; 2) Endocrinology, PGIMER, Chandigarh, Chandigarh, India.

  Congenital Adrenal Hyperplasia (CAH) is autosomal recessive disease, with a wide range of clinical manifestations from severe classical form to late onset form. Most cases of CAH, the inherited inability to synthesize cortisol, aldosterone with subsequent overproduction of androgens, are caused by mutations in steroid 21 Hydroxylase enzyme encoded by CYP21A2 gene. Our aim was to identify novel mutations subsequently their functional implication in enzyme by in silico analysis in 55 patients. Novel mutations were identified by SSCP technique and subsequently sequencing of amplified product. Multiple sequence alignment (MSA) was done to evaluate the functional impact of the regions where novel mutations were present. Functional implication of novel mutations was analysed by various mutation severity prediction softwares. 3-D analysis of the interaction of wildtype and mutant amino-acid with other interacting partners within enzyme was analysed by swiss-PDB viewer. We identified 4 novel mutations viz., F306V, D234D, P357P and H365N.They accounted for 1.8% in Indian population. It was deduced after the alignment that Histidine in case of H365N mutant is present in conserved region and is involved in binding of 21-OHase enzyme to heme. Histidine at 365 position is conserved in different species. Although phenylalanine at 306 position is not conserved residue as seen by the result of multiple sequence alignment by CLUSTAL W but this residue lies in the region forming I-helix of the protein. The I-helix of the protein is involved in substrate recognition. The severity prediction softwares viz., PROVEAN, SIFT and PolyPhen predicted novel mutations to be deleterious, affect protein function and probably damaging to the protein. 3D structure of 21-hydroxylase depicted that Histidine at 365 position interacts with the heme- ligand. Upon substitution with asparagine i.e.H365N, the interaction between heme and the mutated amino acid residue is interrupted leading to unstable protein. Phenylalanine at 306 position is illustrated that upon substitution with valine that causes interruption in interaction as present in wild type protein. Disruption of the π-π stacking interaction among the interacting amino acid residues W302, F306, and F304 with F306 prevent stable packing interactions. Hence, the relevant information about the mutation severity can be acquired from the bioinformatic tools within a period of time.

Association of airway abnormalities with 22q11.2 deletion syndrome.
R. Sacca[1], K.B. Zur[2,4], K.D. Valverde[1], D.M. McDonald-McGinn[3,4]. 1) Genetic Counseling Master's Program, Arcadia University, Glenside, PA; 2) Pediatric Voice Program and The Center for Pediatric Airway Disorders, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) 22q and You and Clinical Genetics Centers, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) The Perelman School of Medicine of the University of Pennsylvania, Philadelphia, PA.

Background: 22q11.2 Deletion Syndrome (DS) presents with complex but variable symptoms most frequently including cardiac, immune, palatal, endocrine, cognitive and psychiatric issues. Structural airway abnormalities have not been formally described. Given the significant morbidity and mortality observed in patients with 22q11.2DS and symptomatic airway disease, we set to document the frequency of this association. **Methods:** We retrospectively reviewed the medical records of patients with 22q11.2DS evaluated at the Children's Hospital of Philadelphia between 1999 and 2015 who were referred to otolaryngology for an airway assessment. The type of airway abnormality observed and the presence of comorbidities such as congenital heart disease, the incidence of tracheostomies, and association with prenatal polyhydramnios were noted. **Results:** 104 patients who underwent an otolaryngology procedure (laryngoscopy or bronchoscopy) were identified. Of these, 77%, ranging in age from 5 months to 37 years, had airway anomalies. Males and females were equally affected. Findings included: tracheomalacia (35%), subglottic stenosis (27%), laryngomalacia (23%), glottic web (23%) and bronchomalacia (15%). The majority of patients (84%) had an associated congenital heart defect with Ventricular Septal Defect and Tetralogy of Fallot being the most prevalent. Importantly, 28% required a tracheostomy and 18% were noted to have a history of polyhydramnios. **Conclusion:** Our findings suggest that airway abnormalities are a common feature of 22q11.2DS leading to significant morbidity particularly when combined with complex cardiac disease. Further, polyhydramnios may be a useful prenatal clue to the diagnosis of 22q11.2DS with airway anomalies. Lastly, postnatal assessment of airway structure and function should be a key component of the evaluation of patients with 22q11.2DS that will help guide patient management. .

2312T

X-chromosome mutations and deletions in a female with premature ovarian insufficiency.
O. Migita[1,2], N. Shimbashi[3,4], S. Igarashi[3], N. Suzuki[1,3], K. Hata[2]. 1) Department of Clinical Genetics, St. Marianna University School of Medicine, Kawasaki, Kanagawa, Japan; 2) Department of Maternal-Fetal Biology National Research Institute for Child Health and Development, Setagaya, Tokyo, Japan; 3) Department of Obstetrics and Gynecology, St. Marianna University School of Medicine, Kawasaki, Kanagawa, Japan; 4) Nanako Ladies' Clinic, Ota, Tokyo, Japan.

Women with premature ovarian insufficiency (POI) have repeatedly been reported X chromosome abnormalities. X chromosome terminal deletion and FMR1 gene premutation are well known risk factors for POI. But it is still unclear what caused POI. The application of new molecular genetic analyzing technology would be help in resolving unknown mechanisms of POI. Cytogenetic and molecular characterization of POI is also important for understanding which genes are crucial for normal ovarian development. We conducted karyotyping and whole exome sequence to address the mechanisms of POI. Cytogenetic study with 643 female who have been diagnosed POI were done. Whole exome sequencing was used to screen for mutation in 47 POI individuals from unrelated families. Our results show 12.1% of patients have chromosomal abnormalities. X chromosome abnormalities are most often observed, which have reported in previous studies. Partial deletions in long arm of chromosome X support the hypothesis that haploinsufficiency of X-linked genes can be on the basis of POI. We intend to determine the causable genetic factors in X chromosome by next generation sequencing technology. Using exome sequencing to find rare variants that could not be found in control data. It is still unkown whether affective mutations are included in our observed variant, or not. Our exome sequencing had identified 157 candidate variants on X chromosome.

2313F

Rare nephronophthisis related ciliopathy identified by next generation sequencing in ten non-consanguineous families. *N. Morisada[1,2], A. Shono[2], K. Nozu[2], T. Ninchoji[2], K. Nagatani[3], T. Ohta[4], J. Shimizu[5], T. Yoshikawa[6], K. Saida[6], S. Ishimori[7], M. Yasui[8], C. Nagano[9], K. Kamei[6], K. Ishikura[6], S. Ito[10], R. Tanaka[11], K. Iijima[2].* 1) Clinical Genetics, Hyogo Prefectural Kobe Children's Hospital, Kobe, Hyogo, Japan; 2) Pediatrics, Kobe University Graduate School of Medicine; 3) Department of Pediatrics, Uwajima City Hospital; 4) Pediatric Nephrology, Hiroshima Prefectural Hospital; 5) Pediatrics, Okayama Medical Center; 6) Nephrology and Rheumatology, National Center for Child Health and Development; 7) Pediatrics, Kakogawa West City Hospital; 8) Pediatrics, Fukuyama Capital Hospital; 9) Pediatrics, Japanese Red Cross Nagoya Daini Hospital; 10) Pediatrics, Yokohama City University Graduate School of Medicine; 11) Nephrology, Hyogo Prefectural Kobe Children's Hospital.

Purpose Nephronophthisis related ciliopathy (NPHP-RC) is a rare hereditary renal disorder manifested by cystic kidney and end stage renal disease (ESRD) in childhood. The patients of NPHP-RC are often complicated by extra-renal symptoms; such as retinitis pigmentosa, skeletal anomaly, liver disorder, cerebellar anomaly and intellectual disability. More than twenty genes have been reported as the cause of NPHP-RC and most of genes associated with NPHP-RC are autosomal recessive inheritance. The most frequent causative gene in NPHP-RC is *NPHP1*, which account for more than 90% of NPHP-RC. Therefore, the causative genes of NPHP-RC other than *NPHP1* are extremely rare. Comprehensive genetic analysis using next generation sequencing (NGS) may be useful to diagnose of rare NPHP-RC. **Methods** We performed genetic analysis for the patients with congenital anomalies of the kidney and urinary tract (CAKUT), NPHP-RC or cryptogenic ESRD in childhood using NGS. We used TruSight One Sequencing Panel or HaloPlex custom kits for gene targeted analyzing in MiSeq platform. This study was approved by the Institutional Review Board of Kobe University Graduate School of Medicine. **Results** We identified seven genes in 10 patients from 10 non-consanguineous families as candidates for their NPHP-RC. Male to female ratio was 3:7, and average diagnosed age was 7.86 (± 8.55 standard deviation, 0.58-27). Identified genes were *OFD1* (2 patients), *WDR19* (2), *WDR35* (2), *SDCCAG8*, *TMEM67*, *MKKS*, and *NPHP3*. A girl with 4 base pairs deletions in *SDCCAG8* and a woman with *MKKS* splice site mutations showed homozygous mutations. Some boys showed hemizygous mutations in *OFD1* gene. Rest of them had compound heterozygous mutation in each gene. In clinical manifestations, 8 patients in this study fell into ESRD and required renal replacement therapy. Other two patients had cystic kidneys with renal dysfunction. 9 patients showed mild to severe intellectual disability. 4 patients had polydactyly and thoracic deformity. 3 had hepatic disorder. Only one patient had congenital heart anomaly. **Conclusion** We presented the rare NPHP-RC related disorders in Japan. NGS is useful for undiagnosed renal disorders.

2314W

Identification of mutations in *GANAB*, a new gene causing polycystic kidney disease. *C. Ferec[1,2,3,4], S. Mastri[3], A. Bertholet-Thomas[5], M. Hourmant[6], E. Cornec-Le Gall[7], Y. Le Meur[7], J.M. Chen[1,2,4], M.P. Audrézet[1,2,3].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U1078, Brest, France; 2) Faculté de Médecine et des Sciences de la Santé, Université de Bretagne Occidentale (UBO), Brest, France; 3) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Universitaire (CHU) Brest, Hôpital Morvan, Brest, France; 4) Etablissement Français du Sang (EFS) – Bretagne, Brest, France; 5) Néphrogones, Centre de Référence des Maladies Rénales Rares, Hôpital Femme-Mère-Enfant, Bron, France; 6) Service de Néphrologie et Immunologie Clinique, CHU de Nantes, France; 7) Service de Néphrologie, Hémodialyse et Transplantation Rénale, CHU Hôpital de la Cavale Blanche, Brest, France.

Autosomal Dominant Polycystic Kidney Disease (ADPKD; MIM#s 173900, 613095) is the most common form of Polycystic Kidney Diseases (PKD) and one of the most common monogenic diseases. ADPKD is characterized by progressive renal cyst formation during the whole life, ultimately resulting in End Stage Renal Disease (ESRD) (Torres et al. Lancet 2007; Harris and Torres. J Clin Invest 2014). ADPKD is genetically heterogeneous with two genes identified: *PKD1* (16p13.3) which encodes polycystin 1 (PC1) and *PKD2* (4q22) which encodes polycystin 2 (PC2). Very recently, a collaborative study coordinated by Peter C. Harris has recruited 327 ADPKD families in which no mutations in the *PKD1* and *PKD2* genes had been identified. Whole exome sequencing (WES) of six families firstly identified a candidate gene named *GANAB* (11q12.3); the gene encodes the catalytic alpha subunit of glucosidase 11 and is expressed in human kidney and liver. The analysis of the other 321 families then led to the identification of eight additional families carrying *GANAB* mutations (Porath et al. Am J Hum Genet. June 2016). Here we analyzed the *GANAB* gene in some 50 French ADPKD families in which no mutations in the *PKD1* and *PKD2* mutations had previously been identified. We found two obvious loss-of-function mutations in the *GANAB* gene that segregated perfectly with the renal phenotype of the disease in two families. The first is a frameshift mutation, c.2733delC, which was found in a family with three affected patients. The second mutation is a splice mutation, c.39-1G>C, which was identified in a family with four affected patients. In addition, we identified two *GANAB* missense mutations each in a single family. None of the *GANAB* mutation-positive patients have so far developed ESRD and the great majority of them displayed also liver cysts. In summary, our results supported the recent finding that *GANAB* is a new gene causing PKD. All *GANAB* mutation-positive patients had rather small renal cysts and reached no ESRD indicated that these patients may be diagnosed as having atypical ADPKD. Genotype/phenotype correlations using larger independent cohorts will improve our understanding of the etiology of the disease. ADPKD patients with few renal cysts and no enlarged kidneys but having also liver cysts should now be analyzed for mutations in the *GANAB* gene.

2315T

Genetic diagnosis of endocrine disorders: Implications for bench to bedside studies. *S. Birla, E. Malik, An. Sharma, T. Grover, A. Sharma.* All India Institute of Medial Sciences, delhi, New Delhi, India.

Successful translation of molecular research in clinical practice is evident by increasing patient referrals for genetic testing in various medical specialties. Impact of genetics is apparent in endocrine disorders (growth hormone deficiency, obesity, endocrine neoplasias, disorders of sexual dysgenesis, skeletal dysplasias etc) which involve confirmation of diagnosis, treatment, management, prevention, effective surveillance, pre- and post- natal diagnostic identification of genetic causes in rare disorders etc. Ours being a tertiary care referral centre, patients with a variety of disorders are referred for treatment and diagnostic testing. We report here the results of cases referred to our laboratory during the period 2011 to 2016 which either ruled out or supported a diagnosis and thus helped in providing effective patient care. A total of 360 patients were tested for more than twenty genes which include *PRKAR1A* (Carneys complex)*, MC4R* (Obesity), *CYP19A1*(Aromatase deficiency), *MENIN*(Multiple endocrine neoplasia-1)*, RET(*Multiple endocrine neoplasia-2*), CYP21A2*(Congenital adrenal hyperplasia), *XOR*(Xanthine cholelithiasis), *TNSALP*(Hypophosphatasia), *CASR*(Hypocalcemia), *GH1* and *GHRHR* (Isolated growth hormone deficiency), *PROP1, POU1F1* and *HESX1*(Combined pituitary hormone deficiency)*, GHR*(Larons Syndrome)*, SRY, NR5A1, DAX* and *DHH*(Disorders of sexual dysgenesis), *COMP* and *COL9A1*(Multiple epiphyseal dysplasia), *COL2A1*(Spondyloepiphyseal dysplasia), *EXT1* (Hereditary multiple exostosis)and *FGFR3*(Achondroplasia) based on the diagnosis. Molecular analysis revealed novel and reported mutations/variations in 88 (24%) cases which were absent in the control database ExAC as well as in 100 healthy controls screened. Some rare disorders like xanthine cholelithiasis and hypophosphatasia were also analysed but no mutations were identified in the *XOR* and *TNSALP* genes. The patient group comprised more of sporadic compared to familial cases. Novel variations were mostly identified in sporadic cases which need characterization. Primary outcome of the study was creation of a database for the northern part of India, providing information on the mutation/variation pattern and their population-specific distribution. Knowledge of molecular lesions not only contributed towards an effective support secondary to clinical assessment and management but also identification of the novel mutations added to the universal pool of genetic variation.

2316F

De novo **missense mutation in** *GRB10* **in a patient with growth restriction and ketotic hypoglycemia.** *A.E. Koehler[1], P. Sharma[1], G.A. Golas[1], J. Fraser[2], T.C. Markello[1,3], D.R. Adams[1,3], M.C.V. Malicdan[1], W.A. Gahl[1,3], C.J. Tifft[1,3].* 1) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, NIH and National Human Genome Research Institute, NIH, Bethesda, MD; 2) Medical Genetics and Genomics Medicine Training Program, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Office of the Clinical Director, National Institutes of Health and Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Growth factor receptor-bound protein 10 (GRB10) is an adaptor protein that interacts with mitogenic receptor tyrosine kinases. Mutations in *GRB10* have not been definitively linked to a human disorder. Through the NIH Undiagnosed Diseases Program (NIH UDP), we describe a growth-restricted child with a monoallelic *GRB10* mutation. The proposita is a 3-year-old girl of European descent admitted to the NIH UDP for failure to thrive, developmental delay, dysmorphic features, and growth restriction (<1st centile height and weight) with normal head circumference. She was previously treated for acquired cataracts, secondary conductive hearing loss, and acquired hypothyroidism. Extensive clinical and biochemical testing revealed hypotonia, macrocytic anemia, ketotic hypoglycemia with low serum insulin, and hepatic steatosis. Additionally, she had a low free T4 with elevated TSH, low IGF1 and tryptophan, and elevated urine organic acids. Whole exome analysis including the parents and two unaffected siblings revealed a *de novo* mutation in *GRB10*. Maternal uniparental disomy of chromosome 7, which includes *GRB10* (7p11.2-p13), is associated with Silver-Russell Syndrome (SRS; OMIM #180860), a disorder marked by intrauterine growth restriction and facial dysmorphisms, thus implicating over-expression of a maternally-expressed gene in growth inhibition. The role of GRB10 in the etiology of SRS, however, is debated as growth plate cartilage does not express GRB10. The protein possesses a C-terminal Src homology 2 (SH2) domain, which binds phosphotyrosine residues of proteins in pathways including mTORC1 and insulin, allowing GRB10 to inhibit insulin and IGF-I stimulated mitogenesis. The mutation in our patient is near the beginning of this SH2 domain. Functional analysis showed decreased GRB10 abundance in fibroblasts of the proband compared to controls, suggesting haploinsufficiency. Additionally, insulin receptor substrate 1 and 2 (IRS1/2) abundances were decreased, but phosphorylation of mTORC1 targets was increased. We hypothesize *GRB10* haploinsufficiency causes a loss of mTORC1 inhibition; consequent mTORC1 hyperactivation could lead to ER stress. We therefore propose that constitutive induction of ER stress, which is linked to low birth weight in humans and fetal growth restriction and hypoglycemia in mice, is a plausible contributor to our patient's phenotype.

2317W

A novel *LHX4* mutation is associated with hypogonadotropic hypogonadism, not combined pituitary hormone deficiency. *M. Takagi[1,2,3], T. Daitsu[4], C. Numakura[5], T. Sato[3], S. Narumi[3], T. Hasegawa[3].* 1) Department of Pediatrics Kawasaki City hospital; 2) Department of Endocrinology and Metabolism, Tokyo Metropolitan Children's Medical Center; 3) Department of Pediatrics, Keio University School of Medicine; 4) Department of Pediatrics, Yamagata City Hospital Saiseikan; 5) Department of Pediatrics, Faculty of Medicine, Yamagata University.

  Background: Mutations in *HESX1*, *SOX3* responsible for combined pituitary hormone deficiency (CPHD) have been identified in a small number of hypogonadotropic hypogonadism (HH), suggesting that the genetic overlap between CPHD and HH. **Case Presentation:** A 2-month-old boy was referred because of micropenis (stretched penile length 1.0 cm) with intrascrotal testes (1 ml). Hormone assays revealed very-low plasma testosterone levels (0.06 ng/mL). LHRH stimulating test performed at the age of 3 months revealed LH peak 7.3 mIU/mL, and FSH peak 20.7 mIU/mL, suggesting pre-pubertal response. Plasma concentrations of thyroxine and insulin-like growth factor-1 were within normal ranges. No episode of hypoglycemia was noted. Clinical diagnosis was HH. Brain MRI showed a normal size anterior pituitary with a visible stalk. **Method:** Using a next-generation sequencing strategy, we sequenced 9 genes implicated in CPHD, including *POU1F1*, *PROP1*, *LHX3*, *HESX1*, *OTX2*, *SOX3*, *SOX2*, *GLI2*, *LHX4*, and 12 genes implicated in HH, including *CHD7*, *FGFR1*, *FGF8*, *GNRH1*, *GNRHR*, *KAL1*, *KISS1*, *KISS1R*, *PROK2*, *PROKR2*, *TAC3*, and *TACR3*. Transcriptional activity of identified LHX4 variant was evaluated by luciferase reporter assays constructed by inserting the *POU1F1* or *αGSU* promoters. We also performed subcellular localization analyses and EMSA assays. **Results:** We identified a novel heterozygous *LHX4* sequence variation, c.661C>T (p.R221W). R221W LHX4 had reduced transactivation and no dominant negative effect. Subcellular localization revealed no significant difference between wild-type and mutant LHX4. EMSA experiments showed that the R221W LHX4 abrogated DNA-binding ability. **Conclusion:** The R221W was proven to be loss-of function mutation. We showed for the first time that *LHX4* mutation is associated with HH, not CPHD. This study extends our understanding of the phenotypic features, molecular mechanism, and developmental course associated with mutations in *LHX4*.

2318T

Utility of targeted exome sequencing as a diagnostic tool for disorders of sex development. *H. Yoo[1,2], E. Kang[1], B. Lee[1,2], G. Kim[2], J. Jang[3], E. Cho[3], J. Choi[1,2].* 1) Dept Pediatrics, Asan Medical Ctr, Seoul, South Korea; 2) Medical Genetics, Asan Medical Ctr, Seoul, South Korea; 3) Green Cross Genome, Yongin, South Korea.

  Purpose: Patients with disorders of sex development (DSD) can present with a large phenotypic spectrum and caused by a number of different genetic defects. Therefore, it is difficult to reach a specific diagnosis using traditional approaches including biochemical analysis and Sanger sequencing of candidate genes in a number of patients with DSD. Recently, next-generation sequencing technologies have revolutionized the identification of causative genes with diseases with genetic heterogeneity using massive parallel sequencing of multiple samples simultaneously. This study was performed to investigate the genetic etiology of DSD patients using targeted exome sequencing of 67 known human DSD associated genes. **Methods:** This study included 37 patients with 46,XY DSD and 8 patients with 46,XX DSD. Exomes were captured using SureSelect kit (Agilent Technologies) and sequenced on the Miseq platform (Illumina, Inc.), which includes 2914 probes targeting a 152.953 kbp region spanning 67 genes. Mean coverage was over 150X for each sample, and approximately 99.46% of the targeted bases were read. We classified variants into five main categories (pathogenic, likely pathogenic, uncertain significance, likely benign, and benign) according to the American College of Medical Genetics and Genomics guidelines. **Results:** We identified known pathogenic mutations or deletion in 11 (24.4%) in the *AR*, *CYP17A1*, *POR*, and *DMRT1/2* genes. Novel variants were identified in 8 patients (17.8%) in the *AR*, *ATRX*, *MAP3K1*, *NR5A1*, *PROP1*, and *WWOX* genes. Of the patients with novel variants, one patients harbored pathogenic frameshift mutation in *AR* (p.Leu446Phefs*56). Two patients had *PROP* exons 1–3 duplication and *WWOX* duplication, respectively. The remaining 5 patients had variants of uncertain significance. **Conclusions:** Whole exome sequencing is expensive and laborious. Thus, targeted strategies provide efficient methods for identification of the genetic causes in DSD patients. This approach allows for early diagnosis of a genetic cause, which could influence clinical management and genetic counseling. *In vitro* or *in vivo* functional analysis is needed to verify functional implications of the novel variants.

2319F

Identifying candidate mutations for rare birth defects through family trio-based exome sequencing. *T. Nicholas[1], D. Koboldt[1], D. Wegner[2], R. Fulton[1], B. Ozenberger[1], J. Wambach[2], D. Grange[2], R. Wilson[1], F. Cole[2].* 1) McDonnell Genome Institute, St. Louis, MO; 2) Department of Pediatrics, Washington University at St. Louis, St. Louis MO.

Genomic information is increasingly relevant for clinical care, particularly with the availability of rapid, inexpensive tools for genome and exome sequencing and analysisand analysis. The McDonnell Genome Institute and the Department of Pediatrics at the Washington University School of Medicine have worked jointly to develop a program for the identification of candidate pathogenic variants associated with rare birth defects. It is estimated that as many as 80% of such cases can be attributed to inherited or *de novo*underlying genetic variation. Families recruited into the program are selected by a board of medical geneticists, clinicians, developmental biologists, and genome scientists, based on phenotypic information, relevant clinical diagnostic studies, family history, and availability of appropriate informed consented samples. This program provides a streamlined approach for combining clinical expertise with genomic methods to better identify causative genetic variants that can inform and aid the diagnosis and treatment of patients with rare birth defects, and reveal the genetic risk of family members. Our strategy primarily involves exome sequencing of the proband and immediate family members (parents and available siblings). The sequence data are aligned to the human reference sequence and assessed for variants, including both single nucleotide variants and indels, which are further annotated with gene and functional information. Candidate causal variants (*de novo* mutations and rare recessive or compound heterozygous variants) are reported and prioritized based on relevant segregation patterns, predicted functional consequences and population allele frequencies. Here, we present an update to findings from exome sequencing of 12 families (44 samples total) with rare birth defects including congenital heart disease, congenital diaphragmatic hernia, genitourinary defects, sternal malformation, and neuromuscular disease. In particular, we highlight a particularly compelling case family featuring two siblings exhibiting ambiguous genitaliapseudohermaphroditism. Each sibling was found to be compound heterozygous for damaging mutations (one previously identified and one novel) in the *HSD17B3.* gene, which Model system and in vivo testing confirmed pathogenicity and helped predict need for testosterone replacement at puberty.

2320W

Impact of genetic testing on the diagnosis and management of congenital diarrheal disorders. *R. Lombardo, D. Montiel, M. Goldschmidt, M. Aub-El-Haija, R. Hopkin.* Cincinnati Children's Hospital and Medical Center, Cincinnati, OH.

Congenital diarrheal disorders (CDD) comprise a group of rare enteropathies that are typically monogenic and autosomal recessive in nature. Over 50 genes have been implicated in this group of disorders with substantial overlap in phenotype. For many of these conditions, patients present within the first few days to weeks of life with severe diarrhea and dehydration. The non-specific presentation, however, makes diagnosis challenging and is complicated by heterogeneous etiology and a broad differential. Nevertheless, rapid identification of the disorder can have significant impact on management and outcome. Traditional diagnostic approach relies heavily on defining the clinical characteristics of the illness and histological evaluation of intestinal tissue. Diagnostic yield of endoscopy, however, is highly variable. We are reviewing our institution's experience with genetic evaluation of CDD. To date, ten patients with congenital diarrhea or intestinal failure have been identified in whom genetic testing established diagnosis and helped guide disease specific management. Seven patients had negative or non-specific findings on esophagastroduodenoscopy and/or colonoscopy, one patient did not receive endoscopy. Molecular sequencing identified several rare disorders including tufting enteropathy (1), congenital sodium diarrhea (1), tricohepatoenteric syndrome (2), mutation in the EFR3B-PI4KA-TTC7A pathway (2), Aicardi-Goutieres syndrome (1), *IARS2* mutation (1), very early onset inflammatory bowel disease (1), and sucrase-isomaltase deficiency (1). Six patients had genetic syndromes for which disease specific management was available. Targeted intervention led to improvement in both symptoms and growth. In two families, a previous child had died prior to diagnosis of the specific disorder. This series demonstrates how genetic testing in conjunction with detailed phenotyping has a direct impact on patient management, leading to improved outcomes. Molecular testing should be considered as a first line diagnostic tool, and may be more appropriate than traditional endoscopy in clinically tenuous patients.

2321T

Identification of a novel variant in X-linked Alport syndrome. A case report. *R. Ortega[1], A.I Sanchez[1], J.C Prieto[1,2].* 1) Bogota, Instituto de genética humana, Universidad Javeriana, Bogota, Bogota, Colombia; 2) Hospital la Victoria SDS, Bogotá Colombia.

　　Introduction: Alport syndrome (AS) is an inherited heterogeneous disorder characterized by hematuria and progressive nephropathy, often associated with high-tone sensorineural deafness and ocular lesions such as lenticonus and maculopathy. Prevalence has been estimated at 1:50,000 live births. It is caused by mutations encoding the collagen IV alfa3-alfa5 chains. Approximately 80% of AS is X-linked; 15% is autosomal recessive, and 5% is autosomal dominant. The X-linked form is caused by mutations in the COL4A5 gene. **Case report:** this is a 9 y/o male patient who was born by uncomplicated spontaneous vaginal delivery, after an uneventful first full term gestation from healthy non-consanguineous parents. Birth weight was 3.7 kg. Significant family history was denied. At age 2 y/o, he started having episodic gross hematuria which became almost persistent at age 9. Overt proteinuria was seen without diminished glomerular filtration rate. Diminished hearing was detectable at age 8 by audiometry, with bilateral reduction in sensitivity to high tones. Ophthalmic examination revealed no abnormalities. Renal biopsy showed diffuse thinning of the glomerular capillary wall with some areas of thickening and multilamellation of the glomerular base membrane. Physical examination revealed no abnormalities. Sequence analysis of COL4A3, COL4A4 and COL4A5 genes was performed. The hemizigous variant c.393dup (p.Gly132Trpfs*26) was identified in COL4A5 gene. **Discussion**: COL4A5 gene is located at Xq22 and encodes for collagen IV that represent a major component of the basement membranes in the glomerulus, cochlea and lens which explains the clinical phenotype. To our knowledge, the variant found in this patient hasn't been report previously in literature. It is known that affected patients with the X-linked form may have severe and progressive disease. **Conclusions**: We present a patient with consisted phenotype of AS; therefore we propose a novel variant in COL4A5 gene for AS. It is important to identify early clinical features to establish an early diagnosis and initiate management to avoid complications and final renal stage disease.

　　Primary distal renal tubular acidosis is a rare and complex genetic disease characterized by inability to maximally acidify urine, thus resulting in metabolic acidosis. Mutations in *SLC4A1*, *ATP6V0A4* and *ATP6V1B1* genes have been described as the cause of the disease, transmitted as either an autosomal dominant or an autosomal recessive trait. Particular clinical features, such as sensorineural hearing loss, have been mainly described in association with mutations in one gene instead of the others. Nevertheless, the diagnosis of distal renal tubular acidosis is essentially based on clinical and laboratory findings and the series of patients described so far are small. Therefore, a strict genotype-phenotype correlation is still lacking and questions about whether clinical and laboratory data should direct the genetic analysis remains open. In this study, we applied next-generation sequencing in 105 patients with a clinical diagnosis of distal renal tubular acidosis, analyzing the prevalence of genetic defects in *SLC4A1*, *ATP6V0A4* and *ATP6V1B1* genes as well as the clinical phenotype. A genetic cause was determined in 60% of cases. In contrast to previous observations, in our group of sporadic cases, the association of the disease with specific clinical features, including sensorineural hearing loss, is not a good indicator of the causal underlying gene. Mutations in *ATP6V0A4* gene are quite as frequent as mutations in *ATP6V1B1*, in patients with an autosomal recessive pattern of inheritance. Our results suggest that when distal renal tubular acidosis is suspected, a complete genetic testing should be performed, irrespective of the clinical phenotype of the patient.

2323W

Biallelic *NUP107* mutations in early childhood-onset steroid resistant nephrotic syndrome. *N. Miyake[1], H. Tsukaguchi[2], E. Koshimizu[1], A. Shono[3], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Second Department of Internal Medicine, Kansai Medical University, Osaka, Japan; 3) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan.

Nephrotic syndrome is a renal disorder caused by disruption of the glomerular filtration barrier, resulting in massive proteinuria, hypoalbuminemia, and dyslipidemia. At least 27 genes have been reported to be associated with steroid resistant nephrotic syndrome (SRNS), but approximately 70% of the patients with childhood-onset SRNS are genetically unknown. To identify the novel responsible gene for SRNS, we performed WES for 18 families (17 Japanese and 1 Korean families) in whom the causative mutations have not been identified in the known SRNS genes. As a result, we identified biallelic *NUP107* mutations in nine affected individuals from five unrelated families who showed early-onset SRNS. Seven of nine affected individuals had compound heterozygous mutation of one truncating mutation (c.1079_1083del or c.969+1G>A) and commonly sheared missense mutation (c.2492A>C). They developed nephrotic syndrome from 2 to 3 years of age and progressed to end stage renal disease until 10 years old. The rest of two patients in one Korean family had compound heterozygous mutation of two missense mutation (c.469G>T and c.2492A>C) and showed milder phenotype with later onset (10 to 11 years old). Interestingly, all patients harbor the identical missense mutation of c.2492A>C (p.Asp831Ala). Then we constructed the haplotype by using informative microsatellite markers and SNPs, and found a 412-kb haplotype shared by all five families. Since they are all East Asian population and this variant is extreme rare except Human Genetics Variation Database (the public exome database of the Japanese population), c.2492A>C could be a founder mutation in East Asians. *NUP107* encodes Nucleoporin 107kDa (NUP107) is a component of the nuclear pore complex embedded in the nuclear envelope, and ubiquitously expressed including in glomerular podocytes. Our *in vitro* experiment showed the mutant NUP107 protein decrease the binding with NUP133 and altered the intracellular localization. Furthermore, *nup107* knockdown zebrafish generated by morpholino oligonucleotides displayed hypoplastic glomerulus structures and abnormal podocyte foot processes, which could partly recapitulate the renal changes in the patients with *NUP107* mutations. In this study, we identified biallelic *NUP107* mutations caused early childhood-onset SRNS and highlighted the importance of nuclear pore complex in human renal disease.

2324T

Mutations of *CFHR* genes in Chinese atypical hemolytic uremic syndrome (aHUS) with CFH autoantibody positive. *Z. Hao[1,2], W. Li[1,2], X. Liu[3].* 1) Center for Medical Genetics, Beijing Children's Hospital, Capital Medical University, Beijing, China; 2) Beijing Pediatric Research Institute, Beijing, China; 3) Department of Nephrology, Beijing Children's Hospital, Capital Medical University, Beijing, China.

Atypical hemolytic uremic syndrome (aHUS) is a severe kidney disease that is characterized by microangiopathic hemolytic anemia, thrombocytopenia, acute renal failure and is associated with defective regulation of complement activation. A special form of aHUS designated as DEAP (DEficiency of CFHR proteins and CFH Autoantibody Positive)-HUS has been described in recent years, but reports from the Chinese patients are still very limited. In the present study, we aim to explore the relationship between clinical features, outcomes and genotypes of DEAP-HUS from a Chinese cohort. Using enzyme linked immunosorbent assay (ELISA), complement factor H (CFH) autoantibodies were detectable in 31 (50.8%) out of 61 patients with aHUS. Plasma levels of CFH were decreased while C3a, C5a, and sC5b-9 were increased significantly in these CFH autoantibody positive patients compared with the healthy controls. Autoantibody positive individuals treated with immunosuppressants in conjunction with plasma exchange had more favorable outcomes. In addition, CFH level was higher in remission stage than in acute stage. Genetic variants of *CFH*, *CFHR1* and *CFHR3* were analyzed in 12 CFH autoantibody positive Chinese patients by real-time PCR and sequencing of genomic DNA. Among these patients, three carried homozygous deletion of *CFHR1/CFHR3*, four carried homozygous deletion of *CFHR1*, one carried novel homozygous nonsense mutation (p.C129X) of *CFHR1*, one carried novel homozygous missense mutation (p.I214N) of *CFHR1*, and one carried heterozygous deletions of *CFHR1*. No pathological mutation was found in the remaining two patients. The copy number of the *CFH* gene was normal in all 12 patients. In summary, we have identified mutations of the *CFHR* genes in 10 CFH autoantibody positive aHUS patients, suggesting that dysregulation of the complement system plays a major role in Chinese DEAP-HUS patients. Based on our experience, the precision genotyping of DEAP-HUS is a prerequisite for personalized treatment of aHUS. *Corresponding authors: liwei@bch.com.cn (W. Li); desin2000@sina.com(X. Liu).

Population history of the *NPHS2* **p. V260E mutation, a cause of childhood SR-FSGS, in Southern Africa.** *G.W. Nelson[1], R. Bhimma[2], K. Asharam[2], S. Limou[1], C.A. Winkler[1].* 1) Leidos Biomedical Research, Frederick National Laboratory, Frederick, MD; 2) University of KwaZulu-Natal, Durban, SA;.

Mutations in genes critical to podocyte structure are common recessive causes of childhood steroid resistant focal segmental glomerulosclerosis (SR-FSGS), a severe kidney disease often leading to kidney failure. These mutations occur sporadically in the population, with disease observed in consanguineous families; in population studies no variant has been reported to account for more than a small percentage of disease. Strikingly, a study of 44 children with SR-FSGS in Durban, South Africa, revealed that 30% carried two copies of a missense mutation, p. V260E, in the podocin gene *NPHS2*. This mutation has been observed associated with FSGS in consanguineous families in Oman and in regions associated with the Omani empire of the 19th century, suggesting spread with this empire. We speculated the variant was recently introduced into Southern Africa, and that the children in our study had cryptically consanguineous parents, reflecting a recent founder event. Parents inheriting a variant from a recent common ancestor will have an extended region of shared haplotype around the variant, resulting in an extended stretch of homozygosity in children inheriting the variant from both parents. To test for this we genotyped 10 individuals homozygous for the mutation, and 74 individuals homozygous for the wild type variant, with the Illumina exome chip. After QC, this chip provided 1674 markers within 20 megabases (Mb) of V260E. Two of the ten individuals homozygous for the V260E mutation had regions of homozygosity of 13 and 14 mB around V260E, suggestive of relatively recent common ancestry of these individual's parents, but the other eight had segments of homozygosity from 1.9 to 3.6 mB. To predict the distribution of lengths of homozygous regions around the locus as a function of number of generations between parents and their common ancestor carrying the mutation, we performed 10,000 coalescent simulations of recombination in each generation, generating a distribution of lengths of homozygosity for each n generations from 6 to 48. Comparing with this simulation, the distribution of observed lengths of homozygosity is inconsistent with a common ancestor within the last 19 generations, and most consistent with the most recent common ancestor being 31 generations removed, ruling out a recent founder effect and suggesting that the mutation originated in Africa and spread from there to the Omani Empire.

mTOR inhibitor therapy demonstrates reduction in renal cysts volume in a 6 year old girl with TSC. *N. Urraca[1], A. Pounders[1], S. Weatherspoon[1,2], J.J. Bissler[1,3].* 1) Le Bonheur Children's Hospital, Memphis, TN; 2) Pediatric Neurology Department, UTHSC, Memphis, TN; 3) Pediatric Nephrology Department, UTHSC, Memphis, TN.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder affecting approximately 1 in every 6,000 newborns. TSC is frequently associated with de novo mutations in *TSC1* or *TSC2* genes encoding the proteins hamartin and tuberin respectively. The hamartin-tuberin complex inhibits the mammalian-target-of-Rapamycin (mTOR) pathway, which controls cell growth and proliferation. TSC is characterized by hamartomatous growth abnormalities in many organs. Renal disease is a major cause of morbidity and mortality. Approximately 75-80% of TSC patients have angiomyolipomas and 50% have renal cysts. The *TSC2* gene lies immediately adjacent to *PKD1*, the major gene causing autosomal dominant polycystic kidney disease (ADPKD). Approximately 2% of TSC patients will present with polycystic kidney disease as part of the contiguous gene deletion syndrome that involves *TSC2* and *PKD1* genes. Here we present a 6 year old female that was sent to our center with a history of contiguous gene syndrome. She was diagnosed with TSC prenatally when cardiac rhabdomyomas were detected by ultrasound. She meets TSC diagnostic criteria due to the presence of mild facial angiofibromas, subependymal nodules, cortical tubers, two retinal astrocytomas, and multiple hypomelanotic macules. Genetic testing confirmed a deletion in *TSC2* (exons 15-41) and *PKD1* genes. At 5 years of age she complained occasionally of right-sided abdominal pain and early satiety. An abdominal MRI demonstrated two very large cysts in her right kidney which were progressively getting larger and multiple small cysts bilaterally. She also developed hypertension secondary to cystic disease. The two very large cysts were marsupialized and everolimus was initiated twelve weeks after surgery to prevent rapid growth of the other cysts. Everolimus inhibits intracellular mTOR complex and has been shown to shrink angiomyolipomas in patients with TSC. It is FDA approved in TSC for adults with angiomyolipomas not requiring immediate surgery. In this patient everolimus was used off label. Six months after starting everolimus renal MRI revealed resolution of the large cysts and reduction of the smaller cysts. This case raises the possibility that an mTOR inhibitor can be a treatment option for renal cysts in children.

Detection of early end-organ damage by endothelial dysfunction with reactive hyperemia-digital peripheral arterial tonometry in patients with Fabry disease. *S. Yano[1], K. Moseley[1], C. Azen[2]. 1) Genetics/Pediatrics, University of Southern California, Los Angeles, CA; 2) Clinical Trial Unit Children's Hospital Los Angeles, University of Southern California, Los Angeles, CA.*

Introduction: Progressive renal and cardiovascular lesions have been known to be the major causes of death in individuals with Fabry disease. Based on recent data from the Fabry Registry, proteinuria has been established as the major risk factor for renal disease progression. Microalbuminuria is considered one of the first signs of impairment of renal function in Fabry disease. There is compelling evidence that proteinuria is an indicator of renal dysfunction and requires immediate intervention with enzyme replacement therapy (ERT) and/or antiproteinuric medications; however, there are no clear guidelines for when to initiate ERT in children with Fabry disease. Currently, there are no non-invasive methods or biomarkers for early diagnosis of kidney changes before they become irreversible and subsequent deterioration of kidney function. Endothelial dysfunction precedes the development of microalbuminuria. Plethysmographic studies of forearm blood flow in individuals with Fabry disease show impaired NO-dependent vasodilatation. The evaluation of endothelial function based on reactive hyperemia-digital peripheral arterial tonometry (RH-PAT) with the EndoPAT 2000, a FDA approved instrument to assess endothelial function by reflecting endothelial NO production, may diagnose endothelial dysfunction before irreversible vascular and renal pathologic changes occur, possibly earlier than detection of microalbuminuria. Objective: To evaluate endothelial function with RH-PAT with Endo-PAT 2000 to detect the earliest pathologic changes in the cardiovascular system prior to detection of microalbuminuria in individuals with Fabry disease. Methods: Young male individuals with Fabry disease were enrolled: study subjects n=14 (age: 6-20 years, untreated with ERT n=3). Evaluation of endothelial function with Endo-PAT 2000 was performed. Microalbumin was measured with first void urine specimens. Results: (1) all study subjects showed abnormal endothelial function (Reactive Hyperemia Index: 1.175 ± 0.225, ref: > 1.67), (2) all study subjects showed normal urine microalbumin levels (5.14 ± 3.35 ug/mg Creatinine, n=14, reference range < 30). Conclusions: Endothelial dysfunction was diagnosed by RH-PAT with EndoPAT 2000 in subjects with Fabry disease with normal microalbuminuria. Early diagnosis of endothelial dysfunction by this non-invasive method provides objective clinical information to determine the timing of initiation for ERT. This study was funded by Sanofi Genzyme.

Neonatal cholestasis is a potentially life-threatening condition requiring prompt diagnosis. Mutations in several different genes can cause progressive familial intrahepatic cholestasis, but known genes cannot account for all familial cases. Here we report four individuals from two unrelated families with neonatal cholestasis. Clinical features of these patients include neonatal onset with rapid progression to end-stage liver disease, vitamin-K independent coagulopathy, low-to-normal serum gamma-glutamyl transferase activity, elevated serum alpha-fetoprotein, and undetectable liver bile salt export pump (ABCB11) expression. Clinical whole exome sequencing for these patients identified mutations in the NR1H4 gene, which encodes the farnesoid X receptor (FXR), a bile acid-activated nuclear hormone receptor that plays central roles in bile acid metabolism. Patients 1 and 2 from the first family both carry a homozygous c.526C>T (p.R176*) pathogenic variant and patients 3 and 4 from the other family carry an in-frame insertion c.419_420insAAA (p.Tyr139_Asn140insLys) and a 30kb gross deletion of the NR1H4 gene. Functional studies showed that the in-frame insertion disrupts DNA binding and transcriptional regulation functions of FXR. In addition, we demonstrated that FXR directly regulates ABCB11 as well as members of the complement and coagulation cascades. Our findings demonstrate a pivotal function for FXR in bile acid homeostasis and hepatoprotection in humans.

HSP90AA1: A new candidate for Camurati-Engelmann-like phenotype.
S. Ehresmann, J. Gauthier, J. Rousseau, J. Michaud, P.M. Campeau. CHU Sainte Justine Universite de Montreal, Montreal, Canada.

   Camurati-Engelmann disease is a condition with hyperostosis of the long bones and the skull, and dominant mutations in *TGFB1* (encoding transforming growth factor beta-1) are found in a majority of patients. We performed whole exome sequencing in an individual with skeletal features of Camurati-Engelmann disease, hypertension and celiac disease, from consanguineous parents. This led to the identification of a homozygous mutation in *HSP90AA1* (NM_005348:c.1486+4A>G), which encodes a chaperone that protects TFGBRs from Smurf2 ubiquitination, and subsequent degradation of the TGFBR complex. Data from the International Mouse Phenotyping Consortium shows that *HSP90AA1* knockout mice have higher Bone Mineral Content to Body Mass ratio, which supports our hypothesis of *HSP90AA1* being a new candidate gene for Camurati-Engelmann disease. The mutation identified is in the splice donor site of exon 9. A decrease splice donor activity could lead to the inclusion of intron 9 in the coding sequence, and a loss of protein function. A minigene assay is underway to assess the effect of the mutation on splicing, and thus substantiate *HSP90AA1* as a new candidate gene for *TGFB1*-negative Camurati-Engelmann-like phenotype.

2330T

Sclerostin antibody treatment improves the bone phenotype of *Crtap$^{-/-}$* mice, a model of recessive osteogenesis imperfecta. *S. Alexander[1], I. Grafe[1], T. Yang[1], C. Lietman[1], E. Homan[1], E. Munivez[1], Y. Chen[1], M. Jiang[1], T. Bertin[1], B. Dawson[1], F. Asuncion[2], H. Ke[3], M. Ominsky[2], B. Lee[1].* 1) Department of Genetics, Baylor College of Medicine, Houston, TX; 2) Amgen, Inc., Thousand Oaks, CA, USA; 3) UCB Pharma, Slough, UK.

   Osteogenesis imperfecta (OI) is a genetic osteodysplasia producing low bone mass, bone deformities, and fractures. Most cases of OI are caused by autosomal-dominant mutations in type I collagen or by autosomal-recessive variants in genes that modulate post-translational type I collagen modifications, including cartilage associated protein (CRTAP). Bisphosphonates, the current standard OI treatment, do not fully correct the bone phenotype, only moderately reduce fracture risk, and are less effective in adult patients, indicating a need for more effective therapies. Sclerostin-neutralizing antibodies (Scl-Abs) improve bone mass and bone formation in animal models of osteoporosis and dominant OI, but have not been evaluated in recessive OI. The purpose of this study was to investigate the effects of Scl-Ab treatment in the *Crtap$^{-/-}$* mouse model of recessive OI. We treated two age cohorts of *Crtap$^{-/-}$* mice (1-week and 6-week-old mice as models of "pediatric" and "young adult" OI, respectively) with Scl-Ab for 6 weeks (25 mg/kg, s.c., twice per week). We assessed spines and femurs by microCT and histomorphometry and femur biomechanical properties by 3-point bending. MicroCT at L4 vertebrae showed Scl-Ab increased bone mass (BV/TV) from 28% to 71% of WT in the pediatric cohort and from 35% to 72% of WT in the young adult cohort. In femurs, Scl-Ab improved trabecular BV/TV from 45% to 69% of WT in the pediatric cohort and from 32% to 100% of WT in the young adult cohort. On histomorphometry, young adult *Crtap$^{-/-}$* mice had increased osteoclasts and decreased bone formation rate (BFR). Scl-Ab rescued the osteoclast parameters to WT levels and increased BFR from 76% to 128% of WT. The pediatric cohort had similar trends, however while Scl-Ab reduced osteoclast parameters, there was no significant effect on BFR. In the young adult cohort, biomechanical testing of femurs showed that Scl-Ab improved maximum load from 65% to 91% and stiffness from 60% to 88% of WT, but had no significant effect on energy to failure. Similar effects were seen in the pediatric cohort, but to a lesser extent. In summary, Scl-Ab treatment improved bone mass and strength in both pediatric and young adult cohorts of *Crtap$^{-/-}$* mice. However, the less pronounced responses in the pediatric cohort suggests possible age-dependent differences in the effects of Scl-Ab treatment in recessive OI. These findings suggest that Scl-Ab could be a promising new treatment option for patients with recessive OI.

Effect of bisphosphonates on bone mineral density and other health outcomes in type I osteogenesis imperfecta. *E. Carter[1], J. Bains[1], K. Citron[1], D. Cuthbertson[2], J. Shapirl[10], R. Steiner[3], P. Smith[8], M. Bober[4], T. Hart[9], J. Krischer[2], P. Byers[7], F. Glorieux[5], F. Rauch[5], S. Nagamani[6], V. Sutton[6], C. Raggio[1], Members of the BBD Consortium.* 1) Ctr Skeletal Dysplasias, Hosp Special Surgery, New York City, NY; 2) Health Informatics Institute, University of South Florida, Tampa, FL; 3) University of Wisconsin School of Medicine and Public Health, Madison, WI; 4) A.I. DuPont Hospital for Children, Wilmington, DE; 5) Shriners Hospitals for Children, Montreal, Quebec; 6) Baylor College of Medicine, Houston, TX; 7) University of Washington School of Medicine, Seattle, WA; 8) Shriners Hospitals for Children, Chicago, IL; 9) Osteogenesis Imperfecta Foundation, Gaithersburg, MD; 10) Suburban Hospital, Bethesda, MD.

Osteogenesis imperfecta (OI) is a heritable disorder characterized by low bone mass and bone fragility. This study uses data from the Linked Clinical Research Centers to examine the treatment effect of bisphosphonates (BP; a class of antiresorptive drugs commonly used to treat OI) on bone mineral density (BMD) and other clinically relevant outcomes. Principal methodology: linear regressions of BMD on age were used to construct expected BMD age progressions for untreated individuals with type I (TI) OI. A 2-sided t-test was then used to assess whether BMDs of individuals with TI OI treated with BP differed from their age-matched untreated counterparts. Treatment increased the BMD of individuals with TI OI by 9% relative to those untreated; this was driven by pre-pubescent (<14yr) individuals whose mean increase with treatment was 12% (p<0.01). There was no significant effect on individuals >14yr. Intravenous BP and treatment durations of >2yrs were particularly effective. The treatment effect did not differ markedly by sex. In males, BMDs in those treated with BP were higher than in the untreated individuals across the entire cohort. In females, this effect was observed only in the pre-pubescent years. All results were corroborated by regression analysis. Several sources of downward bias affect this study (*e.g.* not a RCT, age of treatment initiation is not reported). As a result, the treatment effect on BMD is likely underestimated. In addition to those with T1 OI, BP improved BMD z-scores in individuals with types IV, V, and VIII. The treatment effect also extended to non-BMD outcomes. Using logistic regression models, we found that for a 1% increase in BMD, in individuals with TI was associated with a 4% decrease in fracture probability while those untreated had an increase by 1% increase (p<.05). Similarly, scoliosis probability exhibited larger drops in treated pre-pubescent individuals with TI OI for a given BMD increase (p<0.01). BP also slowed the acceleration in scoliosis probability with age in the pre-pubescent individuals with TI OI (p<.01). This suggests that treatment may improve aspects of bone structure more difficult to measure than bone mass, such as bone architecture and mineralization. Linear regression analysis showed that BP treatment also increased mobility in TI OI over the whole age sample (p<.01), providing further evidence that improvements in bone mass and structure raise patient quality of life in multiple ways.

A founder mutation in the *ZNF687* gene is responsible for giant cell tumor associated with Paget's disease of bone. *G. Divisato[1], F. Scotto di Carlo[1], T. Esposito[1], D. Merlotti[2], L. Pazzaglia[3], E. Siris[4], P. Orcel[5], J.P. Brown[6], M.S. Benassi[3], M.L. Cancela[7], L. Michou[6], D. Rendina[8], L. Gennari[2], F. Gianfrancesco[1].* 1) Institute of Genetics and Biophysics, National Research Council of Italy, Naples, Italy; 2) Department of Medicine, Surgery and Neurosciences, University of Siena, Italy;; 3) Laboratory of Experimental Oncology, Rizzoli Orthopaedic Institute, Bologna, Italy; 4) Department of Medicine, Columbia University Medical Centre, New York, USA; 5) Pole Appareil Locomoteur, Service de Rhumatologie B, Hopital Lariboisiere, Assistance Publique–Hopitaux de Paris, France; 6) Division of Rheumatology, Department of Medicine, Universite´ Laval, Quebec, Canada; 7) Department of Biomedical Sciences and Medicine and Centre of Marine Sciences, University of Algarve, Faro, Portugal; 8) Department of Medicine and Surgery, Federico II University, Naples, Italy.

Paget disease of bone (PDB) is a skeletal disorder characterized by focal abnormalities of bone remodeling, which result in enlarged and deformed bones in one or more regions of the skeleton. In some cases, the pagetic tissue undergoes neoplastic transformation, resulting in osteosarcoma and, less frequently, giant cell tumor of bone (GCT/PDB). We performed whole-exome sequencing in a large family with 14 PDB affected members, four of whom developed GCT at multiple pagetic skeletal sites, and we identified the c.2810C>G (p.Pro937Arg) missense mutation in the zinc finger protein 687 gene (*ZNF687*). The mutation precisely co-segregated with the clinical phenotype in all affected family members. The sequencing of seven unrelated GCT/PDB individuals, identified the same mutation in all unravelling a founder effect. The evidence of a common ancestral chromosome was also corroborated by the segregation of rare variants in genes surrounding the *ZNF687* mutation, suggesting that c.2810C>G mutation originated from a unique haplotype. Our results also showed that *ZNF687*, indicated as a target gene of the NFkB transcription factor by ChIP-seq analysis, was also upregulated in the peripheral blood of PDB-affected individuals with or without mutations in *SQSTM1*, encouraging additional studies to investigate its potential role as a biomarker of PDB risk.

2333T

Identification of novel *COL2A1* mutations that results in dysspondyloenchondromatosis: Support for expansion of *COL2A1* associated disorders. *L.M. Hurd[1], M. Fathy[2], S.M. Kirwin[1], K. Rogers[2], C.P. Ditro[2], W.G. Mackenzie[2], V.L. Funanage[1], M.B. Bober[3].* 1) Molecular Diagnostics Laboratory, Nemours/Alfred I. duPont Hospital for Children, Wilmington, Delaware; 2) Department of Orthopaedics, Nemours/Alfred I. duPont Hospital for Children, Wilmington, Delaware; 3) Division of Genetics, Nemours/Alfred I. duPont Hospital for Children, Wilmington, Delaware.

Enchondromatosis is a rare disorder distinguished by the presence of ectopic, benign cartilaginous growth within the bone. Dysspondyloenchondromatosis (DSC) is characterized as a subtype of enchondromatosis with vertebral involvement. Clinical symptoms of this disorder can include vertebral irregularities (anisospondly) and profuse enchondromas in the long and flat bones. Other remarkable characteristics include short stature, progressive kyphoscoliosis and asymmetric limb shortening. Phenotypic similarity with other collagen type II disorders, including spondyloepimetaphyseal dysplasia-Strudwick type have alluded to deleterious variants in *COL2A1* as a potential cause of DSC. We report on two unrelated patients with this rare type of skeletal dysplasia where thoraco-lumbar kyphoscoliosis and windswept deformity of the lower limbs are the major abnormalities encountered. We performed traditional Sanger sequencing to identify potential pathogenic variants within the *COL2A1* gene. Using DNA isolated from bone and cartilage tissues, we have identified likely pathogenic missense mutations in the triple-helical region of *COL2A1* in both patients. Patient one harbors a c.1555 G>C, p.Gly519Arg substitution in exon 24, and patient two exhibits a c.3572G>A, p.Gly1191Glu substitution in exon 50. *COL2A1* as the cause of DSC has remained controversial. Cases of DSC have presented both with and without the presence of a deleterious variant in *COL2A1,* suggestive of genetic heterogeneity or possible mosaicism. We could hypothesize that patients which present clinically with DSC, but fail to exhibit deleterious variants in *COL2A1* may be mosaic for a deleterious allele. Genotyping DNA isolated from tissues affected by disease may play a crucial role in genetic diagnosis. We provide further support for the expansion of the collagen type II spectrum of disorders to include DSC by discovery of these novel mutations.

Identification of a novel osteogenesis imperfecta gene. *M.K. Hytönen[1,2,3], G. Vidgren[4], K. Kyöstilä[1,2,3], A.K. Lappalainen[5], S. Malkamäki[2], K. Vainio-Siukola[4], M. Arumilli[1,2,3], M. Anttila[4], H. Lohi[1,2,3].* 1) Research Programs Unit, Molecular Neurology, University of Helsinki, Helsinki, Finland; 2) Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 3) The Folkhälsan Institute of Genetics, Helsinki, Finland; 4) Pathology Unit, Finnish Food Safety Authority, Evira, Helsinki, Finland; 5) Department of Equine and Small Animal Medicine, University of Helsinki, Helsinki, Finland.

Osteogenesis imperfecta (OI) is a group of genetic disorders affecting the connective tissue and featured by fragile bones resulting in easily fractured bones and skeletal deformities. The disorder is commonly caused by mutations affecting the synthesis or post-translational modification of the collagen type I. As a model of human OI, we have studied a severe form of OI in the Finnish Lapphund dog breed to identify its genetic cause. The affected dogs die neonatally or have to be euthanized soon after birth due to multiple fractures. The postmortem examination of 15 affected puppies in several litters demonstrated osteopenia as a prominent feature. A pedigree analysis suggested an autosomal recessive disease. A genome-wide association study using 15 cases and 15 controls mapped the locus at region on chromosome 21 that did not contain known OI genes. Whole genome and exome sequencing data analysis under recessive model in three cases identified a case-specific coding structural variant in a gene related to calcium-phosphate metabolism. Our ongoing analyses aim to validate the candidate variant in a large cohort of cases and controls in the breed. Our preliminary data has revealed a novel OI locus and suggests a physiologically relevant candidate gene with a novel disease mechanism. Canine OI patients will serve as large animal models for additional functional and clinical intervention studies.

Achondroplasia: PEDICAT as an assessment of the impact on daily functionality. *M.D. Irving, C. Coleman, M.S. Cheung, J.A. Hulse.* Guy's and St Thomas" NHS Trust, London, United Kingdom.

Achondroplasia is the most common cause of genetic disproportional short stature. It is caused by a recurrent mutation in *FGFR3*, the gene encoding the fibroblast growth receptor type 3, which is a transmembrane protein expressed in growth plate cartilage chondrocytes. Achondroplasia is associated with a number of physical and medical complications, as a consequence of abnormal bone formation, resulting in elbow contractures, middle ear dysfunction and the impact upon activities of daily living through skeletal disproportion. The significant morbidity and mortality risks of these can be largely overcome through anticipatory surveillance, bit it remains that the physical effects of the condition can have a significant impact upon affected individuals in their daily activities, including functionality. PEDICAT (Pediatric Evaluation of Disability Inventory – Computer Adaptive Test) measures functional abilities in three domains: daily activities, mobilities and social/cognition. It is a tool that has established applicability across a number of pediatric conditions illustrating the impact on the activities of daily living. Here we demonstrate the use of PEDICAT as a tool in highlighting the specific cognitive and functional needs of children with achondroplasia. It applies especially to those requiring earlier intervention, with a view to developing further a multidisciplinary service that addresses the functional needs of this group of patients, as well as addressing their needs based on medical complications. The PEDICAT tool was administered to over 30 pediatric patients attending the dedicated achondroplasia clinic at the Evelina London Children's Hospital. Mostly the data depicts single episodes, but, also, in a limited number of patients, longitudinal assessment of functionality. Here we summarise the data based upon PEDICAT assessment of daily functionality in children aged between 5-16 with achondroplasia and highlight the main factors used to determine improvement of our clinical service to address the specific needs highlighted.

2336T

Farber disease: Acid ceramidase deficiency is more common than previously thought, and slowly progressive phenotypes may only be diagnosed in adulthood. *J. Mitchell[1], A. Solyom[2], X. He[3], C. Simonaro[3], E.H. Schuchman[3].* 1) Pediatric Endocrinology, Montreal Children's Hospital, Montreal, Canada; 2) Plexcera Therapeutics LLC, New York, USA; 3) Genetics and Genomic Sciences, Icahn School of Medicine at Mt. Sinai, New York, USA.

Farber disease is caused by mutations in the *ASAH1* gene, resulting in acid ceramidase deficiency and accumulation of the pro-inflammatory and pro-apoptotic lipid, ceramide. Patients usually present in infancy or late childhood with one of three characteristic symptoms: early-onset polyarticular arthritis, subcutaneous nodules and dysphonia. Acid ceramidase deficiency can also cause another disease, Spinal Muscular Atrophy with Progressive Myoclonic Epilepsy (SMA-PME). The prevalence of both Farber disease and SMA-PME is currently unknown, and awareness is extremely limited due to their rarity and lack of specific treatments; both are likely underdiagnosed. Data including genotypes, clinical, biochemical and immunologic phenotypes, is being collected on a growing cohort of 40 Farber patients from around the world. This is the largest Farber cohort yet reported. Findings to date reinforce the validity of the characteristic symptoms of Farber disease. However, they also reveal that there are patients who present with only one or two of these symptoms, and that the spectrum of disease includes remarkably attenuated forms with relatively little associated disability. Such patients are likely to be misdiagnosed or experience a significant delay in diagnosis. Three siblings were recently diagnosed with Farber, by whole exome sequencing, after developing peripheral osteolysis at over 40 years of age. Currently, Farber disease can be treated with hematopoietic stem cell transplantation, which has shown variable results and carries a severe burden for the patients. Acid ceramidase enzyme therapy is under development, and a natural history study is planned to better understand disease progression and factors influencing the different phenotypes. Based on the information gathered so far from this cohort, screening of selected patient populations (such as patients with early-onset, therapy-resistant polyarticular arthritis, or with peripheral osteolysis of unknown cause) for Farber disease is indicated.

2337F

Evidence that bi-allelic mutations in *NPR3* result in a peculiar phenotype with tall stature, arachnodactyly, long halluces and multiple extra epiphyses in hands and feet. *G. Mortier[1], T.R. de Jong[2], H.S.A. Heymans[3], J.M. Wit[4], W. Van Hul[1], E. Boudin[1].* 1) Center of Medical Genetics, University of Antwerp & Antwerp University Hospital, Antwerp, Belgium; 2) Department of Plastic and Reconstructive Surgery and Hand Surgery, Isala Clinics, Zwolle, The Netherlands; 3) Department of Pediatrics, Emma's Childrenshospital- Academic Medical Centre, Amsterdam, The Netherlands; 4) Department of Pediatrics, Leiden University Medical Center, Leiden, The Netherlands.

   Studies in mice and humans have shown that natriuretic peptides and their corresponding receptors control endochondral ossification and linear bone growth. Reciprocal translocations resulting in an increased production of the C-type natriuretic peptide (CNP) and heterozygous activating mutations in the natriuretic peptide receptor 2 (NPR2) have been reported in individuals with tall stature. In contrast, bi-allelic inactivating mutations in *NPR2* have been identified in patients with severe short stature (acromesomelic dysplasia Maroteaux type). With this paper we provide strong evidence that bi-allelic hypomorphic mutations in the clearance receptor *NPR3* can also result in enhanced growth. Compound heterozygosity for a missense (NM_001204375.1, c.442T>C;p.Ser148Pro) and nonsense mutation (NM_001204375.1, c.1524delC, p.Tyr508*) was identified by WES in two affected sibs born to non-consanguineous, healthy parents of Dutch origin. Both the parents and the unaffected younger sib are heterozygous carriers. Using mRNA isolated from whole blood, we demonstrated that the frameshift mutation resulted in nonsense mediated mRNA decay while localization studies revealed that the mutant NPR3 receptor with the p.Ser148Pro substitution was not incorporated into the plasma membrane. These data suggest that both mutations have a loss-of-function effect on the protein. The phenotype observed in both affected boys was characterized by tall stature (Marfanoid habitus), generalized joint hyperlaxity with hypotonia, mild pectus excavatum, long fingers (arachnodactyly) and markedly long halluces. In addition, hand radiographs revealed the presence of extra (pseudo)epiphyses in first metacarpals and all proximal and middle phalanges. Extra (pseudo)epiphyses were also visible in the proximal phalanges of both feet. This remarkable radiographic finding is retrospectively also visible in the family with an activating mutation of NPR2 reported by Miura K et al. (PLoS ONE 2012). It suggests that enhanced growth due to defects in either the NPR2 or NPR3 controlled signaling pathways may be partially mediated through the creation of extra growth plates in tubular bones.

2338W

Raine syndrome (OMIM #259775), caused by mutations in *FAM20C*, is congenital sclerosing osteomalacia with cerebral calcification (OMIM 259660). *S. Mumm[1,2], W.H. McAlister[3], M.D. Fallon[4], M.E. Pierpont[5], V.N. Bijanki[2], S. Duan[1], G.A. Otaify[1,2,6], W.S. Sly[7], M.P. Whyte[1,2].* 1) Div of Bone and Mineral Diseases, Washington Univ Sch of Med, St Louis, MO, USA; 2) Center for Metabolic Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO, USA; 3) Dept of Pediatric Radiology, Washington Univ Sch of Med, St. Louis, MO, USA; 4) Dept of Surgical Pathology, Univ of Pennsylvania Sch of Med, Philadelphia, PA, USA; 5) Dept of Pediatrics, Univ of Minnesota Sch of Med and Children's Hosp of Minnesota, Minneapolis, MN, USA; 6) Dept of Clinical Genetics, Centre of Excellence of Human Genetics, National Research Centre, Cairo, Egypt; 7) Doisy Dept of Biochemistry, St. Louis Univ, St. Louis, MO, USA.

   In 1985, we briefly reported two sisters with a new, lethal, autosomal recessive disorder that we called congenital sclerosing osteomalacia with cerebral calcification. In 1986, our findings entered *Mendelian Inheritance In Man* (MIM) as osteomalacia, sclerosing, with cerebral calcification (MIM 259660). However, no attestations followed. Instead, in 1989 Raine and colleagues published a concise description of an affected neonate and considered the striking clinical and radiographic features unprecedented. In 1992, after two additional unrelated newborns were reported, the disorder became "Raine syndrome" and entered MIM formally as osteosclerotic bone dysplasia, lethal (MIM #259775). In 2007, the etiology was discovered to be loss-of-function mutations of the FAM20C gene that encodes family with sequence similarity 20, member C. *FAM20C* is highly expressed in calcified tissues and its translated protein is a kinase for most of the secreted phosphoproteome including FGF23, osteopontin, and several additional regulators of skeletal mineralization. Here, we detail the clinical, radiological, biochemical, histopathological, and *FAM20C* findings of the sisters. Following pre-mortem tetracycline labeling, the proposita's post-mortem skeletal histopathology revealed no rickets but documented osteomalacia accompanying severe osteosclerosis. Her sister showed evidence of hypophosphatemia. Archival DNA from the proposita and her parents and brother indicated the etiology of the disorder was compound heterozygosity for a unique missense defect and a novel deletion in *FAM20C*. Heterozygous family members carrying the missense mutation seemed susceptible to trigonocephaly. Our findings clarify the function of *FAM20C* and show that Raine syndrome is congenital sclerosing osteomalacia with cerebral calcification.

2339T

Defect in phosphoinositide signaling through a homozygous mutation in *PLCB3* causes a new form of spondylometaphyseal dysplasia with corneal clouding. *S. Robbins[1], S. Ben-Salam[2], N. Sobreira[1], A. Lyon[3], A. Al-Shamsi[4], B. Islam[5], N. Akawi[6], A. John[2], P. Thachillath[7], D. Valle[1], B. Ali[2], L. Al-Gazali[7].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pathology, College of Medicine and Heath Sciences, United Arab Emirates University; 3) Chemistry and Biological Sciences, 560 Oval Drive, West Lafayette, IN 47907, BRWN 3130C, USA; 4) Department of Paediatrics, Tawam Hospital, Al-Ain, United Arab Emirates; 5) School of Pharmacy, University College London, 29-39 Brunswick Square, London WC1N 1AX; 6) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SA, UK; 7) Department of Paediatrics, College of Medicine and Heath Sciences, United Arab Emirates University, Al-Ain, United Arab Emirates.

Skeletal dysplasias are a large group of osteochondrodysplasias affecting the growth and structure of the skeletal system. Here, we report the clinical and molecular delineation of a new form of spondylometaphyseal dysplasia with cloudy corneas in two affected male cousins from a consanguineous Emirati family. Both patients had postnatal growth deficiency with profoundly shortened limbs with involvement of proximal and distal segments, irregular iliac abnormalities, narrow chest, hypertelorism, prominent eyes, depressed nasal bridge, short upturned nose and corneal clouding. Whole genome SNP genotyping and homozygosity mapping identified a region of homozygosity spanning 19.32 Mb over 11q12.1-q13.1. Whole exome sequencing in the 2 affected cousins and an unaffected sib of each revealed homozygous variants in 5 autosomal genes (*CELF1, PRPF19, FEN1, INCENP, PLCB3*), the latter 4 of which are in the 11q12.1-q13.1 region, plus 1 hemizygous X-linked variant (*CETN2*) shared by the affected cousins but not present in the unaffected sibs. Because pathogenic variants in genes involved in phospholipid metabolism, *PLCB4* and *PCYT1A,* have also been reported to cause bone disease with or without eye anomalies, we focused on *PLCB3* as our main candidate gene. The *PLCB3* encodes phospholipase C beta which catalyzes the conversion of PIP2 to IP3 and DAG. The *PLCB3* missense variant *(*p.A878S) we identified alters single amino acid in the Ha2' element of the proximal CRD domain. We transfected wild type *PLCB3* and variant *PLCB3*-A878S into COS7 cells and compared their enzymatic activity. The enzymatic activity encoded by the *PLCB3*-A878S allele was ~7% of control, indicating the missense variant produced a hypomorphic allele. Interestingly, Lowe syndrome (OMIM 309000), an X-linked recessive phenotype, characterized by thick clouding of the lenses in both eyes, delayed development, and renal Fanconi syndrome, is caused by variants in *OCRL* which encodes PIP2 5-phosphatase that catalyzes an alternate reaction in PIP2 degradation. Suchy and Nussbaum (2002) suggested that elevated PIP2 levels in patients with Lowe syndrome cause abnormalities in the actin cytoskeleton. Here, we hypothesize that *PLCB3* loss of function variants may lead to elevated levels of PIP2 in affected cells causing the eye and skeletal phenotype in our patients. To test our hypothesis, we are performing F-actin staining to quantify stress fiber formation in patient fibroblasts.   .

2340F

Deletion of the first exon of *COL1A2* results in a mild form of osteogenesis imperfecta mediated by loss of transcription from the mutant allele. *J. Schleit[1], T. Tran[1], Y. Liu[1], T. Fields[1], D. Leistritz[1], E. Carter[2], J. Davis[2], P. Fernhoff[3], P.H. Byers[1,4].* 1) Department of Pathology, University of Washington, Seattle, WA; 2) Division of Genetics, Hospital for Special Surgery, New York, NY; 3) Department of Human Genetics, Emory University, Atlanta, GA; 4) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA.

More than 90% of individuals with osteogenesis imperfecta (OI) have variants in the type I procollagen genes, *COL1A1* and *COL1A2,* that encode the proα1(I) and proα2(I) chains, respectively. Approximately 70% of individuals with OI have variants within *COL1A1*. Almost half of the variants identified in *COL1A1* are heterozygous null variants due to introduction of a premature termination codon by any of several mechanisms. In contrast, null variants in *COL1A2* are rarely reported, perhaps because the phenotypic consequences are usually minor. We identified a heterozygous 851bp deletion within one allele of *COL1A2* that includes 54bp upstream of the translation start site, exon 1, and 760bp of intron 1in all members of a four generation family who had a history of fractures. This deletion prevented expression of one allele of *COL1A2*, confirmed by sequencing of cDNA, and resulted in reduced synthesis of proα2(I) chains of type I procollagen. Analysis of type I procollagen under non-reducing conditions showed increased formation of proα1(I) trimers. Identification of this variant indicates that *COL1A2* null variants can cause bone fragility and deletion/duplication analysis of both *COL1A1* and *COL1A2* should be considered when a genetic etiology of bone fragility is suspected.   .

2341W

Identification of novel compound heterozygous *BMP1* mutations in osteogenesis imperfecta with increased bone mineral density. *A. Shimada[1,2], M. Takagi[2,4], H. Fujita[3], S. Narumi[4], T. Hasegawa[4], G. Nishimura[5].* 1) Department of Pediatrics, Tama-Hokubu Medical Center, Tokyo, Tokyo, Japan; 2) Department of Endocrinology and Metabolism, Tokyo Metropolitan Children's Medical Center; 3) Department of Rehabilitation, Hokkaido Medical Center for Child Health and Rehabilitation; 4) Department of Pediatrics, Keio University School of Medicine; 5) Department of Radiology, Tokyo Metropolitan Children's Medical Center.

    Osteogenesis imperfecta (OI) is a spectrum of genetic disorders characterized by bone fragility and increased fracture risk. More than 90% cases of OI are caused by heterozygous mutation in *COL1A1* and *COL1A2* encoding for the two α-chains of collagen type I. In most of the cases, patients show markedly decreased bone mineral density reflecting abnormal synthesis of type I collagen. Here, we report an OI patient with high bone mineral density harboring mutation in *BMP1*. The patient is a 2-year-old Japanese boy who suffered from recurrent fractures from the neonatal period. He was the first child of nonconsanguineous healthy parents and born at term after uneventful pregnancy. Birth weight, length, and OFC were 3542g (+1.2 SD), 51.0cm (+0.8 SD) and 34cm (+0.4 SD) respectively. After the first fracture admitted on day 3, he experienced recurrent fractures without any episodes of significant trauma. Radiographs showed dense bone of lower limbs and no remarkable finding as OI was identified. Unexpectedly, he showed high bone mineral density at 11 months (BMD 0.26 g/cm^2, Z score +1.5 SD). On the suspicion of OI from the patient's clinical history, we sequenced 10 causative genes of OI by next generation sequencing and identified *BMP1* mutations (E214Q/X731S). Glutamine 214 is a highly evolutionarily conserved amino acid. BMP1 remove the C-propeptides from procollagen precursors and enable mature collagen monomers to form collagen fibrils. So far, fourteen patients of OI caused by *BMP1* mutation in 11 families were reported. BMD were evaluated in 7 families and increased bone mineral density was noted in 5 families. We also experience another case of OI with high bone mineral density harbouring a mutation in COL1A1 C-propeptide cleavage site. We should keep in mind that OI patients not always show decreased bone mineral density.

2342T

Whole exome sequencing ends the diagnostic odyssey for an infant with osteopetrosis. *C. Trujillo[1], L.C. Burrage[2], M. Jain[2], M.K. Alwasiyah[4,5], S. Jhangiani[3], D.M. Muzny[3], H. Bouazzi[6], B.H. Lee[2], R. Gibbs[3].* 1) Dept Gen, Erfan Hospital, Jeddah, Saudi Arabia; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030, USA; 4) Aziziah Maternity & Children Hospital, Jeddah, Saudi Arabia; 5) Center of Excellence in Genomic Medicine Research (CEGMR), King Abdulaziz University, Jeddah, Saudi Arabia; 6) Necker-Enfants Malades Hospital, Paris Descartes University, Paris, France.

    Osteopetrosis is a rare skeletal disorder associated with increased bone density secondary to impaired osteoclast differentiation or function. Osteopetrosis is genetically heterogeneous with multiple genes associated with the phenotype. Here, we present a 2 month old girl born to a consanguineous couple who was referred to us for pallor, growth failure and hepatosplenomegaly. On hematological examination, thrombocytopenia, leukocytosis and myelophthisic anemia were noted. Bone marrow studies suggested a possible diagnosis of "osteopetrosis." Radiographs, which showed uniformly increased bone density, confirmed the diagnosis. In particular, radiographs of the skull demonstrated thickened and dense bone, especially at the base, and sinuses were small and underpneumatized. By six months of age, macrocephaly with progressive blindness and deafness were noted Initially, Sanger sequencing of *TNFS11* was performed and was negative. Then, a next-generation sequencing panel of 14 genes associated with high bone mass was sent and was also negative. Consequently, whole exome sequencing was performed and revealed an apparently homozygous pathogenic variant in *SNX10* (p.Glu128fs) which is predicted to result in a frameshift in this gene and which was confirmed using Sanger sequencing. Pathogenic variants in *SNX10* have been associated with a diagnosis of osteopetrosis, autosomal recessive 8 (OMIM #615085), and this gene was not included on the previously performed gene panel. This diagnosis ended the diagnostic odyssey for this patient, and moreover, this case demonstrates the utility of whole exome sequencing in the setting of a negative gene panel for disorders with increasing genetic heterogeneity.

2343F

Mutation in the gene for osteoprotegerin in two families with calcium pyrophosphate deposition arthropathy. *C. Williams[1], A. Ortiz[1], U. Qazi[2], A. Kaell[2], M. Bernstein[2], G. Eshel[3], A. Rosenthal[4].* 1) Biomedical Sciences, Cooper Medical School of Rowan University, Camden, NJ; 2) John T Mather Memorial Hospital-SUNY Stony Brook Medicine, Port Jefferson, NY; 3) Department of Medicine, Assaf Harofe Medical Ctr, Tel Aviv, Israel; 4) Department of Medicine, Medical College of Wisconsin, Milwaukee, WI.

Calcium pyrophosphate deposition disease (CPDD) is characterized by the deposition of calcium-containing crystals in affected joints. When the disease occurs in families, it is inherited in an autosomal dominant manner and, in some cases, the occurrence of CPP crystals coincides with premature primary generalized osteoarthritis (PGOA). Two distinct genetic loci have been linked to the disease. The first locus, CCAL1, is on chromosome 8q while the second locus, CCAL2, is on chromosome 5p. To date, eight families with CPDD have been linked to the CCAL2 locus and missense, insertion, and frameshift mutations in the progressive ankylosis (ANKH) gene have been demonstrated. In 2015, a second gene for CPDD was reported with the discovery of a substitution mutation in the Stop codon of the TNFRSF11B gene in a Dutch CPPD/PGOA family (Ramos YF et al, Ann Rheum Dis 74(9):1756-1762, 2015). This gene codes for osteoprotegerin (OPG), a decoy receptor for RANKL that inhibits the binding of osteoclast-bound RANK thus inhibiting the differentiation of osteoclasts. We examined two CPDD families, one from Israel and one from the Northeastern US, for mutations in both ANKH and TNFRSF11B. While no mutations were observed in ANKH for either family, both families displayed the same read-through mutation of the termination codon (Stop402Leu) of the TN-FRSF11B gene as observed in the Dutch family. Genotyping of SNPs in and around the TNFRSF11B gene in affected members of each family demonstrated that the kindreds are apparently unrelated. Studies performed by Ramos et al suggest that this TNFRSF11B mutation results in a gain of function with respect to the ability of mutant OPG to inhibit osteoclastogenesis. In order to assess the potential impact of mutant OPG on pyrophosphate (PPi) generation, we performed metabolic labeling studies on fibroblasts from two affected members of our Israeli family and observed that levels of extracellular PPi were similar to those obtained for cultured fibroblasts from several unaffected controls. Furthermore, adding OPG to chondrocytes did not increase levels of extracellular ATP, a precursor of extracellular PPi. Finally, steady-state expression levels of ANKH transcript were unchanged in comparison to unaffected controls. These observations suggest that the Stop402Leu mutation in TN-FRSF11B does not significantly impact ANKH expression or function. Future studies will elucidate the role of OPG in CPDD.

2344W

An activating *IDH1* variant leading to inherited bilateral atypical hyaline cartilage neoplasms of the mastoid. *P.R. Blackburn[1], D. Oglesbee[2], T.R. Caulfield[3], N.J. Boczek[4,5], M.A. Cousin[4,5], J.M. Carter[2], R.H. Gavrilova[6,7], C.Y. Inwards[2], E.W. Klee[4,5].* 1) Center for Individualized Medicine, Mayo Clinic, Jacksonville, FL 32224, USA; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN 55905, USA; 3) Department of Neuroscience, Mayo Clinic, Jacksonville, FL 32224, USA; 4) Center for Individualized Medicine, Mayo Clinic, Rochester, MN 55905, USA; 5) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; 6) Department of Neurology, Mayo Clinic, Rochester, MN 55905, USA; 7) Department of Clinical Genomics, Mayo Clinic, Rochester, MN 55905, USA.

We report a family (mother and two sons) presenting in childhood with atypical cartilaginous tumors of the mastoid consistent with low-grade chondrosarcoma. The mother developed a unilateral middle ear mass that was resected with a mastoidectomy at 12-years-of-age. Her sons at 9- and 11-years-of-age presented with headaches, facial paresis, and conductive hearing loss requiring bilateral tympanomastoidectomy after the confirmation of bilateral mastoid tumors. The clinical presentation and radiologic features were suggestive of an atypical hyaline cartilaginous neoplasm with no clonal abnormality detected within the tumors. Research whole exome sequencing was performed on the germline of the proband, mother, father, and the proband's half-brother identifying a novel heterozygous missense variant in isocitrate dehydrogenase 1 (*IDH1*, NM_001282386.1, c.299G>A, p.R100Q) that was unique to the three affected individuals. IDH1 is a NADP-dependent enzyme that decarboxylates isocitrate into alpha-ketoglutarate (α-KG), an intermediate that is utilized by DNA and histone demethylases. Recently, somatic variants have been observed in conserved IDH1 residues that confer gain-of-function activity producing 2-hydroxyglutarate (2-HG) with neomorphic effect. In particular, the IDH1 p.R100Q protein variant has been shown to produce this oncometabolite and is observed in ~ 1% of gliomas. It is presumed that 2-HG inhibits the activity of α-KG-dependent dioxygenases and plays a role in tumor development through global dysregulation of the cellular epigenetic environment. Other somatic heterozygous variants in *IDH1* leading to missense changes at p.R132 are frequently found in Ollier disease (MIM# 166000), Maffucci syndrome (MIM# 614569), and metaphyseal enchondromatosis with urinary excretion of D-2-hydroxyglutaric acid (MIM# 614875). Tumors of the mastoid bone are exceedingly rare, with only a few cases reported to date and there have been no described cases of bilateral tumors developing independently at the same location. Here, we report the first case of a germline *IDH1* variant leading to development of rare bilateral chondrosarcoma of the mastoid. We hypothesize that p.R100Q protein variant may lead to low levels of 2-HG production, impede endochondral ossification, and promote tumor formation within embryonic cartilage rests.

2345T

'Corner fracture' type spondylometaphyseal dysplasia – heterogeneous disorder overlapping with type II collagenopathies. *K. Machol[1], M. Jain[1], M. Almannai[1], T. Orand[1], J. Lu[1,4], A. Schlesinger[3], R. Gibbs[1,4], S. Unger[2], L. Bonafe[2], A. Superti-Furga[2], B. Lee[1], P. Campeau[5], L. Burrage[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine , Houston, TX; 2) Center for Molecular Diseases, University of Lausanne, Lausanne, Switzerland; 3) Department of Pediatric Radiology, Texas Children's Hospital, Houston, TX; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics, CHU Sainte-Justine, University of Montreal, Montreal, QC, Canada.

Spondylometaphyseal dysplasias are a heterogenous group of disorders characterized by vertebral and metaphyseal abnormalities. Although the molecular basis for most of these disorders is known, the causative gene has not yet been identified for several of these disorders. Spondylometaphyseal dysplasia (SMD) 'corner fracture' type (also known as SMD 'Sutcliffe' type, MIM 184255) is a rare skeletal dysplasia that presents with mild to moderate short stature, developmental coxa vara, mild platyspondyly, corner fracture-like lesions and metaphyseal abnormalities with sparing of the epiphyses. The molecular basis for this disorder has yet to be clarified. We describe two patients with SMD 'corner fracture' type who have been found to harbor heterozygous pathogenic variants in *COL2A1* by Whole Exome Sequencing (WES). Patient 1 was found to have a de novo heterozygous missense variant in *COL2A1* gene (p.Gly345Asp) that was previously reported in a patient with spondyloepimetaphyseal dysplasia (SEMD) 'Strudwick' type. This is a type II collagenopathy characterized by defective growth and modelling of the spine and long bones with clinical features including disproportionate short stature, malformed vertebrae and abnormal epiphyses or metaphyses. Patient 2 was found to have a novel de novo heterozygous missense variant in *COL2A1* gene (p.Gly876Ser). Both variants are predicted to be pathogenic as they change a glycine residue in the type II collagen protein. These two cases, together with a third case of SMD 'corner fracture' type with a heterozygous *COL2A1* variant (p.Gly181Arg) previously described in the literature, suggest that this disorder is heterogeneous and overlaps with type II collagenopathies. The finding of one of the pathogenic variants in a previously reported case of SEMD 'Strudwick' type and the significant clinical similarity between the two syndromes, suggest an overlap between SMD 'corner fracture' and SEMD 'Strudwick' types.

Nonsense mutation in WTX gene and osteopathy striata with cranial sclerosis: Early onset of complications. *J. Prieto[1,2], M. Garcia-Acero[1].* 1) Instituto de Genetica Humana, Pontificia Universidad Javeriana , Bogota Cundinama, Bogota, Colombia; 2) Hospital La Victoria, SDS, Bogota, Colombia.

Introduction: Osteopathy striata with cranial sclerosis is a bone dysplasia, dominant X-linked inheritance caused by mutations in WTX a repressor of Wnt, which mediates bone formation, the alteration affects bone density by imbalance between osteoblasts and osteoclasts. Presents with skeletal abnormalities with radiographic findings in form of regular hyperdense linear bands from the metaphysis to diaphysis of long bones, fan-shaped striations in the iliac bones and sometimes is associated with craniofacial hyperostosis and extra-skeletal anomalies. The linear striations of long bones do not cause symptoms, while the cranial sclerosis is often symptomatic due to cranial deformities and injuries due to cranial nerve compression. To date, approximately 100 have been described cases. **Case presentation:** We present a female patient of 4 years with prenatal history of macrocephaly and history of global developmental delay, short stature and congenital ventricular septal defect, at physical examination had macrocephaly, prominent forehead, hypertelorism and cutaneous syndactyly in hands associated with headache, bilateral sensorineural hearing loss and decreased visual acuity. In the context of investigation of short stature, radiographs were requested with evidence of thickening of the cranial vault, longitudinal linear grooves in long bones and spiral fluted ilia. Exome sequencing identified a heterozygous nonsense mutation c.1072C>T in WTX gene, which leads to production of a truncated protein (p.R358X), the change not was evident in the parents, suggesting a de novo change confirming the clinical and radiological diagnosis of this patient. **Discussion.** Osteopathia striata with cranial sclerosis (OS-CS) is a bone dysplasia characterized by longitudinal striations of the metaphysis of long bones, sclerosis of the craniofacial bones and extra-skeletal symptoms. Diagnosis is based on clinical and radiological examinations. The clinical presentation is highly variable, skeletal manifestations ranging from mild to multisystem organ disorders. This patient had early onset of complications with prenatal evidence of cranial anomaly and auditory visual impairment secondary to severe cranial sclerosis. **Conclusion.** The OS - CS is a rare, lethal entity in men and highly variant in women. It should be considered as a differential diagnosis in the fetus/child with macrocephaly. The prognosis depends on the associated anomalies and multidisciplinary management. .

Vosoritide in children with achondroplasia: Updated results from an ongoing Phase 2, open-label, sequential cohort, dose-escalation study. *J. Hoover-Fong[1], M. Irving[2], C. Bacino[3], X. Cao[4], J. Charrow[5], V. Cormiere-Daire[6], W. Dummer[4], P. Harmatz[7], K. Jayaram[4], L. Katz[4], K. Larimore[4], J. Phillips[8], S. Vaidya[4], R. Savarirayan[9].* 1) Inst Genetic Med, Johns Hopkins Univ, Baltimore, MD; 2) Guy's and St. Thomas' NHS Foundation Trust, Evelina Children's Hospital, London, UK; 3) Baylor College of Medicine, Houston, TX, USA; 4) BioMarin Pharmaceutical Inc., Novato, CA, USA; 5) Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, USA; 6) Institut Imagine, Universite Paris Descartes, Hopital Necker - Enfants Malades, Paris, France; 7) UCSF Benioff Children's Hospital Oakland, Oakland, CA, USA; 8) Vanderbilt University Medical Center, Nashville, TN, USA; 9) Murdoch Children's Research Institute, Royal Children's Hospital Victoria, University of Melbourne, Parkville, Victoria, Australia.

Background and objectives Achondroplasia (ACH), the most common form of dwarfism, is caused by a mutation in the fibroblast growth factor receptor 3 gene (*FGFR3*) which leads to inhibition of endochondral bone growth. Vosoritide is an analog of C-type natriuretic peptide (CNP), a potent stimulator of endochondral bone growth. This global phase 2, multi-center, open-label, sequential cohort, dose-escalation study was designed to evaluate the safety, tolerability and efficacy of vosoritide for up to 24 months in children with ACH aged 5-14 years. Design and methods Subjects completed at least 6 months of pre-treatment growth measurements in an observational study prior to enrollment to establish baseline annualized growth velocity (AGV). 26 children (mean age 7.8 ± 1.8 years) were enrolled into 3 dose cohorts: 2.5 μg/kg/day (Cohort 1, n=8), 7.5 μg/kg/day (Cohort 2, n=8), and 15 μg/kg/day (Cohort 3, n=10) given daily by subcutaneous route. Based on favorable safety and efficacy data in Cohort 3 after 6 months of vosoritide at 15 μg/kg/day, 12 subjects at lower doses were subsequently escalated to 15 μg/kg/day for ≥6 months. Cohort 3 subjects received vosoritide at 15 μg/kg/day for at least 12 months. Results Vosoritide was generally well-tolerated at a dose of 15 μg/kg/day. The majority of adverse events (AEs) were mild and no serious AEs were reported as study drug-related. Common study drug-related AEs reported for Cohort 3 subjects during 12 months of treatment were injection site reactions (90% of subjects) and asymptomatic hypotension (40% of subjects), which were all mild. The safety profile in subjects escalated to 15 μg/kg/day for ≥6 months was similar, although two AEs of transient symptomatic hypotension were reported in two subjects of which one event was study drug-related. Both subjects continued to receive vosoritide without dose modification and the event did not recur. After 12 months at 15 μg/kg/day, Cohort 3 subjects had 1.9 ± 2.0 cm/year (46%) increase in mean AGV from baseline (p=0.02). Twelve subjects escalated to 15μg/kg/day for ≥6 months had an increase of 2.3 ± 1.9 cm/year (65%) in mean AGV from baseline. No worsening of body proportions was observed as measured by upper-to-lower segment ratio. Conclusions Vosoritide was generally well-tolerated at a dose of 15 μg/kg/day for up to 12 months. Safety and efficacy data support further evaluation and development of vosoritide for the treatment of children with ACH.

2348T

Whole genome sequencing identifies a paracentric mcro-inversion in a Chinese family with isolated split-hand/foot malformation type I. *W. Yang[1,2], Y.Z. Huang[2], D. Lv[2], Y.M. Xu[2], X.L. Zhao[2], X. Zhang[2].* 1) Center for Medical Genetics, Beijing Children's Hospital, Beijing, Beijing, China; 2) Department of Medical Genetics, Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences, Beijing, China.

Backgrounds: Six genetic loci have been identified for Split-hand/foot malformation (SHFM). Among them, Split-hand/foot malformation 1 (SHFM1[MIM 183600]) is caused by deletion, duplication, or rearrangement of chromosome 7q21.3, involving the *DLX5* (MIM 600028), *DLX6* (MIM 600030) genes and possible regulatory elements in the region. Some of those mutations can be detected directly by chromosome banding, chromosome microarray, but others of them, the micro or complex ones, maybe difficult to determine. **Purpose:** We collected a Chinese family with dominantly inherited non-syndromic SHFM and tried to find the causative mutation of the family. **Methods:** Blood samples were gathered from 12 family members including 4 patients. High resolution karyotype analysis and copy number variation (CNV) analysis by SNP array were carried out. Two point linkage analysis were performed on all known SHFM loci with dominant inheritance pattern. Candidate genes (*DSS1*[MIM 601285], *DLX5*, *DLX6*, *DYNC1I1*[MIM 603772]) and some conserved elements around *DLX5/DLX6* were screened by PCR-Sanger sequencing and qPCR. Finally, whole-genome sequencing (WGS) was performed on the proband, and variations within the 17Mb minimal shared haplotype of the family were analyzed. For a structure variation revealed by WGS, the breakpoint junctions were sequenced, then co-segregation analysis were performed by the junction PCR. **Results:** No causative abnormality was revealed through karyotyping or CNV analysis. After linkage analysis, five known SHFM loci were excluded, while SHFM1 was suggested linked. By Sanger sequencing or qPCR, no causative mutations were found at candidate genes or elements in the SHFM1 region. WGS revealed a 2.03Mb inversion at 7q21.3 (AC_002540.1:g65233_AC_091654.4:g16inv), which demonstrated co-segregating with the SHFM malformation in the family. *DLX5*, *DLX6* gene were found almost in the midst of the inverted fragment, and the proximal breakpoint located in intron 13 of the *SLC25A13* gene. At least three elements have been reported with enhancer activity in embryonic limb and just centromeric to the proximal breakpoint. The results above suggested that the 2.03Mb inversion was the cause of the limb malformation of the family, and it may result in the deformity by disturbing the proper interaction between the target genes such as *DLX5*, *DLX6*, and their limb-specific enhancers during embryo development.

Role of next generation sequencing (NGS) in genetic testing and counseling of hereditary skeletal dysplasias in developing countries. *L. Bhatnagar[1], K.J. Keerthi[1], M. Suraj[1], K. Das[1], K.A. Priya[1], S. Poornima[1], R. Jaiswal[2], S. Bopanna[3], Q. Hasan[1].* 1) Department of Genetics and Molecular Medicine, Kamineni Hospital, L.B. Nagar, Hyderabad, India; 2) Department of Orthopedics, KAMS & RC, L.B. Nagar, Hyderabad, India; 3) Department of Radiology, KAMS & RC, L.B. Nagar, Hyderabad, India.

‘Skeletal Dysplasia (SD)’ is an umbrella term for disorders, which affect the growth of bone and cartilage resulting in abnormal skeletal shape, size, and disproportionate stature. The current census (2011) documented nearly 3 crore disabled people in India, of which >50 lakh have movement disability, some of this is due to trauma, but a large number are due to neurological deficits or SD. The incidence of SD is approximately 1 in 5000, hence, a large proportion of moderate to severe disability is of this category. In developing countries where most of the population has to cater to their own health needs and there are very few support services for the disabled, having more than one affected child/individual in the family is devastating. SD is currently identified based on clinical and radiographical findings. Due to overlapping features exact diagnosis is difficult without molecular testing, hence most remain undiagnosed. In this pilot study, Next generation sequencing (NGS) was employed for exact diagnosis and appropriate management and prevention of hereditary SD through counseling. Twelve cases of SD identified after clinical evaluation and skeletal imaging were referred to the genetics unit of a tertiary care hospital in South India (2015-2016). Seven of the referred patients after detailed history and pedigree analysis by a genetic counselor were evaluated by NGS. Age of the patients ranged from 6 days to 32 years. A panel of 78 genes were assessed and all cases were diagnosed based on these: Osteogenesis Imperfecta (OI) I (*COL1A1*) and OI type VI (*SERPINF1*), Osteopetrosis 1 (*LRP5*) and 2 (*CLCN7*), Mucolipidosis type III (*GNPTG*), Fibrochondrogenesis 2 (*COL11A2*) and Mucopolysaccharidosis (*MPS*) type II (IDS). Specific, targeted mutation analysis was advised to high-risk family members after case-specific genetic counseling based on the type of hereditary disorder i.e., autosomal dominant, autosomal recessive, X-linked recessive. In this way, the benefit of the NGS could be extended to > 32 individuals belonging to these seven families. This pilot study indicates that NGS, though currently expensive, is the best option in developing countries like India, where the subsequent medical costs/disability support can be reduced after proper diagnosis and genetic counseling. The government should include this in its public health policy to both categorize cases of disability and prevent these from increasing to mitigate large-scale suffering.

2350W

A probably new type of mesomelic dysplasia with acral synostoses with scoliosis, antecubital pterigium, and aberrant flexion creases on palms and digits. *J.R. Corona-Rivera[1,2], B. Isidor[3], E. Zapata-Aldana[2], C. Peña-Padilla[2], S. Olvera-Molina[2], L. Bobadilla-Morales[1,2], A. Corona-Rivera[1,2].* 1) Instituto de Genetica Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) Servicio de Genética, Hospital Civil de Guadalajara "Dr. Juan I. Menchaca", Guadalajara, Jalisco, México; 3) CHU Nantes, Service de Génétique Médicale, Nantes, F44093, France.

Introduction. Mesomelic dysplasia (MD) with acral synostoses (AS) includes only the Verloes-David-Pfeiffer syndrome (VDPS, [MIM 600383]), and the mesomelic dysplasia Kantaputra type (MDK, [MIM 156232]). VDPS is characterized by short stature, typical facial gestalt, palatal abnormalities, and MD with AS, this last with proximal carpometacarpal fusion, proximal fusion of metacarpals 4 and 5, and brachydactyly (complex, postaxial). In MDK, the facial features and hands are normal, the fibula, talus, and calcaneus are small and the AS affects predominantly the lower limbs, including fibulocalcaneal synostosis, tibio-talus fusion, and the feet are described as ‘ballerina-like standing’. **Objective**: Here, we describe a mother and its daughter with a form of MD with AS that could correspond to a new type, since both have other previously unreported abnormalities. **Clinical reports.** *Patient 1*. The 21-year-old mother of this report had a height of 138 cm, normal intelligence, expressionless face, mild eyelid ptosis, micrognathia, mesomelic shortening in both upper and lower limbs (mild), antecubital pterigium, short fifth fingers (only), limited flexion of fingers, absence of digital flexion creases, aberrant palmar creases, and bilateral club foot. She had a progressive limited motion of joints. On radiographs, she had thoracic scoliosis, short ulna and radius with bowing (mild) and dislocated at elbow; fusion of carpal bones, proximal fusion metacarpals 4 and 5; coxa valga, short femoral necks, mild tibial and fibular shortening (without bowing), cuboid and cuneiform synostoses, and short metatarsals and phalanges (postaxial). *Patient 2*. She is the unique proposita's daughter and was born at term, with a birth length of 44.5 cm (<3rd percentile). She showed an overall phenotype almost similar to his mother, excepting for scoliosis and those age-related manifestations. In both, no evidence for deletions of *SULF1* and *SLCO5A1* genes at 8q13 was found using whole-genome oligonucleotide array CGH. **Discussion.** Although the phenotype in our patients resembles more the VDPS, array CGH ruled out this diagnosis. Associated abnormalities previously unreported in VDPS or MDK, including scoliosis, antecubital pterigium, and aberrant flexion creases on palms and digits, suggest that the disorder in this family probably represents a new form of autosomal dominant MD with AS. .

2351T

MEP1A mutation identified by whole exome sequencing in a family with slipped capital femoral epiphysis. *Y. Guo[1], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 2) Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 3) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

Slipped capital femoral epiphysis (SCFE) is an important pediatric and adolescent hip disorder in which a fracture through the growth plate (physis) results in slippage of the overlying end of the femur (epiphysis). Risk factors include sex (boy vs girl ratio around 2:1), ethnicity (Africans and Polynesians have higher rates), overweight/obesity (found in 2/3 of SCFE cases), and metabolic endocrine disorders (e.g. hypothyroidism, panhypopituitarism, hypogonadism, renal osteodystrophy, and growth hormone abnormalities). In a family with dominantly inherited bilateral SCFE and severe obesity, we performed whole exome sequencing in two affected kids and found a missense mutation in an enzyme gene MEP1A (meprin A subunit alpha; also known as endopeptidase-2, N-benzoyl-L-tyrosyl-p-aminobenzoic acid hydrolase, PABA-peptide hydrolase, or PPH). Sanger validation showed that this mutation is shared by two affected children and their affected mother. The mutation is located at a highly conserved genomic region (astacin) across vertebrates with very deleterious predictions, and is absent from any public database including ExAC of ~60,000 samples. The human BMP1 gene (bone morphogenetic protein-1) has the same domain astacin, mutations in which can cause osteogenesis imperfecta with SCFE relevant manifestations such as lack of bone modeling with wide distal metaphyses of femora. There are previous reports associating MEP1A gene variants with insulin metabolism, showing the importance of metalloendopeptidases in the breakdown of the gut hormone, and also linking metalloproteases meprin α and meprin β which are C- and N-procollagen proteinases to collagen assembly and tensile strength. Functional experiments are ongoing to characterize the role of MEP1A in developing SCFE related phenotypes.

2352F

Studying the genetic basis of idiopathic short stature using whole exome sequencing. *C.T. Thiel[1], N.N. Hauer[1], E. Schöller[1], S. Schuhmann[1], M.T. Wittmann[1], B. Popp[1], S. Uebe[1], C. Buettner[1], A.B. Ekici[1], R. Abou-Jamra[2], K. Kutsche[3], D. Wieczorek[4], H. Sticht[5], H.-G. Doerr[6], A. Reis[1].* 1) Institute of Human Gentics, Friedrich-Alexander-University of Erlangen-Nuremberg, Erlangen, Germany; 2) Institute of Human Genetics, University of Leipzig, Leipzig, Germany; 3) Institute of Human Genetics, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; 4) Institute of Human-Genetics, University Duisburg-Essen, Essen, Germany; 5) Institute of Biochemistry, FAU Erlangen-Nürnberg, Erlangen, Germany; 6) Department of Pediatrics and Adolescent Medicine, FAU Erlangen-Nürnberg, Erlangen, Germany.

Shortness of stature is a common medical concern in childhood and has an incidence of 3 % in the general population. After excluding defects of the growth hormone pathway and recognizable syndromes the underlying cause remains unknown in approximately 80-85 % of individuals. We now recruited and clinically characterized in detail a large study group of 560 families with idiopathic short stature and selected 200 individuals where common genetic causes were excluded. We first performed trio whole exome sequencing (WES) of affected individuals and their parents of normal height for 100 individuals (trio analysis). Variants were selected unbiased based on all possible modes of inheritance in agreement with the segregation in the families and their potential effect on protein function. To further evaluate candidate genes we performed WES in 100 further individuals with targeted follow-up of single variants in parents. In 21 individuals we found mutations in known short stature genes including *COL2A1*, *CUL7*, *PDE3A* and *KDM5A* (59% dominant, 14% recessive and 27% X-linked inheritance). The underlying diagnosis was missed clinically as characteristic clinical features of the syndromes were missing. The most common mutated gene was ACAN. In the remaining 89 trios we found potential protein affecting variants in 126 novel candidate genes in 62 of the affected individuals. Within our study, a second variant with a compatible inheritance was found for 16 of the 126 candidate genes in the 100 patients of the affected only analysis. Two further genes were also recently listed in another WES study for idiopathic short stature in agreement with our observed dominant *de novo* model of inheritance. The functional analysis of the remaining 120 candidate genes reveled 31 genes with gene-level relevance, suggesting that they are involved in idiopathic short stature. In conclusion, exome analyses of 200 patients with idiopathic short stature identified a known cause of shorted stature in 11% of cases. As the clinical spectrum of most known genetic defects is yet to be explored, an unbiased genetic analysis of patients with idiopathic short stature can help establish a diagnosis in these cases. Furthermore, we found 126 potential novel candidate genes in 62% of the individuals including 18 genes with independent mutations in two individuals each. Thus, our data strongly suggest that single gene defects may be a frequent cause for idiopathic short stature.

2353W

Novel mutations in the fourth β-propeller domain of *LRP4* **are associated with isolated syndactyly with fusion of the third and fourth fingers.** *R. Sukenik Halevy, B. Heinz, N. Ahituv.* Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA.

LRP4 mediates *SOST*-dependent inhibition of WNT signaling and therefore has a negative impact on bone formation. Mutations in this gene cause 3 known syndromes; Myasthenic syndrome, Cenani-Lenz syndactyly syndrome and Sclerosteosis 2 with the latter two having various limb malformations including syndactyly. Using exome sequencing on a trio with a child that has isolated bilateral hand syndactyly with complete fusion of the 3rd and 4th fingers, we identified mutations in *LRP4* to be associated with this phenotype. The patient is a compound heterozygote for two non-synonymous variants, each inherited from a different parent: p.Q1564K and p.D1403H. These variants have not been previously reported in online databases and have CADD scores above 20. No other limb malformation associated *de novo* coding mutations were identified. Analysis of a healthy sib showed that he is not a carrier of these mutations. These variants are located in the 16th and 19th repeats of the LDL-receptor class B protein domain which are within the 4th β-propeller of the extracellular domain of this protein. The extracellular ß –propeller domain is thought to be critical for ligand release and recycling of the receptor as well as for the inhibitory action of sclerostin during WNT signaling. Mice carrying two recessive mutations in the *Lrp4* gene were reported to have polysyndactyly and abnormal nails and incisors. Targeted phenotypic evaluation of our patient revealed no phenotypic features related to any of the known syndromes except for growth parameters which were in the upper normal range (probably constitutional), 5th finger clinodactyly and missing three teeth. To functionally validate these mutations, we are using luciferase reporter assays to assess WNT signaling in the presence and absence of these mutations. In addition, we are currently sequencing exons 28-32, which code for the 4th propeller domain, in a cohort of patients with similar isolated syndactyly phenotypes. In summary, we report a novel *LRP4* phenotype in a patient with isolated bilateral third and fourth finger syndactyly. The two mutations found in our patient are located at a domain in which mutations have not been reported before, indicating the existence of a new attenuated LRP4 phenotype. Acknowledgments: Sequencing was provided by the University of Washington Center for Mendelian Genomics and was funded by the NHGRI and the NHLBI grant 2UM1HG006493 to Drs. Nickerson, Bamshad and Leal.

2354T

Severe Osteogenesis Imperfecta (OI) in 3 Vietnamese siblings with a homozygous mutation of prolyl 3-hydroxylase 1 (*P3H1***), also known as** *LEPRE 1*. *E. Elias[1], B. Tucker[2].* 1) Dept Genetics & Pediatrics, Children's Hospital Colorado, Aurora, CO; 2) Colorado Fetal Care Center, Children's Hospital Colorado, Aurora, CO.

Osteogenesis Imperfecta (OI) is a disorder of connective tissue, usually caused by dominant mutations in type 1 collagen. Patients have been reported with recessive mutations in genes associated with post-translational modifications of type 1 collagen, including P3H1. A Vietnamese family is reported with three affected siblings, presenting with a severe but non-lethal form of OI. These patients help to expand the phenotype and ethnic background of patients with confirmed P3H1 mutations. **Case 1:** 1965 g male product of a 37 week gestation to healthy non-consanguineous Vietnamese parents. The pregacy was closely followed due to a history of two prior children with OI as well as prenatally detected short stature and multiple fractures. At birth the baby was vigorous, but required nasal cannula oxygen. The baby had a transverse defect of the R hand. Post-natal films showed multiple fractures of all long bones, gracile ribs with many fractures, and markedly decreased calvarial mineralization. The baby fed well and was discharged on 0.5L oxygen. He had hearing loss on newborn screen. **Case 2:** 5 yr old sister of case 1, with multiple fractures seen pre- and post-natally. She required nasal cannula O2 during infancy but has no current respiratory issues. She had multiple renal stones as an infant, which resolved with bisphosphonate treatment. She can ambulate with assistance following rodding of her lower extremities. She is cognitively normal with a normal brain MRI. Xrays show diffuse osteopenia and gracile bones but no popcorn epiphyses. **Case 3:** 9 yr old sister of case 1, with multiple fractures pre- and post-natally. She had no respiratory issues. She had hypercalciuria during infancy, but no renal stones. Her brain MRI showed basilar invagination which resolved by age 8. She has had multiple rodding procedures and is a wheelchair ambulator. She is cognitively bright. Xrays show no popcorn epiphyses. **Genetic Testing:** a homozygous c.1170+5G>C (IVS6+5G>C) mutation was seen in all 3 siblings, which disrupts the intron 6 splice site causing exon 6 skipping. **Conclusions:** The phenotype of this homozygous mutation in P3H1 includes severe but non-lethal OI, minimal respiratory issues, basilar invagination and hypercalciuria. No popcorn epiphyses were noted, as has been reported in other patients with LEPRE 1 mutations. These cases provide additional proof that DNA testing in patients with OI can help clarify the diagnosis, as well as provide accurate recurrence risk.

2355F

Nager syndrome presenting with osteoporosis in a 10 year-old male with a novel mutation of SF3B4. *A. Labilloy[1], R. Stottmann[1], C. Gordon[2], B. Kline-Fath[3], H. Saal[1], R. Hopkin[1].* 1) Human Genetics, Cincinnati Children's Medical Center, Cincinnati, OH; 2) Plastic Surgery, Cincinnati Children's Medical Center, Cincinnati, OH; 3) Radiology and Medical Imaging, Cincinnati Children's Medical Center, Cincinnati, OH.

Nager syndrome (MIM 154400) is a type of acrofacial dysostosis characterized by hypoplasia of 1st and 2nd branchial derivatives and preaxial limb abnormalities. The condition is most commonly caused by mutations in SF3B4, which encodes a spliceosome-associated protein involved in BMP signaling, a major mediator of bone development and homeostasis. Estimated prevalence is 1:250,000. We report clinical outcomes of a 10 year-old male prenatally diagnosed with Nager syndrome due to sonographic and fetal MRI findings concerning for severe micrognathia and severely shortened upper limbs with apparently normal brain development. Patient was delivered at 35 weeks by scheduled EXIT procedure for upper airway obstruction requiring tracheotomy while on placental bypass. At birth, multiple craniofacial anomalies were noted, including severe micrognathia with cleft palate, hypoplasia of mastication muscles, microtia with bilateral hearing loss, lid coloboma. Other findings included sacral dimple and hypospadias. MLB/FOB revealed dysplastic epiglottis, posterior glottic stenosis and laryngotracheoesophageal cleft. In addition several skeletal abnormalities were observed, including asymmetric foreshortened upper extremities with absent radius and thumb and bifid humerus, genu valgum, pes planus, Morton's toe with sandal gap deformity and C1 ring hypoplasia. He has a history of two fractures, and at age 10 he was found to be osteopenic with gracile bones on foot Xray. A DEXA scan showed severe osteoporosis (Z score -5.7). Patient is gastrostomy and tracheostomy-dependent, and has a history of motor and speech delays. He has a mouth aperture of 35 mm. He is cognitively and behaviorally appropriate for his age and socially active independently. Molecular testing revealed a novel c.34+15A>T transversion in IVS1 of SF3B4 gene, predicted to generate a new donor splice site, with the potential to result in aberrant mRNA processing. This case illustrates the importance of screening patients with Nager syndrome for osteoporosis, especially those with history of fractures. Given a possible pathogenic link between SF3B4 and bone homeostasis, osteoporosis and skeletal involvement beyond upper limbs are predictable, but unreported features of Nager syndrome. Long-term natural history data for patients with Nager syndrome are crucial for management decisions with the most severe patients. Long-term survival and good QOL are possible.

2356W

Association between the *p.Pro392Leu* mutation within *SQSTM1* gene and air pollutants in Paget's disease of bone. *L. Michou[1,2,3], M.S. Numan[1], J.P. Brown[1,2,3], S. Jean[2,4].* 1) CHU de Québec Research Centre, Quebec (Quebec) Canada; 2) Department of Medicine, Laval University, Quebec (Quebec) Canada; 3) Department of Rheumatology, CHU de Québec, Quebec (Quebec) Canada; 4) Institut national de santé publique du Québec, Quebec (Quebec), Canada.

Purpose: The *p.Pro392Leu* mutation in *SQSTM1* gene is the most frequent mutation linked to Paget's disease of bone (PDB). Associations between PDB and environmental factors such as rural residency, tobacco smoke and wood heating, were also reported. We searched for potential association between the *p.Pro392Leu* mutation and air pollutants in PDB. **Methods**: We studied a subgroup of our French-Canadian cohort consisting in 110 patients, including 39 carriers of the *p.Pro392Leu* mutation, and 113 noncarriers healthy controls. We used a questionnaire on the history, during life, of residence and proximity to sources of outdoor air pollutants (highways, bus, train or airport stations, gas stations). For indoor air pollutants, questions on heating combustibles (carbon, wood, oil) used in past residences and tobacco exposure were also used. Associations between air pollutant exposures and PDB were assessed with Chi-squared, Fisher and t tests. Odds ratio (OR) and 95% confidence intervals were calculated. Multivariate analysis was performed by stepwise selection of variable with p<0.1 in univariate analyses. In a subgroup of patients (n=11 to 29) and controls (n=12 to 48), urinary concentration of 17 heavy metals measured by mass spectrometry were compared by the use of a Wilcoxon test. **Results:** In multivariate analysis, PDB patients carrier of the *p.Pro392Leu* mutation were less frequently exposed than controls to residence close to highways (OR=0.04 [0.02-0.13], p<0.0001). They were less frequently exposed to tobacco smoke in the residence in childhood (OR=0.25 [0.07-0.86], p=0.04) and to forced air from central carbon heating system (OR=0.15 [0.04-0.59], p=0.02). Exposure to forced air from central oil heating systems was the only indoor air pollutant positively associated with pagetic patients carrier of the *p.Pro392Leu* mutation (OR=5.04 [0.92-27.52]) but not with sporadic PDB patients (OR=0.64 [0.24-1.77], p=0.05). Only mean levels of urinary lead were found to be higher among patients with the mutation than controls (p=0.07). **Conclusions:** Patients with PDB carrier of the *p.Pro392Leu* mutation were less frequently exposed to outdoor air pollutants during childhood, which is consistent with the known association of PDB with rural residency, whereas they were more frequently exposed to forced air from oil heating systems. Higher levels of urinary lead in patients with PDB carrier of the mutation may support some potential role for air pollutants in PDB.

Previously unreported *TCIRG1* mutation in a young girl with osteopetros-is. *A. Nastro[1], V. Neerukonda[1], K. Kerr[2], G. Kennedy[2], H. Gao[3], G. Amundson[4], I. Kharode[5], J.A. Brochstein[6], I. Sahdev[6], J. Gross[5], R.R. Lebel[1].* 1) Center for Development, Behavior and Genetics, SUNY Upstate Medical University, Syracuse, NY; 2) Division of Pediatric Hematology-Oncology, SUNY Upstate Medical University, Syracuse, NY; 3) Fulgent Diagnostics, Temple City, CA; 4) Division of Pediatric Radiology, SUNY Upstate Medical University, Syracuse, NY; 5) Department of Pediatrics, SUNY Upstate Medical University, Syracuse, NY; 6) Division of Pediatric Hematology-Oncology, Cohen Children's Medical Center of NY, New Hyde Park, NY.

We report a 2-year-old female with infantile malignant osteopetrosis, type 1B (OPTB1), with heterozygous mutations at the *TCIRG1* gene, one previously unreported and the other known. She also has a mutation of unknown significance in the *OSTM1* gene. Pathogenic mutations at both of these loci are recessive for infantile malignant osteopetrosis. Pregnancy and delivery were uneventful. However, the neonate returned a few days after birth due to poor feeding and irritability. She was found to have petechiae, hepatosplenomegaly, thrombocytopenia, anemia, leukocytosis, and hypocalcemia with elevated PTH. All of these are features of OPTB1. Her condition worsened, and infantile malignant osteopetrosis was diagnosed via plain film chest x-ray and clinical correlation. She had not yet displayed any dysmorphic features, but after a few months frontal bossing was noted. Skeletal dysplasias NGS Panel, which sequenced 161 genes, revealed heterozygous mutations at the *TCIRG1* gene, leading to a formal diagnosis of OPTB1. *TCIRG1* encodes for the 116kD subunit of the osteoclast-specific vacuolar proton pump, and mutations in this gene are the most common recessive cause of infantile malignant osteopetrosis. *OSTM1* encodes for osteopetrosis-associated transmembrane protein 1. Mutations in this gene are a recessive cause of a very severe form of infantile malignant osteopetrosis. Our patient is heterozygous for *TCIRG1* mutation NM_006019.3:c2066G>A (p.Trp689*), a variant not previously reported in the HGMD database or the Broad ExAC dataset. This is a nonsense mutation and considered to be pathogenic. She is also heterozygous for mutation NM_006019.3:c.1674-1G>A, which is thought to affect RNA splicing by changing the canonical acceptor splice site at the -1 position in intron 14. This variant has been reported previously as pathogenic for osteopetrosis. Finally, she is heterozygous at the *OSTM1* gene, for mutation NM_014028.3:c.143c>G (p.Ser48Trp). This allele has been noted previously, and has been noted at 0.83% in the African population. This is a missense mutation, likely to be benign. Computation tools (Align GVGD and MAPP) predict it to be benign, but SIFT predicts it to be deleterious. Ser and Trp have a large physiochemical difference, thus further computational analysis and correlation with other instances of *OSTM1* mutations is necessary to determine the extent to which the three mutations together could be exacerbating the pathologic phenotype of our patient.

2358F

Expanding the clinical and mutational spectrum of *B3GALT6*-associated Ehlers-Danlos syndrome and spondyloepimetaphyseal dysplasia with joint hypermobility type 1. *F. Malfait[1], T. Van Damme[1], X. Fournel-Gigleux[2].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, OV, Belgium; 2) MolCelTEG Team, UMR 7365 CNRS-Université de Lorraine (IMoPA), Biopôle UL, Faculté de Méde-cine, Vandoeuvre-lès-Nancy, France; 3) Department of Clinical Genetics, Maastricht UMC, Maastricht, The Netherlands; 4) Department of Human Genetics, Radboud UMC, Nijmegen, The Netherlands; 5) Kariminejad-Na-jmabadi Pathology & Genetics Center, Tehran, Iran; 6) Department of Pediatric Genetics, Amrita Institute of Medical Sciences & Research Centre, Cochin, Kerala, India; 7) Service de Génétique Médicale, CHU liège, Liège, Belgium; 8) Department of Pediatrics, University of Colorado, Colorado, USA; 9) Department of Cardiology, University of Colorado, Colorado, USA; 10) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Proteoglycans (PGs) are among the most abundant and structurally complex biomacromolecules, and are indispensable in many biological functions. They are composed of a core protein onto which one or more glycosaminoglycan (GAG) side chains are covalently attached via a tetrasaccharide linker region. Biallelic mutations in *B3GALT6*, encoding the linker region enzyme β3GalT6 or galactosyltransferase II, were recently shown to cause a spectrum of human Mendelian disorders ranging from spondyloepimetaphyseal dysplasia with joint hypermobility type 1 (SEMDJL1) to a severe pleiotropic Ehlers-Danlos syndrome (EDS) like disorder with joint hyperlaxity, progressive contractures, kyphoscoliosis, muscle hypotonia, skin and bone fragility and spondyloepi-metaphyseal dysplasia. We report on 11 novel patients (8 families) with either SEMDJL1 (4 families) or β3GalT6-deficient EDS (4 families), and expand the clinical spectrum to include severe and potential life-threatening complications, including atlanto-axial instability, aortic root dilatation, tracheomalacia, and respiratory dysfunction. Whole-exome sequencing or traditional Sanger sequencing identified biallelic *B3GALT6* mutations, mostly frameshift and missense mutations, in all families. Using immunofluorescence microscopy, we show that *B3GALT6* mutations reduce the amount of β3GalT6 protein in patient derived cultured dermal fibroblasts. In addition, high performance liquid chromatography showed a (near-) complete loss of galactosyltransferase activity towards the towards Galβ1-4Xyl(2-*O*-phosphate)-O-MethoxyNaphthyle substrate, and a decreased ability to prime GAG synthesis in patient-derived β3GalT6-deficient fibroblasts. We were unable however to correlate protein level or enzymatic activity with observed phenotypes. Finally, we observed impaired glycanation of the small chondroitin/dermatan sulfate PG decorin, and ultrastructural abnormalities in collagen fibril organization which empha-sizes the importance of GAG chains in this process. In conclusion, our study expands the molecular and clinical spectrum of B3GALT6-associated EDS and SEMDJL1.

Whole-exome sequencing identified novel compound heterozygous mutations in a Japanese patient with Geroderma Osteodysplastica. *R. Takeda[1], M. Takagi[2], H. Shinohara[3], S. Narumi[4], T. Hasegawa[5], H. Yoshihashi[1].* 1) Department of Medical Genetics, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 2) Department of Endocrinology and Metabolism, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan; 3) Department of Pediatrics, Ibaraki Seinan Medical Center, Ibaraki, Japan; 4) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan; 5) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan.

[;Introduction];Geroderma Osteodysplastica (GO) is one of the subtypes of Cutis Laxa syndrome, which is characterized by congenital wrinkly skin, prematurely aged face, severe short stature, and osteoporosis leading to recurrent fractures. GO is inherited in an autosomal recessive pattern, and caused by loss of function mutation in GORAB gene that encodes a protein important for Golgi-related transport process. We report whole-exome sequencing identifies novel compound heterozygous nonsense mutation of the GORAB gene in a patient with GO. [;Case report]; The patient is 14 years old Japanese boy born through normal delivery at 38 weeks of gestation with a birth weight was 2,680g (-0.8 SD) and length was 50.6 cm (+0.8 SD). Wrinkle skin and joint laxity were present at birth. At 1 year of age, he was clinically diagnosed with Cutis Laxa syndrome based on recurrent long bone fracture and clinical features such as wrinkle skin, joint laxity, and distinctive face. His gross motor and cognitive development were not retarded. At 10 years of age, he was treated with oral bisphosphonate and vitamin D because of recurrent multiple spontaneous fractures of vertebral and extremities bone associated with lower bone mineral density (BMD). After the initiation of bisphosphonate treatment, his BMD and fracture rate were significantly improved. Whole-exome sequencing revealed two novel compound heterozygous nonsense mutations in the GORAB gene (p.R60*, p.Q124*), and established the diagnosis of GO.[;Discussion]; GO is a rare connective tissue disorder; with only 40 cases have been described in the literature so far, and this is the first report from Japan. There are few reports on the effects of the bisphosphonate treatment for GO patients with recurrent spontaneous fractures. We propose that oral bisphosphonate and vitamin D were effective and safe treatment option in the management of recurrent fractures with GO. It is important to make a precise diagnosis of GO to prevent recurrent fractures and for selecting better treatment.

2360T

Dominant cutis laxa with progeroid features due to a novel, *de novo* **mutation in** *ALDH18A1***.** *P.T. Bhola[1], S.N. Nikkel[2], T. Hartley[1], D.A. Dyment[1], K.M. Boycott[1], Care4Rare Consortium.* 1) Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Medical Genetics, BC Women's Hospital and Health Centre, Vancouver, British Columbia, Canada.

Autosomal recessive cutis laxa type 3, or De Barsy syndrome, is a rare condition characterized by cutis laxa, a progeroid appearance, ophthalmological abnormalities and intellectual disability. It is caused by biallelic mutations in the gene *PYCR1*, which encodes pyrroline-5-carboxylate reductase 1 or biallelic mutations in *ALDH18A1*, which encodes pyrroline-5-carboxylate synthase (P5CS). These gene products are mitochondrial enzymes that have a role in proline biosynthesis. It was recently recognized that there is a dominant form of De Barsy syndrome that is caused by *de novo* mutations in *ALDH18A1*. The individuals with *de novo* mutations all have a recurrent substitution at p.Arg138. We report the case of an 8 year old male who presented to Genetics with cutis laxa and suspected photophobia at 1 month of age. His medical history includes corneal clouding, cataracts, global developmental delay, bilateral adducted thumbs, bilateral congenital hip dislocation and inguinal hernias. The family is of Somali descent and the patient's parents are consanguineous. At age 8, cutis laxa and distinctive features were present and growth parameters of head circumference, height and weight were 5-6 standard deviations below the mean. Clinical genetic testing revealed a normal chromosomal SNP microarray. Due to the presumed recessive inheritance of the disorder and consanguinity in the family, the patient was enrolled in a whole exome research study at the Children's Hospital of Eastern Ontario, which also identified the heterozygous Arg126His mutation. No other pathogenic or likely pathogenic mutations were found. *In silico* analysis of this mutation predicted that it was deleterious. Segregation analysis in the parents by Sanger sequencing showed that the mutation was *de novo*. This report describes a novel dominant mutation in *ALDH18A1* in a patient with cutis laxa with progeroid features. As with the Arg138 mutation, the Arg126His mutation affects the gamma-glutamyl kinase domain of P5CS. Certain heterozygous mutations in A*LDH18A1* affecting the gamma-glutamyl kinase domain or the glutamyl-phosphate reductase domain of P5CS are causative for spastic paraplegia 9A, which is characterized by progressive spasticity. A greater understanding of dominant cutis laxa with progeroid features and of mutations in *ALDH18A1* will have implications for diagnosis and genetic counselling of these patients.

De novo missense variant in the *KIT* proto-oncogene in a child with piebaldism. *E. Tan, J.C. Nagaputra, E. Lim, H.W. Lim, M. Brett, M. Koh.* KK Women's & Children's Hospital, Bukit Timah Road, Singapore.

   Piebaldism is a rare congenital pigmentation disorder caused by the absence of melanocytes and melanin in certain areas of the skin. It is characterised by depigmented patches of skin and hair. Physical presentation include white forelock, hypopigmented patches on the face, trunk and limbs, often with islands of hyperpigmentation.   We report the findings in a Eurasian girl conceived via *in vitro* fertilization. Her mother is of Chinese ancestry while her father is German. She was born prematurely at 33 weeks of gestation via emergency caesarean section for IVF dichorionic diamniotic twins in labour. There was no family history of pigmentation disorders and her non-identical twin sister was normal. At birth, she was noted to have a white forelock with patches of depigmentation and multiple café-au-lait macules. When she was reviewed at 4 years of age, she had the white forelock with multiple well-demarcated, depigmented patch over the central forehead, neck and limbs. There were also multiple café-au-lait spots, and inguinal freckling. Her cognitive and physical development is normal for her age.   Genomic DNA was extracted from venous blood and sequenced using the TruSight One panel on the MiSeq System. Analysis revealed no pathogenic mutation for *SPRED1* and *NF1*, but a heterozygous missense mutation was detected in *KIT*. This variant results in the substitution of Leucine with Arginine in the intracellular tyrosine kinase domain of the *KIT* protein. It has not been reported in the Human Gene Mutation Database or in published literature. It is not found in the DNA from the saliva sample of her unaffected sister or the blood samples of her parents. This change is predicted to be pathogenic according to SIFT and Polyphen2. The phenotype of the patient is consistent with the diagnosis of piebaldism with depigmented patches and islands of normal/hyperpigmented skin. The presence of a pathogenic variant in the heterozygous state is consistent with the molecular genetics of this autosomal dominant disorder. Our report of this novel missense variant adds to the spectrum of pathogenic mutations in the *KIT* gene in patients with piebaldism.

New mutations and genotype/phenotype correlation in patients from consanguineous families from Saudi Arabia and Pakistan with different forms of autosomal recessive congenital ichthyosis. *D.Lima Cunha[1,2,3], O.M. Alakloby[4], K.M. Eckl[1,2,7], M. Rauch[2], R. Casper[3], N. Kakar[5], B. Krabichler[2], R. Gruber[2,6], J. Altmüller[3], P. Nürnberg[3], J. Zschocke[2], G. Borck[5], M. Schmuth[6], K.A. Alnutaifi[4], A.S Alabdulkareem[8], H.C. Hennies[1,2,3].* 1) Dept. of Biological Sciences, University of Huddersfield, Huddersfield, United Kingdom; 2) Div. of Human Genetics, Innsbruck Medical University, Innsbruck, Austria; 3) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 4) Dept. of Dermatology, University of Dammam, Dammam, Saudi Arabia; 5) Inst. of Human Genetics, University of Ulm, Ulm, Germany; 6) Dept. of Dermatology, Innsbruck Medical University, Innsbruck, Austria; 7) Dept. of Biology, Edge Hill University, Ormskirk, United Kingdom; 8) King Saud Medical City, Riyadh, Saudi Arabia.

   Autosomal recessive congenital ichthyosis (ARCI) is a genetically and phenotypically heterogeneous skin disease with varying features and degrees of severity. Several but not all genes with underlying mutations have been identified, but no clear correlation between the genetic causes and the clinical picture has been described to date. Our study included 13 families from Saudi Arabia and 5 from Pakistan. All patients were diagnosed with a form of ARCI and had a family history of consanguinity. We used homozygosity mapping as an initial screening tool and identified homozygous causal mutations in all patients by massively parallel and/or Sanger sequencing. Mutations were in five different genes and included several known and five unknown mutations: a splice site and a missense mutations in *TGM1*, a splice site mutation in *NIPAL4*, and missense mutations in both *ABCA12* and *CYP4F22*. New insights in phenotype/genotype correlations were accomplished, with *TGM1* mutations resulting in coarse dark brownish scaling, in contrast with *NIPAL4*, *ALOXE3* and *CYP4F22* patients, who presented with more localized, light-colored scales and partly erythematous skin. Our patients with *ABCA12* missense mutations, who were initially diagnosed with congenital ichthyosiform erythroderma, showed the most severe phenotype with generalized fine white scales and severe erythema. Patients with a "self-healing" phenotype, referred to as self-improving congenital ichthyosis, who had hardly any remaining signs of skin disease in early childhood, were also shown to have missense mutations in *TGM1*. Within the spectrum of ichthyosis phenotypes, we can attribute *TGM1* and *ABCA12* mutations to the most severe forms of lamellar and erythematous ichthyoses, respectively. The other mutations confirm the presence of a phenotypic spectrum, however, still lead to a rather lamellar course of the disease. This is in accordance with the assumption that these gene products are involved in ceramide metabolism of terminally differentiating keratinocytes, whereas ABCA12 contributes to transport of various lipids, including glucosylceramides, and inactivation of ABCA12 might result in intracellular accumulation of lipids such as gangliosides. Our findings contribute to expanding the mutational spectrum of ARCI and give further important insights into the genotype/phenotype correlation that is much needed for an easier and more precise diagnosis and the definition of targets for more specific therapies for ARCI.

Congenital contractural arachnodactyly (CCA) is an autosomal dominant connective tissue disorder manifesting joint contractures, arachnodactyly, crumpled ears, and scoliosis as main features. Its rarity and substantial overlap with other conditions including Bethlem myopathy, Marfan syndrome and distal arthrogryposes, make the diagnosis challenging, though important for clinical management. CCA is caused by mutations in FBN2. We performed a comprehensive clinical and molecular assessment in a large cohort of CCA patients to delineate clinical diagnostic criteria and guide molecular analyses for FBN2. FBN2 analysis using either Sanger Sequencing or PCR-based next-generation sequencing was performed in 122 clinically well-characterized probands. We collected data on 10 main clinical characteristics, and determined the sensitivity, specificity, and positive and negative predictive value to find an FBN2 mutation for each feature in order to establish a weighted clinical scoring system on 20 points. Forty-seven probands harbored an FBN2 mutation (mutation uptake rate 39%). All but 2 mutations were located in the neonatal region (exons 22-36) with half of them altering or producing cysteines. Two patients carried inframe multi-exon deletions, one had a premature truncating mutation. Logistic regression analysis revealed a significantly higher clinical score in FBN2+ versus FBN2- patients (resp. 11,6 vs 7,7; p<0,001). ROC curve analysis revealed that a clinical score of 11+ yields a sensitivity of 84% and a specificity of 60% to find an FBN2 mutation. A score of 6 or lower is unlikely to be associated with an FBN2 mutation, unless in adult patients. In addition, review of cardiovascular features revealed non- or slowly progressive aortic root dilatation in 5 FBN2+ patients and 6 FBN2- patients. Though aortic root dilatation is a non-discriminative feature, its occurrence in CCA does warrant echocardiographic follow-up. .

2364F

Autosomal dominant adermatoglyphia is attributed to a 50kb deletion impacting *SMARCAD1. X. Chang, L. Tian, Y. Liu, R. Pellegrino, P. Sleiman, H. Hakonarson, L. Castelo-Soccio.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Adermatoglyphia (ADG) is an extremely rare genetic disorder, which causes a person to have no fingerprints. ADG with associated anomalies such as congenital facial milia and acral blisters, digital contractures, and nail abnormalities, is also described as Basan Baird Syndrome. All ADG-causing mutations identified to date are transversions, which disrupt a single conserved donor splice site adjacent to the 3' end of a noncoding exon (the first exon of the short isoform) and result in haploinsufficiency for a skin-specific isoform (short isoform) of *SMARCAD1*. Here we report on a family trio where the father and child were affected with ADG and associated anomalies including bilateral webbing of toes, bilateral contractures. The father and child also exhibited milia on the face and blistering of the feet in the neonatal period consistent with what has been reported as Basan Baird Syndrome. We sequenced the blood DNA samples of this family by whole exome sequencing (WES). No previously reported mutations were found in any members of this family though an additional family members are not affected . However, a heterozygous deletion covering the first 10 exons of the long isoform and the first exon of the short isoform in *SMARCAD1* was detected in both the affected father and child by XHMM. The deletion was further confirmed by PCR validation. In comparison with the four ADG families previously reported, our ADG cases also displayed additional phenotypes, including but not limited to bilateral webbing of the toes, bilateral contractures and milia, suggesting that the disruption of the long isoform may be associated with those phenotypes. In addition, the long isoform of *SMARCAD1* has been shown to regulate the expression of transcriptional factors, histone modifiers and development-associated genes. This is the first report of an ADG family caused by a copy number variation.

2365W

Protein replacement therapy for autosomal recessive congenital ichthyosis (ARCI). *H.C. Hennies[1,2,3], R. Plank[1,2], G. Yealland[4], R. Casper[2], K. Obst[4], M. Hermann[5], E. Miceli[6], M. Calderón[6], S. Hedtrich[4], K.M. Eckl[1,2,7].* 1) Dept. of Biological Sciences, University of Huddersfield, Huddersfield, United Kingdom; 2) Div. of Human Genetics, Innsbruck Medical University, Innsbruck, Austria; 3) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 4) Inst. of Pharmacy, Freie Universität Berlin, Berlin, Germany; 5) Dept. of Anaestesiology, Innsbruck Medical University, Innsbruck, Austria; 6) Inst. for Chemistry and Biochemistry, Freie Universität Berlin, Berlin, Germany; 7) Dept. for Biology, Edge Hill University, Ormskirk, Lancashire, UK.

   Autosomal recessive congenital ichthyosis (ARCI) is a rare, genetically heterogeneous cornification disorder characterized by impaired skin barrier function, with no causative therapy available to date. Skin diseases caused by inactivating mutations or lack of protein synthesis are considered favourable targets for local protein substitution. Unpacked therapeutic proteins, however, are usually unable to penetrate the epidermal permeability barrier, owing to their high molecular weight and hydrophilicity. Here we aim for a novel, personalized ARCI therapy in which defective transglutaminase 1 (TGase1) is exogenously substituted with the help of nanotransporters developed for protein delivery into the skin for topical application. We have synthesized mammalian TGase1 in HEK 293 cells. The protein was assessed by flow cytometry and Western blot analysis, and enzyme activity was confirmed by *in vitro* assays. Next we coupled TGase1 to thermoresponsive polyglycerol-based nanogels (dPG-NG) that contain poly(N-isopropylacrylamide) as thermoresponsive linker. The protein-loaded nanogels exhibited a thermal trigger point at 35°C, favourable for cutaneous applications. Staining experiments showed that TGase1 was successfully delivered into keratinocytes. Analysis over time revealed nearly all extrinsic protein was gone 24h after delivery, therefore we defined a treatment schedule with repeated applications of dPG-NG/TGase1. 3D full-thickness skin models, which exhibited functional barrier properties comparable to the epidermal barrier of the skin, were generated as disease models for therapeutic applications with keratinocytes and fibroblasts from ARCI patients or keratinocytes where *TGM1* was knocked-down. As expected, they showed a clearly reduced barrier activity and an increased permeabilitiy. After treatment with dPG-NG/TGase1, TGase1 was present in suprabasal epidermal layers, TGase1 activity was confirmed in the models with *in situ* assays, and permeability assays showed that the barrier dysfunction of treated ARCI models was significantly ameliorated. Thus, our findings revealed an advanced topical drug delivery system suitable for cutaneous protein replacement as a promising approach for causative therapeutic intervention in ARCI. The approach is being optimised for epidermal delivery and protein dosage. After toxicity tests will be accomplished, we want to adapt the system for use with other proteins involved in autosomal recessive cornification disorders.

Homozygous *ATP6V1E1* and *ATP6V1A* mutations in metabolic cutis laxa syndromes: New clinical and pathogenetic insights. *B. Callewaert[1], T. Van Damme[1], M. Mohamed[2], T. Gardeitchik[2], A. Kariminejad[3], B. Guillemyn[1], W. Steyaert[1], S. Ghaderi-Sohi[3], D. Syx[1], S. Wong[4], D. Lefeber[2], P.J. Coucke[1], S. van Kraaij[2], D. Dalloyaux[2], R. De Rycke[5], A. De Paepe[1], S. Symoens[1], T. Hack[6,7], P. Freisinger[8], E. Morava[4], F. Malfait[1], R. Wevers[2].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Departments of Laboratory medicine, Pediatrics and Genetics, Radboudumc, Nijmegen, The Netherlands; 3) Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Iran; 4) Hayward Genetics Center, Tulane University School of Medicine, New Orleans, LA; 5) Department of Biomedical Molecular Biology, Inflammation Research Center, Ghent University, Ghent, Belgium; 6) Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 7) Institute of Human Genetics, Technische Universität München, Munich, Germany; 8) Department of Pediatrics, Kreisklinken Reutlingen, Reutlingen, Germany.

   Defects of the vacuolar-type H+-ATPase pump (V-ATPase) impair acidification of vesicular compartments and interfere with intracellular trafficking of membrane-bound compartments including secretory granules, endosomes, and lysosomes. Mutations in ATP6V0A2, encoding the a2 subunit of the V0 domain cause autosomal recessive cutis laxa type 2, a congenital disorder of glycosylation with multisystem manifestations including a loose redundant skin, skeletal, and often neurological abnormalities. We report on mutations in two subunits of the V1 domain of the V-ATPase complex in four independent cutis laxa families. In addition to generalized cutis laxa, these patients presented with similar dysmorphic facial features, hypotonia, a marfanoid habitus, and variable cardiopulmonary involvement (ventricular hypertrophy, aortic root dilatation, and pneumothorax). Whole-exome sequencing identified homozygous missense mutations in ATP6V1E1 (c.383T>C, p.(Leu128Pro); c.634C>T, p.(Arg212Trp)) and ATP6V1A (c.1012C>T, p.(Arg338Cys); and c.215G>A, p.(Gly72Asp)), encoding respectively the E1 and A subunitof the V1 domain. Structural modeling using the S. cerevisiae V-ATPase as template indicated that all substitutions affect critical residues, and alter either inter- or intrasubunit interactions. V-ATPase complex profiling using liquid chromatography tandem mass spectrometry showed a reduction in the amount of assembled V1 domain in patient samples, indicating that substitutions in the E1 and A subunits affect either the assembly or the stability of the V1 part of the complex. Transferrin isoelectric focusing showed a type II glycosylation defect in patients with ATP6V1E1 and ATPP6V1A mutations. Vesicular trafficking defects were evidenced by delayed retrograde translocation of Golgi membranes to the endoplasmic reticulum after Brefeldin A treatment, and abnormal swelling and fragmentation of the Golgi apparatus in patient derived cultured dermal fibroblasts on transmission electron microscopy (TEM). In addition, we observed lysosomal storage bodies on a dermal skin sample of one of the affected patients. Finally, TEM of the patient dermis showed severe changes in the amount, structure and organization of elastic and collagen fibers. In conclusion, our study expands the molecular and clinical spectrum of metabolic cutis laxa syndromes, and provides new insights on the cellular processes involved in proper assembly and homeostasis of the extracellular matrix.

2367F

Increased expression of mutant elastin alleles in autosomal dominant cutis laxa is normalized by transforming growth factor beta treatment. *S. Akcay, E.C. Lawrence, Z. Urban.* Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Increased expression of mutant alleles in autosomal dominant diseases is rarely observed, but is generally found to result in more severe presentation, as observed in Huntington's disease and familial hypercholesterolemia. Examining the relative expression of mutant and wild type elastin (*ELN*) alleles in skin fibroblasts from 7 individuals with autosomal dominant cutis laxa (ADCL), with 4 distinct frameshift mutations, we observed 1.5-2-fold increased expression of mutant alleles at the mRNA level. Treatment of mutant fibroblasts with 5 ng/mL transforming growth factor beta 1 (TGFB1) for 10 days yielded an increase in the expression of the wild type alleles but a decrease in the expression of the mutant alleles, abolishing the differences in allelic expression. TGFB1 treatment also normalized the amount of insoluble elastin deposited by ADCL cells. The mechanism of differential regulation of mutant and wild type mRNA levels by TGFB1 is likely related to altered accessibility of the TGFB1-target miR29 to mutant and wild type *ELN* transcripts. Our studies implicate increased mutant allele expression as a contributor to the molecular mechanism of ADCL, and support TGFB1 augmentation as a possible therapeutic approach.

2368W

Identification of a novel mutation in *FBN1* gene in an infant with Marfan syndrome. *B. Lazalde[1,2], G. Aguirre-Hernández[1], R.M. González-Arreola[1], J.L. Venegas-Rodríguez[1], A.E. González-Font[3].* 1) Department of Genetics, Faculty of Medicine and Nutrition, Juárez University of Durango State, Durango, Dgo., Mexico; 2) Biomedical Reserach Unit, Mexican Institute of Social Security. Durango, Dgo., Mexico; 3) Department of Cardiology, Maternal and Child Hospital of Durango. Durango, Dgo., Mexico.

Aim: To report a case of an infant with Marfan syndrome (MFS) (MIM 154700) presenting a novel mutation in *FBN1* gene. **Case report:** A female infant was born at 42 weeks of gestation to a 31 years old (gravida 4, parity 2) healthy mother and 33 years old healthy and not related father. At 18 months of age a clinical survey revealed an IV-VI grade holosystolic heart murmur, and the echocardiogram confirmed a moderate to severe mitral insufficiency with mitral valve prolapsed. The physical examination at two years of age in the genetics service, showed proportionate tall stature, height 94 cm (>97th percentile), weight 16.3 kg (25-50th percentile), upper/lower segment ratio of 1.19 and armspam/height ratio of 1.04, dolicocephaly, long shaped facies, downslanting palpebral fissures, malar hypoplasia, high palate, anteverted auricular pavilions, pectus carinatum, scoliosis, articular hyperelasticity, long fingers and toes, and hindfoot deformity. Ophthalmologic evaluation revealed myopia and excluded ectopia lentis. A fibrillinophaty was suspected and molecular diagnostic tests of the *TGFBR1*, *TGFBR2* and *FBN1* genes were conducted. **Results:** The gene Sanger sequenciation revealed a heterozygous duplication of 4 nucleotides (c.5662_5665dupATGT) in *FBN1* gene, that creates a shift in the reading frame at codon 1889 and the new reading frame ends in a stop codon 6 positions downstream (p.Cys1889Tyrfs*7), which is very likely to result in a truncated protein. This variant was absent in both parents and has not been described previously associated to MFS or other fibrillinopathy. Last echocardiogram performed at the age of 4 years showed a dilated aortic root (24mm, Z value ≥+3) and prolapsed mitral valve with severe regurgitation. **Discussion:** Although several conditions have been recognized which present overlapping clinical characteristics associated to *FBN1* mutations, according to revised Ghent nosology (positivity of two out of four criteria in patients without a family history), the patient fit the criteria for classic MFS because she has a systemic score of 7, aortic dilatation with a Z value ≥+3, and a nonsense mutation in *FBN1* gene. **Conclusion**: The novel mutation c.5662_5665dupATGT in *FBN1* gene is a putative disease causing mutation associated to a MFS. .

Ectodermal dysplasias (EDs) are a complex and genetically heterogeneous group of conditions that affect the development of tissues derived from early embryonic ectoderm. Clouston syndrome, also known as hidrotic ectodermal dysplasia type-2 (HED2, OMIM#129500), is an autosomal dominant ED characterized by congenital or childhood-onset partial to total hair loss, abnormal nails, and palmar/plantar dyskeratosis. In this paper, a seven year old Turkish girl who were born to a consanguineous family and had Clouston disease with a recessively acting, homozygous and novel *GJB6* mutation. Our data strongly implicate p.G45R in *GJB6* as the cause of an autosomal recessive form of Clouston syndrome. Thus, while most patients with Clouston syndrome have dominantly acting mutations, recessive inheritance should not be precluded especially in the presence of consanguinity.

2370F

Identification of a novel homozygous nonsense mutation of *CAST* **gene in a PLACK family.** S. Temel[1,2], H. Sarcaoğlu[3], B. Türkgenç[4,5], U. Kıran[3], B. Ergüner[6], B. Yücetürk[6], M. Sağıroğlu[6], M.C Yakıcıer[7]. 1) University of Near East, Faculty of Medicine, Department of Histology & Embryology, Lefkosia, Cyprus; 2) University of Uludag, Faculty of Medicine, Department of Histology & Embryology, Bursa, Turkey; 3) University of Uludag, Faculty of Medicine, Department of Dermatology, Bursa, Turkey,; 4) 4Marmara University, Faculty of Medicine, Department of Medical Biology and Genetics, Istanbul, Turkey; 5) University of Acibadem, Acibadem Genetic Diagnostic Center, Istanbul, Turkey; 6) Advanced Genomics and Bioinformatics Research Group (İG-BAM) TÜBİTAK BİLGEM UEKAE, Gebze/Kocaeli, Turkey,; 7) 7University of Acibadem, Faculty of Arts and Sciences, Department of Molecular Biology and Genetics,, Istanbul, Turkey.

Peeling skin syndrome (PSS) is characterized by continuous shedding of the stratum corneum of the epidermis with onset from birth or infancy and lasting throughout life. Skin peeling can be accompanied by erythema, vesicular lesions, or other ectodermal features including fragile hair and nail abnormalities. PSS can be divided into acral and generalized PSS. We report a 5.5 year old boy who initially presented with skin fragility. He was the first-born of IVF twins from a consanguineous marriage at 33+5 week gestational age with hypotonia at birth. The main clinical findings included fragile skin, woolly hair, sparse eyelashes and brows, palmoplantar punctate keratoderma, follicular hyperkeratosis, knuckle pads and cheilitis. Moreover mild cerebral atrophy and mild muscle involvement were observed on his MRI and NCV/EMG, respectively. His aunt also had similar clinical features but in milder form with in addition nail dystrophy. Exome sequencing revealed a homozygous c.544G>T (p.Glu182*) nonsense mutation in the *CAST* gene. The segregation of this rare variant in the family was confirmed by Sanger sequencing. This novel stop-gain *E182X* variant produces a truncated protein lacking inhibitory domains II-IV. CAST is an endogenous specific inhibitor of calpain, a calcium-dependent cysteine protease. Recently, autosomal recessive loss of function mutations in CAST were described in PLACK syndrome characterized by generalized peeling skin, leukonychia, acral punctate keratoses, cheilitis, and knuckle pads. As far as we know our case is the fifth case of PLACK syndrome without leukonychia but with some additional previously unreported associated features including mild cerebral atrophy and muscle involvement. .

Periodontal Ehlers-Danlos syndrome (EDS) is an autosomal dominant disorder characterized by aggressive periodontitis and cutaneous tissue fragility (also called EDS VIII). A locus was mapped to 12p13.1 but no candidate gene identified. Whole exome sequencing in 7 families with the clinical phenotype allowed identification of different mutations in *C1R* (5 families) and *C1S* (2 families). Further analysis by capillary DNA sequencing in an additional 10 families (total of 93 individuals) identified additional mutations in *C1R*. The C1R and C1S genes are similar in structure and sequence and are located in tandem at 12p13.1. We identified heterozygous missense or in-frame insertion/deletion variants in *C1R* or *C1S,* which encode the C1r and C1s subunits of the first component of complement. The variants we identified involve residues essential to maintain the C1r/C1s, C1r/C1r or C1r/C1q interfaces or the hinges between interaction and catalytic domains of C1r and C1s. Overexpression of *C1R* missense mutants in HEK293 cells showed intracellular retention of C1r and mild endoplasmic reticulum enlargement similar to that seen in patient fibroblasts in skin. The clinical features observed in these families included aggressive periodontitis, structural gingival abnormalities, skin fragility, easy bruising, pretibial hyperpigmentation, and musculoskeletal symptoms. None had the clinical features of lupus that are associated with homozygous loss of either or both *C1R* and *C1S* and also did not have the findings of angioedema seen with loss of the C1 esterase inhibitor. These findings point to a gain of function effect. The proteases C1r and C1s form a proenzyme tetramer that associates with the collagen-like stems of C1q, are sequentially activated to form proteases that, in turn, activate the classical complement pathway. *C1R* and *C1S* variants in periodontal EDS likely have a gain-of-function effect, may interact with alternative targets, and/or interfere with local immune functions. Our findings define periodontal EDS as a genetically distinct EDS subtype, caused by mutations in *C1R* and *C1S*, and open new ways to understand relationships between inflammatory pathways and connective tissue homeostasis.

2372T

Clinical and molecular description in a patient with Keratitis-ichthyosis-deafness syndrome presenting a severe phenotype. *V. Cortés-González[1], A. Serrano-Ahumada[2], L. González-Huerta[3], C. Villanueva-Mendoza[1].* 1) Genetics Department, Asociación para Evitar la Ceguera en México, Hospital Dr. Luis Sánchez Bulnes; 2) Ophthalmology Department, Asociación para Evitar la Ceguera en México, Hospital Dr. Luis Sánchez Bulnes; 3) Unit Research of Human Genetics Department, Hospital General de México, Dr. Eduardo Liceaga.

Keratitis-ichthyosis-deafness (OMIM #148210) is a rare autosomal dominant ectodermal dysplasia syndrome. Cardinal features of the phenotype include sensorineural deafness, erythrokeratoderma, vascularizing keratitis, alopecia, and reticulated hyperkeratosis of the palms and soles. This entity is frequently due to mutation in a gene encoding connexin 26 protein affecting certain tissues of ectodermal origin such as epidermis, cochlea, and cornea. The most common pathological genetic variant of this connexin 26 is p.Asp50Asn, leading to substitution of conserved residues in the cytoplasm amino terminus or first extracellular domain which is crucial for voltage gating and connexon-connexon interactions. We present the systemic and ocular findings in a patient with Keratitis-ichthyosis-deafness (KID) syndrome, with contractures, skeletal handicap and an ocular neoplasia. The proband is a 30-year-old male with decreased visual acuity, blurry vision, eye redness, tearing and photophobia. He had history of congenital deafness; his skin was seborrheic at birth and then became erythematous and thick; by 10 years he developed contractures and deambulation was limited, now he is confined to a wheelchair. Ophthalmic evaluation demonstrated best corrected visual acuity of 20/300 in the right eye and 20/250 in the left eye; he had madarosis, hyperkeratotic lesions of the eyelids, bilateral and total corneal neovascularization, and in the right eye an intraepithelial lesion suggestive of an ocular squamous neoplasia. Systemic examination demonstrated alopecia, generalized dry and erythematous skin, severe hyperkeratotic plaques especially at pressure sites as buttocks and talus, kyphoscoliosis, flexion contractures and dystrophic nails. His parents were healthy and there was no relevant family history. With this phenotype it was considered the diagnosis of KID syndrome. Molecular analysis by PCR amplification and automated DNA sequencing of the complete *GJB2* gene (OMIM *121011) coding sequence revealed an apparently the novo heterozygous mutation c.148G>A (p.Asp50Asn). KID patients have an increased risk of infections and the occurrence of squamous cell carcinomas. This syndrome illustrates that gap junction communication plays a role in immune response and epidermal carcinogenesis.

Functional validation of a novel missense variant in *TGFBR2* **in a patient with aortic dilatation and aneurysms.** *M.A. Cousin[1,2], A.J. Mathison[3], M.T. Zimmermann[1], P.R. Blackburn[1,2], N.J. Boczek[1,2], G.R. Oliver[1], G.A. Lomberk[3], D.R. Deyle[2,4], R.A. Urrutia[2,3], E.W. Klee[1,2,4].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Center for Individualized Medicine, Mayo Clinic, Rochester, MN; 3) Department of Medicine, Gastroenterology Research Unit, Mayo Clinic, Rochester, MN; 4) Department of Clinic Genomics, Mayo Clinic, Rochester, MN.

Heritable connective tissue disorders characterized by cardiovascular defects including aortic dilatation and aneurysms often involve dysregulated TGF-β signaling, have overlapping symptoms, and have variable penetrance and expressivity. Panel-based testing is a highly utilized approach to identify the disease-causing genetic variant(s) in patients with a suspected genetic disorder. Unfortunately, the variants they identify frequently have uncertain clinical significance thereby obscuring the genetic diagnosis until more information becomes available or appropriate functional studies resolve the pathogenicity of the variant(s) in question. Here we describe a patient with a suspected connective tissue disorder harboring a variant of uncertain significance (VUS) in the *TGFBR2* gene and provide a detailed account of the subsequent functional studies used to establish its pathogenicity. A 197.7 cm tall 43-year-old man presented to Mayo Clinic's Department of Clinical Genomics with a history of ascending aorta dilatation and aneurysms in the common iliac arteries, all requiring surgical repair. Following examination, his Marfan systemic score was 9 indicating a clinical diagnosis of Marfan syndrome. He has no family history of aortic dilatation or aneurysm, but some reports of joint pain, teeth crowding, flat feet, and varicose veins. Clinical gene-panel testing identified a c.1255G>T; p.Val419Leu VUS in *TGFBR2*. We assessed the structural and functional consequence of this VUS using *in silico* protein modeling and *in vitro* cell-based assays. A high-quality homology-based model of TGFβR2 was generated and computational mutagenesis followed by refinement and Molecular Dynamics (MD) simulations was used to assess structural and dynamic changes. Relative to WT, the V419L induced conformational and dynamic changes that may affect ATP binding. Experimentally, we measured the canonical TGF-β signaling pathway activation at two points. The V419L significantly delayed SMAD2 phosphorylation by western blot and reporter assays showed decreased TGF-β-induced gene transcription. Interpreting these functional results in light of our MD simulations, we believe that V419L leads to a dynamic alteration of the ligand-binding site, which results in decreased enzymatic activity, decreased TGF-β signaling, and decreased downstream gene transcription. The aberrant TGF-β signaling leads to Loeys-Dietz syndrome 2 (OMIM:610168) and the clinical presentation in our patient.

2374W

Types of albinism in southern Africa and genetic investigation of pigment-related genes. *R.A. Kerr, J.G.R. Kromberg.* Division of Human Genetics, University of the Witwatersrand and NHLS, Johannesburg, Gauteng, South Africa.

The first aim of this study was to describe and classify the different types of albinism found in the local southern African black population. Secondly, a mutation screen was undertaken to identify disease-causing mutations in a group of black OCA subjects. All subjects were initially screened for the common black *OCA2* [MIM 611409] mutation: the 2.7 kb deletion mutation. Subjects where one or two mutations remained to be identified were included in an *OCA2* mutation screen (N=63). Certain individuals with "unclassified" OCA were investigated further. Classification of types involved a descriptive survey in which 96 affected individuals underwent a clinical and/or dermatological examination. The *OCA2* genetic screen involved Sanger sequencing of all 25 exons of the gene. Certain individuals were also investigated at the *Tyrosinase* (*TYR* [MIM 606933]) or *Tyrosinase-Related Protein 1* (*TYRP1* [115501]) locus. Most (79/96; 82%) subjects had classic OCA2 [MIM 203200] and a further 11/96 (12%) had the brown oculocutaneous albinism (BOCA [MIM 203200]) subtype. The remainder of the subjects (6/96; 6%) had rufous oculocutaneous albinism (OCA3 or ROCA [MIM 203290]), caused by mutations in the *TYRP1* gene. In the black OCA2 patients, four mutations which are likely to be pathogenic were found. No further mutations (besides the 2.7kb deletion) were identified in the BOCA sample. In conclusion, the most common types of OCA found locally are OCA2 and OCA3. No patients with OCA1 were described. Besides the 2.7kb deletion, no other common *OCA2* mutation has been found. Approximately 20% of mutations remain unidentified. Genotyping of particular unusual cases suggests that variation at more than one pigment locus is responsible for the resulting phenotype.

2375T

Males with Incontinentia Pigmenti: Somatic and germ line mosaicism for the NEMO/IKBKG mutation underline the risk of recurrence. *F. Fusco[1], A. Diociauti[2], S. Bigoni[3], R. Sabbatella[1], A. Ferlini[3], M. El Hachem[2], M.B. Lioi[4], M.V. Ursini[1].* 1) Institute of Genetics and Biophysics 'Adriano Buzzati-Traverso', IGB-CNR,, Naples, Italy; 2) Dermatology Unit, Bambino Gesù Children's Hospital- IRCCS, Rome, Italy; 3) UOL of Medical Genetics, Ferrara University Hospital, Ferrara, Italy; 4) University of Basilicata, Potenza, Italy.

The Incontinentia Pigmenti (IP; OMIM#308300) is an X-linked dominant disease lethal in males and therefore the only expected type of transmission is from the IP mother to the daughter. However, some IP male cases have been reported. The discovery of *NEMO/IKBKG* as the causative gene has enabled the molecular genetic confirmation of IP in mosaic male. All the IP-males were isolated cases presenting a postzygotic genetic mosaicism that produces a cellular condition comparable to that of heterozygous female, who are functional mosaics due to random X-inactivation. Amongst the 421 IP cases that comprises our cohort (IPGB, http://www.igb.cnr.it/ipgb) there are currently 40 IP male, 38 are teenagers and two presented an unexpected father-to-daughter transmission for an X-linked male lethal disease. We demonstrated that the underlining cause of such transmission is the somatic and germ line mosaicism for the NEMO/IKBKG mutation in the IP fathers of the two families. The father of Family 1 presented classical IP, with typical cutaneous rush and epilepsy and has one IP affected daughter. They both carried the new p.Gln132X mutation. The father of Family 2 with a mild form of IP has two IP affected daughters. They all carry the common exon4-10 deletion of *NEMO*. The levels of mosaicism was 20% of *NEMO* mutated cells in the affected skin, 8.3% in the urine and 16.7% in germ line in father of Family 1 and 25% of *NEMO* mutated cells in the urine and 35% in germ line in father of Family 2. Those are the first molecularly documented evidences of somatic and germline mosaicism for the NEMO/IKBKG mutation in IP cases that implicate a risk for the disease to be transmitted from the father to multiple offspring.

2376F

Postzygotic *KITLG* mutation in a congenital non-progressive linear nevoid hyperpigmentation. *A. Sorlin[1], A. Maruani[2], J.-B. Rivière[1,3,4], Y. Duffourd[1,3], P. Kuentz[1,3,4], J. St-Onge[1], M. Chevarin[1], T. Jouan[1], C. Thauvin-Robinet[1,3,5], J. Thevenon[1,3,5], L. Faivre[1,3,5], P. Vabres[1,3,5,6].* 1) Laboratoire Génétique des Anomalies du Développement, Dijon, France; 2) Service de Dermatologie, Tours University Hospital, Université François Rabelais, France; 3) FHU TRANSLAD, Dijon University Hospital and Université Bourgogne-Franche Comté University, Dijon, France; 4) Molecular Biology, Dijon University Hospital, Dijon, France; 5) Centre de référence Anomalies du Développement et Syndromes Malformatifs, Dijon University Hospital, Dijon, France; 6) Dermatology, Dijon University Hospital, Dijon, France.

Linear and whorled naevoid hypermelanosis (LWNH) - hyperpigmented macular swirls and streaks following Blaschko's lines - has often been considered as a nonspecific manifestation of mosaicism. It has sometimes been mistaken with the pigmentary stage of incontinentia pigmenti. In a few patients, various X chromosome rearrangements have been reported, but the molecular basis of LWNH has remained unknown. We performed deep exome sequencing on skin DNA from a 6 year-old patient with congenital non-progressive linear naevoid hyperpigmentation following Blaschko's lines on his trunk and limbs, without other cutaneous or neurosensory symptoms. We identified a postzygotic heterozygous *KITLG* c.329A>G (p.Asp110Gly) mutation, confirmed by targeted deep sequencing in skin fibroblasts (28% of reads) and blood (18%). *KITLG* (c-KIT Ligand, also known as Stem Cell Factor) regulates skin pigmentation through control of melanocyte migration, proliferation and survival, and melanin synthesis. Germline *KITLG* mutations have been reported in patients with Familial Progressive Hyper-and Hypopigmentation (FPHH), who exhibit early-onset hyperpigmented macules, increasing in size and number until adulthood, and hypopigmented macules. *KITLG* mutations have also recently been found in patients with isolated hearing loss or Waardenburg syndrome type 2A (congenital hearing loss, pigmentary abnormalities of the hair, skin, and eyes). This is the first report of a genetic basis for LWNH, which can now - at least in this patient - be considered as a mosaic presentation of a Mendelian disorder, FPHH The p.Asp110Gly mutation is also the first reported mosaic mutation of *KITLG*, in a patient with normal hearing, extending the spectrum of clinical manifestations associated with mutations in *KITLG*.

2377W

Postzygotic *MTOR* activating mutations in hypomelanosis of Ito with brain overgrowth. *P. Vabres[1], V. Parker[2], J. St-Onge[1], Y. Duffourd[3], D. Rodriguez[4], C. Mignot[4], R. Knox[2], A. Boland[5], R. Olaso[5], M. Delepine[5], V. Darmency[1], C. Vincent-Delorme[6], B. Catteau[6], L. Guibaud[7], A. Arzimanoglou[7], M. Keddar[1], P. Callier[1], D. Bessis[8], D. Geneviève[8], J.F. Deleuze[5], R. Semple[2], L. Faivre[1], J.B. Rivière[2].* 1) CHU Dijon Bourgogne, DIJON, France; 2) Institute of Metabolic Science, Cambridge, UK; 3) Université de Bourgogne Franche-Comté, Dijon, France; 4) Assistance Publique – Hôpitaux de Paris, Paris, France; 5) 9Centre National de Génotypage, Evry, France; 6) Centre Hospitalo-Universitaire, Lille, France; 7) Hospices Civils de Lyon, Bron, France; 8) Centre Hospitalo-Universitaire, Montpellier, France.

   Hypomelanosis of Ito consists of hypopigmentation along Blaschko's lines (naevus depigmentosus) associated with neurological features. Except for inconstant mosaic chromosomal anomalies, its genetic basis had remained elusive. Recently, postzygotic *MTOR* mutations have been identified. We performed whole-exome and targeted deep sequencing from skin and blood-derived DNA in four unrelated patients with extensive nevus depigmentosus or patchy depigmentation, brain overgrowth, intellectual disability and epilepsy. We identified mosaic activating missense *MTOR* mutations on skin biopsy, usually absent in the blood in all patients. One had severe cognitive impairment, intractable seizures, and carried an *MTOR* p.Glu2419Lys variant. Analysis of her dermal fibroblasts showed upregulation of mTOR signaling, with increased phosphorylation of AKT and p70 ribosomal protein S6 kinase. Since this mTOR mutation was sensitive to rapamycin *in vitro* and *in vivo*, we initiated everolimus therapy, which however failed to improve seizures. Hypopigmentation may specifically result from mTOR activation, as in tuberous sclerosis complex. Despite failure to improve neurological symptoms in one patient, rapamycin remains a candidate drug for treatment neurological symptoms in patients carrying an MTOR mutation.

2378T

A novel *PLEC1* nonsense homozygous mutation (c.7159G>T; p.Glu2387*) causes epidermolysis bullosa simplex with muscular dystrophy and diffuse alopecia: A case report. *L. Mota-Vieira[1], Z. Argyropoulou[1], L. Liu[2], L. Ozoemena[2], J.A. McGrath[2], A. Reis-Rego[3], R. Senra[3].* 1) Molecular Genetics and Pathology Unit, Hospital of Divino Espírito Santo of Ponta Delgada, Azores Islands, Portugal; 2) The National Diagnostic EB Lab, St Thomas' Hospital, London, UK; 3) Internal Medicine Department, Hospital of Divino Espírito Santo of Ponta Delgada, Azores Islands, Portugal.

   Epidermolysis bullosa simplex with muscular dystrophy (EBS-MD; OMIM #226670) is a autosomal recessive disease, characterized mainly by skin blistering at birth or shortly thereafter, the primary clinical manifestation, by progressive muscle weakness with highly variable age of onset (from infancy to the fourth decade life), and rarely by alopecia. EBS-MD is caused by mutations in the *PLEC1* gene (OMIM *601282), which encodes the cytolinker protein plectin expressed in many tissues (*i.e*., skin, mucous membranes, gut, muscle and heart). Here, we described a patient affected with EBS-MD and diffuse alopecia in which we identify a novel pathogenic variant in the *PLEC1* gene. The patient was a 28 year old girl and the only child of consanguineous (first degree cousins) healthy parents from the Azorean island of São Miguel (Portugal), born after an uneventful pregnancy. From the second day after birth, she developed blistering of the skin and oral mucosa, accompanied by hoarseness of the voice. In addition, at early age, she suffered from recurrent upper tract respiratory infections, and showed extensive nail dystrophy and hair weakness. All developmental milestones were normal, with exception of weight (below the 5th percentile). Muscle weakness was first noted in adolescence and gradually progressed, resulting in the inability to perform activities of daily living. On physical examination, we observed sparse, tense blisters and hemorrhagic crusts distributed over the patient's body. Diffuse non-scarring alopecia was evident on the scalp, and onychodystrophy (pachyonychia) were found to affect all 20 nails; she also presented decayed teeth, mild dysphonia, and severe muscle atrophy in the extremities. On the neurological examination, reflexes were profoundly diminished. To identify the pathogenic mutation, we performed PCR amplification of all coding exons and exon–intron boundaries of the *PLEC1* gene (isoforms 1a, 1b, and 1c), followed by bidirectional Sanger sequencing. This strategy revealed the patient to be homozygous for the novel nonsense mutation c.7159G>T (p.Glu2387*) in exon 31 (according to the isoform 1c: NM_00445/NP_00336). Presumably, this mutation predicts the expression of shortened plectin polypeptides (*i.e.,* the rodless truncated forms of plectin without the full-length isoform). To our knowledge, the present case corresponds to the second reported mutation with EBS-MD and diffuse alopecia in the literature. (luisa.mq.vieira@azores.gov.pt).

2379F

Reverse phenotyping of a patient with *CRIPT* gene mutation and further delineation of the associated phenotype. *B. Demeer[1,2], A. Dadban[3], P. Vabres[4,5], A. Varenterghem[7], J. Thevenon[4,8], D. Bremond-Gignac[9], J.B Riviere[4,6], C. Thauvin[4,8], L. Faivre[4,8].* 1) genetics department, Amiens University hospital, Amiens, France; 2) EA 4666, Université de Picardie Jules Verne, Amiens, France; 3) dermatology department, CHU Amiens-Picardie, Amiens, France; 4) Equipe d'Accueil 4271 Génétique des Anomalies du Développement, Fédération Hospitalo-Universitaire, Université de Bourgogne, Dijon, France; 5) Service de Dermatologie, CHU Le Bocage, Dijon, France; 6) Laboratoire de Génétique moléculaire, FHU-TRANSLAD, Plateau technique de Biologie, CHU, Dijon, France; 7) Pediatric gastroenterology department, CHU Amiens-Picardie, Amiens, France; 8) Centre de Référence Maladies Rares "Anomalies du Développement et Syndromes Malformatifs" de l'Est, Centre de Génétique et Pédiatrie 1, Hôpital d'Enfants, Dijon, France; 9) Ophtalmology department, CHU Amiens-Picardie, Amiens, France.

We report on a 3 ½ year old boy, with prenatal onset growth deficiency (height : -4SD), microcephaly (OFC :-3.5 SD) , transient neonatal pancyto-penia, facial dysmorphism, feeding difficulties, developmental and speech delay, global hyperlaxity, significant sleep disturbance, and genital, ocular and extremities anomalies. He also presented with generalized pigmentation anomalies, and signs of ectodermal dysplasia. When last seen for follow-up at 5 years old, he had developed epilepsy. Array CGH (Agilent 60k), cytogenetic diagnosis of chromosomal breakage syndrome and metabolic screening were negative. Whole exome sequencing performed found a homozygous frame-shift mutation of the *CRIPT* gene, recently described as a novel primordial dwarfism gene (Shaheen et al, 2014). The mutation (c.132delA), described as "probably pathogenic", was confirmed by sanger sequencing. Both healthy consanguineous parents were proved to be carrier in the heterozygous state. Few available clinical data of the 2 described patients shows very similar clinical appearance with strikingly facial dysmorphism, growth deficiency, microcephaly, psychomotor delay, and ocular and extremities anomalies. Mottled hypopigmentation is noted in the older patient described. This description is an example of "reverse phenotyping". The first description of the *CRIPT* gene by Shahen et al, helped us to reach a diagnosis in our patient. Nevertheless considering this new case the term of "primordial dwarfism" seem to be too restrictive. For instance, cutaneous signs are specific in our patient. Reports of additional patients will help to further delineate the associated phenotype of this unique syndrome.

2380W

Pain related polymorphisms in COMT and SCN9A are significantly higher in patients with Ehlers-Danlos Syndrome. *P. Coucke, S. Symoens, A. De Paepe, D. Syx, F. Malfait.* Medical Genetics, University Ghent, Ghent, Oost-Vlaanderen, Belgium.

Acute and chronic pain are common, though variable, manifestations observed in individuals suffering from Ehlers-Danlos syndrome (EDS). This clinically and genetically heterogeneous group of heritable connective tissue disorders is characterized by joint hypermobility, skin fragility and generalized soft connective tissue fragility. Although pain is a frequent cause for seeking medical help, it is often inadequately controlled and represents an unmet medical need. Currently, the pathogenic basis of EDS-related pain is poorly understood and virtually unexplored. Intriguingly, pain is frequently observed in the classical and hypermobility type of EDS, but less so in the vascular type. As genetic polymorphisms related to pain sensitivity in genes such as *COMT* and *SCN9A* have been described, we investigated the occurrence of these variants for the 3 EDS subtypes.   A group of 59 and 46 patients with molecu-larly proven classical (*COL5A1/COL5A2)* or vascular (*COL3A1)* EDS, respec-tively, and 64 clinically diagnosed familial cases with hypermobile EDS, were analysed. A random group of 123 individuals from the same ethnic population was used as control. We investigated two polymorphisms in *COMT* (rs4680; rs4818) and two polymorphisms in *SCN9A* (rs6746030; rs6754031).   In the cohort of classical EDS patients the presence of the A-allele (rs4680) in *COMT* was significantly higher ($p<0.05$) compared to controls whereas no differences were observed for all 3 other *COMT* or *SCN9A* polymorphisms. In the cohort of hypermobile EDS patients, we observed a significant difference ($p<0.05$) of the G-allele (rs6754031) in *SCN9A* whereas no significant differences were observed for the 3 other polymorphisms. The A-allele in *COMT* and the G-allele in *SCN9A* are reported to be associated with a higher pain sensitivity. No statistical differences were observed for any of these polymorphisms in the vascular EDS cohort.   Although further investigations are necessary, these observations suggest a role for polymorphisms in genes related to pain sensi-tivity in the pain pathology of classical and hypermobile EDS.

2381T

Growth characteristics in osteogenesis imperfecta – Results from an observational study from the Linked Clinical Research Centers. *A. Tam[1], M. Jain[1], J.R. Shapiro[2], R.D. Steiner[3], P.A. Osteogenesis imperfecta (OI) predisposes to recurrent fractures and bone deformities, which are factors that affect growth. There are no large-scale studies that have systematically investigated growth in patients with OI. The Linked Clinical Research Centers (LCRC) is a network of five clinical centers across North America established to advance clinical research and care for OI. From the LCRC data, we compared height, weight, BMI and arm-span to height ratio in 553 individuals with OI (types I n=244; III n=110; IV n=150; V n=16; VI n=12; VII n=5; unclassified n=16). The classification of OI was predominantly based on clinical features; however, genotypic information was used to reclassify patients whenever available. The large number of individuals with OI types I, III and IV enrolled in the study allowed for detailed statistical comparisons. In the pediatric population (age < 20 years), the median (IQT) of Z-scores for height in OI types I, III, and IV were -0.66(-1.43,-0.02), -6.91(-8.41,-5.17) and -2.79 (-3.95,-1.69) respectively. Furthermore, in OI type I adults without an affected parent, 48% were below 2 standard deviations from the expected mid-parental height. Although the median Z-score for weight in children with OI type III was -4.55, the odds of them being classified as overweight (>85th percentile for BMI) and obese (>95th percentile) were 2.48 and 5.23, respectively, as compared to OI type I. The median (IQT) of Z-scores for BMI in the pediatric population in OI types I, III and IV were 0.10(-0.58-0.94), 0.91 (0.42-1.61) and 0.67 (-0.18-1.33). Hence, the standard method for calculation of BMI in the general population may not be accurate in OI. The arm-span/height was significantly different in adults with OI types III and IV, as compared to OI type I, and thus demonstrates axial and lower limb growth restriction/deformation compared to the upper extremities. Generalized linear model analyses demonstrated that reduced height Z-score positively correlates with severity of OI subtype (p<0.001), age, bisphosphonate use and rodding (p<0.05). From this cross-sectional analysis of the largest cohort of individuals with OI, we provide median values for height, weight and BMI Z-scores which can aid in evaluation of overall growth in the clinical setting. With further collection of longitudinal data through the Brittle Bone Disorders Consortium, we plan to develop standardized longitudinal age and sex-based growth curves specific to OI.

2382F

Insights in the clinical features and molecular pathogenesis of Spinocerebellar Ataxia 38 (SCA38). *E. Di Gregorio[1,2], B. Borroni[3], M. Ferrero[2], L. Boccone[4], C. Costanzi[3], L. Orsi[5], S. Cavalieri[2], E. Giorgio[2], C. Mancini[2], E. Pozzi[2], N. Mitro[6], D. Caruso[6], A. Brusco[1,2].* 1) Medical Genetics Unit, Città della Salute e della Scienza University Hospital, Turin, Italy; 2) Department of Medical Sciences, University of Turin, Turin, Italy; 3) Neurology Unit, Department of Clinical and Experimental Sciences, University of Brescia, Brescia, Italy; 4) Ospedale Regionale Microcitemie, ASL 8, Cagliari, Italy; 5) Neurologic Division 1, Department of Neuroscience and Mental Health, Città della Salute e della Scienza University Hospital, Turin, Italy; 6) Department of Pharmacological and Biomolecular Sciences, University of Milan, Milan, Italy.

SCA38 is a rare form of autosomal dominant ataxia caused by mutations in the elongase gene *ELOVL5*. At present, only two missense mutations have been reported in the gene, c.689G>T (p.Gly230Val; three Italian families) and c.214C>G (p.Leu72Val; one French family). In twenty-one SCA38 patients, from three families, with the *ELOVL5* c.689G>T mutation, we characterized clinical features and disease course. SCA38 showed an onset in the fourth-fifth decade of life with slow progression, and complete penetrance by age 50 yrs. The clinical picture corresponded to a pure cerebellar ataxia and included gait ataxia, nystagmus and dysarthria as the foremost manifestations. Among features helping the diagnosis, *pes cavus* without paraparesis (82% of cases) and early hyposmia/anosmia (73% of cases) were annotated. Disease progression was characterized by cerebellar symptoms (limb ataxia, dysarthria, dysphagia, and ophtalmoparesis) followed, in the later stages, by ophtalmoplegia. Pathogenetic mechanisms underlying the disease are still poorly defined. We previously demonstrated a subcellular mislocalization of p.Gly230Val ELOVL5 protein in different cellular models. The wild type protein localized as expected in the endoplasmic reticulum (ER) compartment. In contrast, aberrant ELOVL5 showed a perinuclear and polarized subcellular localization. Based on these data, we hypothesized p.Gly230Val-ELOVL5 is a misfolded protein able to activate the cellular unfolded protein response (UPR). We showed ELOVL5 protein expression was significantly increased in SCA38 fibroblasts after a treatment with the proteasome inhibitor MG-132, supporting ELOVL5 folding was affected by p.Gly230Val. By western blot analysis of the UPR markers CHOP, ATF-4 and XBP1, all significantly increased in COS7 cells stably expressing p.Gly230Val ELOVL5, we demonstrated activation of ER-stress response. Based on these data, we reasoned that the use of the chemical chaperone PBA might act on misfolded ELOVL5 reverting to physiological ER distribution of the protein and to cellular rescue from ER-stress. Our preliminary data on COS7 cells, stably expressing p.Gly230Val ELOVL5, demonstrated that PBA treatment relocalized the protein into ER. In conclusion, our results support a role for altered ER-stress response in SCA38 pathogenesis, suggesting chemical chaperones might be useful in the treatment, as already proposed for other neurodegenerative diseases. .

Clinical characteristics and detailed haplotype analysis of patients with SCA36 in Japan. *K. Koh[1], H. Ishiura[2], Y. Ichikawa[3], T. Matsukawa[2], J. Goto[4], J. Mitsui[2], Y. Takahashi[5], M. Kawabe[2], K. Doi[6], J. Yoshimura[6], S. Morishita[6], M. Namekawa[7], T. Ogawa[8], Y. Sunada[9], T. Itoh[9], T. Inoue[9], H. Kurizaki[10], K. Hasegawa[11], S. Tsuji[2], Y. Takiyama[1].* 1) Neurology, University of Yamanashi, Chuo, Yamanashi, Japan; 2) Department of Neurology, Graduate School of Medicine, The University of Tokyo; 3) Department of Neurology, Kyorin University; 4) Department of Neurology, International University of Health and Welfare, Mita Hospital; 5) Department of Neurology, National Center Hospital, National center of Neurology and Psychiatry; 6) Department of Computational Biology, Graduate School of Frontier Sciences, The University of Tokyo; 7) Department of Neurology, Jichi Medical University, Saitama Medical Center; 8) Department of Neurology, International University of Health and Welfare Hospital; 9) Department of Neurology, Kawasaki Medical School; 10) Department of Neurology, National Hospital Organization, Tokyo National Hospital; 11) Department of Neurology, National Hospital Organization, Sagamihara National Hospital.

   Purpose Spinocerebellar ataxia type 36 (SCA36) [MIM 614153] was originally identified in Japan. Thereafter, SCA36 has been also reported from, Spain, France, Portugal, and China. SCA36 is caused by a large hexanucleotide GGGCCTG repeat expansion in the first intron of *NOP56* [MIM 614154] gene. We screened SCA36 in our spinocerebellar ataxia patients and tried to identify disease-relevant haplotype. Methods Eighty six probands of SCA families with unknown genetic cause after mutation analyses of SCA1, SCA2, MJD/SCA3, SCA6, SCA7, SCA8, SCA12, SCA17, and DRPLA were enrolled for screening of SCA36. A large expansion ;in the first intron of *NOP56* had been screened by repeat-primed PCR. To determine the disease causing haplotypes, we genotyped all the patients and family members available using Genome-wide SNP array 6.0. Haplotypes were reconstructed manually by minimizing the number of recombination events. When the genotypes of the other family members were unavailable, we determined haplotypes using homozygosity mapping method. We also performed whole genome sequence analysis for detecting rare variants near the mutation. Result We found 17 SCA36 patients from nine families. Our patients developed symptoms in their 40s to 80s. All 17 patients revealed truncal ataxia, and 15 patients revealed limb ataxia. Muscle atrophy, tongue atrophy, and tongue fasciculation were observed in only one patient. Brisk tendon reflexes were revealed in all the patients, though only one patient showed positive Babinski sign. We found a founder haplotype around *NOP56* spanning more than 2.1 Mb in 6 families originated from the western part of Japan. On the other hand, three families originated from the eastern part of Japan shared another haplotype around *NOP56* spanning 2.5 Mb. Using rare variants detected by whole genome sequence analysis, the common region of the two disease-relevant haplotypes were less than 22 kb, raising a possibility that the repeat expansion originated independently. Conclusion In this study, we found 17 SCA36 patients from nine families. Detailed haplotype analysis revealed two haplotypes. Minimum shared haplotype around *NOP56* was less than 22 kb, raising the possibility that the repeat expansion originated independently, although the notion that all the families were originated from a very far ancestor could not be completely excluded.

2384T

The c.1529C>T (p.Ala510Val) *SPG7* missense mutation in sporadic cerebellar ataxias in Italy. *C. Mancini[1], E. Giorgio[1], S. Cavalieri[1], E. Pozzi[1], M. Ferrero[1], E. Di Gregorio[2], M. Ferrone[1], S. Bagnoli[3], S. Piacentini[3], L. Orsi[4], M. Zibetti[4], L. Pradotto[5], A. Brusco[1,2].* 1) Dep. Medical Sciences, University of Torino, Torino, Italy; 2) Medical Genetics Unit, "Città della Salute e della Scienza" Hospital, Torino, Italy; 3) Dep. of Neuroscience, Psychology, Drug Research and Child's Health, University of Florence, Florence, Italy; 4) Dep. of Neuroscience and Mental Health, Città della Salute e della Scienza University Hospital, Torino; 5) Division of Neurology and Neurorehabilitation, San Giuseppe Hospital, IRCCS-Istituto Auxologico Italiano, Piancavallo (VB), Italy.

   Ataxias are a clinically, genetically, and etiologically heterogeneous group of neurodegenerative disorders, characterized by a cerebellar syndrome associated with various other manifestations. More than 150 genes have been reported so far, with overlapping pathogenic mechanisms (e.g., cellular aggregates, mitochondrial dysfunction, defects in autophagic functions). However, the causative mutation is unknown in >40% of patients. A recent report suggested that *SPG7* mutations, causing the most common form of autosomal recessive spastic paraplegia (MIM#607259), account for approx. 18.6% of cases with unexplained ataxia in UK. All were homozygotes or compound heterozygotes for the c.1529C>T (p.Ala510Val) missense mutation (Pfeffer et al., 2015). We set up a rapid assay for c.1529C>T/p.Ala510Val using restriction enzyme analysis after PCR amplification, and screened 600 ataxic patients of Italian origin. We identified three homozygotes and 14 heterozygotes. We further extended mutation analysis by sequencing the entire *SPG7* coding region in 10 available heterozygotes. We found three cases with a second mutation: two were reported mutation (c.1617delC; c.2102A>C) and one was novel (c.1553-2delAG splicing mutation). Thus, *SPG7* mutants account for approx. 1% of sporadic cerebellar ataxias in Italy. In seven carriers of p.Ala510Val the pathogenicity of *SPG7* gene needs further studies to be confirmed. Clinical data collection is in progress. All patients were recruited for ataxia as initial presentation, and in most cases a pure cerebellar ataxia, without pyramidal signs was reported. The relatively high frequency of the *SPG7* allele c.1529C>T in the ataxic patients suggests it should be considered as priority test in the presence of pure ataxia even with absent or subtle pyramidal signs. Moreover, these findings further highlight the heterogeneity of disease spectrum linked to mutations in components of the mitochondrial *m*-AAA protease.

2385F

De novo missense variants in *CACNA1A* can cause congenital cerebellar ataxia with global developmental delay. *J.A. Rosenfeld[1], T. Harel[1], X. Luo[1], S. Yamamoto[1], M. Hall[2], K. Wierenga[2], M. Pastore[3], D. Bartholomew[3], M. Delgado[4], J. Rotenberg[5], R.A. Lewis[1], M. Almannai[1], L. Emrick[1], T. Lotze[1], M. Ummat[1], C.A. Bacino[1], M. Eldomery[1], Z. Coban Akdemir[1], F. Xia[1], H. Bellen[1], J. Lupski[1], Y. Yang[1], B. Lee[1], S.R. Lalani[1], M. Wangler[1], Members of the UDN.* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Nationwide Children's Hospital & The Ohio State University, Columbus, OH; 4) Texas Scottish Rite Hospital, Dallas, TX; 5) Houston Specialty Clinic, Houston, TX.

Variants in *CACNA1A* [MIM 601011], encoding the α-1A subunit of the neuronal P/Q type voltage-dependent Ca^{2+} channel, are known causes of ataxia: triplet repeat expansions extending a polyglutamine tract in the protein cause adult-onset spinocerebellar ataxia, type 6 [MIM 183086], and heterozygous variants (typically loss-of-function) cause childhood-onset episodic ataxia, type 2 [MIM 108500]. Additionally, missense variants in the gene cause autosomal dominant familial hemiplegic migraines [MIM 141500]. We report five individuals with congenital, non-fluctuating ataxia, hypotonia, ophthalmologic abnormalities, and global developmental delay. Four individuals had a recurrent, *de novo* c.4991G>A/p.R1664Q variant, which has been described previously in another individual with early-onset, persistent limb and trunk ataxia. The fifth individual has a *de novo* missense variant, c.5018G>C/p. R1673P. Both missense variants alter arginine residues within the fourth transmembrane domain, changing the pattern of positive charges within the voltage sensor. This pattern is also altered by other severe pathogenic alleles, suggesting that more severe clinical phenotypes could result from disruption of this specific domain. A sixth individual with a severe presentation of neonatal stroke and subsequent refractory epilepsy had a *de novo* variant within this transmembrane domain, c.5075T>A/p.L1692Q. To explore the functional consequences of these variants, we generated a loss-of-function (LOF) allele in the homologous gene (*cac*) in *Drosophila* that will allow expression of these human variant forms. This LOF allele recapitulates the lethal phenotypes previously observed in *cac* mutant flies. Human variants will be assessed through their ability to rescue the loss of *cac* in *Drosophila* photoreceptors, where conditional knockout causes neurodegeneration, synaptic transmission deficits and neuronal accumulation of autophagic vesicles. This cohort, combined with previous reports, shows that variants in *CACNA1A* can cause congenital non-fluctuating cerebellar ataxia and other severe neonatal presentations, thus expanding the spectrum of ataxia and other features associated with this important neuronal calcium channel gene. Functional studies in model organisms will provide further insight into this disease spectrum.

2386W

Rapamycin and bafilomycin A1 regulated autophagy against reactive oxygen species -induced apoptosis in transformed lymphoblastoid cells from patients with Machado-Joseph disease. *H. Tsai[1], L. Chen[2], C. Wu[1].* 1) Sch Med Tech, Chung Shan Med Univ, Taichung, Taiwan; 2) Department of Nursing, National Taichung University of Science and Technology.

Machado–Joseph disease (MJD) or spinocerebellar ataxia type 3 (SCA3), it is the commonest autosomal dominant spinocerebellar ataxias worldwide. Alleles of the *ATXN3* gene on chromosome 14q24.3-q31 that carry 13-36 CAG-trinucleotide repeats are present in normal individuals. Contrariwise, alleles with a CAG triplet 51-79 repeats are present in patients with MJD. Although the detail mechanism of pathogenesis is yet to be defined, neurotoxin, especially reactive oxygen species (ROS), release from aggregated mutant proteins, may play a role in the pathogenic process. We proposed that enhancement of autophagy lysosome pathway may be beneficial for some neurodegenerative disorders, such as MJD, in which the accumulation of misfolded/aggregated proteins and the dysfunction of mitochondria are the two major pathogenesis. Rapamycin is an inducer of autophagy, as inhibition of mTOR mimics cellular starvation by blocking signals required for cell growth and proliferation. Bafilomycin A1 is a known inhibitor of the late phase of autophagy. We investigated rapamycin and bafilomycin A1 regulated autophagy against ROS, a toxin created by oxidative stress and implicated in neurodegenerative disease, in mutant ataxin-3 cells. Results found the autophagy marker protein, Atg8 (LC3 class II) were increased in mutant ataxin-3 cells, which treated with rapamycin or bafilomycin A1. Moreover, rapamycin or bafilomycin A1 increased the levels of the anti-apoptotic protein Bcl-2, and decreased pro-apoptotic protein Bax. These results show that rapamycin and lowly concentration bafilomycin A1 may be a potential therapeutic candidate for neurodegenerative diseases involving glutamate cytotoxicity such as MJD.

2387T

De novo alterations in *KLF7* are a novel cause of intellectual disability, psychiatric and neuromuscular issues. *D.N. Shinde[1], Z. Powis[1], J.S. Cohen[2], D. Escolar[2], J. Burton[3], C.M.A. van Ravenswaaij-Arts[4], A.P.A. Stegmann[5,6], R. Chikarmane[7], A. Begtrup[7], S. Tang[1].* 1) Clinical Genomics, Ambry Genetics, Aliso Viejo, CA 92656, USA; 2) Kennedy Krieger Institute, Baltimore, MD 21205, USA; 3) University of Illinois College of Medicine at Peoria, Peoria, IL 61603, USA; 4) University Medical Center Groningen, The Netherlands; 5) Clinical Genetics, Maastricht University Medical Center, Maastricht, The Netherlands; 6) Radboud University Medical Center, Nijmegen, The Netherlands; 7) GeneDx, Gaithersburg, MD 20877, USA.

The *KLF7* gene (MIM 604865) encodes the Krüppel-like factor 7 (KLF7), a transcriptional activator belonging to the KLF family with roles in several developmental processes including apoptosis, cell proliferation, differentiation and energy metabolism. Mouse and *in vitro* studies implicate *KLF7* in neurogenesis (axon guidance in hippocampus, olfactory bulbs and cortex), differentiation and quiescence, and demonstrate high expression in skeletal muscle. *KLF7* is also a candidate gene for the 2q33.3-q34 deletion phenotype in patients with Autism Spectrum Disorder (ASD) and Rett-like features, microcephaly, hypotonia, psychomotor retardation and mild dysmorphic features. Here we report three unrelated affected individuals with *de novo* missense alterations in *KLF7* detected by Diagnostic Exome Sequencing (DES). The first individual was 2 years old at the time of evaluation with hypotonia, gross motor delay, mild language and cognitive delay, swallowing issues, mildly elevated creatine kinase levels and later ASD. DES identified a *de novo KLF7* c.410C>T (p.T137M) alteration predicted by *in silico* methods to be a part of the F-box motif (137-TPPSSP-142), involved in protein-protein interactions and ubiquitin-mediated proteolysis, an important part of cell cycle progression. The second individual is 15 years old and reported to have intellectual disability (ID), tonus dysregulation, motor dyspraxia, coordination issues and is described as anxious and shy. She was previously reported to have neonatal feeding issues and hypertonia. DES revealed a *de novo KLF7* c.415C>T (p.P139S) alteration, also part of the F-box motif and located two amino acids away from the alteration identified in the first individual. The third individual is 16 years old and reported to have severe ID, ADD/anxiety and self-injuring behavior, feeding difficulties, decreased tone in upper extremities and increased tone in lower extremities. DES identified a *de novo KLF7* c.790G>A (p.D264N) alteration located in the zinc finger-containing DNA binding domain shown to bind to the minimal enhancer of the *NTRK1* gene (MIM 191315) encoding a receptor for nerve growth factor. These findings suggest a phenotype for individuals with *KLF7* alterations including developmental delay/ID, abnormal muscle tone, feeding/swallowing issues, psychiatric features and neuromuscular issues. Additional patients with *KLF7* alterations are needed to delineate the phenotypic spectrum and make genotype-phenotype correlations.

2388F

HARS-related Charcot-Marie-Tooth disease mimicking adult polyglucosan body disease. *B. Royer-Bertrand[1,2], L. Mittaz Crettol[1], J.A. Lobrinus[3], P. Tsouni[4], J. Ghika[5], C. Wider[5], A. Superti-Furga[1,6,7], C. Rivolta[2], T. Kuntzer[4], C. Tran[1,8].* 1) Center for Molecular Diseases, Lausanne University Hospital (CHUV), Lausanne, Switzerland; 2) Department of Computational Biology, Unit of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 3) Department of Pathology, University Hospital Geneva, Geneva, Switzerland; 4) Nerve-Muscle Unit, Department of Clinical Neurosciences, Lausanne University Hospital (CHUV), Lausanne, Switzerland; 5) Department of Clinical Neurosciences, Lausanne University Hospital (CHUV), Lausanne, Switzerland; 6) Medical Genetics Service, Lausanne University Hospital (CHUV), University of Lausanne, Lausanne, Switzerland; 7) Department of Pediatrics, Lausanne University Hospital (CHUV), University of Lausanne, Lausanne, Switzerland; 8) Service of Endocrinology, Diabetes and Metabolism, Lausanne University Hospital (CHUV), Lausanne, Switzerland.

Pathogenic monoallelic variants in the histidyl-tRNA synthetase gene (*HARS*) were recently associated with inherited Charcot-Marie-Tooth (CMT) disease, characterized by axonal or demyelinating sensorimotor neuropathy. We investigated a 51-y old man with adult-onset pes cavus, hammer toes, stuttering, dysarthria, and mild cognitive amnestic deficit with emotional blunting. Electrodiagnostic studies were consistent with a late onset demyelinating peripheral neuropathy; a brain MRI study showed slight cerebellar atrophy; and sural nerve biopsy showed presence of polyglucosan bodies suggesting a diagnosis of adult polyglucosan body disease. Whole-exome sequencing (WES) was done with appropriate informed consent, and in house bioinformatics pipelines were used to extract rare, non-synonymous, high quality variants that were not present among sizeable healthy control cohorts. While known genes associated with polyglucosan storage myopathy (*GYS1*, *GYG1*, *GBE1*, *RBCK1*, *PFKM*, *EPM2A*, *EPM2B*, *PRDM8* and *PRKAG2*) were negative, WES identified a novel heterozygote mutation in *HARS*: c.397G>T (p.Val133Phe). The amino acid substitution is in close proximity of other substitutions associated with CMT type 2. The variant was confirmed by Sanger sequencing in the patient, and shown to be absent in maternal DNA (paternal DNA unavailable). While the newly identified *HARS* gene variant is a likely explanation for the peripheral neuropathy, a cognitive deficit has not been reported so far in patients with HARS-related CMT mutations. It is possible that this phenotypic trait is only a chance occurrence. Yet, it seems likely that HARS mutations are more pleiotropic than hitherto assumed, and that their clinical expression may comprise polyglucosan body disease. .

Huntington Disease: Case report, clinical and genetic molecular diagnosis. *M.A. Aceves-Aceves[1], S.A. Alonso-Barragán[1,2,3], I.M. Salazar-Dávalos[1], A. Ochoa-Morales[4], L. Martínez-Ruano[4], M.G. González-Mercado[2], N.O. Dávalos[1,2], D. García-Cruz[1,2], I.P. Dávalos[1,2,3].* 1) CUCS, Instituto de Genética, Universidad de Guadalajara, Guadalajara, Jalisco, México; 2) DGH, CUCS, Universidad de Guadalajara, México; 3) CIBO, HE, IMSS, México; 4) Instituto Nacional de Neurología y Neurocirugía, México.

INTRODUCTION Huntington Disease (HD) MIM #143100, is an autosomal dominant, neurodegenerative disorder with a worldwide prevalence of 5 - 10 per 100,000, typically diagnosed between 30 to 50 years of age. HD is clinically characterized by progressive motor, cognitive and behavioral manifestations. HD is caused by trinucleotide repeat expansion (CAG) in the huntingtin gene (HTT) on chromosome 4p16.3. OBJECTIVE To present a female patient with clinical diagnosis of Huntington Disease, confirmed by genetic molecular analysis. CASE REPORT A 54 years old female, with a history of involuntary movements of head, neck and hands; and onset at 48 years old. At present emotional instability is evident; abnormal movements have been progressed and she presented speech disorder. Family history: the mother and four brothers are similarly affected. The patient has three sons, apparently healthy, without symptoms. At physical examination she presented dysarthria, abnormal movements, normal tendon reflexes in limbs, and no muscular weakness neither dementia. Brain CT scans showed cortical atrophy. Clinical features, family history and CT findings were suggestive of HD. Molecular analysis was performed (informed consent). The genetic molecular test detected an allele with a trinucleotide repeat expansion CAG (n) in the huntingtin gene (HTT). Number of CAG repeats 15/48. CONCLUSIONS The clinical course of the HD is progressive and incapacitating, the survival since the onset is approximately of 20 years. The clinical features, family history and cortical atrophy revealed in brain CT scans lead us to consider the diagnosis of Huntington Disease in this patient, confirmed by genetic molecular analysis.

Cranial irradiation in childhood mimicking neurofibromatosis type II. *S. Ben-Shachar[1,3], T. Dubov[3], H. Toledano-Alhadef[1,3], R. Bernstein-Molho[2,3], S. Constantini[1,3], D.G. Evans[4].* 1) The Gilbert Israeli Neurofibromatosis Center, Tel-Aviv Medical Center, Tel-Aviv, Israel; 2) Department of Oncology, Tel-Aviv Medical Center, Tel-Aviv, Israel; 3) Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel; 4) 4Genomic Medicine, University of Manchester, Manchester Academic Health Science Center, Institute of Human Development, Center Manchester NHS Foundation Trust, Manchester Royal Infirmary, Manchester, UK.

Background Neurofibromatosis type II (NF2) is a genetic disease characterized by bilateral vestibular schwannomas (VS) and other nerve system tumors. However, such tumors may be associated with environmental, rather than a genetic, etiology. **Methods** Individuals fulfilling the clinical criteria of NF2 who had been treated by head ionized irradiation at a young age were compared for disease characteristics and molecular analysis with non-irradiated sporadic NF2 cases. **Results** Three of 33 sporadic adult cases fulfilling NF2 diagnostic criteria had a history of early age cranial irradiation exposure. None of the irradiated patients had bilateral VS compared with 73.3% of the non-irradiated individuals. One of the irradiated patients had no VS, while none of the non-irradiated NF2 cases had absence of VS. All of the irradiated individuals had brain meningiomas and thyroid tumors compared with 47% and 0%, respectively, of the non-irradiated individuals. Molecular analyses for *NF2* mutations in blood of the irradiated individuals failed to detect disease-causing mutations. **Conclusions**: Environmental factors may mimic NF2. Identifying such non-genetic cases fulfilling clinical criteria of the genetic disease may be crucial for the purposes of genetic counseling and patient management.

Ribosomal RNA-processing protein 7 homolog A (RRP7A) is associated with primary microcephaly and localizes to the centrosome and primary cilia. *M. Farooq[1], L. Lindbæk[2], V.S. Nielsen[2], M. Mönnich[1], Y. Mang[1], L.B. Pedersen[2], K. Møllgaard[1], L. Hansen[1], K.W. Kjær[1], S.M. Baig[3], N. Tommerup[1], S.T. Christensen[2], L.A. Larsen[1].* 1) Department of Cellular and Molecular Medicine, University of Copenhagen, Blegdamsvej 3 DK-2200 Copenhagen, Denmark; 2) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 3) Human Molecular Genetics Laboratory; Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering (NIBGE, PIEAS), Faisalabad, Pakistan.

Primary microcephaly (MCPH) is a rare autosomal recessive neurodevelopmental disorder in which the cerebral cortex is reduced in size leading to mild to severe mental retardation. MCPH is genetically heterogeneous, and most of the MCPH proteins are associated with the centrosome and play an important role in neuronal progenitor cell proliferation. In a search for novel centrosomal genes associated with MCPH, we performed linkage analysis and whole exome sequencing of a large consanguineous family and identified a homozygous missense mutation affecting a highly conserved amino acid residue in the ribosomal RNA-processing protein 7 homolog A (*RRP7A*). *RRP7A* encodes a 280 amino acids long protein which contains a RNA recognition motif. The missense mutation, predicted to be pathogenic by SIFT and Polyphen2 prediction tools, was present neither in the exome variant databases nor in 300 healthy controls of Pakistani origin. Both endogenous and GFP-tagged RRP7A localize to the nucleoli, centrosomes and spindle poles during all stages of mitosis as well as to primary cilia in various cell types, including patient-derived primary skin fibroblast. Primary patient fibroblasts show increased frequency of di-nucleated cells, mis-shaped nuclei and have decreased proliferation. RNA *in situ* hybridization in zebrafish embryos revealed that *rrp7a* is widely expressed in different brain compartments at 1-2 days post fertilization. Zebrafish *rrp7a* mutants have impaired craniofacial development, small heads and eyes, cell proliferation defects and increased apoptosis. Protein mass spec analysis and Co-IP assays show that RRP7A interacts with CEP164 and DNA damage-binding protein 1 (DDB1). Further studies are underway to characterize the molecular mechanisms of RRP7A function in the centrosome, primary cilia, neuronal development and MCPH.

2392W

De novo mutations of *RERE* cause a genetic syndrome with features that overlap those associated with proximal 1p36 deletions. *B.M. Fregeau[1], B.J. Kim[2], A. Hernández-García[2], V.K. Deletions of chromosome 1p36 affect approximately 1 in 5,000 newborns and are associated with developmental delay, intellectual disability, and defects involving the brain, eye, ear, heart, and kidney. Arginine-glutamic acid dipeptide repeats (*RERE*) is located in the proximal 1p36 critical region. RERE is a widely-expressed nuclear receptor coregulator that positively regulates retinoic acid signaling. Animal models suggest that RERE deficiency might contribute to many of the structural and developmental birth defects and medical problems seen in individuals with 1p36 deletion syndrome, although human evidence supporting this role has been lacking. In this report, we describe ten individuals with intellectual disability, developmental delay, and/or autism spectrum disorder who carry rare and putatively damaging changes in *RERE*. In all cases in which both parental DNA samples were available, these changes were found to be de novo. Associated features that were recurrently seen in these individuals included hypotonia, seizures, behavioral problems, structural CNS anomalies, ophthalmologic anomalies, congenital heart defects, and genitourinary abnormalities. The spectrum of defects documented in these individuals is similar to that of a cohort of 31 individuals with isolated 1p36 deletions that include *RERE* and are recapitulated in RERE-deficient zebrafish and mice. Taken together, our findings suggest that mutations in *RERE* cause a genetic syndrome and that haploinsufficiency of *RERE* might be sufficient to cause many of the phenotypes associated with proximal 1p36 deletions.

2393T

Absence of the autophagy adaptor SQSTM1/p62 causes childhood-onset neurodegeneration with ataxia. *T.B. Haack[1,2], E. Ignatius[3,4], J. Calvo-Garrido[5], A. Iuso[1,2], P. Isohanni[3,4], C. SQSTM1 (sequestosome 1; also known as *p62*) encodes a multidomain scaffolding protein involved in various key cellular processes, including the removal of damaged mitochondria by its function as a selective autophagy receptor. Heterozygous variants in *SQSTM1* have been associated with Paget disease of the bone and might contribute to neurodegeneration in amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Using exome sequencing, we identified three different bi-allelic loss-of-function variants in *SQSTM1* in nine affected individuals from four families with a childhood- or adolescence-onset neurodegenerative disorder characterized by gait abnormalities, ataxia, dysarthria, dystonia, vertical gaze palsy, and cognitive decline. We confirmed absence of the SQSTM1/p62 protein in affected individuals` fibroblasts and found evidence of a defect in the early response to mitochondrial depolarization and autophagosome formation. Our findings expand the *SQSTM1*-associated phenotypic spectrum, and lend further support to the concept of disturbed selective autophagy pathways in neurodegenerative diseases.

2394F

A suppressor screen in *Mecp2* mice reveals pathways for Rett syndrome pathogenesis. *M.J. Justice[1,2,3], S.M. Kyle[1,3], J. Ruston[1], R. Zeng[1].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Dept. of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas USA.

Mutations in methyl CpG binding protein 2 (*MeCP2*) cause Rett syndrome, an X-linked neurological disorder with autistic features and developmental regression. Mutation of *MeCP2* causes widespread gene dysregulation, making the syndrome difficult to treat. *Mecp2* mouse mutants provide an excellent animal model to identify molecules that are important for disease pathogenesis. Studies of the mouse model show that the symptoms can be reversed by re-introduction of *Mecp2*, providing evidence that therapeutic intervention is possible in humans. *MeCP2* mutation impacts many biological pathways, but it is unclear which are relevant to symptom onset and progression. A modifier screen is a forward-genetic approach to find mutations that suppress or enhance a phenotype of interest, allowing the organism to reveal important pathways for morbidity. Here, random unbiased mutagenesis with *N*-ethyl-*N*-nitrosourea (ENU) was employed to isolate mutations that suppress clinical signs and improve overall health in a *Mecp2* mouse model. Strikingly, the lesions identified by whole exome sequencing in 46 trait-suppressing lines reveal 32 candidate genes that predominantly lie in four pathways. A modifying mutation in Squalene epoxidase (*Sqle*) showed that cholesterol synthesis was abnormal in *Mecp2* mice, and revealed the importance of brain lipid homeostasis to neurological function (1). Subsequent data show that MECP2 is required to link a repressor complex that regulates lipid homeostasis to DNA, resulting in metabolic syndrome (2). Of the pathways that contribute to Rett syndrome morbidity, it is clear that metabolism plays a key role in disease, and metabolic modulators such as statin drugs improve health in mice. Lipid homeostasis thus represents a potential new therapeutic target for Rett syndrome treatment and statin clinical trials are underway. Altogether, our data suggest that multiple factors will be required to reverse disease entirely, requiring combination therapies. A similar genetic approach could be exploited to identify targetable pathways involved in other "untreatable" diseases, opening a new field for translational discovery. (1) Buckovecky CM, et al. (2013) A suppressor screen in *Mecp2* mutant mice implicates cholesterol metabolism in Rett syndrome. *Nature Genetics* 45(9): 1013-1020. 2395W

Screen for *de novo* mutations in epileptic encephalopathy genes in a cohort of patients with brain malformations. *A.M. Muir[1], N.T. Nguyen[1], G.L. Carvill[1], H. Crabtree[1], S. Hermans-Beijnsberger[1], W.B. Dobyns[2], I.E. Scheffer[3,4,5], H.C. Mefford[1].* 1) Department of Pediatrics, Division of Genetic Medicine, University of Washington, Seattle, Washington 98195, USA; 2) Pediatrics and Neurology, University of Washington, Seattle, WA, 98195, USA; 3) Epilepsy Research Centre, Department of Medicine, Austin Health, The University of Melbourne, Heidelberg, Victoria, 3084, Australia; 4) Florey Institute of Neuroscience and Mental Health, The University of Melbourne, VIC 3010, Australia; 5) Department of Paediatrics, Royal Children's Hospital, The University of Melbourne, Parkville, Victoria, 3050, Australia.

Malformations of cortical development (MCDs) are brain abnormalities affecting the cerebral cortex that arise from disruption in the proliferation, differentiation, migration, or post-migrational organization of neurons in the developing cortical plate. Many MCDs appear to have an underlying genetic etiology, and mutations in a number of genes involved in cortical development and neuron migration have been shown to cause MCDs. The disruption of normal neuronal circuitry from MCDs can lead to a number of downstream clinical consequences including epileptic seizures. Epileptic encephalopathies (EEs) are severe, early-onset epilepsy disorders associated with intractable seizures and poor developmental outcome. Typically, epilepsy associated with MCDs and EE, which typically occurs without MCD, are thought to have distinct etiologies. However, as more patients undergo testing by whole exome sequencing or large gene panels, it is clear that there is some shared genetic etiology. *De novo* mutations in genes involved in cortical development and associated with brain malformations such as *FLNA* and *ARX* have been found in patients with EE, and mutations in *DEPDC5* have been found to cause focal epilepsy with and without focal cortical dysplasia in the same family. Together, this suggests that overlapping molecular mechanisms exist between MCDs and epilepsy. While *DEPDC5, FLNA,* and *ARX,* illustrate specific examples of shared etiologies between MCDs and epilepsy, a more comprehensive approach is needed to determine the extent to which common mechanisms are contributing to these two disorders. To systematically investigate the role of EE genes in MCD, we are screening 53 known EE and focal epilepsy genes in a cohort of 425 probands with MCDs including polymicrogyria (n=319), subcortical band heterotopia (n=43), and cortical dysplasia (n=29). We are currently using Molecular Inversion Probe (MIP) technology to sequence the coding regions from the epilepsy gene panel using a targeted capture sequencing approach. SNVs and indels will be filtered to identify rare, protein-changing variants. Since the cohort is comprised primarily of sporadic cases of MCDs, segregation testing will also be preformed to identify *de novo* variants, as these are most likely to be disease causing. *De novo* mutations in this screen would not only identify additional MCD genes but also provide further evidence towards the common underpinnings of MCD and epilepsy.

2396T

***GPAA1* mutations cause a new GPI-anchor biosynthesis defect with developmental delay, epilepsy, cerebellar hypoplasia and osteopenia.** *T.T.M. Nguyen[1], Y. Murakami[3], E. Sheridan[4], J. Chai[8], L. Fairbrother[5], A. Bateman[7], T. Reimschisel[6], E. Berry-Kravis[5], F. Xia[9], J. Tardif[1], J.A. Rosenfeld[9], C. Johnson[4], J.G. Gleeson[8], T. Kinoshita[3], P.M. Campeau[1,2].* 1) CHU-Sainte Justine Research Centre, University of Montreal, Montreal, QC, Canada; 2) Department of Pediatrics, University of Montreal, Montreal, QC, Canada; 3) Immunology Frontier Research Center, and Department of Immunoregulation, Research Institute for Microbial Diseases, Osaka University, Japan; 4) Faculty of Medicine and Health University of Leeds, UK; 5) Rush University Medical Center, Rush University, Chicago, IL , USA; 6) Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, TN, USA; 7) Vanderbilt University Medical Center, Monroe Carell Children's Hospital, Nashville, TN, USA; 8) Department of Neurosciences, University of California, San Diego, CA, USA; 9) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Approximately one in every 200 mammalian proteins are anchored to cell membranes through a glycosylphosphatidylinositol (GPI) anchor, and these proteins play important roles in neurological development and function, as well as in most other systems. GPAA1 together with PIGK, PIGS, PIGT, and PIGU form the GPI anchor transamidase complex which is responsible for the attachment of GPI anchors to protein precursors. We found bi-allelic *GPAA1* mutations in seven patients from four unrelated families by exome sequencing. Features present in most individuals include global developmental delay, hypotonia, early-onset seizures, cerebellar hypoplasia, and osteopenia. Plasma alkaline phosphatase was normal. These features overlap with those of other known GPI biosynthesis defects. Mutations identified include frameshift (NM_003801.3:p.G307Afs*11, p.Q327Hfs*102), splicing (c.1164+5C>T) and missense mutations (p.S51L, p.W176S, p.L291P, p.A389P). Flow cytometry studies on five available patient samples showed that several GPI-anchored proteins had decreased cell surface expression in leukocytes (FLAER, CD16, CD55) and fibroblasts (FLAER, CD73, CD87, CD109). Lentiviral rescue studies are underway. These findings thus allow us to include GPAA1 deficiency in the expanding group of GPI-anchor biosynthesis defects, and highlight the role of the transamidase complex in the formation and function of the cerebellum and bone. TTMN, YM and ES contributed equally to the work.

2397F

THAP11 mutations in a patient with a *cblX*-like phenotype implicates the HCFC1/THAP11 complex in regulation of cobalamin metabolism and early vertebrate development. *A.M. Quintana[1], H. Yu[2], A. Brebner[3], M. Pupavac[3], E.A. Geiger[2], W. Cheung[3], S. Chen[3], D. Watkins[3], T. Pastinen[3], F. Skovby[4], B. Appel[5], D.S. Rosenblatt[3], T.H. Shaikh[2].* 1) Biological Sciences, University of Texas El Paso, El Paso, TX; 2) Pediatrics, Section of Genetics, University of Colorado School of Medicine, Aurora, CO; 3) Human Genetics, McGill University, Montreal, Quebec H3A 1B1, Canada; 4) Clinical Genetics, Rigshospitalet, Copenhagen, Denmark; 5) Pediatrics, Section of Developmental Biology, University of Colorado School of Medicine, Aurora, CO.

Mutations in *HCFC1* are associated with *cblX* (MIM309541), an X-linked recessive disorder, characterized by defects in cobalamin metabolism, nervous system development, neurological impairment, failure to thrive and mild to moderate facial dysmorphism. Functional analyses have demonstrated that *HCFC1* mutations disrupt cobalamin metabolism via the down-regulation of *MMACHC*. HCFC1 is a transcriptional co-regulator which requires interaction with transcription factors in order to regulate the expression of a myriad of genes. Notably, HCFC1 appears to regulate the expression of *MMACHC* through its interaction with THAP11, a THAP domain-containing transcription factor. In addition, the HCFC1/THAP11 complex has been shown to bind to regulatory regions of numerous genes involved in diverse cellular functions including cell cycle, proliferation and transcription. Thus, it is likely that mutations in *THAP11* may also result in biochemical and other phenotypes similar to those observed in patients with *cblX*. We report a patient who presented with phenotypic features that overlap *cblX*, but did not have any mutations in either *MMACHC* or *HCFC1*. We sequenced *THAP11* by Sanger sequencing and discovered a potentially pathogenic, homozygous variant in *THAP11*, c.240C>G (p.Phe80Leu). Functional analysis in the developing zebrafish embryo, demonstrate that both Thap11 and Hcfc1 regulate the proliferation and differentiation of neural precursors, suggesting important roles in normal brain development. Further, the loss of *thap11* in zebrafish embryos, results in craniofacial abnormalities including the complete loss of Meckel's cartilage, the ceratohyal, and all of the ceratobranchial cartilages. These data are consistent with our previous work which demonstrated a role for HCFC1 in vertebrate craniofacial development. Furthermore, our high throughput RNA-sequencing analysis reveals several overlapping gene targets of HCFC1 and THAP11 that likely contribute to the biochemical as well as other phenotypes associated with *cblX*. Taken together, our results provide evidence that the HCFC1/THAP11 complex plays an important role in the regulation of cobalamin metabolism as well as other pathways involved in early vertebrate development.

2398W

Non-optic gliomas in adults and children with neurofibromatosis 1 (NF1). *L. Sellmer[1], M. Marangoni[2], M. Heran[2], P. Birch[1], S. Farschtschi[3], V.-F. Mautner[3], J. Friedman[1].* 1) Child and Family Research Institute, University of British Columbia, Vancouver, Canada; 2) Department of Radiology, University of British Columbia, Vancouver, Canada; 3) University Hospital Hamburg-Eppendorf, Hamburg, Germany.

Background: Non-optic gliomas are one of the most common tumours in patients with NF1. The natural history and frequency of these tumours in children and especially in adults are incompletely understood. Methods: 1722 head MRI scans were obtained from 562 unselected individuals with NF1 at the NF outpatient department of the University Hospital Hamburg-Eppendorf between 2003 and 2015. We analyzed the clinical features of non-optic gliomas and focused on the differences between adults and children. Results: The number of scans per patient ranged from 1 to 12; patients were followed for a median of 3.7 years. We identified 23 patients (4.1%) with non-optic gliomas, a prevalence about twice that reported in most previous studies. Median age of these patients at first scan was 22.4 years, much higher than previously reported in the literature. 13 tumours were located in the cerebellum, 8 in the brain stem, 4 in the corpus callosum, 3 in the temporal lobe, 1 in the frontal lobe, 1 in the thalamus and 1 in the internal capsule. Only 7 of the 23 glioma patients were symptomatic. Histology was available on 9 tumours and showed 8 pilocytic astrocytomas and one dysembryoplastic neuroepithelial tumour. 4 individuals developed a tumour after having at least one tumour-free scan, and 4 cases showed progression. The risk of new tumour development was 0.19% (95% confidence interval 0.06% to 0.52%) per patient year of follow-up for all patients older than 10 years of age. There were no newly appearing tumours in children under the age of 10, and the prevalence of non-optic gliomas in children under 10 years of age was only 1.1%. Non-optic tumours in this study only progressed in the first 4.9 years after diagnosis and only in patients younger than 22.3 years of age. The rate of progressing non-optic gliomas per patient years of follow-up in the first 5 years after tumour diagnosis was 4.9% (95% confidence interval 1.6% to 13%). Conclusion: Non-optic gliomas are twice as common in an unselected cohort of NF1 patients as previously reported. This is most likely due to increased frequency of diagnosis of asymptomatic tumours when routine head MRIs are performed and a higher prevalence in older individuals, who are poorly represented in previously reported series.

The clinical usefulness of performing NGS in the clinical setting varies for different disorders. The identification of the underlying disease etiology can be challenging, given the clinical heterogeneity, sporadic status and the increasing number of causative genes. Many still remain without a molecular diagnosis, despite extensive investigation, exposing the need to study rare genetic variants in genes not yet linked to human diseases. Alterations of microtubule dynamics can lead to neurodevelopmental defects. Five conserved tubulin cofactors/chaperones (including *TBCD*, *TBCE*, and *ARL2*) regulate α- and β-tubulin assembly into heterodimers and maintain the soluble tubulin pool in the cytoplasm, but their physical mechanisms are unknown. The Tubulin Folding Cofactor D (*TBCD*) modulates microtubule dynamics by capturing GTP-bound beta-tubulin (TUBB). It also acts as a GTPase-activating protein (GAP) for ADP-Ribosylation Factor-Like 2 (ARL2). Here we describe a novel autosomal-recessive disease in six individuals from 4 unrelated kindred; biallelic mutations in *TBCD*, encoding one of the five co-chaperones required for assembly and disassembly of the α-β-tubulin heterodimer, the structural unit of microtubules, underlie a neurodegenerative disease characterized by early-onset cortical atrophy with microcephaly, thin corpus callosum, developmental delay and intellectual disability, seizures, optic atrophy, and spastic quadriplegia. Biochemical analyses documented variably reduced levels of TBCD, indicating relative instability or insolubility of mutant proteins, and defective β-tubulin binding in a subset of the tested mutants. Reduced/defective TBCD function resulted in decreased soluble α/β-tubulin levels and accelerated microtubule polymerization in fibroblasts from affected subjects, demonstrating an overall shift towards a more rapidly growing and stable microtubule population. These cells also displayed an aberrant mitotic spindle with disorganized, tangle-shaped microtubules and markedly reduced aster formation, which however did not alter appreciably the rate of cell proliferation. Our findings establish that defective TBCD function underlies a recognizable neurodegenerative disorder and causes accelerated microtubule polymerization and enhanced microtubule stability, underscoring a tight link between aberrant microtubule dynamics and neurodegeneration.

Focal Cortical Dysplasia (FCD) is a brain malformation often associated with the occurrence of refractory seizures and it has been considered a mild phenotype within the hemimegalencephaly-tuberous sclerosis (TS) spectrum. The goal of our work is to search for germline and mosaic mutations in patients with FCD. Deep-Whole Exome Sequencing (WES) was performed in genomic DNA extracted from brain tissue resected by surgery (BTRS) and blood leucocytes of four patients. We performed capture and enrichment with Nextera® Expanded Kit. Samples were sequenced following a 200bp paired-end protocol in a Hiseq2500 to achieve at least 200x of average coverage. Realignment around indels and SNP clusters were performed using the Genome Analysis Toolkit (GATK). Variants were filtered prioritizing frameshift, missense, nonsense and splicing site mutations that were localized in coding regions or exon-intron boundaries. In addition, mosaicism was evaluated using Somatic Sniper and Mutect. Variants were classified as mosaic mutations when less than 50% of reads do not align to the sequence reference and are present only in BTRS. WES sequencing revealed a c2026T>A variation in the *TSC1* gene present both in BTRS and lymphocytes of a patient with FCD. This variant results in a missense mutation (W676R, Q92754) in *TSC1*. Furthermore, mosaicism analysis performed in additional patients identified several somatic mutations in BTRS, including nine variants on genes belonging to the mTOR pathway. This is the first description of a pathogenic germline variant in *TSC1* leading to FCD and supports the concept that FCD may be indeed a *forme fruste* of TS. Moreover, since mosaic mutations in genes associated with the mTor pathway have been reported in patients with FCD, we believe that the somatic variants identified in our cohort of patients are strong candidates to be involved with FCD etiology.

Severe growth retardation, microcephaly, intellectual disability, and characteristic facial features due to homozygous mutation in the QARS gene: Expanding the phenotype. *C. Vinkler[1,2], E. Leshinsky-Silver[2,6,7], J. Ling[3], C. Jalas[5], T. Lerman-Sagie[2,4,6], D. Lev[1,2,6].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Metabolic-Neurogenetic Clinic; Wolfson Medical Center, Holon, Israel; 3) Department of Microbiology and Molecular Genetics, The University of Texas, Health Science Center at Houston, Houston, TX 77030, USA; 4) Pediatric Neurology Unit; Wolfson Medical Center, Holon, Israel; 5) Bonei Olam, Center for Rare Jewish Genetic Disorders, Brooklyn, New York, USA; 6) Sackler School of Medicine, Tel-Aviv University, Tel-Aviv, IsraelI; 7) Molecular Genetics Laboratory, Wolfson Medical Center, Holon, Israel.

Aminoacyl-tRNA synthetases (the aaRS family) are enzymes responsible for the proper pairing of codons on mRNA with amino acids and essential for interpreting the genetic code. They also form a multisynthetase complex (MSC) which participates in various other cell functions. Glutaminyl tRNA synthase is a member of class I aaRS enzymes. It is responsible for synthesis of the cytosolic pool of glutaminyl-tRNA^{Gln} (Gln-tRNA^{Gln}). Human GlnRS is encoded by QARS gene and is highly expressed in the developing fetal human brain. Mutations in *QARS* gene have been previously reported in patients from three unrelated families presenting with progressive microcephaly, cerebral-cerebellar atrophy and intractable seizures. We describe two sisters who are homozygous for a yet undescribed mutation in QARS. These girls have been recently reported by us presenting a new recessive syndrome. They were born to healthy unrelated parents of Ashkenazi-Jewish origin. They have six healthy siblings. The girls have severe linear growth retardation, poor weight gain, microcephaly, characteristic facial features, cutaneous syndactyly of the toes, high myopia and severe intellectual disability. Homozygosity mapping together with exome sequencing revealed homozygous missense (V476I) mutation in the QARS gene. The mutation is located in the catalytic domain. The parents and three of the healthy siblings are heterozygote carriers. Indeed, the patient's fibroblasts demonstrated a disrupted QARS aminoacylation activity in vitro. The clinical presentation in our patients differs from the original QARS-associated syndrome in the severe postnatal growth failure, non-progressive microcephaly, dysmorphic features and the absence of seizures. Mutations in QARS causing reduction in hGlnRS activity, may manifest not only as neurological disorder of brain development but should be considered also in patients with severe linear growth, microcephaly and intellectual disability.

2402T

Variants spectrum in 31 Chinese newborns with idiopathic seizures revealed by next-generation sequencing. *L. Yang[1], Z. Li[2,3], B. Sun[1], M. Mei[1], W. Tian[2], H. Wang[3], W. Zhou[1,3,4].* 1) Children's Hospital of Fudan University, Shanghai, Shanghai, China; 2) Department of Biostatistics and Computational Biology, Life Science, Fudan University; 3) Key Laboratory of Birth Defects, Children's Hospital of Fudan University, Shanghai, China; 4) Key Laboratory of Neonatal Diseases, Ministry of Health, Children's Hospital of Fudan University.

Background: The etiology of the idiopathic neonatal seizures is important to identify as it may serve a significant effect on diagnosis, prognosis, treatment and outcome. **Objectives:** The purpose of this study is to get the whole spectrum of mutation spectrum in 31 Chinese unrelated patients with idiopathic neonatal seizures. **Methods:** We performed *KCNQ2* gene Sanger sequencing and disease-targeted multi-gene next-generation sequencing across 741 nervous system-related genes in 31 unrelated neonates with idiopathic seizures. *Results:* A total of 8 variants in *KCNQ2* gene, including 7 possible pathogenic mutations in 7 patients (7/31, 22.6%) were identified by Sanger sequencing. The patient with R213W mutation suffered from epileptic encephalopathy, which updates the genotype-phenotype correlation of *KCNQ2*. Expanded to 741-gene panel, more 8 possible disease-causing mutations (in 5 genes) in 8 probands (8/31, 25.8%) were detected. In addition, the results of this study extend mutation spectrum in neonatal seizures in several related genes such as *KCNQ2*, *DEPEC5* and *SCN2A*. **Conclusions:** For first-tier clinical screening, a focused panel including just about 6 important genes with about 50% contribution is more cost effective, and *KCNQ2* should be a priority during genetic screening. This study enhances the current knowledge of genotypic and phenotypic heterogeneity of idiopathic neonatal seizures, which will assist both clinical diagnoses and personalized treatments of Chinese newborns with idiopathic seizures.

In a previous genome-wide linkage study on an autosomal dominant Alzheimer disease (AD) family, we identified a genetic locus of 5.44 Mb at chromosome 7q36, but the underlying pathogenic mutation remained elusive (Rademakers et al. 2005). To reinvestigate the unresolved linkage, we performed whole genome sequencing on 4 patients from the pedigree. Bioinformatics revealed within the 7q36 locus, the presence of low copy repeats (LCRs), known to be prone to genomic instability. In the 4 sequenced individuals, we detected a chromosomal inversion of *c.a.* 4 Mb on the disease haplotype. The breakpoints were located in the LCRs in intron 1 of the dipeptidyl peptidase 6 (*DPP6*) gene and in an intergenic region outside the linked locus. Due to i) the heterogeneous clinical presentation - without definite pathological confirmation - of the linkage family, with an AD patient presenting with frontal signs and ii) reduced DPP6 protein expression in the brain of AD patients (Hondius et al., 2016), we assessed the genetic contribution of rare *DPP6* mutations to the dementia spectrum. We performed massive parallel sequencing of *DPP6* in Dutch AD (n=82), Belgian AD (n=335) and frontotemporal dementia (FTD, n=435) patients cohorts as well as control individuals (n=755). This revealed a significant enrichment of rare variants in FTD patients, when known pathogenic mutation carriers were excluded (19/359, 5.3%) compared to control individuals (13/755, 1.72%; SKAT-O p-value=0.001, relative risk=3.1, 95% confidence interval (CI)=1.54–6.37). We also identified two premature stop codon mutations in patients supporting the hypothesis of loss-of-function (LoF) as the underlying molecular mechanism. DPP6 regulates synaptic excitability by modulating the expression and function of the potassium channel Kv4.2 in brain. Expression studies on brain tissue of patient carriers of missense mutations showed a decreased expression of DPP6 transcript (p-value=0.0096), confirmed on protein level. Kv4.2 protein expression was also decreased in these patients. Electrophysiology studies in *Xenopus laevis* oocytes showed a significant negative effect (p-value <0.05) on Kv4.2 gating properties when the channel was co-expressed with two premature stop codon mutations. Our data support a risk association of *DPP6* with frontotemporal dementia that may involve brain network activity alterations.

2404W

First report of a Mendelian disease caused by a mutation in the *HTR2C* gene. *C. Vural[1], R. Scott[1], L. Cantor[2], M. Banikazemi[1].* 1) Regional Medical Genetics Center, Boston Children's Health Physicians, Valhalla, NY; 2) CWPW Neurology, Boston Children's Health Physicians, Sleepy Hollow, NY.

HTR2C, a clinically novel gene on Xq23, encodes the 5-HT2CR receptor, a member of a family of G-protein-coupled-receptors that control physiological responses to serotonin. Animal studies have implicated mutations in this gene to be associated with seizures, appetite abnormalities, hyperinsulinemia, and other pre-diabetic symptoms. It has also been hypothesized that polymorphisms in *HTR2C* gene are associated with symptoms including psychiatric disorders, hallucinations, and increased BMI, but no Mendelian disease in humans has yet been shown to be caused by mutations in *HTR2C*. We present the first report of a 6 year old boy with seizure disorder, tremors, and psychiatric symptoms including hallucinations, paranoia psychosis, and disruptive behavior due to mutation of the *HTR2C* gene. We have treated this patient since initial presentation at 6 months of age when he presented with infantile spasm. His physical growth has remained appropriate, but his seizures and psychiatric symptoms have become more difficult to control with conventional anti-epileptic and anti-psychotic medications. He has demonstrated delay in his cognitive development and progressive decline in his psychosocial development expanding to self-injurious behavior, prolonged and frequent crying, agitation, restlessness, trouble sleeping, claustrophobia, visual hallucinations, acute episodes of psychotic symptoms, speech delay, and autistic behsviors. He has required several hospitalizations for worsening of his symptoms. He has shown improved behavior, mood and severity of tremors after recent addition of Seroquel to his treatment. Whole Exome Sequencing (WES) was completed through Ambry Genetics and revealed a deleterious mutation (HTR2C c.1219_1222del) on the proband's only copy of the HTR2C gene. The proband's mother, who is heterozygous for this deletion, remains asymptomatic. Despite the clinical ambiguity surrounding the *HTR2C* gene, the patient has sufficient overlapping clinical symptoms with the *HTR2C* gene family for us to declare that the proband's deletion in *HTR2C* is responsible for his presentation. This is the first description of a pathogenic mutation in the *HTR2C* gene in a patient with infantile spasms, seizures, psychiatric symptoms, tremors, autism, and pre-diabetes. Our findings suggest that WES is an important diagnostic tool for detecting the genetic etiology of psychiatric symptoms and seizure disorders as well as for the discovery of novel causative gene mutations.

2405T

Compound heterozygous *TRPV4* mutations causing severe global developmental delay and overlapping phenotype of neuropathy, myopathy and skeletal involvement. *M. Thibodeau[1], C.H. Peters[2], K. Townsend[1,3], Y. Shen[4], G. Hendson[5], S. Adam[1], K. Selby[6], P.M. Macleod[7], C. Gershome[2], P. Ruben[2], S. Jones[1,4], J.M Friedman[1], W. Gibson[1], G. Horvath[8], the FORGE Canada Consortium.* 1) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 2) Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, Canada; 3) Child and Family Research Institute, Vancouver, Canada; 4) Canada's Michael Smith Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, Canada; 5) Department of Anatomic Pathology, University of British Columbia, Vancouver, Canada; 6) Department of Pediatrics, Division of Pediatric Neurology, University of British Columbia, Vancouver, Canada; 7) Victoria General Hospital, Division of Medical Genetics, Victoria, Canada; 8) Department of Pediatrics, Division of Biochemical Diseases, University of British Columbia, Vancouver, Canada.

   Background: Several genes of the transient receptor potential channel family are known to cause hereditary channelopathies when mutated. *TRPV4* gene encodes a polymodal calcium-permeable plasma membrane channel. Dominant pathogenic mutations in the *TRPV4* gene lead to a wide spectrum of human phenotypes.We investigated the molecular mechanism underlying the complex neuromuscular, skeletal and neurodevelopmental phenotypes of two affected siblings in relation to their compound heterozygous state for *TRPV4* missense variants p.E840K (c.2518G>A, NM_021625.4) and p.N833S (c.2498A>G, NM_021625.4). **The Family**: A brother and sister presented with severe intellectual disability, progressive peripheral neuropathy and myopathy, severe sensorineural hearing loss, severe kyphoscoliosis, joint contractures, and small hands and feet. The brother also had retinopathy. Both sibs manifested signs within the first year of life. No other relatives had any of these conditions. Muscle biopsies, nerve biopsies and nerve conduction studies showed peripheral axonal neuropathy and myopathy in both patients. **Sequencing**: Whole exome sequencing was performed in both children and their unaffected mother. Compound heterozygous candidate *TRPV4* missense variants p.E840K and p.N833S were identified. Both variants are rare and p.E840K is predicted to be damaging. These variants were identified in both affected children; unaffected relatives had either variant but not both. The boy was the only family member with compound heterozygous *ABCA4* missense variants p.G863A (c.2588G>C, NM_000350.2), previously described as pathogenic in the literature, and p.R152Q (c.455G>A, NM_000350.2), which probably explains his retinopathy. **Methods and Results**: Functional assays of the p.E840K and p.N833S variants transfected into CHOk1 cells revealed decreased gated current densities, despite normal protein immunostaining localization assay. **Conclusions**: We report here the first two individuals with compound heterozygous *TRPV4* variants and classical TRPV4-related neuromuscular phenotypes. In the light of previously well-described dominant inheritance for this group of disorders, our study provides supporting evidence for compound heterozygosity leading to a far more severe neuromuscular phenotype than expected with a single *TRPV4* pathogenic variant. Unexplained severe developmental delay was noted in both affected children and future studies might implicate *TRPV4* gene in cortical neurogenesis.

2406F

Relationship between various clinical features in a genotyped population investigated for tuberous sclerosis complex. *N. Ishihara[1], H. Sasaki[2], T. Kato[3], H. Inagaki[3], M. Tsutsumi[3], R. Shiroki[2], H. Kurahashi[3].* 1) Dept Pediatrics, Fujita Health University, Toyoake, Aichi, Japan; 2) Dept Urology, Fujita Health University, Toyoake, Aichi, Japan; 3) Div Molecular Genetics, Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Aichi, Japan.

   Introduction: Tuberous Sclerosis Complex (TSC) is a multi-system disorder, typically involving severe neurological symptoms, such as epilepsy, cognitive deficit and autism, severe cutaneous manifestation, and various tumors, such as subependymal giant cell astrocytoma (SEGA), renal angiomyolipoma (rAML) and lung lymphangioleiomyomatosis (LAM). TSC is inherited in an autosomal dominant pattern and is caused by mutations in either the TSC1 or TSC2 genes, which enhance activation of the mammalian target of rapamycin (mTOR) signaling pathway. As recent studies have suggested that mTOR inhibitors such as rapamycin can reverse TSC-associated deficits, the advent of pharmacological therapies has made early diagnosis important in patients with TSC. Although there is a substantial overlap in the clinical phenotype produced by TSC1 and TSC2 mutations, accumulating evidence indicates that TSC2 mutations cause more severe manifestations than TSC1 mutations. In this study, we investigated patients with various TSC manifestations to reveal the difference with genotype. Patients and Methods: We retrospectively investigated in a cohort of TSC outpatients of Fujita Health University Hospital, clinical manifestations and genetic mutations. Thirteen patients who were diagnosed as TSC clinically underwent genetic testing, and causal gene mutations were found in 12 patients. Genetic testing was performed with target exome sequencing, and validated with Sanger sequencing. Result: Clinical manifestations of 12 patients were following; epilepsy in 9 patients, rAML in 9 patients, LAM in 3 patients, and SEGA in 2 patients. Eleven patients had mutations in TSC2 gene, and one had in TSC1 gene. Mutations were following; nonsense mutation in 2 patients, frameshift mutation in 7 patients, missense mutation, one amino acid deletion and exonal deletion in one patient, respectively. The patient with exonal deletion had concomitant PDK1 deletion which led to contiguous gene syndrome. Conclusion: In our cohort, many of them have epilepsy and rAML, and have TSC2 truncated mutations, indicating that the TSC2 truncated mutation is linked to much severe clinical manifestations. Early pharmacotherapy interventions based on genotype may be available for our TSC patients.

2407W

Wieacker-Wolff syndrome and *ZC4H2*: Case report and discussion of proposed neural mechanism. *J. Moeschler, J. Ozmore.* Pediatrics, Medical Genetics, Dartmouth-Hitchcock Med Ctr, Lebanon, NH.

Wieacker-Wolff syndrome (OMIM 314580) is an X-linked recessive neuro-developmental disorder characterized by fetal akinesia sequence. Affected boys present with severe distal arthrogryposis, delayed motor development, facial and bulbar weakness, characteristic dysmorphic facial features, and skeletal abnormalities, such as hip dislocation, scoliosis, and equinovarus. Wieacker et al (1985) described this apparently novel X-linked syndrome in 6 males in 4 sibships of 3 generations of a family. Hirata et al (2013) identified a family with affected individuals who presented with neonatal respiratory distress, arthrogryposis multiplex congenita, muscle weakness, and ptosis. Hirata et al also identified the *ZC4H2* gene associated with this syndrome in 2013. Miles and Carpenter (1991) reported on a single family of 3 brothers and a male cousin with intellectual disability in association with exotropia, microcephaly, distal muscle wasting, and 10 low digital arches. Until 2015, no gene was noted associated with this syndrome. Miles-Carpenter syndrome (OMIM 309605) was reported in one family. The case reported herein is of an infant boy who presented at birth with distal arthrogryopsis, weakness, hypotonia, and poor feeding. Later he demonstrated cortical vision impairment and severely delayed development. He also had sinus bradycardia requiring pacemaker placement at age 5 months; and, myoclonic seizures. Abnormal brain MRI was noted: thin corpus callosum, mega cisterna magnum, non-specific signal abnormality in globus pallidus, left lateral genticulate, hypothalamus, and central tegmental tracts; irregular formation of folia of cerebellum. Whole exome sequencing identified in this patient a pathogenic variant in *ZC4H2* gene: c.593G>A, p.Arg198Gly. This variant was maternally inherited and has been reported (family 2) by Hirata et al. Hirata et al identified pathogenic variants in *ZC4H2* in four families with Wieacker-Wolff syndrome. May et al (2015) identified four mutations in *ZC4H2*, three missense and one in-frame insertion, in the original family with Miles-Carpenter syndrome and three other families with a constellation of microcephaly, short stature, contractures, spasticity and ID. Wieacker Wolff, Miles Carpenter and XLID syndromes associated with *ZC4H2* will be discussed together with published information regarding a proposed mechanism for the clinical phenotype.

2408T

Sleep movement disorders in adults with 22q11.2 deletion: A new dopamine-related manifestation? A case report. *G.M. Repetto[1], R. Fritsch[2], R. Fadic[3], P. Chana[4], C. Ornstein[2], C. Juri[3], V. Kramer[5], R. Pruzzo[5], H. Amaral[5], A. Ocampo[6].* 1) Center for Genetics and Genomics, Clin Alemana- Univ Desarrollo; 2) Departamento de Psiquiatria y Salud Mental Hospital, Clinico Universidad de Chile; 3) Departamento de Neurologia, P Universidad Catolica de Chile; 4) Centro de Trastornos del Movimiento (CETRAM); 5) Nuclear Medicine and PET/CT Center PositronMed-FALP; 6) Facultad de Medicina, Universidad de Chile, Santiago, Chile.

Adults with 22q11 microdeletion (22q11DS) are at high risk of developing early-onset movement disorders such as Parkinson disease (PD) or parkinsonism, either primarily as part of the syndrome or as a side effect of antipsychotic medication. A role for dopaminergic dysregulation has been suggested. Certain parasomnias (sleep disorders that involve abnormal movements, behaviors and/or perceptions) are frequent in PD. Patients can have non-specific non-REM sleep disorders such as periodic limb movements (PLM). On the other hand, REM behavior disorder is considered a prodromal and specific feature of PD. We report a 45 year old female with 22qDS with psychosis, who developed tremor, bradykinesia, rigidity and insomnia while treated with haloperidol. Her abnormal movements improved after its withdrawal and addition of trihexyphenidyl. A cerebral PET CT scan with the dopamine transporter ligand 18F-PR04.MZ showed bilateral symmetric increased uptake of the radioligand in putamen and caudate nuclei (130% of control). A sleep study showed intense and frequent periodic limb movements during REM sleep, consistent with Periodic Limb Movement Disorder (PLMD) and associated with a high number of microawakening episodes. The condition manifests intermittently and the movements may cause poor sleep and subsequent daytime somnolence. Treatment involves either dopaminergic medication in an attempt to modify activity of the subcortical motor system or, more commonly, sedative medications to allow uninterrupted sleep. The etiology of PLMD is uncertain. Suprasegmental disinhibition of the descending inhibitory pathways may be a factor. Vetrugno et al (2007) proposed neuronal hyperexcitability with involvement of the central pattern generator for gait as the pathophysiology of PLMD. This leads to decreased dopamine transmission, potentially supporting the use of dopaminergic therapy to treat the condition. This combination of symptoms due to elevated (psychosis) and low (Parkinson) dopamine signaling constitute a relevant therapeutic challenge for patients with 22qDS. We propose that sleep movement disorders are another manifestation of altered dopamine signaling of 22q11DS phenotype in adults. It is relevant to explore their frequency and impact on daily life in a large patient cohort. Funded by Fondecyt-Chile grant #1130392.

2409F

Huntington disease reduced penetrance alleles occur at high frequency in the general population. *C. Kay[1], J.A. Collins[1], Z. Miedzybrodzka[2], G.E. Wright[1], S.J. Madore[3], E.S. Gordon[3], N. Gerry[3], E.R. Fisher[1], M. Davidson[2], R.A. Slama[1], M.R. Hayden[1].* 1) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 2) Medical Genetics Group, School of Medicine and Dentistry, University of Aberdeen, Aberdeen, UK; 3) Molecular Biology Group, Coriell Institute for Medical Research, Camden, New Jersey.

Huntington disease (HD) is a fatal neurodegenerative disorder caused by an expanded CAG trinucleotide repeat in the Huntingtin (HTT) gene. HD is diagnosed in 10.6-13.7 individuals per 100,000 in Western populations (1 in 7300), but the general population frequency and penetrance of the causative CAG repeat expansion is unknown.   To directly estimate the frequency of CAG repeat alleles associated with Huntington disease (HD), CAG repeat length was evaluated in 7315 individuals from three population-based cohorts in British Columbia, the United States, and Scotland. The allelic frequency of ≥36 CAG alleles was assessed out of a total of 14630 alleles, and the genotypic frequency assessed out of a total of 7315 individuals. 18 of 7315 individuals had ≥36 CAG, revealing that approximately 1 in 400 individuals in the general population have an expanded CAG repeat associated with HD (0.246%). Individuals with CAG 36-37 genotypes are the most common (36, 0.096%; 37, 0.082%; 38, 0.027%; 39, 0.000%; ≥40, 0.041%).   To directly estimate the penetrance of the most common HD-associated alleles in our general population sample, the frequency of CAG 36-38 repeat alleles was compared to the prevalence of HD patients with genetically confirmed CAG 36-38 in a multisource clinical ascertainment across British Columbia, Canada. The penetrance of 36-38 CAG repeat alleles for HD was directly estimated for individuals ≥65 years of age and compared against previous inferred clinical penetrance estimates for this age class. General population CAG 36-38 penetrance rates are lower than inferred clinical penetrance rates, suggesting that a large proportion of individuals with 36-38 CAG repeat alleles are not clinically diagnosed with HD over a typical lifespan. The relatively infrequent diagnosis of HD at 36-38 CAG repeats suggests low penetrance in this range. However, given that 36-38 CAG repeats result in the latest average age of onset in clinical cohorts, and another contributing factor may be reduced ascertainment of HD in those of older age. Our data imply that an aging population will lead to higher prevalence rates of HD, and that improved ascertainment of late-onset HD, particularly with 36-38 CAG repeat alleles, may lead to further increases in the future.

2410W

A 78 kb interchromosomal insertion from 8q24.3 into a mutation hotspot palindrome at Xq27.1 causes X-linked Charcot-Marie-Tooth neuropathy (CMTX3). *M.H. Brewer[1,2], R. Chaudhry[1,2], J. Qi[1,3], A. Rationale: Charcot-Marie-Tooth (CMT) disease is an inherited peripheral neuropathy affecting both the motor and sensory neurons. An X-linked subtype, CMTX3, was previously mapped to Xq26.3-q27.3 in two large, multigenerational families. Both families had the same disease haplotype suggesting they shared a disease mutation inherited from a common founder. Extensive mutation scanning of the coding exons, splice-sites and untranslated regions of all annotated genes within the disease locus did not reveal a causative mutation. Therefore we hypothesised that a large structural variation within the CMTX3 locus is the cause of disease. **Objective:** To identify the genetic mutation causing CMTX3 in our two large families using whole genome sequencing (WGS). **Methods and results:** Six individuals (two affected males and one unaffected male from each family) underwent WGS to identify all non-coding point mutations and structural variants in the CMTX3 locus. Analysis of WGS data identified a 78 kb interchromosomal insertion from 8q24.3 into a 180 bp palindrome sequence at Xq27.1 in all four patient samples that was not in the two unaffected controls. The insertion break points were confirmed by Sanger sequencing and the novel mutation segregated with the disease phenotype in the all available members of both families (25 affected males, 30 carrier females and 50 normal family members). The 8q24.3 interchromosomal insertion physically interrupts a gene desert between the genes *LOC389895* and *SOX3*. Preliminary data from patients with CMTX3 showed that mRNA expression of the *FGF13* gene (located ~300 kb from the insertion) is elevated in patient lymphoblast cells. This suggests that the interchromosomal insertion can dysregulate the transcription of nearby genes. Interestingly, large unique interchromosomal insertions that disrupt the same palindrome sequence on chromosome X have been associated with hypoparathyroidism, hypertrichosis, XX sex reversal and ptosis. Comparison of the sequence breakpoints for these different diseases suggests that these Xq27.1 interchromosomal insertions are mediated by double-stranded DNA breaks occurring within the chromosome X palindrome followed by microhomology-mediated template switching repair. **Conclusion:** Our data suggests this large structural variant [der(X)dir ins(X;8)(q27.1;q24.3)] is the underlying genetic cause of CMTX3 in these two families. This is the first report of an interchromosomal insertion causing CMT disease.

2411T

Omics-analysis of an iPSC derived model for Alzheimer's disease (APP p.V717I) exposed to low-energy diet reveals disease specific metabolic changes. *J. Klar[1], J. Schuster[1], L. Laan[1], L.P. Lorenzo[1], J. Nordlund[2], M. Shah-savani[3], A. Falk[3], N. Dahl[1].* 1) Department of Immunology, Genetics and Pathology, Science for Life Laboratory, Uppsala University, Sweden; 2) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden.

   Background: Early-onset Alzheimer's disease is a complex neurodegenerative disorder that can be caused by pathogenic variants in the gene encoding amyloid precursor protein (APP) in a subset of cases. Recent studies have indicated that ketogenic diet (KD) may have beneficial effects on cognitive functions in AD patients. The diet is believed to have a neuroprotective effect but the underlying mechanisms are poorly understood. **Aim:** We have used patient derived neural cells to investigate the effect of low glucose and ketogenic diet on Alzheimer cells. **Methods:** We have used induced pluripotent stem (iPS) cell derived neural cells to study the effects of KD and reduced glucose levels. Neuroepithelial stem (NES) cells derived from an AD patient who carries the familial p.V717I "London" mutation and a healthy control were differentiated towards neurons in low glucose (2 mM), in KD conditions (2 mM glucose + 6 mM beta-hydroxybuturate) and in standard glucose concentrations (20 mM), respectively. After four weeks of differentiation, we analyzed transcriptome, metabolome, parameters for differentiation and cell death. **Results**: We detected 1255 differentially expressed genes when comparing healthy control neurons and AD neurons cultured in low glucose (2 mM) conditions, and 3178 genes when comparing control vs. AD under KD conditions. Analysis for GO categories revealed extra-cellular matrix structural constituents (GO:0005201) and lipid transporter activity (GO:0005319) as the most are dysregulated functional modules in AD cells. Metabolome analysis confirmed strong differences in intracellular lipid levels when comparing AD neurons with healthy control neurons. **Conclusion:** Our data indicate that low glucose and/or KD result in dramatic changes in neuronal cell metabolism with specific characteristics for cells with the APP p.V717I variant. The specific metabolic responses in neuronal cells with a genetic predisposition to AD may reveal pathways and factors for further therapeutic considerations.

2412F

Somatic mosaicism in Nemaline myopathy detected by next generation sequencing. *T. Yokoi[1], M. Minatogawa[1], C. Abe[1], Y. Tsurusaki[1], Y. Enomoto[1], K. Watanabe[2], T. Naruto[3], K. Kurosawa[1].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Kanagawa, Japan; 2) Division of Neurology, Kanagawa Children's Medical Center, Kanagawa, Japan; 3) Department of Stress Science, Tokushima University Faculty of Medicine, Tokushima, Japan.

   <Background>Nemaline myopathy (NM) represents a group of clinically and genetically heterogeneous neuromuscular disorders. Different clinical-genetic entities have been characterized in recent years, with implications for diagnostics and genetic counseling. In this report we experienced a case of NM with somatic mosaicism. <Case report>He was born at 42 weeks' gestation, weighing 3018 g. He was admitted to neonatal intensive care unit because of apnea and feeding difficulty. He showed hypotonia, contraction of hand and knee, high arch, micrognathia and long thin finger. Electromyogram of extremities showed low amplitude. Muscle biopsy of quadriceps were performed. The result showed Nemaline bodies observed on Gomori trichrome stain and electron microscopic examination which are typical findings for NM. <Method>Using the patient's DNA from peripheral blood, we performed Mendelian disorders related gene-based Next Generation Sequencing (TruSight One, 4813 genes) on the Illumina Miseq. <Results> We identified missense mutation in *ACTA1*; c.478G>A (read depths 10/29: 33%), p.G160S. The pathogenicity of G160S is severely deleterious by ANNOVAR. Sanger sequencing demonstrated that mutation was *de novo*. <Discussion> This is the first report of the patient of NM with somatic mosaicism. Generally, mosaicism of genetic disorder shows milder manifestation. Similarly, He shows milder manifestation than expected. Motor development of this patient is gradually improved as he grew up. Even though the pathological findings are typical for NM, genetic identification for mosaicism in sample of other tissue can be useful for prediction the prognosis. NM is inherited in an autosomal dominant or autosomal recessive manner. Although genotype-phenotype correlation remains poorly defined in NM, genetic analysis is crucial to identify the inheritance and useful for genetic counseling. In conclusion, next generation sequencing is useful for the diagnostics and the detection of mosaicism for NM.

2413W

Initial, 24 week results of heparan sulfate levels in cerebrospinal fluid, brain structural MRI and neurocognitive evaluations in an open label, phase I/II, first-in-human clinical trial of intravenous SBC-103 in mucopolysaccharidosis IIIB. *C.B. Whitley[1], M.L. Escolar[2], S. Vijay[3], G. Parker[4], X. Zhang[5], A. Cinar[5], G. Bubb[5], K.C. Patki[5], S. Rojas-Caro[5].* 1) Department of Pediatrics, University of Minnesota, Minneapolis, MN, USA; 2) Children's Hospital of Pittsburgh, University of Pittsburgh Medical Center, Pittsburgh, PA, USA; 3) Birmingham Children's Hospital, Birmingham, United Kingdom; 4) Bioxydyn Limited, Manchester, United Kingdom; 5) Alexion Pharmaceuticals, Inc., New Haven, CT, USA.

   Purpose: Mucopolysaccharidosis IIIB (MPS IIIB; Sanfilippo syndrome type B) is caused by a marked decrease in alpha-N-acetyl-glucosaminidase (NAGLU) enzyme activity which leads to the accumulation of heparan sulfate (HS) in the brain and other organs, progressive brain atrophy, neurocognitive decline and behavioral disturbances. **Methodology**: This was an open label study with 3 parallel dose groups. SBC-103 [0.3 mg/kg (n=3), 1 mg/kg (n=4), and 3 mg/kg (n=4)] was administered as an IV infusion every other week in patients aged 2-12 years (developmental age ≥1 year) for 24 weeks. Primary objective: assessment of safety and tolerability of IV SBC-103. Secondary objectives included effect of SBC-103 on total HS levels in cerebrospinal fluid (CSF), brain structures (MRI) and neurocognitive status, and pharmacokinetic (PK) profile of SBC-103. **Results**: Eleven patients were enrolled (median age 4 years; range 2-10 years) and received IV SBC-103. During the 24 weeks, there were 3 treatment-emergent serious adverse events (SAEs) in a single patient and 6 infusion-associated reactions in 3 patients. No SAEs were considered related to SBC-103. At week 24, total HS percent change from baseline (mean [SD]) in the CSF was 10.9 [14.7], -0.43 [11.9] and -26.2 [20.9] for 0.3 mg/kg, 1 mg/kg, and 3 mg/kg groups, respectively. HS reduction in CSF was linearly correlated with SBC-103 serum PK exposures. Preliminary volumetric MRI (cortical gray matter volume) and neurocognitive outcomes (age equivalent/developmental quotient) suggested potential for disease stabilization in subjects receiving the 3 mg/kg QOW for 24 weeks compared to their baseline. In the 3 mg/kg group, 3 out of 4 (75%) subjects had an increase or no change in cortical gray matter volume and 3 out of 4 (75%) subjects had an increase in age equivalent/developmental quotient compared to their baseline. Overall, response profiles among the 3 mg/kg treatment groups suggest a potential dose effect as compared to the 0.3 mg/kg and 1 mg/kg groups. **Conclusions**: These initial observations suggest that IV SBC-103 was biologically active and well tolerated in MPS IIIB patients. Potential blood brain barrier penetration of IV SBC-103 was illustrated by PK/PD correlation for HS reduction in CSF. Preliminary evidence of disease stabilization in pharmacodynamics (PD)/efficacy was suggested after 24 weeks of IV SBC-103 in some patients. These data support plans to test higher doses in the study.

2414T

Investigation of genes of the mTORC1 pathway in familial focal epilepsies. *S. Baulac[1], E. Marsan[1], E. Leguern[1], F. Picard[3], S. Ishida[1], M. Chipaux[2], M. Pende[4], S. Weckhuysen[1].* 1) ICM INSERM U1127, Paris, France; 2) Department of Pediatric Neurosurgery, Fondation Rothschild, Paris, France; 3) Department of Neurology, University Hospitals of Geneva (HUG), CH-1211 Geneva 14, Switzerland; 4) Institut Necker-Enfants Malades, CS 61431, Paris, France.

   Abstract 150-200 words   Epilepsy is characterized by spontaneous and recurrent seizures and affects ~1% of the worldwide population. Combining genetics and functional studies, we aim to unravel the molecular basis of familial forms of focal epilepsies. We use family-based whole-exome sequencing and gene panels to search for new genes. In a field so-far dominated by mutations in genes encoding ion channels and neurotransmitter receptors, we identified mutations in genes (*DEPDC5*, *NPRL2*, *NPRL3*,) encoding repressors of the mechanistic target of rapamycin (mTOR) pathway, which controls protein synthesis, cell growth and proliferation. Mutations are found in a range of phenotypes from non-lesional focal epilepsies to epilepsies associated with brain cortical malformations such as focal cortical dysplasia. Concomitantly, we confirmed mTOR hyperactivation by immunohistochemistry in resected brain tissue from patients carrying mutations. Besides, we generated and characterized a constitutive knockout rat model of *Depdc5*. While the *Depdc5*-/- rats are lethal due to mTOR upregulation, the *Depdc5*+/- rats reproduce the disease at the histological level, which is rescued by rapamycin, an mTOR inhibitor. Altogether, *Depdc5* knockout rats exhibit multiple features of rodent models of mTORopathies, and thus, stand as a relevant model to study their underlying pathogenic mechanisms. .

2415F

Wnt signalling holds the molecular key to unlocking a 70 year old Aicardi Syndrome mystery. *T.T. Ha[1], R. Burgess[2], M. Newman[3], M. Li[4], A. Gardner[5], D. Pham[5], R. Kumar[5], C. Reid[6], S. Corbett[5,9].* 1) School of Biological Sciences, University of Adelaide, Adelaide, South Australia, Australia; 2) Epilepsy Research Centre, University of Melbourne, Heidelberg, Victoria, Australia; 3) Alzheimer's Disease Genetics Laboratory, University of Adelaide, Adelaide, South Australia,, Australia; 4) Florey Institute of Neuroscience and Mental Health, Parkville, Victoria, Australia; 5) School of Medicine, University of Adelaide, Adelaide, South Australia, Australia; 6) Department of Paediatrics, University of Melbourne, Parkville, Victoria, Australia; 7) Department of Neurology, Women's and Children's Hospital, North Adelaide, South Australia, Australia; 8) Department of Medicine, Royal Melbourne Hospital, Parkville, Victoria, Australia; 9) Australian Collaborative Cerebral Palsy Research Group, University of Adelaide, Adelaide South Australia, Australia; 10) Department of Neurosciences, Lady Cilento Children's Hospital, South Brisbane, Queensland, Australia; 11) School of Medicine, Duke University, Durham, North Carolina, United States; 12) South Australian Health and Medical Research Institute, Adelaide, South Australia, Australia.

   Aicardi Syndrome (OMIM 304050; AIC) is a rare neurodevelopmental disorder defined by chorioretinal lacunae, infantile spasms and a spectrum of brain malformations including agenesis of the corpus callosum. AIC has traditionally been considered an X-linked male lethal disorder. The molecular mechanism(s) underlying the disease are not well understood despite considerable research. We aimed to identify the genetic and molecular cause(s) of AIC. We performed whole exome sequencing (WES) on nine proband-parent trios and five additional probands with AIC. We enriched for likely causative variants based on: predicted pathogenicity, amino acid conservation, variant allele frequency and clinical significance. We identified a *de novo* variant in four individuals, each in a different gene: *SLF1, HCN1, SZT2* and *WNT8B*. In one female we found a paternally inherited variant in *TCF4,* a gene implicated in Pitt-Hopkins Syndrome. Using *in vitro* assays we showed that the *HCN1* variant produced a left-shift in the voltage-dependence of activation consistent with a loss of function. The *WNT8B* variant had a dominant negative effect leading to a 1.5-fold reduction in luciferase activity (p-value < 0.05). The effects of *SZT2* and *SLF1* variants are as yet unknown. From expression databases, we found all five genes are expressed in the mouse brain; *Slf1* and *Wnt8b* are tightly coexpressed in the forebrain. Finally, we investigated morpholino knockdown of the genes, and a gene (*TEAD1*) previously implicated in AIC in zebrafish studies. In embryos at 72 hours post fertilisation, we observed a unifying morphant phenotype of AIC-like eye and brain defects among 3/5 genes tested. Our data demonstrate that AIC is a genetically heterogenous malformation-eye-epileptic encephalopathy syndrome and challenges the dogma that AIC is X-linked. We show that the Wnt signaling pathway, which is fundamental to eye and brain development, is likely a major contributor to the molecular pathogenesis of AIC. Collectively, the genes that others and we implicated in AIC show convergence on TCF/LEF mediated transcription. Both the Wnt (*WNT8B, TCF4*) and Hippo (*TEAD1*) signaling pathways can act through this family of transcription factors. Furthermore, SZT2 has been shown to interact with TCF4 by high throughput yeast two-hybrid assay. Our results likely hold the key to unlocking the 70 year old mystery behind the molecular pathogenesis of AIC.

Minassian[2].* 1) Sainte Justine Hospital Research Center, Montreal, Quebec, Canada; 2) Program in Genetics and Genome Biology and Division of Neurology, Department of Pediatrics, The Hospital for Sick Children, and University of Toronto, Ontario, Canada; 3) Institute of Genetic Medicine, International Centre for Life, Newcastle upon Tyne, UK; 4) Pediatric neurology, Newcastle General Hospital, Newcastle upon Tyne, UK; 5) Center for Human Genetics, UH Case Medical Center, Cleveland, OH, USA; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 7) Baylor Miraca Genetics Laboratories, Houston, TX 77030, USA; 8) The Deciphering Developmental Disorders study, Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 9) Division of Neurology, CHUM Notre-Dame, Hospital University of Montreal, Montreal, Quebec, Canada; 10) Department of Pediatrics, University of Montréal, Quebec Canada; 11) Department of Neurosciences, University of Montreal, Quebec, Canada.

   Voltage-gated sodium channels (Nav) are mainstays of neuronal function and mutations in the genes encoding CNS Navs [Nav1.1 (SCN1A), Nav1.2 (SCN2A), Nav1.3 (SCN3A), Nav1.6 (SCN8A)] are causes of some of the most common and most severe genetic epilepsies and epileptic encephalopathies (EE). This suggests that other genes encoding Nav–binding proteins, such as fibroblast growth factor homologous factors (FHFs), may be also involved in these pathologies. Recently, Siekierska et al. (2016) reported the identification of a germ-line mosaic heterozygous de novo mutation (NM_004113.5:c.155G>A, p.R52H) in *FGF12*, which encodes FHF1, in 2 siblings with early onset EE. Functional studies showed that the p.R52H missense confers a gain-of-function, increasing the depolarizing shifts in Nav1.6 voltage-dependent fast inactivation. These findings indicated that the p.R52H mutation was likely causal of the EE phenotype; however, the identification of additional similarly affected unrelated cases was still required to confirm the role of FHF1 in the disease. Here, using whole genome and exome sequencing, we report the identification of 3 additional unrelated EE cases each of which carries the de novo FHF1 p.R52H mutation. Phenotype comparison of our 3 cases and the 2 siblings described by Siekierska et al. indicates that the core FHF1 p.R52H encephalopathy comprises neonatal-onset persistent intractable epilepsy and moderate-to-severe intellectual disability. Radiologically, neurodegeneration, especially cerebellar, is present, which, beyond a mutational consequence, appears to be aggravated by the severity and frequency of status epilepticus (SE). It may also be exacerbated by treatment of SE; indeed, all four patients with cerebellar atrophy, including the siblings reported by Siekierska et al., were on Phenytoin, an anti-epileptic drug whose toxicity was previously reported to cause cerebellar abnormalities. In conclusion, our findings confirm the role of FHF1 in early onset EE and allow a better profiling, from infancy to adulthood, of the phenotypes caused by its recurrent p.R52H mutation.

2417T

Recessive *AP3B2* mutations cause severe developmental delay, epilepsy, cortical visual impairment and hyperkinetic motor disorder. *D. Josifova[1], A. Onoufriadis[2], R. Williams[3], A. Barnicoat[4], R. Robinson[5], A. Siddiqui[6], M. Simpson[2]*. 1) Clinical Genetics, Guy's Hospital, 7th Floor, Borough Wing, London, United Kingdom; 2) Department of Medical & Molecular Genetics, Division of Genetics and Molecular Medicine, Faculty of Life Sciences & Medicine, King's College London, 8th Floor Tower Wing, Guy's Hospital, Great Maze Pond London SE1 9RT, United Kingdom; 3) Department of Neurology, Evelina Childrens' Hospital, Guy's and St. Thomas NHS Trust, Westminster Bridge Road, London SE1 7EH, United Kingdom; 4) Department of Clinical Genetics, Great Ormond Street Hospital, Great Ormond Street, London WC1N 3JH, United Kingdom; 5) Department of Neurology, Great Ormond Street Hospital, Great Ormond Street, London WC1N 3JH, United Kingdom; 6) Department of Radiology, St. Thomas Hospital, Guy's and St. Thomas NHS Trust, Westminster Bridge Road, London SE1 7EH, United Kingdom.

Next generation sequencing technology has revolutionised the study of the human genome and led to rapid aetiological resolution of many rare genetic conditions. By using this approach, we have identified a homozygous mutation in *AP3B2* [OMIM 602166] in three individuals from two branches of a consanguineous Turkish family, affected with severe global developmental delay, epilepsy with onset in infancy, cortical visual impairment, and progressive hyperkinetic motor disorder. *AP3B2* codes for a subunit of the clathrin-associated adaptor protein, AP-3. Structurally a hetero-tetramer, AP-3 plays a role in protein sorting in the late-Golgi/trans-Golgi network and endosomes. Unlike other subunits, *AP3B2* is expressed exclusively in neurons. By inference, mutated AP3B2 protein was anticipated to give rise to a neurological phenotype, and this is the first report of clinical cases associated with mutations in this gene in humans. Given the significant recurrence risk for carrier parents, it is an important gene to consider in appropriate cases, to establish an aetiological diagnosis, to provide counselling and facilitate reproductive options. Identification of further patients will help understand the breadth of the clinical phenotype.

2418F

Coexistence and coinheritance of two noble mutations, G325A of *KDM6A* causing Kabuki syndrome and G1877V of *SCN1A* gene causing GEFS+ in a family, confused with Dravet syndrome. *C. Lee*. Division of Pediatric Neurology, Department of Ped, College of Medicine, Eulji Unive, Seoul, Nowon-gu, South Korea.

Objective Co-existence of two rare genetic syndromes is extremely rare. Generalized epilepsy with febrile seizures plus (GEFS+) is a genetic epileptic syndrome with a variable clinical phenotype spectrum for which a variety of causative mutations have been identified. Kabuki syndrome (KS) is a rare, multiple congenital anomaly syndrome with two molecular subtypes of *MLL2* (KS1) and *KDM6A* (KS2). **Study design** We performed a genetic analysis of a family with GEFS+ and suspicious KS. First, a cytogenetic study including G-band karyotyping and SNP microarray was performed. Next, molecular analysis using targeted-exome sequencing and Sanger sequencing were conducted for molecular confirmation and differential diagnosis in the family. **Results** The proband, a 7-year-old male was initially misdiagnosed with Dravet syndrome, and presented with GEFS+, dysmorphic facial features, short status, developmental delay, and intellectual disability. His mother and her elder sister had FS+ and dysmorphic facial features. G-band karyotyping and SNP microarray of the proband were normal. Targeted exome sequencing identified two noble missense mutations: G-to-C transition at single nucleotide 974 (p.G325A) in *KDM6A* responsible for KS and GA-to-TT at two nucleotides 5630-5631 (p.G1877V) in *SCN1A* responsible for GEFS+. **Conclusion** This family is the first in the literature with the co-existence and dominant co-segregation of GEFS+ and KD2 to be confirmed molecularly. Furthermore, two affected female patients with X-linked KS2 showed a partial escape X-inactivation pattern of *KDM6A* with milder phenotypes than the male affected proband in this study. .

2419W

New *SMARCA2* mutation in Nicolaides Baraitser syndrome and Myoclonic astatic epilepsy. *S. Tang[1], E. Hughes[2], K. Lascelles[2], M.A. Simpson[1], D.K. Pal[1], EuroEPINOMICS RES Myoclonic astatic epilepsy working group.* 1) King's College London, London, London, United Kingdom; 2) King's Health Partners, London, UK.

  Myoclonic astatic epilepsy is a genetically heterogenous rare childhood epilepsy syndrome characterised by the onset of myoclonic, myoclonic-atonic or atonic seizures between the ages of 6 months to 6 years. Prognosis is variable from a complete seizure remission to a drug resistant epileptic encephalopathy. Approximately 10% of cases have an identifiable genetic aetiology but the majority remain unexplained. We report a *de novo SMARCA2* missense mutation c.3721C>G, p.Gln1241Glu (ENST00000349721 NM_0030703), on whole exome sequencing and confirmed by Sanger sequencing in a patient with myoclonic astatic epilepsy. This novel variant is not reported in 1000G, ExAC or EVS and in the ExAC database there are only very rare missense and stop gain variants in the region (MAF<0.0005). Annotation from insilico prediction tools was SIFT 0.184 (tolerated), PolyPhen2 0.900 (possibly damaging), mutation taster 0.999 (disease causing) and CADD 22.5 (top 1% most deleterious). A specific role for *SMARCA2* mutations has been implicated in Nicolaides Baraitser syndrome. Nicolaides Baraitser syndrome is a well delinated phenotype with sparse hair, microcephaly, typical facial morphology, brachydactyly, prominent interphalangeal joints, intellectual disability with marked language impairment and seizures. Following the identification of the mutation, the patient was reassessed and observerved to have features consistent with Nioclaides Baraitser syndrome: sparse hair, skin wrinking, slightly thick distal phalanges in the hands, specific craniofacial features, reduced speech, intellectual disability with a verbal IQ 51 (0.1th centile), performance IQ 57 (0.2th centile) and full scale IQ 47 (<0.1th centile) and autism.   This *de novo SMARCA2* missense mutation c.3721C>G, p.Gln1241Glu is the only reported mutation on exon 26 and the second mutation outside the ATPase domain of SMARCA2 to be associated with Nicolaides Baraitser syndrome. We hypothesize that this mutation similarly affect ATP hydrolysis and chromatin remodeling. We report that the epilepsy phenotype in Nicolaides Baraitser syndrome can be consistent with myoclonic astatic epilepsy syndrome. This study also underlines the fact that, in rare genetically heterogenous condidtions like myoclonic astatic epilepsy, whole exome sequencing can lead to unexpected clinical diagnosis.

2420T

***PIGG* is associated with developmental delay, early onset seizures and cerebellar ataxia.** *A.C. Thuresson[1], J. Zhao[1], J. Halvardson[1], A. Knaus[2], P. Krawitz[2], P. Georgii Hemming[1,3], P. Baeck[4], L. Feuk[1].* 1) Dept. of Immunology, genetics & Pathology, Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 2) Institute for Medical Genetics and Human Genetics, Charité Universitätsmedizin Berlin, Berlin, Germany; 3) Dept of Molecular Medicine and Surgery, Karolinska Institute, Karolinska University Hospital Solna, Stockholm, Sweden; 4) Childrens Clinic, County Hospital, Kalmar, Sweden.

  Glycosylphosphatidylinositol (GPI) is a glycolipid that tethers more than 150 different proteins to the cell surface. Aberrations in biosynthesis pathway of GPI anchors cause congenital disorders of glycosylation with clinical features including moderate to severe developmental delay, seizures and facial dysmorphism. To date mutations in 12 genes of the GPI-anchor synthesis pathway have been reported in association with multi-system disease. Here we present two siblings from a consanguineous family with symptoms including development delay, cerebellar hypoplasia, cerebellar ataxia, early onset seizures and minor facial dysmorphology. Microarray analysis indicated several large homozygous regions across the genome, making up approximately 4% of the genome sequence. Using exome sequencing, we identified a novel homozygous nonsense mutation, p.Trp539*, in the gene Phosphatidylinositol Glycan Anchor Biosynthesis, Class G (PIGG), located within a stretch of homozygous sequence. Both siblings have a lower expression of PIGG compared to their parents, and the parent show a clear reduction in expression of the mutated allele, indicative of nonsense-mediated decay. Mutations in several other GPI anchor synthesis genes lead to a reduced expression of GPI-APs that can be measured by flow cytometry. Here, the patients' fibroblasts and granulocytes were tested for GPI-APs CD55 and CD59. Surface expression of the GPI anchor itself was measured using fluorochrome conjugated aerolysin (FLAER). No significant differences could be detected in the patients' blood, however, in fibroblasts FLAER test showed a generally reduced level of GPI anchor on the patient cells. Based on genetic and functional evidence we propose that mutations in PIGG are affecting the GPI biosynthesis pathway and cause a congenital disorder of glycosylation.

2421F

Diagnostic exome sequencing of Danish families with rare genetic diseases. *J. Ek, L. Risom, E. Østergaard, M. Dunø.* Department of Clinical Genetics, Copenhagen University Hospital, Copenhagen, Denmark.

Background: The advancement in DNA sequencing has in recent years highly increased the likelihood of identifying causative variants among patients with various disorders. Whole Exome Sequencing (WES) facilitates an unbiased screening for genetic defects. We have implemented WES for the genetic work-up of patients primarily under suspicion for neurological and mitochondrial disorders, or complex syndromes involving intellectual disability. A precise molecular diagnosis is important for treatment, follow-up, prognosis, and a prerequisite for prenatal testing and preimplantation genetic testing. The aim of this study was to increase the number of patients receiving a genetic diagnosis and further to evaluate in which groups of patients WES gives the highest diagnostic yield. Materials and methods: This is a retrospective study of *in-house* whole exome sequencing conducted at the Department of Clinical Genetics at Copenhagen University Hospital in the period from first of January 2014 and forth, and includes more than 60 probands and their families. The majority of the surveyed probands were included on the suspicion of neurological disorders and mitochondrial disorders or on the basis of intellectual disability. All the patients/families were prior to analysis thoroughly assessed by medical specialists and counselled by a clinical geneticist, in order to provide detailed and complete clinical information, aiding variant classification. Results: Causative mutations were identified in approx. 35% of the patients. One fifth of the mutations had arisen de novo or was found in mosaic form in one parent. Approx. 75% of the identified mutations were absent from the literature and common mutation databases, i.e. novel mutations. Four variants were initially classified as incidental findings of which two were reported back to the patient/parents. Interpretation: In this study, WES facilitated a genetic diagnosis in approx. 35% of patient with complex etiologies such as neurological disorders, intellectual disability, or mitochondrial disorders. The tight collaboration and discussions between clinicians and laboratory scientists is instrumental in reaching a conclusive diagnosis. WES will move to the forefront of genetic work-up and become the first tier analysis for disorders of complex aetiology. Most likely, this will result in an even higher diagnostic yield of WES, when it is used in the initial screening in patients with suspected genetic disorders.

2422W

Novel *de novo* mosaic triallelic mutation in *SPAST* may result in autosomal dominant spastic paraplegia-4. *A.M. Matthews[1,2,3], M. Tarailo-Graovac[1,2,3], E.M. Price[2,3], I. Blydt-Hansen[4], W.P. Robinson[2,3], C.J. Ross[1,2,3], W.W. Wasserman[1,2,3], H. Siden[3,5,6], C.D. van Karnebeek[1,3,4].* 1) Centre for Molecular Medicine and Therapeutics, Vancouver, BC, Canada; 2) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Child & Family Research Institute, Vancouver, BC, Canada; 4) Division of Biochemical Diseases, Department of Pediatrics, BC Children's Hospital, Vancouver, BC, Canada; 5) Division of General Pediatrics, Department of Pediatrics, BC Children's Hospital, Vancouver, BC, Canada; 6) Canuck Place Children's Hospice, Vancouver, BC, Canada.

Case study: The index is a 12 year-old male, born to healthy, non-consanguineous parents. At 12 months he presented with speech and motor delay and was noted to be dysmorphic. Spastic paralysis was first observed at 1 year, initially as spastic lower extremity diplegia with normal upper-extremity function. His condition progressed to a state of ascending spastic tetraplegia with significant accompanying contractures. Family history was unremarkable for spastic paralysis and neurological disorders, but remarkable for a paternal great-grandfather's sister with cerebral palsy-like symptoms post-fever. Extensive metabolic testing, karyotype (46,XY) and multiple single gene tests were normal. **Background**: Hereditary Spastic Paraplegia (HSP) is caused by mutations in over 60 genes and is characterized by progressive weakness and spasticity. 45% of HSP cases have been linked to autosomal dominant spastic paraplegia-4 due to heterozygous mutations in Spastin (*SPAST*), generally affecting the lower extremeties. **Methods**: Exome sequencing was performed on DNA extracted from blood for index and parents with data analysis via the TI-DEX semi-automated bioinformatics pipeline. Pyrosequencing was performed to determine the degree of mosaicism in multiple tissues (n=6) from the index and parents. **Results**: Exome sequencing followed by Sanger revealed a triallelic (G/C/T) variant in *SPAST* at chr2:32362241 (hg19); parents were homozygous reference (G/G). Both alternative alleles (NM_014946.3:c.1477G>C p.Asp493His and c.1477G>T p.Asp493Tyr) were predicted to be highly damaging by multiple *in silico* tools. Chromosome micro-array was normal in this region and no alternative alleles were detected in parental blood, suggesting that both alternative alleles arose as *de novo* variants in the index. Based on Pyrosequencing, the percentage of reference alleles in the index ranged from 44% in urine to 58% in saliva and blood. The reference to alternative ratio across tissues suggested the presence of three cell populations, two different heterozygous reference/alternative cells (G/C and G/T) in addition to double mutant cells (C/T). **Conclusion**: This is the first report of an individual with the HSP phenotype due to more than one damaging *SPAST* variant, in the same or different cells. Bi-allelic variant or double mutant cells may explain the extreme phenotype observed in the index; mosaicism on the other hand (with heterozygous variants present as well) potentially explains viability.

2423T

A new form of epileptic encephalopathy caused by mutations of the Arf4 guanine-nucleotide exchange factor *DENND5A.* *A.G. Minassian[1], C. Han[2], R. Alkhater[3], T. Froukh[4], M. Galatti[2], R. Han Lui[2], M. Fotouhi[2], J. Sommerfeld[5], A.J. Alfrook[6], C.R. Marshall[1], S. Walker[1], P. Bauer[5], S.W. Scherer[1], O. Riess[5], R. Buchert[5], B.A. Minassian[3], P.S. McPherson[2].* 1) The Centre for Applied Genomics, Genetics and Genome Biology, The Hospital for Sick Children, 686 Bay Street, Toronto, Ontario M5G 0A4, Canada; 2) Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, 3801 University Street, Montreal, Quebec H3A 2B4, Canada; 3) Program in Genetics and Genome Biology, Department of Pediatrics (Neurology), Hospital for Sick Children, University of Toronto, 686 Bay Street, M5G 0A4, Toronto, Ontario, Canada; 4) Department of Biotechnology and Genetic Engineering, Faculty of Science, Philadelphia University, Jarash Road, Amman, Jordan; 5) Institute of Medical Genetics and Applied Genomics, Rare Disease Center, University of Tübingen, Calwestr. 7, 72076, Tübingen, Germany; 6) Private Clinic, Amman, Jordan.

With a lifetime incidence of 3%, epilepsy is a common neurological disorder. Epileptic encephalopathies are a catastrophic group of epilepsies characterized by refractory seizures and cognitive arrest resulting from abnormal brain development. Here we identify a new epileptic encephalopathy that additionally features cerebral calcifications and coarse facial features, caused by recessive loss-of-function mutations in *DENND5A*. We performed Whole Exome Sequencing (WES) on two sisters affected with epileptic encephalopathy and born of consanguineous parents. We discovered a shared homozygous 2bp frameshift deletion in exon 4 that results in a premature stop codon at amino acid 173 (p.Asp173Profs*8). We then performed functional experiments on DENND5A, which we discovered is expressed predominantly in developing neuronal tissues in rats. Further, we found that loss of function in this gene leads to disrupted trafficking of neurotrophin receptors, enhanced receptor levels and signaling, and massive alterations in neuronal development. Identification of loss-of-function mutations in *DENND5A* in a second family with two affected children, and of predicted damaging compound heterozygous variants absent from any control databases in a third family, all with features closely similar to our original family, further shows that we have identified a novel epileptic encephalopathy gene. Ongoing work on the functions of *DENND5A* will elucidate a heretofore unknown facet of neurodevelopment. Note: The first two authors contributed equally.

2424F

Heterozygous missense mutation in *SEC24A* **encoding a coat protein complex II vesicle associated with autosomal dominant spinocerebellar ataxia.** *T. Morikawa[1], S. Miura[1,2], K. Kosaka[1], R. Fujioka[3], K. Sano[2], A. Yorita[2], K. Aoki[1], Y. Uchiyama[4], T. Taniwaki[2], H. Shibata[1].* 1) Division of Human Molecular Genetics, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Division of Respirology, Neurology and Rheumatology, Department of Medicine, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 3) Department of Food and Nutrition, Beppu University Junior College, Beppu, Oita, Japan; 4) Department of Radiology, Kurume University School of Medicine, Kurume, Fukuoka, Japan.

Hereditary spinocerebellar ataxia (SCA) comprises a group of clinically and genetically heterogeneous inherited disorders mainly characterized by slowly progressive cerebellar ataxia. We ascertained a Japanese pedigree with ADCA consisting of four family members including three patients. The cardinal clinical features of this family were as follows: i) slow progression; ii) around 40 at onset; iii) gait and limb ataxia; iv) cerebellar dysarthria ; v) gaze evoked nystagmus; vi) saccadic pursuit ; vii) ocular dysmetria ; viii) upward gaze palsy; and iv) hyperreflexia, spasticity, and impaired vibration sense with dominancy in the lower limbs. We first confirmed the absence of repeat expansion in known genes responsible for SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA12, SCA17, and dentatorubral-pallidoluysian atrophy. We performed the whole exome sequencing for the three patients with the average of sequencing depth in the target regions to be 28.7x. We identified 1,143 functional single nucleotide variants (SNVs) shared by the three patients. We identified only two candidate SNVs, P361L in *SEC24A* and N588S in *SGOL2* of which allele frequencies are less than 0.002 in the public variants databases (1000G Project, Ensemble, DBexome) and in 11 in-house exome data, By Sanger sequencing we confirmed that both SNVs were absent in the unaffected individual in the pedigree. We also confirmed the absence of both of the SNVs in 520 healthy Japanese individuals by Sanger sequencing. Only one of the two SNVs, P361L in *SEC24A* was predicted to be damaging by PolyPhen-2 while the other SNV, N588S in *SGOL2* was predicted to be benign. *SEC24A* encodes a component of coat protein II (COPII)-coated vesicles that mediate protein transport from the endoplasmic reticulum. The SNV is located in the highly conserved region in *SEC24A* among vertebrates (SIFT score = 0.02). Since the pathological variants have not been reported in *SEC24A*, this can be the first case of human disease caused by a variant in *SEC24A*. It is notable that SEC24A protein is known to interact with p125 that harbors the DDHD domain. Recently several genes with the DDHD domain have been reported to be responsible for spastic paraplegia (SPG), such as *DDHD1* and *DDHD2*. Therefore, SPG-like symptoms such as hyperreflexia and spasticity observed in the present family can be explained by the DDHD dysfunction caused by the variant of *SEC24A*.

2425W

SLC13A5 is the second gene associated with Kohlschütter-Tönz syndrome. *S. Raskin[1], A. Schossiga[2], A. Bloch-Zupanb[3], N.I. Wolf[4], M. Cohen[5], F. Giuliano[6], J. Jurgens[7], B. Kohlschütter-Tönz syndrome (KTZS) is a rare autosomal recessive disease characterised by epilepsy, intellectual disability, and yellowish discolouration of the teeth. It is frequently caused by biallelic mutations in *ROGDI*. Here we report that the majority of individuals with *ROGDI*-negative KTZS carry biallelic *SLC13A5* mutations. We studied seven families by clinical and dental evaluation, parametric linkage analysis (one family), and exome and/or Sanger sequencing. Consistent dental findings in *SLC13A5*-KTZS include small and widely spaced teeth with a smooth enamel surface, suggesting smooth-hypoplastic amelogenesis imperfecta. Discolouration of the teeth is variable and may be mild. Dental findings differ from individuals with homozygous *ROGDI* mutations, where the enamel is usually rough and discolouration is more intense due to hypomineralized-hypoplastic amelogenesis imperfecta. Epileptic encephalopathy in *SLC13A5*-KTZS usually presents in the neonatal and (less frequently) early infantile period. We conclude that *SLC13A5* is the second major gene associated with Kohlschütter-Tönz syndrome; careful clinical delineation provides clues for the likely candidate gene. .

2426T

Diagnostic exome sequencing reveals disruptive splice-site variants in VPS13C in a sporadic case of early-onset Parkinson disease. *B. Schormair[1,2], D. Kemlink[3], O. Fiala[3,4], E. Graf[5], T.-M. Strom[5], J. Roth[3], E. Ruzicka[3], J. Winkelmann[1,2,6,7]. 1) Institute of Neurogenomics, Helmholtz Zentrum München, Munich, Germany; 2) Institute of Human Genetics, Technische Universität München, Munich, Germany; 3) Department of Neurology and Center of Clinical Neuroscience, Charles University, 1st Faculty of Medicine and General University Hospital, Prague, Czech Republic; 4) Institute of Neuropsychiatric Care (INEP), Prague, Czech Republic; 5) Institute of Human Genetics, Helmholtz Zentrum München, Munich, Germany; 6) Neurologische Klinik und Poliklinik, Klinikum rechts der Isar, Technische Universität München, Munich, Germany; 7) Munich Cluster for Systems Neurology, SyNergy, Munich, Germany.*

Recently, truncating variants in vacuolar protein sorting 13C (*VPS13C*) have been described as a cause of autosomal-recessive early-onset Parkinson disease (EOPD). A total of three unrelated subjects with homozygous or compound heterozygous truncating mutations in *VPS13C* were reported, all with rapid and severe disease progression and early cognitive decline. The identification of additional carriers of such variants in independent EOPD cases is needed to confirm the causal role of *VPS13C* in EOPD. We have performed diagnostic whole exome sequencing in individuals with sporadic EOPD (age of onset ≤ 40 years) of Caucasian ancestry. Exomes were generated with SureSelect XT 50Mbv5 kit and sequenced on a HiSeq2500 system. Alignment was done with BWA and SNVs and small indels were called with SAMTools and Pindel. Annotation was performed with SAMTools, custom Perl scripts and Variant Effect Predictor. For analysis we kept rare variants (minor allele frequency < 0.01 in public databases) which disrupt protein function (splice, nonsense, frameshift). One individual was found to carry two variants affecting canonical splice sites in *VPS13C*: c.[2029+2T>G];[3215-1G>T]. Variant c.2029+2T>G is predicted to alter the splice acceptor site in intron 31, variant c. 3215-1G>T the splice donor site in intron 21 of *VPS13C* (NM_020821.2). Both variants were not present in 7,500 control exomes sequenced on the same platform, the 1000 Genomes Project and the EVS dataset. One heterozygous carrier of the c.2029+2T>G variant was found in the non-Finnish European ExAc population. For the affected individual, 98.2% of the exome target regions were covered at least 20x. The individual does not carry pathogenic or likely pathogenic variants in other PD-associated genes. Age of onset of PD symptoms was 39 years with rigidity and micrographia as the initial symptoms, followed by mild tremor, speech impairment, and mild dystonia. Cognitive changes include attention difficulties, delusions and memory impairment. Due to severe complications, treatment was switched to deep brain stimulation after five years. We are currently performing segregation analysis of the variants in the family and RT-PCR-based analysis of the splicing defects in *VPS13C*. Positive results will provide additional evidence that biallelic disruptive variants in *VPS13C* are a rare cause of autosomal-recessive early-onset Parkinson disease.

2427F

Identification of new genes in consanguineous Tunisian Arab-Berber families with Parkinson disease. *J. Trinh[1], E. Gustavsson[1], I. Guella[1], M. McKenzie[1], S. Bortnick[1], B. Chen[1], S.B. Sassi[2], E. Hentati[2], F. Nabli[2], E. Farhat[2], R. Amouri[2], F. Hentati[2], M.J. Farrer[1]. 1) Medical Genetics, University of British Columbia, Vancouver, BC, BC, Canada; 2) Mongi Ben Hamida National Institute of Neurology, La Rabta, Tunis, 1007, Tunisia.*

Parkinson disease (PD) is an insidious neurodegenerative disorder. LRRK2 p.G2019S is responsible for 30-40% of familial patients from Tunisia. Recessive PINK1 mutations account for 10-15% of familial PD. However, there are many families affected with PD in Tunisia with unknown genetic cause. Eighteen Tunisian Arab Berber families multi-incident for parkinsonism (30 patients) without known pathogenic mutations were investigated. Exome sequencing was performed using the using the Ion AmpliSeq exome kit (57.7Mb) and sequenced on an Ion Proton sequencer (Life Technologies, Carlsbad, CA, USA). Single nucleotide polymorphisms (SNP) were genotyped using the Illumina Multi-Ethnic Genome Arrays (MEGA). Further genotyping was performed on larger patient-control series (2650 patients and 2264 control subjects). We prioritized homozygous variants in the consanguineous families predicted to produce frameshifts, stop codons, missense or splice defects that would disrupt protein function and were rare or novel. We report two consanguineous families that presented juvenile parkinsonism in a Tunisian consanguineous family with a homozygous recessive mutation in sepiapterin reductase (SPR) and hexokinase 3 (HK3). We have also identified multiple low frequency DNAJC6 variants segregating with PD in three families. Subsequent genotyping and sequencing has identified higher frequency of rare variants in these genes compared to controls. Furthermore, a shortlist of candidate genes has been identified from these families and validation is in progress. Identification of novel candidates in consanguineous families will help in developing targeted therapeutic treatment and understanding the basic pathophysiology of the disease.

2428W

Accelerating the novel *NTRK1* variants in patients with HSAN-IV phenotype via whole exome sequencing. *S. Majid[2], R. Al Tassan[1], H. Al Saud[2], T. Masoodi[2], H. Al Dosssari[2], B. Meyer[2], O. Mohammad[1]. 1) Dept. of Genetics, KFSHRC, RIYADH; 2) Dept. of Medical Genetics, KFSHRC, RIYADH.*

Genomic technologies have emerged as powerful tools delving and dissecting human genome that allows the rapid evaluation of the underlying genetic causes of diseases in various motor and sensory neuropathies. Hereditary sensory autonomic neuropathy type IV (HSAN-IV) is a rare autosomal recessive disorder that usually begins in infancy and is characterized by anhidrosis, insensitivity to noxious stimuli leading to self-mutilating behavior, and intellectual disability. HSAN-IV is caused by mutations in the Neurotrophic Tyrosine Kinase, Receptor, Type 1 gene, *NTRK1*, encoding for the high-affinity receptor of nerve growth factor (NGF). Patients with HSAN-IV lack all NGF-dependent neurons, the primary afferents and sympathetic postganglionic neurons responsible for pain sensation and the presence of anhidrosis, respectively. Herein, we report nine patients from nine unrelated families with HSAN-IV due to various mutations in *NTRK1*, five of which are novel. The affected patients had variable intellectual deficits, and some had delay in the diagnosis of HSAN-IV. In addition to being the first report of HSAN-IV from the Arabian Peninsula, this report expands the mutational spectrum of patients with *NTRK1* mutations.

2429T

Clinical implication of the *FMR1* **intermediate alleles in the Spanish population.** *M. Mila[1,2], M.I. Alvarez-Mora[1,2], S. Izquierdo[3], A. Feliu[1], A. Vilumara[1], I. Madrigal[1,2], L. Rodriguez-Revenga[1,2].* 1) Biochemistry and Molecular Genetics, Hospital Clinic, Barcelona, Barcelona, Spain; 2) CIBERER and IDIBAPS; 3) Servicio de Bioquímica Clínica, Genética Clínica. Hospital Miguel Servet, Zaragoza. Spain.

The *FMR1* premutation (55-200 CGG) has mainly been associated with Fragile X-associated primary ovarian insufficiency (FXPOI), and fragile X-associated tremor/ataxia syndrome (FXTAS). Several lines of evidence suggest that carriers of the *FMR1* premutation allele present with a higher risk of medical, psychiatric, and cognitive symptoms than the general population. On the other hand, there is controversy regarding smaller expansions named as "gray zone" (45-54 CGG) or intermediate alleles (IA). Although the frequency of these alleles varies greatly among different populations, several studies have reported an excess of these alleles in patients either with Parkinsonism, cognitive/behavioural phenotypes (CBP) or primary ovary insufficiency (POI). It is well accepted that depending on the AGG interruptions number IA confers an increased risk of expansion. In an attempt to provide new insights on the clinical impact of IA in the *FMR1*-associated phenotypes, we have studied the frequency of IA in three pathologies, spinocerebellar ataxias (SCAs), POI and CBP, in Spain. Among 5115 CBP patients 93 IA were detected (1.82%), 5 among 304 patients with spinocerebellar ataxia (1.64%) and 9 among the 346 patients presenting POI (2.60%). Regardless of whether we take into account patient or allele frequencies (ID, 1.77%; SCAs, 1.12%; POI, 1.30%), the results obtained did not differ from those observed in the control population (1.71%). Although our results do not support an excess of IA in the *FMR1*-associated pathologies, it is advisable to refer individuals carrying an IA to a genetic counsellor in order to study the AGG interruptions and evaluate the possible risk of expansion of these alleles during transmission.

2430F

A genetic survey of Charcot-Marie-Tooth disease in Turkey. *E. Battaloglu[1], A. Candayan[1], H.I. Akcay[2], H. Durmus[2], M. Sivaci[1], F. Deymeer[2], P. Oflaz-er-Serdaroglu[2], Y. Parman[2].* 1) Department of Molecular Biology and Genetics, Bogazici University, Istanbul, Turkey; 2) Department of Neurology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey.

Charcot-Marie-Tooth (CMT) (MIM 118220) disease is the most common hereditary polyneuropathy that is characterized with distal weakness and atrophy. More than 40 CMT genes have been identified that is a challenge for genetic diagnostics especially in populations with frequent consanguineous marriages as in Turkey.   In this study, we investigated 310 Turkish CMT patients using direct gene sequencing and thirty three of these patient samples were analyzed by whole exome sequencing (WES). Mutations were identified in 159 patients (51%). Eighty percent had *PMP22* duplication or *GJB1, GDAP,* or *MFN2* mutations. *PMP22* duplication was the most common (46%) cause and *SH3TC2, MTMR2, MTMR13, FGD4, KIFB1, DNM1, and HSPB1* mutations were rarely observed. Age of onset was 1- 57 with a mean of 13.85±12.2 among genetically diagnosed cases and the inheritance patterns were autosomal dominant (62%), X-linked (13%), or autosomal recessive (21%). Isolated cases constituted about 2% of this group. Most common CMT type was CMT1 (81/159) that was followed by CMT2 (28/159), CMT4 (28/159), and CMTX (22/159). Mean age of onset was higher in CMT1 than in other types, but age of onset was also heterogeneous in this group of patients that was in between 4-57 years. Majority of CMT1 patients were carrying *PMP22* duplication (93%) and five had *MPZ* mutations. These patients usually showed typical phenotype that was relatively benign compared with other subtypes and almost all patients remained ambulatory throughout their life. Most of the recessive cases (CMT4 and CMT2) had an earlier age of onset and severe clinical picture. The causative gene could not be identified in 151 patients (49%) most of which were isolated cases. For the 33 patients analyzed by WES, genetic diagnosis was possible in 13 (39%). Absence of mutations in known CMT genes in 49% of our cohort implicates further genetic heterogeneity for the disease. WES analysis is a suitable approach to be used for genetic diagnosis of this genetically heterogeneous disorder especially for isolated cases and in countries with high rate of consanguineous marriages. .

2431W

First report of mutations in human *CLDN5*: A neurological phenotype associated with disruption of blood-brain barrier tight junctions. *C. Cytrynbaum[1], S. Walker[2], A.G. Minassian[2], C. King[3], R. Loh[4], G. Jones[5], H. Lango Allen[5], S. Ellard[5], S.W. Scherer[2], R. Newbury-Ecob[3], R. Weksberg[1].* 1) Div Clinical & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON Canada; 3) Department of Clinical Genetics, University Hospitals Bristol NHS Foundation Trust, Bristol, UK; 4) Royal United Hospital, Bath, UK; 5) Molecular Genetics, Royal Devon & Exeter NHS Foundation Trust, Exeter, UK.

Claudins are a family of proteins that are crucial structural and functional components of tight junctions (TJ). TJs have important roles in regulating paracellular permeability and maintaining cell polarity in epithelial and endothelial cell sheets. The claudins interact with multiple proteins and are intimately involved in signal transduction to and from the tight junction. Several human diseases have been shown to be caused by mutations in claudin genes (i.e. *CLDN1*, *CLDN14*, *CLDN16*, *CLDN19*). Claudin-5 (*CLDN5*) is the predominant claudin expressed in endothelial TJs which are particularly important in vascular endothelium of the blood-brain barrier (BBB). Here we report two unrelated patients with similar clinical features including microcephaly, brain calcifications and seizures who were both found to have *de novo* heterozygous single base substitutions in *CLDN5*. The first patient had intractable epilepsy and died at 6 months of age. The second patient has global developmental delay (not sitting independently and not verbal at 21 months of age). Both patients have missense mutations in exon 1b (p.Gln148Lys and p.Val126Met respectively) resulting in changes to highly conserved amino acids. In silico prediction programs (SIFT/Mutation Tester) predict both variants to be deleterious. Several claudin-deficient mouse models have been generated and the diversity of phenotypes observed demonstrates their important roles in the maintenance of tissue integrity in various organs. CLDN-5-deficient mice demonstrate size-selective loosening of the BBB. It is possible that impairment of the BBB, even in a size selective manner, could be harmful to CNS activity. In fact, Claudin-5 null mice died within 10 hours of birth, although the underlying cause was unclear. Based on the role of *CLDN5* in the BBB, we propose that mutations in *CLDN5* lead to a severe neurologic phenotype as seen in our patients. Functional studies including transcriptional and protein assays in fibroblast cells from the second patient are ongoing.

2432T

Cerebral vascular malformations in patients with *ACTA2* mutations. *C. Abe[1,2], T. Yokoi[2], M. Takagi[3], Y. Enomoto[2], Y. Tsurusaki[2], T. Naruto[4], T. Goto[3], H. Ueda[5], Y. Fujii[6], N. Aida[6], K. Kurosawa[2].* 1) Pediatric Neurology, Kasugai, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center; 3) Department of Neurology, Kanagawa Children's Medical Center; 4) Institute of Health Biosciences, The University of Tokushima Graduate School; 5) Department of Cardiology, Kanagawa Children's Medical Center, Yokohama, Japan; 6) Department of Radiology, Kanagawa Children's Medical Center, Yokohama, Japan.

α2-actin protein, encoded by *ACTA2*, is expressed in vascular smooth muscle cells of various organs. Heterozygous *ACTA2* mutations are reported to cause aortic aneurysm diseases and strokes. Strokes caused by *ACTA2* mutations indicate severe cerebral arteriopathy that is different from other diseases. Detailed radiological investigation including the neurovascular survey should be considered in the patients supposed to be caused by the *ACTA2* mutations. Here we report on 2 patients with *ACTA2* mutation representing cerebral vascular malformations. Patient 1 had a history of patent ductus arteriosus (PDA) ligation at 2 months old and aneurysm resection of left brachial artery at 4 months old. At age of 13 years, he presented dilatation of Valsalva sinus and started taking angiotensin-converting-enzyme inhibitor (ACEI). He also presented transient left paresis. His cerebral MRI revealed reduced diffusion in diffusion-weighted images (DWIs) involving the territories of the right middle cerebral artery (MCA) that is consistent with infarction. Magnetic resonance angiography (MRA) also showed narrowing of the right vertebral artery, and fusiform dilatation of CAs. After medication for brain infarction, his symptoms improved and he showed only slight hypoesthesia of left body at the time of discharge. Patient 2 was 11 years old. At age of 4 days, she showed poor sucking and diagnosed to have PDA, dilatation of ascending aorta, and congenital midriasis. She had an episode of nonsymptomatic dilatation of urinary duct at 6 months old. At age of 6 years, MRA showed irregular forms of MCAs and 5 years later MRI showed chronic ischemic lesions in parietal lobe. MRA also showed diffuse fusiform dilatation of both CAs and narrowing in the branches covering the multiple areas. We performed a targeted high-throughput sequencing of genes. We identified heterozygous mutations c.772C>T: p.R258C in patient 1 and c.536G>A: p.R179H in patient 2 in ACTA2, respectively. Sanger sequencing confirmed the mutations. Specific features of cerebral images (MRIs and MRAs) in both patients are confident with previous reports. ACTA2 mutations cause vascular malformations in multiple organs including central nervous system (CNS). Cerebral infarctions found in the patients are part of CNS involvements resulted from vascular anomalies. Molecular analysis and neurovascular investigation are important for the patients with the disorder.

2433F

A bioinformatic pipeline for studying non-coding variants in disease: Application to hereditary sensory and autonomic neuropathy patient genomes. *M.H. Couse[1], F.R. Zahir[1], G. Horvath[1], C. Shyr[1], M. Tarailo-Graovac[1], C. Nislow[2], C. van Karnebeek[1], J.M Friedman[1].* 1) BC Children's Hospital, Vancouver, Canada; 2) University of British Columbia, Vancouver, Canada.

Hereditary and sensory autonomic neuropathies (HSAN) are a group of clinically and genetically heterogeneous disorders of the peripheral nervous system. We are working with eight children affected by early-onset HSAN, whose symptoms include loss of pain sensation, developmental delay, and gastrointestinal complications. We have performed whole genome sequencing on these patients and analyzed coding variants, but have only reached a diagnosis in two cases. We hypothesize that the pathogenic variants in these patients lie in regulatory regions of genes associated with HSAN. We investigated rare variation in regulatory elements of the genome associated with 50 hereditary neuropathy genes: promoters, enhancers, untranslated regions, and regions sensitive to purifying selection. We associated distal regulatory elements to genes of interest by their presence within topological associated domains encompassing hereditary neuropathy genes. We implemented a custom bioinformatics pipeline that filters rare regulatory SNVs, indels, and SVs from patient whole genome vcf and bam files. We found a single heterozygous SNV in one patient at a conserved locus in the 5'UTR of *PMP22* that is predicted by CADD and FATHMM-MKL scores to be deleterious. Although the phenotype of this patient is not typical of the classical CMT1A seen with *PMP22* duplications or of the variant CMT phenotypes reported in association with missense mutations of the *PMP22* coding segment, PMP22 is dosage-sensitive and can cause a broad range of phenotypes. Further validation assessment of our non-coding variant is in progress. The pipeline developed for this study is easily modified to analyze other rare genetic diseases, and may be valuable for discriminating non-coding, pathogenic variants in future studies.

WDR45 **mutations in three male patients with West syndrome.** *M. Nakashima[1], K. Takano[2,3], Y. Tsuyusaki[2], S. Yoshitomi[4], M. Shimono[5], Y. Aoki[6], M. Kato[7,8], N. Aida[9], T. Mizuguchi[1], S. Miyatake[1], N. Miyake[1], H. Osaka[2,10], H. Saitsu[1,11], N. Matsumoto[1].* 1) Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Division of Neurology, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Japan; 4) Shizuoka Institute of Epilepsy and Neurological Disorders, Shizuoka, Japan; 5) Department of Pediatrics, University of Occupational and Environmental Health, Kitakyushu, Japan; 6) Department of Pediatrics, Asahi General Hospital, Asahi, Japan; 7) Department of Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan; 8) Department of Pediatrics, Showa University School of Medicine, Tokyo, Japan; 9) Department of Radiology, Kanagawa Children's Medical Center, Yokohama, Japan; 10) Department of Pediatrics, Jichi Medical University, Tochigi, Japan; 11) Department of Biochemistry, Hamamatsu University School of Medicine, Hamamatsu, Japan.

West syndrome is an early-onset epileptic encephalopathy characterized by clustered spasms with hypsarrhythmia seen on electroencephalogram. West syndrome is genetically heterogeneous, and its genetic causes have not been fully elucidated. *WDR45* resides on Xp11.23, and encodes a member of the WD repeat protein interacting with phosphoinositides (WIPI) family, which is crucial in the macroautophagy pathway. *De novo* mutations in *WDR45* cause beta-propeller protein-associated neurodegeneration characterized by iron accumulation in the basal ganglia. In this study, we performed whole exome sequencing of individuals with West syndrome and identified three *WDR45* mutations in three independent males. Two novel mutations occurred *de novo* and the remaining mutation detected in a male patient and his affected sister was inherited from the mother, harboring the somatic mutation. The three male patients showed early-onset intractable seizures, profound intellectual disability and developmental delay. Their brain magnetic resonance imaging (MRI) scans showed cerebral atrophy. We found no evidence of somatic mosaicism in the three male patients. Our findings indicate that hemizygous *WDR45* mutations in males lead to severe epileptic encephalopathy.

2435T

The epidemiological and molecular analysis of Paroxysmal Kinesigenic Dyskinesia (PKD) in Japan. *N. Kurotaki[1], Y. Morimoto[1], K. Kurotaki[1], Y. Kusumoto[1], K. Shirotani[3], N. Iwata[3], H. Ozawa[1], K. Yoshiura[2].* 1) Neuropsychiatry, Nagasaki University School of Medicine, Nagasaki, Japan; 2) Department of HUMAN GENETICS, Atomic Bomb Disease Institute, Nagasaki University , Nagasaki, Japan; 3) Genome-based Drug Discovery, Nagasaki Univ. Sch. of Pharmaceut. Sci., Nagasaki, Japan.

Paroxysmal kinesigenic dyskinesia (PKD) is characterized by recurrent, brief attacks of involuntary movement triggered by sudden voluntary movement. In 2011, PRRT2 on chromosome 16 is responsible for PKD reported by the Chinese group. A year later, our group found that the mutation is almost concentrated into c.649dupC (p.Arg217Profs*8) and involved in benign infantile seizure (Ono et al., 2012). Additionally, several reports show that PRRT2 is related to not only infantile seizure, but also migraine, and other epileptic disorders. The papers of both Wood H. in the Nat Rev Neurology (2012) and one of Scheffer IE.'s in the Nat Rev Neurology (2013) emphasized the PRRT2 gene in clinical neurology. In this situation, we proposed epidemiological study of PKD in Japan and have performed the molecular analysis to estimate the relationship between PKD and its complications. First, we conducted the survey by using a questionnaire about the frequency and the complications of PKD, and the medical treatments of the members of both Japanese Society of Neurology and Japanese Society of Child Neurology. Japanese Society of Psychiatry and Neurology kindly recommended the study. A total of all members are 6000 and the response rate of a questionnaire was about 50%. In this survey, 426 cases of PKD have reported by members of these societies. Interestingly, 147 cases had various complications including epileptic seizure, autistic disorders, bipolar disorders and other neurological disorders. Until now, we analyzed PRRT2 mutations in 68 cases resulting c.649dupC of PRRT2 is main gene alterations as reported previously. However, some cases have no mutation of PRRT2. We will perform further investigation utilizing the next generation sequence technology in the cases without any PRRT2 mutation. Otherwise, we are estimating Clinical features of pure PKD and PKD with other complications combined with genotype of each case. Our study will show the genotype - phenotype correlation of PKD. Also, we could shed light on the molecular genetic aspect of neuropsychiatric diseases including autistic disorders, mood disorders based on the results of molecular analysis of PKD. This study received the ethical approval from the Committee for Ethical Issues in Human Genome and Gene Analysis at Nagasaki University, Japan. Also, this study is supported by Health Labour Sciences Research Grant.

Heterozygous mutations in *TUBB2A* associated with brain abnormalities, severe delay and joint contractures. *R. Ejaz[1], A. Lionel[2], S. Blaser[4], C. Hawkins[5], S. Walker[2], S. Scherer[2], R. Babul-Hirji[1], C. Marshall[2,3], D. Stavropoulos[3], D. Chitayat[1,6].* 1) Division of Clinical & Metabolic Genetics, Department of Pediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Genome Diagnostics, Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Diagnostic Imaging, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Pathology, Mount Sinai Hospital, Toronto, Ontario, Canada; 6) The Prenatal Diagnosis and Medical Genetics Program; Department of Obstetrics and Gynecology, University of Toronto, Toronto, Ontario, Canada.

The formation of the mammalian cortex requires the generation, migration, and differentiation of neurons. The discovery that mutations in tubulin genes such as *TUBA1A*, *TUBB2B* and *TUBB3* cause different neurodevelopmental conditions, including lissencephaly, polymicrogyria, and an ocular motility disorder shows the important role of these genes in brain formation and function. We described a third individual with a germline *TUBB2A* mutation, with the hitherto undescribed phenotype of joint contractures, facial dysmorphism, vocal cord paralysis, severe developmental delay, seizures, optic nerve hypoplasia and MRI findings of polymicrogyria. The patient was born at term to a 21-year-old primigravida mother via emergency caesarean section for fetal distress. Prenatal ultrasounds were unremarkable. He was hypotonic with overriding sutures, prominent nasal bridge, downslanted palpebral fissures, midface hypoplasia, low-set and posteriorly-rotated ears, and a short neck. Musculoskeletal examination revealed camptodactyly, second and fifth fingers overlapping the third and fourth, single palmar creases, right rocker bottom foot, and joint contractures. Brain MRI at 2 days of life showed bilateral posterior sylvian polymicrogyria with asymmetric ventricles and frontal gyration. Ophthalmologic assessment revealed bilateral optic nerve hypoplasia. The patient had global developmental delay, contractures and developed seizures at 19 months of age. He died at 28 months of age of acute bronchopneumonia. Given the association of polymicrogyria and optic nerve hypoplasia with *TUBA8* mutations, the suspicion of a tubulinopathy was raised. However, as the child had other features not previously reported in tubulinopathies, whole exome sequencing (WES) was pursued and revealed a de novo *TUBB2A* (NM_001069) mutation [c.G785A:p.R262H], in the same highly conserved GTP-binding domain as the two previously reported cases. Our patient further supports the association between heterozygous mutations in the *TUBB2A* gene and abnormal cortical development. While the two previously reported individuals had simplified gyral patterning, our patient had polymicrogyria-like cortical dysplasia, with microcephaly, facial dysmorphism, and musculoskeletal anomalies. Seizures and developmental delay were shared. Our case suggests a broader phenotype to *TUBB2A* mutations than currently reported. More reports are needed for further delineation of the manifestations associated with this gene mutation.

A missense mutation in the *PPIG* gene encoding the peptidyl-prolyl isomerase G in patients with autosomal dominant benign adult familial myoclonic epilepsy. *R. Fujioka[1], S. Miura[2], K. Yamada[3], T. Morikawa[3], H. Motooka[4], K. Uchiyama[5], Y. Aso[6], N. Kimura[6], K. Sano[2], K. Yamamoto[7], T. Taniwaki[2], H. Shibata[3].* 1) Department of Food and Nutrition, Beppu University Junior College, Beppu, Oita, Japan; 2) Division of Respirology, Neurology, and Rheumatology, Department of Medicine, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 3) Division of Genomics, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 4) Department of Neurpsychiatry, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 5) Department of Radiology, Kurume University School of Medicine, Kurume, Fukuoka, Japan; 6) Department of Neurology, Faculty of Medicine, Oita University, Yufu, Oita, Japan; 7) Department of Medical Chemistry, Kurume University School of Medicine, Kurume, Fukuoka, Japan.

Benign adult familial myoclonic epilepsy (BAFME) is an inherited epileptic syndrome characterized by adult-onset cortical tremors and seizures. Here, we investigate the responsible variant for an autosomal dominant BAFME ascertained from Oita prefecture, Japan using exome sequencing combined with linkage analysis. The cardinal clinical features of the present family were as follows: 1) slow progression; 2) myoclonic tremor; 3) very low frequency of the occurrence of generalized seizure; 4) upper motor neuron sign; 5) bradycardia; 6) deep sensory involvement in the lower limbs. By the multipoint linkage analysis of seven family members including five patients, we identified ten regions located in eight chromosomes (2, 3, 4, 8, 11, 14, 15, and 19) in which the logarithm of odds (LOD) scores were over 1.0. Subsequently, we performed exome sequencing of the seven family members with the average depth of 88.7x. From the total of 6,062,467 variants observed, we identified 23 patient-specific novel nonsynonymous variants. These variants were then filtered with the criteria of the minor allele frequency < 0.4% in the 1000G Project and the absence in 30 in-house exomes of unrelated Japanese individuals. From the remaining 13 nonsynonymous variants, we selected three variants located within the ten linkage regions. By Sanger validation of the 3 candidates, we confirmed only two variants, His429Asp in *PPIG* and Val240Leu in *LRTM1* are cosegregated with the disease in our pedigree. We further confirmed their absence in 500 healthy unrelated Japanese individuals. Since the variant in *PPIG* was predicted to be damaging (SIFT score = 0.04, PolyPhen-2 = possibly damaging), while the variant in *LRTM1* was predicted to be benign (SIFT score = 0.36, PolyPhen-2 = benign), we concluded the novel single nucleotide substitution, c.1505C>G (p.His429Asp), located in the *PPIG* gene, is highly likely to be the causative variant in our BAFME pedigree. *PPIG* encodes peptidyl-prolyl isomerase G also known as cyclophilin G that is a member of the cyclophilin family of peptidyl-prolyl cis/trans isomerases. PPIG is expressed in multiple tissues including brain and is known to be associated with transcription elongation, as well as splicing. This is the first report of a human disease related to PPIG.

2438T

Adenylate kinase 9 (*AK9*) mutation is a novel disease gene for congenital myasthenic syndrome with limb girdle myasthenia. *C.W. Lam.* Department of Pathology, The University of Hong Kong, Hong Kong, China.

Neuromuscular junction (NMJ) is clinically important because abnormal neuromuscular transmission can cause myasthenic syndrome. Single-gene defects causing myasthenic syndrome are called as congenital myasthenic syndrome (CMS). A special type of CMS causes only limb-girdle myasthenia. Here, we aim to determine the molecular basis of CMS in a consanguineous family with limb girdle type of CMS. There were two clinically affected siblings (P1, P2) and two clinically unaffected sisters (S1 and S2). Homozygosity mapping was performed using high-density single-nucleotide polymorphism microarray. Mutations were identified by WES and WGS and genotypes of the family members were confirmed by Sanger sequencing. A region of homozygosity (ROH) of 20 MB was mapped on chromosome 6q15–21. This ROH region is the only ROH region that is present in all the clinically affected siblings (P1 and P2), absent in all the clinically unaffected siblings (S1 and S2). Bioinformatics analysis of WES and WGS data showed a novel single-nucleotide variant (SNV) of the adenylate kinase (*AK9*) gene located in this region. P1 and P2 were homozygous for the SNV, S1 is heterozygous for the SNV, and the SNV is absent in S2. The parents were heterozygous for the SNV. This mutation was not present in EXAC, ESP6500, 1000 Genomes, and ClinVar databases.This SNV creates a cryptic transcriptional signal in intron 5 of the *AK9* gene by creating a start codon, i.e., start-gain mutation. An *AK9* knockout zebrafish model created by TALEN-mediated gene targeting showed fatigue in swimming consistent with the human CMS phenotype. The gene *AK9* is a novel disease gene for limb girdle myasthenia and CMS. AK9 is located in the cytosol and is involved in production of NDP and NTP. NTP is required for synthesis of dolichol phosphate and nucleotide-sugars for N-glycosylation of proteins. This novel link of *AK9*, N-glycosylation will pave a new way for studying the biology of NMJ and synapses. Since genes of the N-glycosylation pathway are associated with CMS with limb-girdle myasthenia, i.e, *GFPT1*, *DPAG1*, *ALG14*, *ALG2, GMPPB,* increasing the nucleotide pools in NMJ by dietary supplements may be a new therapeutic option of treating patients with CMS with limb girdle myasthenia.

Meisler[1]. 1) Human Genetics, Univ Michigan, Ann Arbor, MI; 2) Dept of Child Psychiatry, Warsaw Medical Univ, Poland; 3) Dept of Exp and Clin Neuropathology, Medical Research Center, Polish Academy of Sciences, Warsaw, Poland; 4) Klinik für Neurologie, Universitätsklinikum Magdeburg, Magdeburg, Germany; 5) Dept of Medical Genetics, Warsaw Medical University, Warsaw, Poland; 6) Dept of Diagnostic Imaging, Institute of Mother and Child, Warsaw, Poland; 7) Klinik für Epileptologie and Life&Brain Center, Universitätsklinikum Bonn, Bonn Germany; 8) Institute of Phys and Path of Hearing, Nadarzyn, Poland; 9) Madison, Wisconsin; 10) Dept of Neurology, Univ of Wisconsin, Madison, Wisconsin.

   The low abundance endo-lysosomal lipid $PI(3,5)P_2$ is generated from $PI(3)P$ by a protein complex with 3 major subunits: the lipid kinase PIKFYVE, the phosphatase FIG4, and the scaffold protein VAC14. Mutations of *FIG4* result in several inherited neurological disorders. We now describe inherited variants of *VAC14* in two unrelated children with neurological dysfunction. At the ages of 18 months and 3 years the children experienced sudden onset of progressive neurological decline characterized by dystonia and regression of developmental milestones. Both became nonambulatory and nonverbal. Striatal abnormalities were present on MRI. A diagnosis of Leigh syndrome was rejected due to normal lactate profiles. Exome sequencing identified biallelic variants of *VAC14* that were inherited from unaffected heterozygous parents in both families. Proband 1 inherited a splice site mutation that results in skipping of exon 13, p.Ile459Profs*4 (not reported in public databases), and the missense variant p.Trp424Leu (reported in one heterozygote in ExAC). Proband 2 inherited two missense mutations in the dimerization domain of VAC14 that result in the amino acid substitutions p.Ala582Ser and p.Ser583Leu (not reported in public databases). Cultured skin fibroblasts from the probands exhibited the accumulation of vacuoles that is characteristic of $PI(3,5)P_2$ deficiency. Vacuolization was rescued by transfection of wildtype *VAC14* cDNA. The similar age of onset and similar neurological progression in these two unrelated children suggest that a specific recessive disorder results from compound heterozygosity for deleterious variants of *VAC14*. To characterize the functional consequences of these missense variants, we are examining the biochemical interactions of the mutant proteins. We are interested in evaluating novel variants of VAC14 identified in individuals with neurological dysfunction. (Supported by R01 NS34509 and R03 NS090142).

   Primary microcephaly is a neurodevelopmental disorder caused by a reduction in brain size attributed to defects in proliferation of neural progenitor cells during development. Mutations in genes encoding proteins that localize to the mitotic spindle and centrosomes have been implicated in the pathogenicity of primary microcephaly. In contrast, the contractile ring and midbody required for cytokinesis, the final stage of mitosis have not previously been implicated in the molecular mechanisms of this phenotype. Citron Kinase (CIT) is a multi-domain protein that localizes to the cleavage furrow and midbody of mitotic cells, where it is required for the completion of cytokinesis. Rodent models of *Cit* deficiency highlighted the role of this gene in neurogenesis and microcephaly over a decade ago. Here we identify recessively inherited pathogenic truncating and splice site variants in *CIT* as the genetic basis of severe microcephaly and neonatal death. We present postmortem data showing that CIT is critical to build a normally sized human brain. Consistent with cytokinesis defects attributed to CIT, multinucleated neurons are observed throughout the cerebral cortex and cerebellum of an affected proband, expanding our understanding of mechanisms attributed to primary microcephaly.

2441T

NR1H3 **and** *P2RX4/P2RX7* **mutations cause multiple sclerosis in families.** *C. Vilariño-Güell[1], W. Song[2], A.L. Traboulsee[3], J.S. Wiley[4], B.J. Gu[4], A.D Sadovnick[1,3].* 1) Medical Genetics; 2) Psychiatry; 3) and Division of Neurology, University of British Columbia, Vancouver, British Columbia, Canada; 4) Florey Institute of Neuroscience and Mental Health, University of Melbourne, Parkville, Victoria, Australia.

   Introduction: Multiple sclerosis (MS) is an inflammatory disease characterized by myelin loss and neuronal dysfunction. Despite the aggregation observed in some families, pathogenic mutations have remained elusive. **Objectives:** The goal of this study is to identify pathogenic mutations responsible for Mendelian forms of MS and variants of major effect on disease risk. **Methods:** Exome sequencing analysis was applied to patients from multi-incident families; and variants of interest validated in a case control series consisting of 2211 MS patients and 880 healthy controls. **Results:** Exome analysis identified pathogenic mutations for MS in *NR1H3* and a *P2RX7-P2RX4* haplotype. *NR1H3* (LXRA) is nuclear receptors that controls the transcriptional regulation of genes involved in inflammation and innate immunity. A LXRA p.R415Q substitution was observed in seven MS patients from two multi-incident families. All patients presented a severe and progressive form of disease, with an average age at onset of 34 years. The p.R415Q position is highly conserved in orthologs and paralogs, and disrupts LXRA heterodimerization and transcriptional activation of target genes. Protein expression analysis revealed that mutant LXRA alters gene expression profiles, suggesting a disruption in transcriptional regulation as one of the mechanisms underlying MS pathogenesis. Additionally, association analysis of common variants in *NR1H3* identified rs2279238 conferring a 1.35-fold increased risk of developing progressive MS. Purinergic receptors are proinflammatory mediators containing genetic variants associated with MS susceptibility risk. In this study we identified a three mutation haplotype encompassing purinergic receptors *P2RX7* (p.T205M and p.N361S) and *P2RX4* (p.G135S) in a multi-incident family with high incidence of MS. This haplotype was observed in five blood-related patients with an average age at onset of 31 years, and a clinical course consistent with relapsing-remitting or secondary progressive MS. Functional analysis revealed that this disease haplotype causes over 95% loss in P2RX7 pore function, and almost completely abolishes its phagocytic activity. This loss of function results from near absence of P2RX7 surface expression due to impaired trafficking or accelerated turnover. **Conclusion:** Exome sequencing analysis of multi-incident MS families can be successfully used for the identification of pathogenic mutations, and to unravel the underlying molecular mechanisms of disease.

2442F

Independent variant analysis of *TEAD1* **and** *OCEL1* **in 38 Aicardi Syndrome patients.** *B.K.Y. Wong[1,6], V.R. Sutton[2], R.A. Lewis[2,3,4,5], I.B. Van den Veyver[1,2,6].* 1) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Medicine, Baylor College of Medicine, Houston, TX; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Department of Ophthalmology, Baylor College of Medicine, Houston, TX; 6) Jan and Dan Duncan Neurological Research Institute Texas Children's Hospital.

   Aicardi syndrome is a severe neurodevelopmental disorder characterized by infantile spasms, typical chorioretinal lacunae, agenesis of the corpus callosum, and other neuronal migration defects. It has been reported recently that *de novo* variants in *TEAD1* and *OCEL1* each may cause Aicardi syndrome in a single individual of a small cohort of females with this clinical diagnosis. These data were interpreted to suggest that the clinical diagnosis of Aicardi syndrome may be genetically heterogeneous. To investigate this further, we sequenced *TEAD1* and *OCEL1* coding regions using DNA from 38 clinically well-characterized girls with Aicardi syndrome. We did not detect the previously reported or any other deleterious variants in any of the analyzed samples. This suggests that the published variants represent either an extremely rare cause of Aicardi syndrome or an incidental finding.

2443W

Biallelic mutations in *UBA5* **reveal the UFM1 cascade as a new pathway for early-onset encephalopathy.** *E. Colin[1,2], J. Daniel[3], A. Ziegler[1,2], J. Wakim[2], A. Scrio[4], T.B. Haack[11], S.    Using whole-exome sequencing, we identified rare autosomal recessive variants in *UBA5* in 5 children from 4 unrelated families affected with a similar pattern of severe intellectual deficiency, microcephaly, movement disorders and/or early-onset intractable epilepsy. *UBA5* encodes the E1-activating enzyme of the ubiquitin-fold modifier 1 (UFM1) protein, a recently identified ubiquitin-like protein. Most members of the UFM1 cascade and target proteins are localized in a large protein complex at the luminal site of the endoplasmic reticulum (ER) and are involved in the regulation of the unfolded protein response (UPR) and ER-stress mediated apoptosis. The UFM1 cascade has also been involved in the development of various cancers. However, the specific biological function of ufmylation and the clinical implications of its dysfunction remain largely uncharacterized. Biochemical studies of mutant UBA5 proteins and studies in fibroblasts from affected individuals revealed that *UBA5* mutations impair the process of ufmylation, resulting in an abnormal endoplasmic reticulum structure. In Caenorhabditis elegans, knockout of *uba-5* and of human orthologous genes in the UFM1 cascade alter cholinergic, but not glutamatergic, neurotransmission. In addition, *uba5* silencing in zebrafish decreased motility while inducing abnormal movements suggestive of seizures. These clinical, biochemical, and experimental findings support *UBA5* mutations as a novel pathophysiological cause for early-onset encephalopathies due to abnormal protein ufmylation.

2444T

The changing face of type 2 Gaucher disease: A natural history study. *T.R. Roshan Lal[1,2], K. Weiss[2], G. Monestime[2], N. Tayebi[2], G. Lopez[2], E. Sidransky[2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 2) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

   Background Gaucher disease (GD), the most common lysosomal storage disorder, results from the inherited deficiency of the enzyme glucocerebrosidase. Neuronopathic type 2 GD is the rarest, as well as the most severe and progressive form. Traditionally, the clinical presentation is considered to be stereotypic; however it can range from hydrops fetalis to the collodion baby phenotype to infants presenting after 6 months of life. Neurological involvement occurs very early on in the disease process, resulting in severe degeneration and death in infancy or early childhood. However in the past decades, infants have been living longer due to more aggressive interventions. The purpose of this study is to delineate the changing clinical course of type 2 GD. Establishing this data may help with the management of these affected individuals as well as their families Also, the collected information will provide an essential baseline for future treatment protocols. **Methods** A cohort of both living and deceased patients with clinically and molecularly confirmed type 2 GD is being identified from patient databases, patient support groups and referring physicians. A structured telephone interview consisting of in-depth medical questions will be conducted with parents of affected type 2 GD individuals. Questions asked during the telephone interview include information regarding disease presentation, disease progression, surgical history, medications, feeding issues, family history, treatment or interventions, disease complications, hospice care, cause of death and the impact of disease on other family members. Medical records will be reviewed when available. **Results** Currently available treatment options, while not curative, appear to be changing the clinical course of type 2 GD. Affected individuals are living longer, but interventions do not appear to markedly impact the neurological manifestations. This study has just begun and is anticipated to highlight newer complications or disease manifestations seen in these patients. **Conclusion** Diagnosing and treating infants with type 2 GD has always been a challenge to clinicians. It is paramount that we understand the baseline and any changes in the clinical course of this disease, as it often impacts not just the patient, but also the entire family. The data generated will be essential in the design of any future interventional protocols, helping to identify goals of treatment and milestones to determine efficacy.

2445F

Examining the risk of Parkinsonism in six sibling pairs with Gaucher disease. *E. Sidransky[1], G. Monestime[1], C. Groden[1], E. Wiggs[1], N. Tayebi[1], A. Zimran[2], G. Lopez[1].* 1) NHGRI, Bethesda, MD; 2) Gaucher Clinic, Share Zedek Medical Center, Jerusalem, Israel.

   Background While the association between mutations in the gene encoding glucocerebrosidase (*GBA1*) and parkinsonism is well established, most *GBA1* mutation carriers do not develop parkinsonian features. In Parkinson disease (PD), by the time patients present with motor symptoms, more than 50% of dopaminergic neurons in their substantia nigra have been lost. Identifying patients at highest risk for developing PD is critical in order to impact patients' prognoses and quality of life. **Methods** We studied six sibling pairs with Gaucher disease longitudinally at the National Institutes of Health Clinical Center. Five of the pairs had Ashkenazi Jewish background. In each discordant sibling pair (DSP), both siblings had the same genotype in *GBA1*, but only one sibling was clinically diagnosed with PD. In all 12, neurological evaluations, family pedigrees, neuroimaging, neuropsychological testing and olfactory testing were performed and motor and non-motor symptoms of PD were assessed. Medical information including age at onset, genotype, clinical presentation, family history, and current medications were also collected. DNA and RNA samples were banked. Subjects were evaluated 1-4 times over 1-10 years. **Results** Five genotypes were detected; N370S/N370S (in two pairs), N370S/L444P, N370S/V394L, c.84insG/N370S and N370S/IVS2+1. The general severity of Gaucher disease was determined based on the degree of skeletal involvement, hematological abnormalities, and organomegaly. In four of the six pairs, the sibling with PD was younger and had milder Gaucher symptoms. No subtle parkinsonian features were observed in any of the non-PD sibs, even among those who underwent multiple sequential evaluations. **Conclusions** Continued longitudinal evaluations and recruitment of additional DSPs will help to power this study and elucidate factors contributing to and/or preventing the development of parkinsonism in these individuals. Genetic studies will explore potential genetic modifiers or environmental factors that may diminish or augment risk. .

2446W

Arthrogryposis associated with a homozygous frameshift variant in *TOR1A*: Fetal-onset dystonia may cause severe congenital joint contractures. *R.D. Clark, J.A. Gold, J. Camacho.* Division of Medical Genetics/Peds, Loma Linda University Medical Center, Loma Linda, CA.

   Regions of homozygosity (ROH), identified by SNP microarray, increase the chance of autosomal recessive (AR) disease due to a homozygous mutation at a locus within the ROH. A term female, born to healthy parents, in the breech presentation had severe arthrogryposis, lack of spontaneous movement, tremors and bulbar dysfunction. She was spastic and hyperreflexic, did not nipple and was fed by G-tube. She had a right inguinal hernia, femoral head dislocation and bilateral acetabular dysplasia. An EMG documented anterior horn cell involvement. MRI of the brain showed colpocephaly with asymmetric enlargement of the occipital and temporal horns and thinning of the corpus callosum. Parents were from the same small town in Mexico but denied consanguinity. A SNP microarray revealed 46.3 Mb of ROH in several chromosomes, including 9q33.2q34.11. The patient died at 4 months of age. Results from clinical exome sequencing, available posthumously, revealed only one homozygous variant, in *TOR1A*: c.790_793del, p.Asp267Ilefs*13, which was reported to be "likely pathogenic" because a frameshift introduced a premature stop codon. *TOR1A* encodes torsin A, which is expressed throughout the CNS in humans. Heterozygous mutation in *TOR1A* causes torsion dystonia type 1 (DYT1, MIM 128100, 605204), a variable autosomal dominant (AD) trait of childhood onset. The common mutation in *TOR1A*, an in-frame GAG deletion in exon 5, has reduced penetrance for dystonia of 30-40%. Arthrogryposis has not previously been associated with *TOR1A* sequence changes. We propose that homozygosity for this variant *TOR1A* allele caused arthrogryposis in our patient due to fetal-onset of severe dystonia that rendered her almost immobile. Other AD genes that cause dystonia may be candidate genes for AR arthrogryposis, especially when a hypomorphic allele or other modifying factor reduces the penetrance. Finally, when ROH are interrogated for genes that could explain a rare phenotype, both AR and AD traits should be considered.

2447T

Family exome sequencing in two founder populations for personalized genetic diagnostics and novel disease gene identification. *C. Gonzaga-Jauregui[1], E. Puffenberger[2], K. Brigatti[2], C. Van Hout[1], A. King[1], K. Williams[2], K. Praveen[1], C. Perry[1], E. Maxwell[1], M. Kuebler[2], J. Staples[1], J.G. Reid[1], J.D. Overton[1], A. Baras[1], S. Mellis[3], A. Shuldiner[1], F. Dewey[1], K.A. Strauss[2].* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals Inc., Tarrytown, NY; 2) Clinic for Special Children, Strasburg, PA; 3) Regeneron Pharmaceuticals Inc, Tarrytown, NY.

Founder populations derive from a small number of individuals and are often culturally or geographically isolated from gene inflow from cosmopolitan populations. Old Order Amish and Mennonite populations maintain a high-degree of cultural and genetic isolation, making them ideal for discovering links between gene variation and disease. We have performed exome sequencing in families of Amish and Mennonite ancestry seen for genetic evaluation at the Clinic for Special Children. We sequenced the exomes of the proband, parents, and all available affected and unaffected siblings (i.e. 'family exome'). We performed pedigree-based variant analyses and segregation in order to identify candidate disease genes and pathogenic alleles in these probands. To date, we have sequenced and analyzed more than 100 probands and their relatives in order to identify the molecular causes of their genetic disease. As expected for founder populations, we identified variants in recessive disease genes, including a case of two recessive disorders segregating together in this population (*SLC26A2*, diastrophic dysplasia; and *SH3CT2*, Charcot-Marie-Tooth type 4C) to produce an unusually severe, early-onset neuro-skeletal syndrome. Interestingly, 55% of the cases where we were able to assign a genetic diagnosis were due to novel *de novo* mutations in recently reported disease associated genes such as *ARID1B*, *SETBP1*, *PURA*, *SYNGAP1*, *TCF4*, *CHD7*, *CTNNB1*, *TUBB3*, among others. In addition, we identified potential novel disease gene associations in 30 probands with previously unreported rare disorders. We demonstrate the utility of genomic sequencing in individuals with genetic disorders and their family members to reach a fast and accurate molecular diagnosis and guide treatment. As in any population, a broad spectrum of pathogenic molecular mechanisms is observed, ranging from autosomal recessive homozygous variants specific to these relatively genetically homogeneous populations to sporadic *de novo* variants. Genetic testing proves especially useful for the evaluation of developmental disabilities and polygenic disease mechanisms. We identified novel candidate disease gene associations that may inform molecular diagnosis for other cases with similar clinical presentations.

2448F

Exome utility in phenotype/genotype association for 6,769 exomes spanning >500 phenotypes. *S.N. Jhangiani[1], Z.H. Coban Akdemir[2], J. Posey[2], W. Charng[2], T. Gambin[2], N. Sobreira[3], K. Doheny[3], C. Boehm[3], D. Avramopoulos[3], A. Hamosh[3], T. Harel[2], E. Karaca[2], Y. Bayram[2], M. Eldomery[2], M.N. Bainbridge[1], H. Dinh[1], Y. Han[1], H. Doddapaneni[1], J. Hu[1], V.R. Sutton[2], D.M. Muzny[1], E.A. Boerwinkle[1], D. Valle[3], J.R. Lupski[2], R.A. Gibbs[1], Baylor-Hopkins Center for Mendelian Genomics.* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD.

The Centers for Mendelian Genomics (CMGs) have sequenced ~19,000 patient samples in collaboration with more than 500 investigators from 36 countries. At its inception in 2011 the Baylor-Hopkins Center for Mendelian Genomics (BHCMG), as one of then three NIH funded CMGs, began its efforts towards: i) novel gene/mutation discovery, ii) elucidating the molecular bases of disease, iii) understanding the genetic susceptibility to disease traits, and iv) determining the genetic/genomic architecture of presumably Mendelian disease. The BHCMG has learned many lessons from its contribution of 6,769 exomes with study subjects spanning 550 clinical phenotypes and presented our findings in more than 100 publications. The Human Genome Sequencing Center at the Baylor College of Medicine has generated 48Tb of whole exome sequencing (WES) data using the HGSC-VCRome capture reagent and now includes 'Spike-in PKv2' to capture more difficult regions and additional gene targets. The HGSC-VCRome capture reagent, along with a multiplex strategy and use of full-length blocking oligos employed for hybridization, has yielded 7.7Gb of data per exome providing a coverage of 96% at 20X or greater. The Spike-in PKv2 reagent is comprised of 3,643 additional unique gene targets derived from GeneTests, OMIM, selected cancer genes and Baylor Miraca Genetics Laboratory positive cases. The addition of this reagent converts >700-800 genes from partially covered to fully covered at ≥ 20X coverage. This high throughput sequencing pipeline, producing 3,000 capture libraries per month, is automated from library construction through annotated VCF generation in part using the 'Mercury' analysis pipeline. Success rates in this program have varied by phenotype and cohort collections ranging from 37% to ~90% of cases in which a likely molecular diagnosis contributing to the disease phenotype is achieved. The BHCMG has established valuable sample acquisition approaches and resources, enhanced sequencing methodology, curated a well-characterized phenotype-rich genetic database enabling genotype/phenotype relationships (i.e. PhenoDB) and encouraged collaborative efforts (i.e. GeneMatcher) to implicate 589 disease genes including 222 novel, 231 known and 136 phenotypic expansion genes. Each discovery has demonstrated the diagnostic capabilities in using whole exome sequencing and has taught lessons in disease mechanisms that continue to drive investigation into those cases that remain unsolved.

2449W

Biallelic mutations in *IARS*, encoding cytosolic isoleucyl-tRNA synthetase, cause growth retardation with prenatal onset, intellectual disability, muscular hypotonia, and infantile hepatopathy. *R. tRNA synthetase deficiencies are a growing group of genetic diseases associated with tissue-specific, mostly neurological phenotypes. In cattle, cytosolic isoleucyl-tRNA synthetase (*IARS*) missense mutations cause hereditary weak calf syndrome. Exome sequencing in three unrelated individuals with severe prenatal-onset growth retardation, intellectual disability, and muscular hypotonia revealed biallelic mutations in *IARS*. Two of the individuals had infantile hepatopathy with fibrosis and steatosis, leading to liver failure in one during the course of infections. Zinc deficiency was present in all affected individuals and supplementation with zinc showed a beneficial effect on growth in one. The functional relevance of the identified variants was confirmed by using a yeast model. All individuals studied are compound heterozygous for one *IARS* loss-of-function allele and one allele with significantly reduced but some residual activity. In situ hybridization and morpholino knockdown of the identified gene homolog in zebrafish were performed to investigate the expression pattern and the gene's role for embryonic development. These experiments suggest an important role for *IARS* in embryogenesis. Downregulation of *IARS* causes high lethality with surviving embryos exhibiting a severe and consistent brain phenotype and a shortening of the body axis reminiscent of the human phenotype. The pathomechanisms of IARS deficiency is not yet fully understood. Given the ubiquitous presence of ARSs in all kingdoms of life and their indispensable function, it is remarkable that mutations in ARSs cause appreciably distinct clinical pictures with tissue-specific phenotypes in humans. In recent years, whole exome sequencing studies have revealed various causes of infantile liver failure with partly specific clinical phenotypes. This study delineates biallelic mutations in *IARS* as underlying a multisystemic disease affecting mainly growth, brain, and liver. For reasons yet to be determined, this disease is associated with zinc deficiency and can be palliated by zinc supplementation.

2450T

Mutations in DCC cause isolated agenesis of the corpus callosum and mirror movements associated with sex-specific penetrance and failure of corticospinal axonal decussation. *A.P.L. Marsh[1,2], D. Background: Deleted in Colorectal Cancer (DCC) is a conserved Netrin-1 binding axon-guidance receptor critical for corpus callosum development. Mice with homozygous *Dcc* mutations display agenesis of the corpus callosum (ACC), as well as corticospinal (CS) tract defects. In humans, *DCC* haploinsufficiency has been associated with mirror movements (MM, OMIM#157600) but not ACC (OMIM#217990). **Methods:** Genetic studies, including whole exome sequencing, were used to investigate the cause of ACC in 4 multigenerational families and 70 sporadic cases. MRI and probabilistic constrained spherical deconvolution (CSD) MRI tractography were utilised to assess brain structure and CS tract wiring. *DCC* expression in human neural stem cells (hNSC) was measured using RNAseq and RT-qPCR following testosterone treatment. **Findings:** Genetic analyses identified *DCC* mutations in 9 unrelated families with isolated ACC with/without MM. All individuals with DCC-related ACC had an intellectual quotient within normal/borderline range. CSD MRI tractography identified a failure of CS axonal decussation in all affected individuals (n=7) from 2 families. All 7 individuals displayed MM, with concomitant ACC in 5. Sex bias in phenotype expression was observed, with *DCC* haploinsufficiency in males significantly correlated with MM while females only presented with ACC. This sex bias was not observed in individuals with missense mutations. Males and females with missense mutations located within the DCC/Netrin-1 binding interface presented with ACC and MM; individuals with missense mutations located outside this region presented with ACC only. Testosterone-treated hNSC showed significant upregulation of *DCC*. **Interpretation:** We show that heterozygous missense and loss-of-function *DCC* mutations

cause isolated ACC, with/without MM. Contrary to the multitude of genes known to cause syndromic ACC, *DCC* mutations are associated with isolated ACC and a relatively mild phenotype with a favourable cognitive outcome. We provide new evidence that MM in *DCC*-mutant individuals results from failure of CS axonal decussation. Our data indicates a distinct molecular mechanism leading to disease in missense mutant compared to haploinsufficient individuals. We provide novel evidence that sex bias in phenotype expression may be the result of increased *DCC* expression caused by higher testosterone levels in males. This is the first report linking mutation of a gene to isolated ACC in multiple, unrelated individuals.

2451F

Clinical and genetic features of 94 Japanese Charcot–Marie–Tooth disease patients with *MFN2* **mutations.** *A. Masahiro, A. Yoshimura, A. Hashiguchi, Y. Hiramatsu, J. Yuan, Y. Higushi, Y. Okamoto, H. Takashima.* neurology, Kagosima university, Kagoshima, Kagoshima, Japan.

   Background and Objective Charcot-Marie-Tooth disease (CMT) is one of the most common inherited peripheral neuropathies(IPN) for which more than 70 causative genes have been reported. The clinical features of CMT are significantly heterogeneous even among patients with mutations in the same gene. In this study, we aimed to describe the clinical spectrum of CMT patients harboring *MFN2* mutations in Japan. **Methods** We analyzed 1513 unrelated cases with clinically suspected IPN who were referred by neurological and neuropediatric departments throughout Japan. All these cases had been proved negative for *PMP22* duplication/deletion. We conducted mutation screening using DNA microarray, targeted resequencing, and/or whole-exome sequencing successively. Candidate variants detected using various platforms were validated by Sanger sequencing, and if possible, segregation analysis was performed. **Results** In 94 suspected CMT2A patients, we identified 49 heterozygous and two homozygous different mutations in *MFN2*. Herein, 20 novel mutations were detected in 27 cases, whereas 31 mutations in 67 cases had been previously described. Segregation analysis was conducted in seven pedigrees with novel mutations. The primary symptom might emerge at 10–50 years of age, with a mean onset age of 12.03 ± 14.3 years in 75 cases with a specific record. The inheritance pattern was determined in 85 cases comprising 43 autosomal dominant, three autosomal recessive, and 39 sporadic cases. The mean onset age in the sporadic cases was lower than that in the autosomal dominant cases (7.58 ± 10.24 vs 14.95 ± 16.06). We reviewed all electrophysiological analyses of 81 cases; five cases with demyelinating type (motor conduction velocity < 38 m/s) and 76 cases with axonal type (motor conduction velocity > 38 m/s) were verified. Interestingly, we also detected mutations in two genes, *MFN2* and *PMP22*, from one patient. In addition, one cases characterized by late-onset axonal CMT, which is rare in *MFN2*-related CMT patients, were found. Furthermore, a patient harboring homozygous R280H mutation presented with a more severe phenotype than that of the heterozygous cases. **Conclusion** *MFN2* was identified as the most common causative gene of CMT2, and the clinical features of patients significantly varied. Notable intragenic mutation diversity could be observed in our Japanese cohort. Regardless of the onset age and inheritance pattern, it is necessary to consider the possibility of *MFN2* mutation in axonal CMT.

2452W

A recurrent mutation in *MYH14* causes autosomal dominant Charcot-Marie-Tooth disease with suspected mitochondrial pathology. *C. Smith[1], T. Shutt[1,2], G. Pfeffer[1,3], R.E. Lamont[1,4], F. Bernier[1,4], J. Parboosingh[1,4], A.M. Innes[1,4], Care4Rare Canada Consortium.* 1) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Department of Biochemistry & Molecular Biology, University of Calgary, Calgary, Alberta, Canada; 3) Department of Clinical Neurosciences, University of Calgary, Calgary, Alberta, Canada; 4) Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada.

Mutations in myosin heavy chain 14 (*MYH14*) are an established cause of autosomal dominant non-syndromic hearing loss (DFNA4A, OMIM: 600652). However, there are two literature reports of a NM_001077186.1 (MYH14): c.2822G>T (p.Arg941Leu) mutation being associated with Charcot-Marie-Tooth Disease (CMT) in addition to hearing loss (PNMHH, OMIM: 608568). Using exome sequencing we have identified a three generation family with CMT and hearing loss that also has the p.Arg941Leu mutation. *MYH14* encodes a non-muscle myosin that has been ascribed roles in cytokinesis, karyokinesis and neuritogenesis. In order to better understand the pathogenesis of the disease, we attempted to characterize the role of MYH14 protein in cell culture. Expression of a GFP tagged protein showed localization to mitochondria. Moreover, MYH14 was observed at sites of mitochondrial fission, where it co-localized with the well studied fission factor DRP1. Overexpression of MYH14 caused cells to take on a subtly more fragmented mitochondrial morphology, while cells overexpressing p.Arg941Leu mutant MYH14 were no different from cells containing an empty vector. Based on these results, we suspect that MYH14 has a role in mitochondrial fission and that dysfunction in this role contributes to the pathogenesis of CMT and hearing loss. This is an attractive hypothesis because disruption of other genes involved in mitochondrial dynamics also cause CMT (*MFN2, GDAP1*). Our experiments in cell culture further suggest a loss-of-function mechanism. Finally, the identification of a third family confirms the association between the p.Arg941Leu mutation and CMT with hearing loss.

2453T

Genotype-phenotype study of patients with VCP valosin-containing protein multisystem proteinopathy. *E. Al-Obeidi[1], A. Surampalli[1], S. Al-Tahan[1], N. Goyal[2], C. Smith[3], M. Omizo[4], D. Waggoner[5], A. Hermann[6], T. Mozaffar[2], V. Kimonis[1].* 1) Div. of Genetics and Genomic Medic, Dept. Pediatrics, University of California- Irvine Irvine, CA; 2) Div. of Neuromuscular Neurology, Dept. of Neurology, University of California- Irvine, Orange, CA; 3) Dept. of Neurology, University of Kentucky Medical School, Lexington, KY; 4) Oregon Osteoporosis Center, Bend, OR; 5) Div. Human Gen, Dept. Pediatrics, University of Chicago, Chicago IL; 6) Bereich Neurodegenerative Erkrankungen, Klinik und Poliklinik für Neurologie, Dresden, Germany.

Missense mutations in valosin-containing protein (VCP) is associated with a unique limb-girdle/ inclusion-body myopathy (IBM) associated with Paget's disease of bone (PDB), frontotemporal dementia (FTD), and amyotrophic lateral sclerosis (ALS). VCP is an ATPase found in all cells and is a key player in protein degradation and autophagy. VCP disease is a progressive, fatal disorder that has an autosomal dominant adult onset progressive disease. To date, 44 disease-causing missense mutations in the *VCP* gene have been reported worldwide. We report the clinical, natural history and molecular findings in the largest cohort in the world. The goal of this study was to examine genotype-phenotype data from 231 individuals (118 males, 113 females) from 36 families carrying 15 different VCP mutations (three of which are novel). We analyzed whether the different mutations were related to age of onset and severity of IBM, PDB, FTD and ALS, and measured the prevalence of these conditions and other comorbidities. Myopathy was present in 89% of the patients, beginning at an average age of 43 years. PDB was diagnosed in 43% of patients with an average age of onset of 41 years. FTD presented in 29% of the individuals at an average age of 56 years. Approximately 9% of patients with VCP mutations had an ALS phenotype, 4% had been diagnosed with Parkinson's disease, and 2% had been diagnosed with Alzheimer's disease. Because of the wide inter and intra-familial variation establishing a genotype-phenotype correlation was difficult. We however did find that the R159C had a later age of onset of myopathy and the absence of PDB. By understanding the typical clinical presentation and age of onset of symptoms, clinicians will be better able to identify and diagnose VCP-related diseases and thus proactively manage associated features more effectively.

Identification of a post-translational modification with ribitol-phosphate and its defect in muscular dystrophy. *T. Toda[1], M. Kanagawa[1], K. Kobayashi[1], M. Tajiri[2], H. Manya[3], A. Kuga[1], Y. Yamaguchi[4], Y. Wada[2], T. Endo[3].* 1) Division of Neurology / Molecular Brain Science, Kobe University Graduate School of Medicine, Kobe, Japan; 2) Department of Molecular Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 3) Molecular Glycobiology, Research Team for Mechanism of Aging, Tokyo Metropolitan Geriatric Hospital and Institute of Gerontology, Tokyo, Japan; 4) Structural Glycobiology Team, Systems Glycobiology Research Group, RIKEN-Max Planck Joint Research Center for Systems Chemical Biology, RIKEN Global Research Cluster Wako, Japan.

Glycosylation is an essential post-translational modification that underlies many biological processes and diseases. α-dystroglycan (α-DG) is a receptor for matrix and synaptic proteins that causes muscular dystrophy and lissencephaly upon its abnormal glycosylation (α-dystroglycanopathies). Here we identify the glycan unit ribitol 5-phosphate (Rbo5P), a phosphoric ester of pentose alcohol, in α-DG. Rbo5P forms a tandem repeat and functions as a scaffold for the formation of the ligand-binding moiety. We show that enzyme activities of three major α-dystroglycanopathy-causing proteins are involved in the synthesis of tandem Rbo5P. Isoprenoid synthase domain-containing (ISPD) is cytidine diphosphate ribitol (CDP-Rbo) synthase. Fukutin and fukutin-related protein are sequentially acting Rbo5P transferases that use CDP-Rbo. Consequently, Rbo5P glycosylation is defective in α-dystroglycanopathy models. Supplementation of CDP-Rbo to ISPD-deficient cells restored α-DG glycosylation. These findings establish the molecular basis of mammalian Rbo5P glycosylation and provide insight into pathogenesis and therapeutic strategies in α-DG-associated diseases.

A novel mutation p.Glu632Lys in *SH3TC2* gene causing Charcot-Marie-Tooth disease type 4C in a Chinese family. *M. Gu[1], Z. Yu[1], J. Zhang[1], Y. Xu[1], W. Shen[2].* 1) Dept. of Medical Genetics, Shanghai Jiao Tong University School of Medicine, Shanghai, China; 2) Dept. of Laboratory Medicine, Renji Hospital, Affiliated to Shanghai Jiaotong University School of Medicine, Shanghai, China.

Background The Charcot-Marie-Tooth disease (CMT) is one of the most common human inherited peripheral neuropathies. Major pattern of inheritance is autosomal dominant, with less often occurrence autosomal recessive and X-linked dominant/recessive inheritance. CMT is generally divided into three forms: demyelinating forms (CMT1), axonal forms (CMT2) and intermediate forms. The autosomal recessive form (AR-CMT1 or CMT4) is accompanied by progressive distal muscle weakness and atrophy of the limbs, pes cavus and claw-like hands, both often observed in CMT. In addition, CMT4 is also characterized by early onset, rapid progression, and varying degrees of sensory loss and spinal deformities. Eleven subtypes of CMT4 have been identified: from CMT4A to CMT4J. Some of these subtypes were clear in pathogenic mechanisms, some had founder mutation, but some still had limited clinical description and mutation analysis. **Objective** To identify potential mutation in a Chinese family affected with CMT4C and analyse the SH3TC2 protein structure. **Methods** Clinical data of a three-generation family from the Zhejiang Province of China was collected, and genomic DNA was extracted from peripheral blood samples of the family members. Seventy-two candidate genes of the proband were captured and sequenced by targeted next-generation sequencing, and the results were confirmed by Sanger sequencing. The protein structure was predicted with PyMOL-1 software. **Results** The proband presented with certain typical CMT4 phenotypes, including symmetrical muscle wasting and a predominating weakness of the distal parts of the lower limbs, pes cavus and claw-like hands. Furthermore, a novel homozygous missense mutation c.1894G>A (p.Glu632Lys) was identified in the exon 11 of *SH3TC2* gene in the index case. The heterozygous mutation (p.Glu632Lys) was also detected in the index case's father, mother and daughter, but not in the healthy family members and 300 normal controls. Retrieval of the NCBI, HGMD and 1000 genome databases has verified the c.1894G>A to be as a novel mutation. Computer simulation has suggested that the mutation has altered the 3D structure of the SH3TC2 protein. **Conclusions** The index case was identified as CMT4C, for which the underlying gene was *SH3TC2* gene. Our finding has expanded the spectrum of *SH3TC2* mutation in associated with CMT4C. This work is partially supported by National Natural Science Foundation of China (Proj. No. 30470951, 31071107).

Recurrent mutations in *HEXB* gene in using targeted sequencing. *S. Mikaeeli[1], R. Shervin-Badv[2,3], N. Mahdieh[4], S. Mikaeeli[5], B. Rabbani[2,4].* 1) Islamic Azad University, North Tehran Branch, Tehran, Iran, tehran, Alborz, Iran; 2) Children's Hospital Center, Tehran University of Medical Center; 3) Growth and Development Research, Tehran University of Medical Center; 4) Genetic Research Center, Rajaie Cardiovascular Medical and Research Center, Iran University of Medical Sciences, Tehran, Iran; 5) Islamic Azad University of Medical Branches, Tehran, Iran.

Sandhoff disease [MIM 268800] or GM2-gangliosidosis type 2 is a rare lysosomal storage disorder with autosomal recessive inheritance. There are different phenotypes for Ssandhoff disease based on biochemical varieties and age of onset including; infantile (acute form; <0.1% activity), late infantile and juvenile (subacute form; 0.5% activity) and adult (chronic; 2-4% activity). There are three types of lysosomal β-hexoaminidase enzyme which deficiency of hexoaminidase A (αβ) and B (ββ) activity is seen in Sandhoff disease. The *HEX* gene encoding β-subunits of these enzymes located on 5q13 chromosome and consists of 14 exons. Mutations in this gene lead to GM2 accumulation in neuronal lysosomes and causes fatal neurodegeneration and apoptosis of neurons. Here we present a patient with a mutation in *HEXB* gene. Genotype was determined by targeted-next generation sequencing (NGS) [P117] for 4 candidate genes (*HEXB, HEXA, GM2A, GLB1*). The determined mutation was confirmed by PCR-RFLP assay. Mutational analysis showed a homozygous mutation at position c.1602C>A of *HEXB* gene in exon 13 that has pathogenesis effects leading to early termination of amino acid sequence (Cys534Ter). RFLP-PCR of the consanguineous parents showed a heterozygous variant at position c.1602C>A. This mutation leads to elimination of last 23 amino acids from the C terminal loop. Also, a homozygous mutation was found at position p.Lys121Arg (c.362A>G) for another patient. The panel based analysis could be important for molecular diagnosis and confirmation of heterogonous phenotype in medical genetic.

2457F

Novel homozygous *SPG11* mutation in the molecular diagnosis of hereditary spastic paraplegia. *B. Burnyte, L. Ambrozaityte, V. Kucinskas, A. Utkus.* Dept. of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania.

Hereditary spastic paraplegia (HSP) is a heterogeneous group of neurodegenerative disorders. *SPG11* mutations are the most common cause of autosomal recessive HSP. *SPG11*, encoding spatacsin, is expressed ubiquitously in the nervous system, but most prominently in the cerebellum, cerebral cortex, hippocampus and pineal gland. The specific role of peptide remains unknown, though it seems to be essential to the survival of neurons. We report the case of a 26-year old male with early onset spasticity, axonal neuropathy, ataxia, dysarthria, narrowed field of vision, persistent acne and cognitive impairment. Next generation sequencing of the 98 genes related to neurodegenerative disorders was negative. Whole exome sequencing was performed to determine the genetic cause of our patient's phenotype. A novel homozygous mutation c.2431C>T; p.Q811* has been identified in the *SPG11* (rs756134516) gene consistent with the diagnosis of HSP type 11 (SPG11). In silico analysis predicts this variant to be disease causing, as the majority of missense/nonsense mutation group of *SPG11* created termination codon. Targeted whole exome sequencing data analysis based on a number of genes of selected neurodegenerative disorders allowed to exclude the presence of pathogenic mutations in other possible genes in the proband. Clinical resemblance between our patient and reported SPG11 cases suggests that the detected homozygous mutation is the phenotype causal mutation in our patient. Further studies are necessary to clarify the pathogenic mechanism of the detected mutation at the protein level as well as the role of SPG11 RNA transcript under both physiological and pathological conditions.

2458W

Enrichment of unamplified DNA and long-read SMRT Sequencing to unlock repeat expansion disorders. *J.M. Ekholm, Y. Tsai, D. Greenberg, T.A Clark.* Pacific Biosciences, Menlo Park, CA.

Nucleotide repeat expansions are a major cause of neurological and neuromuscular disease in humans, however, the nature of these genomic regions makes characterizing them extremely challenging. Accurate DNA sequencing of repeat expansions using short-read sequencing technologies is difficult, as short-read technologies often cannot read through regions of low sequence complexity. Additionally, these short reads do not span the entire region of interest and therefore sequence assembly is required. Lastly, most target enrichment methods are reliant upon amplification which adds the additional caveat of PCR bias. We have developed a novel, amplification-free enrichment technique that employs the CRISPR/Cas9 system for specific targeting of individual human genes. This method, in conjunction with PacBio's long reads and uniform coverage, enables sequencing of complex genomic regions that cannot be investigated with other technologies. Using human genomic DNA samples and this strategy, we have successfully targeted the loci of Huntington's Disease (HTT; CAG repeat), Fragile X (FMR1; CGG repeat), ALS (C9orf72; GGGGCC repeat), and Spinocerebellar ataxia type 10 (SCA10; variable ATTCT repeat) for examination. With this data, we demonstrate the ability to isolate hundreds of individual on-target molecules in a single SMRT Cell and accurately sequence through long repeat stretches, regardless of the extreme GC-content. The method is compatible with multiplexing of multiple targets and multiple samples in a single reaction. This technique also captures native DNA molecules for sequencing, allowing for the possibility of direct detection and characterization of epigenetic signatures.

[Background] Hereditary spastic paraplegia (HSP) is a neurodegenerative disorder characterized by spasticity and pyramidal weakness of the lower limbs. The causative genes for autosomal recessive HSP (ARHSP) are more heterogeneous than those of autosomal dominant HSP and about 60% of ARHSP patients remain to be elucidated. In the majority of the families, affected individuals are singletons, making it difficult to efficiently narrow the candidate region with linkage analysis. We tried to identify novel causative gene for ARHSP based on exome sequencing of index patients from individual families. [Methods] From 253 patients with HSP likely having autosomal recessive inheritance, 136 patients of undiagnosed HSP were enrolled. Non-synonymous, frameshift, and splicing variants whose minor allele frequencies were <0.2% were selected from exome data. We then searched for genes carrying biallelic rare variants that were shared by multiple families and were not shared by control subjects. [Results] We identified biallelic mutations in *CAPN1* in four patients. We found two homozygous nonsense mutations (c.461G>A, p.W154*; c.1153C>T, p.R385*) and one homozygous missense mutations (c.658G>A, p.G220R) in two families. Homozygous nonsense mutations strongly support loss-of-function mutations and the missense mutation is located in the conserved catalytic domain. The haplotypes surrounding the missense mutation were identical in the two families. The clinical presentations of these four patients are characterized by ataxia or dysarthria in addition to spastic paraparesis. Taken together with a missense mutation was found in dogs presenting with ataxia and spasticity, *CAPN1* is considered to be causative gene for complicated ARHSP. In addition, we identified nine other possible candidate genes including *AP5B1*, in which two index patients share biallelic mutations. In the present study, the causative mutations were found in 121 of the 253 patients (47.8%), including five SPG28 families showing retinitis pigmentosa as a novel phenotype in addition to spastic paraparesis. [Discussion] Utilizing exome data of singletons, we attempted to identify causative genes for ARHSP, focusing on genes with biallelic variants shared by multiple families. The fact that we identified *CAPN1* as a novel causative gene for ARHSP indicated that our study paradigm is efficient for identifying causative genes even though only singletons from individual families are available for the analysis.

Frontotemporal lobar degeneration (FTLD) is the third most common cause of dementia and accounts for about 5-10% of all dementia patients. Mutations in the granulin (*GRN*) gene represent about 5-10% of frontotemporal lobar degeneration (FTLD). We present the clinical and neuropathological features of a family with a novel *GRN* c.687T>A, p.(Tyr229*) mutation. The mutation was found in the proband of the family using whole exome sequencing. The mutation caused a severe FTLD neuropathological phenotype with TDP43 inclusions in the proband. The nephew of the proband was found to have similar but milder FTLD pathology and several other family members had had early-onset dementia. Gene expression studies using commercial TaqMan gene expression assay showed decreased *GRN* gene expression in mutation carriers' blood samples. The novel *GRN* mutation results in haploinsufficiency of *GRN* and a severe neuropathologic FTLD phenotype. .

2461W

Dominant mutations in the *ALDH18A1* gene cause hereditary spastic paraplegia SPG9. *E. Panza[1,2], J.M. Escamilla-Honrubia[3], C. Marco-Marín[3,4], N. Gougeard[3,4], G. De Michele[5], V. SPG9 (MIM 601162) is a form of autosomal dominant hereditary spastic paraplegia, mapped in two families of Italian and English origins. This complex form of spastic paraplegia is characterized by the presence of early cataracts, persistent vomiting and upper motor neuron signs. In the SPG9 critical region the *ALDH18A1* gene was present and previously associated with recessive disorders (MIM 219150), with some common traits among these forms. *ALDH18A1* encodes for Δ^1-pyrroline-5-carboxylate-synthetase (P5CS) a bifunctional enzyme (glutamate-5-kinase and reductase domains G5K and GPR), catalyzing the first step of ornithine and proline biosynthesis. In each family we identified one *ALDH18A1* mutation in heterozygosis, cosegregating with the disease. The mutations identified, c.727G>C (p.Val243Leu) or c.755G>A (p.Arg252Gln), are in the exon 7 of the *ALDH18A1* gene, and are positioned nine amino acids apart in the sequence of the glutamate-5-kinase (G5K) component of P5CS. These mutations did not prevent synthesis nor cause cellular mislocalization of the P5CS protein, as judged by fluorescence microscopy of the transiently expressed GFP-tagged P5CS in CHO cells, or by P5CS immunofluorescence of patient fibroblasts. Low fasting plasma ornithine, citrulline and hydroxyproline in SPG9 patients suggested a loss-of-function of P5CS. Indeed, when these mutations have been introduced into recombinant human P5CS, they essentially inactivated the enzyme activity and promoted dissociation of the P5CS hexamer. To reconcile the loss-of-function effect with the dominant inheritance, we propose a dominant negative effect in which even the presence of a single mutant subunit introduces architectural defects in the P5CS oligomer that inactivate the entire oligomer of bifunctional subunits. In summary, dominant mutations in *ALDH18A1* cause SPG9. The existence of another very rare condition associated to *ALDH18A1*, presenting with a similar phenotype but having recessive inheritance indicates that *ALDH18A1* mutations can be associated with recessive or dominant inheritance in an allele-specific way. An accurate comparison of the phenotypes and mutations of the *ALDH18A1*-related disorders is necessary to better understand the pathogenetic mechanism of these group of conditions. *Grants: Telethon Fondation Onlus, GGP06209 & GGP10121 (AMS,Gubbio) & It.Min.Health; (VR) PrometeoII/2014/029 (Valencian Government) and BFU2014-58229-P (Spanish Government).*

First report of a contraction of the *C9ORF72*-**hexanucleotide repeat expansion.** *P. Weydt[1], T. Mussotter[2], V. Müller[1], A. Knehr[1], J. Weishaupt[1], A. Ludolph[1], C. Kubisch[3], A. Volk[3].* 1) Neurology, Univ Ulm, Ulm, Germany; 2) Human Genetics, Univ Ulm, Germany; 3) Human Genetics, Univ Medical Center Hamburg-Eppendorf, Germany.

The GGGGCC-repeat expansion in *C9orf72* is the most frequent mutation in patients with amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) and one of the most common genetic causes of a neurodegenerative disease in general. The exact cut-off between normal, intermediate and pathologic alleles is currently unclear. Also, our understanding of possible genotype-phenotype correlations is still evolving. Studies applying Southern-blot (SB) analyses reported smaller repeat expansion in patients with an earlier age of onset. However another study reported a healthy elderly man carrying an intermediate repeat who transmitted larger expanded alleles to several affected children. The latter would be in line with the phenomenon of anticipation as observed in the majority of currently known repeat diseases. Here, we present a family in which a 70 year old male was diagnosed with ALS according to the revised El Escorial criteria. As his father had died of ALS at the age of 57 a familial form was suspected. Indeed, genetic testing confirmed the diagnosis and revealed a non-expanded allele with 5 repeats and expanded allele with 1800-2400 repeats as determined by PCR-based techniques and SB analysis. Subsequently, one of his children opted for predictive genetic testing to learn about his personal risk for *C9orf72*-associated diseases. The neurological exam in this 38 year old man was unremarkable. Genetic testing showed one allele with 2 repeats and one carrying 100-120 repeats. As an inheritance of the expanded allele by the mother was excluded and paternity was confirmed by genetic testing with polymorphic markers the most plausible explanation for the presence of the 100-120 repeat allele is a contraction of a larger expanded allele or somatic mosaicism in the father. Both scenarios highlight our currently limited knowledge on the *C9orf72* repeat and the resulting challenges for genetic counselling. If the father has a somatic mosaicism at least a larger expansion could be detected in blood cells and somatic instability with larger expansions within the brain have been described in other patients before. Also, a repeat contraction seems difficult to interpret in this context as the exact cut-off for pathologic alleles remains to be determined and smaller repeat expansions had been associated with an earlier age of onset.

2463F

Genetic analysis of Parkinsonism among Norwegian patients. *E. Gustavsson[1,2,3], J. Trinh[1], I. Guella[1], M. McKenzie[1], J. Aasly[2,3], M. Farrer[1].* 1) Djavad Mowafaghian Centre for Brain Health, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Neuroscience, Norwegian University of Science and Technology, Trondheim, Norway; 3) Department of Neurology, St. Olav's Hospital, Trondheim, Norway.

Parkinson's disease (PD) is an age-associated disease and the second most common neurodegenerative disease. It is a heterogeneous clinical syndrome characterized by a range of motor symptoms. Definitive and early diagnosis is imperative for optimal treatment, clinical trials and biomarker research. Approximately 14% of patients report a positive family history of PD. Many causal genes have been linked to parkinsonism including mutations in *SNCA*, *LRRK2, VPS35, DNAJC13, ATP6AP2* and *CHCHD2* in late-onset dominant disease, and in *PRKN and PINK1* in recessive early-onset parkinsonism. Mutations in *DJ-1, ATP13A2, PLA2G6, FBXO7, DNAJC6* and *SYNJ1* also result in recessive early/juvenile-onset parkinsonism albeit with atypical presentations. We have studied 105 unrelated patients with early-onset parkinsonism and the probands of 11 pedigrees with multi-incident late-onset dominant PD. All subjects are of Norwegian origin. Genome-wide SNP genotyping has been performed using the Illumina Multi-Ethnic Genome Array (MEGA) and whole-exome sequencing has been completed using the Ion AmpliSeq™ Ion Proton system. Initially we describe variability in genes previously shown to cause PD/parkinsonism for all patients with early-onset disease, familial affected probands and 50 control subjects. Disease in none of the 11 pedigrees is explained by previously known genes. However, 16 patients with early-onset disease were seen carrying pathogenic variants in genes previously implicated in parkinsonism. Subsequently, CNV analysis from MEGA has identified a significant burden of duplications among patients, including a subset highlighting genes for dystonia, a prevalent phenotype among patients with parkinsonism. Mapping of novel variability within shared runs of homozygosity, in patients with early-onset parkinsonism and segregation analysis within multi-incident pedigrees has nominated novel genetic variability as causal. These findings and their further evaluation within additional case-control series will be reported.

2464W

Analysis of mitochondria-related gene from clinically suspected Charcot-Marie-Tooth patients. *Y. Hiramatsu[1], Y. Okamoto[1], A. Yoshimura[1], M. Ando[1], J. Yuan[1], Y. Higuchi[1], A. Hashiguchi[1], S. Tsuji[2], H. Takashima[1].* 1) Department of Neurology and Geriatrics, Kagoshima University Graduate School of Medicine and Dental Sciences, Kagoshima city, Japan; 2) Department of Neurology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

Background Charcot-Marie-Tooth (CMT) disease is a clinically and genetically heterogeneous disorder that causes inherited distal symmetric peripheral neuropathy. In spite of more than 80 causative genes linked to CMT till now, the unexpected low detection rate suggests more undiscovered genes that could result in CMT phenotype. Mitochondria-related gene like *MFN2* and *GDAP1* are well known CMT disease-causing genes, and patients with mitochondrial disorders could develop peripheral neuropathy. Methods We enrolled 768 clinically suspected CMT patients. We first screened the CMT disease-causing genes using DNA microarray (Affymetrix; 27 genes) or targeted resequencing (Illumina MiSeq; 40 genes). All of the mutation-negative patients in these pre-screening underwent a whole-exome sequencing (WES). On the basis of their inheritance pattern, 247 CMT patients grouped as autosomal recessive (AR) or sporadic were selected for a further analysis with 167 mitochondria-related genes. Results In the pre-screening state, the most common mitochondria-related gene was *MFN2*, in which pathogenic mutations were detected from 47 patients. *GDAP1* mutation, as the second common reason, was identified in 6 patients. All of these mutations were previously described or validated by segregation analysis. Additionally, using WES, we detected seven novel likely pathogenic variants from 167 mitochondria-related genes. These patients presented with diverse neurological symptoms, comprising encephalopathy, mental retardation, optic atrophy, and hearing loss. Conclusions Since mitochondrial dysfunction frequently leads to polyneuropathy, it is essential to check the mitochondria-related genes in patients with a CMT phenotype, particularly for the patients accompanied with additional neurological findings like encephalopathy or optic atrophy.

2465T

Loss of glycine transporter 1 (GLYT1) causes congenital abnormal muscle tone, arthrogryposis, respiratory failure and mildly elevated CSF glycine. *A. Kurolap[1,2], T. Hershkovitz[1], A. Mory[1], T. Paperna[1], G. Tal[3], Y. Nijem[4], E. Sella[4], N. Ekhilevitch[1,2], H. Mandel[2,3], H.N. Baris[1,2].* 1) The Genetics Institute, Rambam Health Care Campus, Haifa, Israel; 2) Rappaport School of Medicine, Technion – Israel Institute of Technology, Haifa, Israel; 3) Metabolic Unit, Rambam Health Care Campus, Haifa, Israel; 4) Pediatric and Neonatal Unit, Nazareth Hospital EMMS, Nazareth, Israel.

Glycine is a major neurotransmitter in inhibitory synapses, activating the glycine receptor, as well as a co-agonist at the glutamatergic NMDA receptors in excitatory synapses. Two high-affinity substrate-selective transporters, glycine transporter-1 and glycine transporter-2 (GLYT1 and GLYT2), play critical roles in regulating intra and extracellular glycine concentrations within the CNS. Glycine dysregulation has been linked to several conditions, including hyperekplexia, and nonketotic hyperglycinemia (NKH). We report four patients originating from two unrelated consanguineous Muslim-Arab kindred from Israel. All patients presented at birth with facial dysmorphism, encephalopathy, severe arthrogryposis with extreme hyperextension of the knee joints, hip dislocations, respiratory failure necessitating mechanical ventilation, and hypotonia progressing to hypertonicity with clonus. Three babies died between ages two days and eight months. One patient, currently two years-old, has been ventilation free for the last several months; she gained social smile and reaches for objects. Mildly elevated cerebrospinal fluid (CSF) glycine levels with normal serum glycine were found in two patients. Whole exome sequencing of the first studied patient of family 1 revealed a rare homozygous frameshift variant in exon 6 of *SLC6A9* which encodes GLYT1. The variant co-segregated as expected within the extended family. Variants related to NKH and hyperekplexia genes were excluded. The phenotypic similarity of the three siblings of family 2 prompted Sanger sequencing of *SLC6A9*, which revealed a homozygous nonsense variant in exon 12, co-segregating appropriately. The essential role of GLYT1 in CNS function has been underscored by the lethal phenotype of homozygous knockout mice, which had severe motor and respiratory deficits and died during the first postnatal day. Zebrafish with *SLC6A9* homozygous missense mutation show diminished escape responses and absent swimming. Noteworthy, several GlyT1-knockout mice escaped premature death, as was seen in the surviving patient; therefore, it is thought that GlyT1 is critical early in life but its role may be compensated thereafter. While GLYT1 has been previously proposed in the etiology of NKH, this is the first description of *SLC6A9* mutations causing a unique human neurological syndrome. The mildly elevated CSF glycine in the presence of normal serum glycine may constitute a diagnostic marker for glycine transporter 1 defects.

Mutations in *RALGAPB* cause seizures, intellectual disability and cortical malformations. *A.A. Larson[1], A.M. Quintana[2], H.C. Yu[1], E.A. Geiger[1], J.A. Hernandez[2], N.V. Stence[3], R.I. Kuzniecky[4], N.J.L. Meeks[1], C.R. Coughlin II[1], T.H. Shaikh[1].* 1) University of Colorado School of Medicine, Department of Pediatrics, Section of Genetics; 2) University of Texas, El Paso, Department of Biological Sciences, Border Biomedical Research Center; 3) University of Colorado School of Medicine, Department of Radiology; 4) New York University School of Medicine, Department of Neurology, NYU Epilepsy Center.

Malformations of cortical development (MCD) are disorders of neurological morphogenesis that may be diagnosed in the setting of seizures and developmental delay. Ocular and endocrine abnormalities may coexist with MCD. We performed trio-based whole exome sequencing (WES) on subjects with MCD as well as optic nerve hypoplasia (ONH) and pituitary hormone deficiency (also known as septo-optic dysplasia). One subject with infantile spasms (IS), severe developmental delay, ONH, perisylvian polymicrogyria and panhypopituitarism was found to have compound heterozygous rare missense variants in *RALGAPB*: c.1980A>G (p.Lys640Glu) and c.2324G>T (p.Arg775Leu). *RALGAPB* encodes a Ral GTPase activating protein. It forms a heterodimeric enzyme with RALGAPA1, for which haploinsufficiency leads to brain malformations. The RALGAP complex downregulates signaling of RalA and B, which are involved in several intracellular signaling pathways. Notably, one of these pathways is the mTOR signaling pathway, which is disrupted in many known causes of MCD. Additionally, *RALGAPB* has been identified as a candidate gene in two large published cohorts of individuals with neurodevelopmental diseases that did not include detailed phenotypic data. We present detailed phenotypic data on one of these individuals reported by the Epi4K consortium with a *de novo* nonsense variant, c.3860C>G (p.Ser1287*), in *RALGAPB*, who had IS, focal cortical dysplasia and developmental delay. The second *de novo* variant, c.865_866delAT (p.Met289Valfs*3), was reported as part of a large cohort of individuals with autism. We were unable to obtain further phenotypic data for this individual. We performed morpholino knockdown of *ralgapb* in zebrafish, showing disruption of brain development, including malformation of the optic tectum and enlargement of the fourth ventricle. Injection of human wild type *RALGAPB* mRNA resulted in phenotype that overlapped those observed in the morphants, while higher concentrations of *RALGAPB* mRNA resulted in nonviable embryos, suggesting that *RALGAPB* overexpression may also be detrimental. Thus, our data suggest that either haploinsufficiency, due to dominant *de novo* variants or compound heterozygosity of missense variants, leading to partial loss of function in both alleles of *RALGAPB*, may lead to abnormalities in nervous system development and resultant neurological disease.

Genetic and clinical modifiers of age at onset in SPAST inherited spastic paraplegia. *L. Parodi[1], G. Banneau[2], F. Danjou[1], J. Guegan[1], E. Petit[1,2], S. Aitsaid[2], S. Fenu[1,2], S. Tezenas du Montcel[3], G. Stevanin[1,2,4], A. Brice[1,2], C. Depienne[5], A. Durr[1,2].* 1) ICM Institut du Cerveau et de la Moelle, INSERM U1127, CNRS UMR7225, Sorbonne Universités – UPMC Université Paris VI UMR_S1127, Paris, France; 2) APHP Department of Genetics, Groupe Hospitalier Pitié-Salpêtrière, Paris France; 3) Sorbonne Universités, UPMC Univ Paris 06 UMR_S1136, and INSERM UMR_S 1136, Institut Pierre Louis d'Epidémiologie et de Santé Publique, F-75013, Paris, France; 4) Ecole Pratique des Hautes Etudes (EPHE), Paris Sciences et Lettes (PSL) Research University, Neurogenetics team, 75013 Paris, France; 5) Institut de Génétique et de Biologie Moléculaire et Cellulaire, INSERM U964, CNRS UMR7104, Strasbourg, France.

Hereditary spastic paraplegias (HSPs) are a group of neurological disorders caused by a progressive upper motoneuron degeneration, resulting in spastic gait as core feature. HSPs are genetically heterogeneous, with at least 59 genes involved. *SPAST*/SPG4 encoding Spastin, a microtubule severing protein, is the most frequently mutated HSP gene, involved in 20-40% of HSPs. The resulting phenotype is characterized by an extreme variable age at onset, ranging from birth up to 70 years, including also unaffected mutation carriers. The aim of our study is to analyze *SPAST* mutation carriers and to search for modifiers such as genetic variants and/or environmental factors. We performed Sanger sequencing and WES in French HSP patients, collected through the SPATAX network and national reference centers for rare diseases in France. We applied a web-based questionnaire assessing environmental factors impact on the disease. Ninety-two questionnaires from *SPAST* carriers have been collected yet. One third (n=621) out of 2123 HSP patients screened for *SPAST* harbored a mutation, with 80% of point mutations mainly affecting Spastin ATPase activity domain. Mean age at onset was 29 ±19 years (from birth to 74 years, n=328) and mean disease duration 17±14 years (from 0 to 66 years, n=328). After assessing the disease severity using the SPATAX disability scale (0, absence of any functional handicap, to 7, bedridden; n=158), we observed that patients with a disease onset after 30 years tended to have a faster disease progression, i.e. faster disease progression seemed to be linked to older age. Survival analysis showed earlier onset associated with missense mutations, predicted pathogenic by at least 3 algorithms. Focusing on the detection of variants possibly modifying age at onset and severity, we identified 12 patients (0,6 %) carrying p.S44L variant, a previously described *SPAST* intragenic modifier, in combination with another major *SPAST* mutation. It was associated to early onset in a *SPAST* mutated family and to late onset in a SPG7 patient. To research other *SPAST* genetic modifiers, we performed WES on 34 SPG4-HSP patients. We detected in two early onset patients the presence of *HSPD1* variant p.G563A, already proposed as age at onset modifier. Our analysis showed evidence of age at onset variations linked to the nature of *SPAST* mutations in a large French cohort and confirmed the role of variant p.S44L, and possibly of variant p.G563A, as age at onset modifiers.

2468T

Whole-exome sequencing in a four-generation family with neuromyotonia and muscle weakness. *E.M. Ramos[1], A. Huang[1], D. Dokuru[1], Q. Wang[1], B. Merriman[2], G. Bettinsoli[1], D. Geschwind[1], A. Woo[3], G. Coppola[1].* 1) Department of Psychiatry and Semel Institute for Neuroscience and Human Behavior, David Geffen School of Medicine at the University of California Los Angeles; 2) Department of Human Genetics, David Geffen School of Medicine at the University of California Los Angeles; 3) Santa Monica Neurological Consultants, David Geffen School of Medicine at the University of California Los Angeles.

We identified a large, four-generation family with an autosomal dominant history of neuromuscular disease, with affected individuals showing proximal hip flexor weakness, neuromyotonia and periodic paralysis attacks. To identify the genetic determinants in this family, we initially performed identity-by-descent mapping in five affected and three unaffected family members using genome-wide SNP genotyping with 250K arrays. This approach identified five candidate loci (segregating haplotypes on chromosomal regions 1p31.1-p22.2, 1q32.3-q41, 2p11.2-q14.1, 11q22.1-q22.3 and 11q25) spanning a total of 43.4Mb. We then performed whole-exome sequencing in all subjects. Briefly, paired-end sequence reads (sequenced on an Illumina HiSeq2500 using a SeqCap EZ Exome capture library) were mapped to the GRCh37/hg19 reference genome and variants were interactively joint-called with GATK Haplotype Caller according to GATK Best Practices recommendations. A total of ~116,000 variants were identified in the five affected and three unaffected samples sequenced. We filtered out variants not segregating with the disease and all non-coding and synonymous changes. Then, under the assumption that the mutation causing this rare autosomal dominant disease is extremely rare, we also excluded variants that are present in the databases with a minor allele frequency greater than 1%. After applying these filtering criteria, we narrowed our search to seven putative disease-causing variants. Of these, six are located in genes within the candidate loci, one of which is a strong biological candidate gene. We are currently following up on these results and recruiting additional family members.

2469F

Partial duplication of *Desert hedgehog* **(***DHH***) gene in patients with minifascicular neuropathy accompanied by 46XY partial gonadal dysgenesis.** *N. Sato[1,2], R. Maekawa[2], H. Ishiura[1], J. Mitsui[1], H. Naruse[2], K. Sugie[3], J. Shimizu[1], J. Goto[4], S. Tsui[1], Y. Shiio[2].* 1) Neurology, The University of Tokyo, Tokyo, Japan; 2) Department of Neurology, Tokyo Teishin Hospital, Tokyo, Japan; 3) Department of Neurology, Nara Medical University, Nara, Japan; 4) Department of Neurology, International University of Health and Welfare Mita Hospital, Tokyo, japan.

Minifascicular neuropathy (MN) is an extremely rare developmental malformation in which peripheral nerves are composed of many small fascicles. Only one case, who was associated with 46XY gonadal dysgenesis (GD), carried a homozygous missense mutation at the initiating codon in exon 1 of the *desert hedgehog* (*DHH*) gene. Molecular genetics of the other cases, however, have not been delineated. *DHH* is a member of the hedgehog family which also includes sonic hedgehog and indian hedgehog, and responsible for signals for the formation of the connective tissue sheathing around peripheral nerves during early development. Here, we analyzed molecular basis of two consanguineous Japanese families with MN. Two of the patients showed 46XY GD, whereas a patient with 46XX karyotype apparently shows normal sexual development. We performed multipoint parametric linkage analysis based on results of genotyping by SNP-array 6.0 (Affymetrix, Santa Clara, CA) in samples from the three affected individuals. After multipoint LOD score calculations using the pipeline software SNP-HiTLink under the assumption of autosomal recessive inheritance, five regions in four chromosomes with the highest multipoint LOD scores of 2.10. The candidate regions overlapped with the locus of *DHH* on chromosome 12. We next tried to amplify the entire *DHH* region employing a long-range PCR method. The size of the PCR products of each individuals was larger by several hundred basepairs than that obtained from a control, suggesting a rearrangement of the genome. Direct nucleotide sequence analysis of the PCR products revealed the tandem duplication of which the 5'-end was in intron 1 and 3'-end in exon 2 of *DHH* gene. Haplotype analysis showed a common founder chromosome. In conclusion, we identified a novel mutation in a human *DHH* gene. The patients with 46XY karyotype exhibited MN accompanied by 46XY GD, whereas a patient with 46XX karyotype apparently shows normal sexual development. These data further support that *DHH* is an important molecule in both male gonadal differentiation and perineural formation in peripheral nerves.

2470W

Whole-exome sequencing identifies a missense mutation in *hnRNPA1* **in a family with flail arm amyotrophic lateral sclerosis.** *S. Shu[1,3], Q. Liu[2,3], R.R. Wang[1,3], F. Liu[1,3], B. Cui[2,3], X.N. Guo[1,3], C.X. Lu[1,3], X.G. Li[2,3], M.S. Liu[2,3], B. Peng[2,3], L.Y. Cui[2,3], X. Zhang[1,3].* 1) McKusick-Zhang Center for Genetic Medicine, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing 100005, China; 2) Department of Neurology and Laboratory of Clinical Genetics, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing 100005, China; 3) Neuroscience Center, Chinese Academy of Medical Sciences, Beijing 100005, China.

Flail arm syndrome (FAS), one of the atypical subtypes of amyotrophic lateral sclerosis (ALS), is typically described as slowly progressive, predominantly proximal, symmetric weakness and wasting of the upper limbs, with no significant lower limb or bulbar muscle disability for several years. Here we report the identification of the disease-causing gene of a family diagnosed as FAS. Using targeted next-generation sequencing, we excluded 24 known ALS genes. We detected a novel missense mutation in *hnRNPA1*, c.862/1018C>T (p.P288S/P340S) through whole-exome sequencing, and it was co-segregated with disease in the FAS family. HnRNPA1 belonging to the hnRNP family, is a widely expressed nuclear protein and shuttles continuously between the nucleus and cytoplasm. The mutation substituted the exact proline residue in the encoded PY-nuclear localization signal (NLS) of hnRNPA1 protein, and the residue is highly conserved in evolution. Mutant *hnRNPA1* showed altered intracellular localization, resulting in formation of cytoplasmic inclusions that co-localized with stress granules in transfected Hela cells. Further mutation screening of *hnRNPA1* in additional 251 Chinese patients with ALS (including 7 sporadic FAS) detected two rare variants with unknown significance. These variants lie in the prion-like domain of hnRNPA1 long isoform, which was detected exclusively in the central nervous system. Our results suggest that *hnRNPA1* is the causative gene in the family with flail arm ALS. This further expanded disease phenotype of *hnRNPA1* mutations.

2471T

Recessive porphyria due to homozygous *HMBS* **mutation: A cause of leukodystrophy with cataracts.** *C. Stutterd[1,2,3], V. Lukic[4], P. Diakumis[4], R. Fullinfaw[5], J. Archer[6], R. Leventer[1,2,3], M. Bahlo[4], P. Lockhart[2,3], M. Delatycki[2,3].* 1) Royal Children's Hospital , Melbourne, Victoria, Australia; 2) Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 3) University of Melbourne, Melbourne, Victoria, Australia; 4) Walter and Eliza Hall Institute, Melbourne, Victoria, Australia; 5) Royal Melbourne Hospital, Melbourne, Victoria, Australia; 6) Austin Hospital, Melbourne, Victoria, Australia.

We have identified a new genetic and potentially-treatable cause for leukodystrophy with cataracts and expanded the known phenotype associated with the rare occurrence of recessive acute intermittent porphyria (AIP). Two adult siblings from a consanguineous family were referred for whole exome sequencing (WES) as part of a gene discovery project investigating unclassified leukodystrophies. They share a novel phenotype characterised by leukodystrophy, childhood-onset cataracts, progressive ataxia, lower limb spasticity and peripheral neuropathy. Their cerebral MRI shows periventricular demyelination with thalamic cavitations. WES identified a homozygous variant in *HMBS* (c.251C>A, p.A84D) in both affected siblings. Their parents and two unaffected siblings were found to be heterozygous for this variant. The pathogenicity of this variant has been demonstrated by reduced erythrocyte HMBS activity in the proband to 20% normal. Heterozygous variants in this gene cause acute intermittent porphyria (AIP), a dominantly inherited neurological disorder with reduced penetrance. Only six cases of recessive AIP have been reported, all presenting in early childhood with severe central and peripheral neurological impairment, four with childhood onset cataracts and one found to have leukodystrophy. All had <4% of normal HMBS activity and died in childhood. The level of residual HMBS activity appears to correspond with disease severity. There are no reported cases of adults with recessive AIP and so this finding represents a novel phenotype and a new genetic cause for leukodystrophy with cataracts. The less affected of the two sibs is being worked up for liver transplantation with the aim of halting progression of this neurodegenerative disorder.

2472F

Genome-wide association study identifies potential genetic modifiers in Charcot-Marie-Tooth Disease type 1A. *F. Tao[1], G. Beecham[1], A. Rebelo[1], S. Blanton[1], L. Abreu[1], F. Baas[2], B.O. Choi[3], D. Pareyson[4], M. Reilly[5], M. Shy[6], S. Zuchner[1], Inherited Neuropathy Consortium.* 1) University of Miami Med School, Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Genome Analysis, Academic Medical Centre, Amsterdam, The Netherlands; 3) Department of Neurology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; 4) Department of Clinical Neurosciences, C. Besta Neurological Institute, Milan, Italy; 5) MRC Centre for Neuromuscular Diseases, UCL Institute of Neurology, London, UK; 6) Department of Neurology, University of Iowa, Iowa City, Iowa.

   Charcot-Marie-Tooth disease type 1A (CMT1A) is caused by a uniform 1.5-Mb duplication on chromosome 17p11.2, which includes peripheral myelin protein 22 (*PMP22)* gene. It is the most common subtype of inherited peripheral neuropathies, and is estimated to affect 1 in 10,000 individuals worldwide. CMT1A patients usually present the classic CMT phenotype, but also with high clinical variability in their phenotypic presentation and disease severity. The cause of the phenotypic variability is largely unclear. This study uses genome-wide association study (GWAS) to identify potential genetic variants that modify the severity of motor function involvement in CMT1A. Using Illumina OmniExpress platform, we analyzed 647,267 genomic markers of 303 CMT1A patients from European ancestry: 165 individuals with severe foot dorsiflexion (MRC score of 0 to 3), and 138 individuals with mild foot dorsiflexion (MRC score of 5). Association analyses were performed using R package GWAF, adjusting for patients' age at exam, sex and family relations in the framework of logistic regression via generalized estimating equations. After Bonferroni corrections, three SNPs showed genome-wide significance in association with severe foot dorsiflexion: rs10910527 (chr1:232509189, P=1.851E-08, odds ratio=12.3, 95% confidence interval=(5.1,29.5)), rs7536385 (chr1:232601208, P=1.851E-08, odds ratio=12.3, 95% confidence interval=(5.1,29.5)), rs4649265 (chr1:232591925, P=2.010E-08, odds ratio=10.1, 95% confidence interval=(4.5,22.7)). The three SNPs are in high linkage disequilibrium, and all locate within intronic regions of signal induced proliferation associated 1 like 2 (*SIPA1L2*), which codes for a putative GTPase with unknown functions. Neuro-2a cells transfected with SIPA1L2-Myc plasmid showed colocalization of SIPA1L2 with actin in growth cones of axonal projections, suggesting potential involvement of *SIPA1L2* in neuronal cell functions. Our results suggest genetic variants in *SIPA1L2* as potential modifiers in the severity of motor function impairment in CMT1A. We are currently analyzing whole genome sequencing data of phenotypically extreme patients to pinpoint specific genetic variation underlying this statistical signal. We will also conduct functional studies to further characterize the role of *SIPA1L2* in the disease.

2473W

Identification of a novel *LAMC3* variant in a girl with seizures, global developmental delay and cortical malformation. *J. Zambonin[1], S. Venkateswaran[2], Y. Xi[3], T. Hartley[4], K. Boycott[1,4], J. Parboosingh[3], D. Dyment[1,4], Care4Rare Canada Consortium.* 1) Department of Medical Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Department of Pediatrics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 3) Department of Medical Genetics and Alberta Children's Hospital Research Institute, University of Calgary, Calgary, Alberta, Canada; 4) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada.

   Occipital cortical malformations (OCCM; MIM 614115) are rare autosomal recessive malformations characterized by pachygyria and polymicrogyria of the occipital lobes. Affected individuals have childhood onset seizure disorders including absence, myoclonic-atonic and generalized tonic-clonic semiology. Homozygous or compound heterozygous mutations in the gamma-3 chain isoform of laminin (gamma-3 or *LAMC3*) gene are causative for this condition. Laminins are a family of extracellular matrix glycoproteins that are necessary for cell adhesion, differentiation, migration and neurite outgrowth. LAMC3 is expressed in the developing fetal brain and is vital for neuronal migration and cortical organization. Until now, only four cases of OCCM with variants in *LAMC3* have been reported in three unrelated individuals and six siblings from a large consanguineous family. All mutations were predicted to result in premature truncation of the *LAMC3* gene product with one individual having a compound heterozygous missense mutation and truncating mutation. Here, we report a novel and likely pathogenic variant in *LAMC3* identified by next-generation sequencing. Our patient was a 13 year old female born to consanguineous parents. She presented with myoclonic, atonic and atypical absence seizures and global developmental delay in keeping with others with mutations in *LAMC3*. Of note, neuroimaging showed bilateral temporoparietal pachygyria and polymicrogyria with only mild involvement of the occipital lobe rather than isolated occipital involvement. Microarray testing did not show any pathogenic copy number variants however there was extensive loss of heterozygosity. Next-generation sequencing was performed using a capture kit that targets over 4800 clinically-relevant disease genes. She was found to have the homozygous and likely pathogenic variant NM_006059.3:c.3190C>T (p.Gln1064*) in *LAMC3*. This mutation has not previously been reported and was predicted to cause a premature truncation of LAMC3. We describe this novel variant in *LAMC3* and expand the phenotype of OCCM to include pachygyria and polymicrogyria in a distribution pattern that involves the posterior parietal and temporal lobes. Therefore the role of LAMC3 appears to extend beyond cortical organization of the occipital regions.

2474T

***CDH18* and *C4orf21* (*ZGRF1*) variants segregate separately in two multigenerational families with overlapping phenotypic presentations of childhood apraxia of speech.** *B. Peter[1,2,3], E.M. Wijsman[4,5], A.Q. Nato[4], M.M. Matsushita[4], K.L. Chapman[6], I.B. Stanaway[7], J. Wolff[4], K. Oda[4], V.G. Gabo[4], W.H. Raskind[4,8], University of Washington Center for Mendelian Genomics.* 1) Speech & Hearing Sci, Arizona State University, Tempe, AZ; 2) Communication Sciences and Disorders, Saint Louis University, Saint Louis, MO; 3) Speech and Hearing Sciences, University of Washington, Seattle, WA; 4) Medical Genetics, Dpt. of Medicine, University of Washington, Seattle, WA, United States; 5) Biostatistics, University of Washington, Seattle, WA, United States; 6) Communication Sciences and Disorders, University of Utah, Salt Lake City, Utah, United States; 7) Environmental and Occupational Health, Environmental Toxicology, University of Washington, Seattle, WA, United States; 8) Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, United States.

Childhood apraxia of speech (CAS) is a severe speech sound disorder characterized by difficulty translating articulatory intentions into precisely timed and coordinated movement sequences. There is evidence that CAS has a genetic etiology, for instance rare inherited *FOXP2* point mutations or a *de novo BCL11A* deletion, but in most cases, the causal variations remain unknown. Here, we present two multigenerational families with familial CAS. Phenotypic manifestation in the two families overlap partially whereas genetic profiles differ completely. Linkage analysis, IBD analysis, and exome sequencing showed that in Family A, affected members share a *CHD18* variant; additional variants of interest were found in *MYO10, NIPBL, GLP2R, NCOR1, FLCN, SMCR8, NEK8,* and *ANRKD12.* In Family B, the affected members share a rare and deleterious *C4orf21* (*ZGRF1*) variant.   Here, we extend these results to phenotypic characteristics associated with inheritance of each genomic region. In both families, affected children did not produce intelligible speech until age 5 or 6 years and required between three and seven years of speech therapy to acquire normalized speech. Affected children and adults with a CAS history in both families had difficulty with nonword imitation and rapid nonword reading, tasks that require intact phonemic awareness, sequential processing, and motor programming. In Family A, affected members showed additional sequential processing deficits in the oral motor domain in that speeds during rapid syllable repetition in the alternating (e.g., /pata/) but not repetitive (e.g., /papa/) condition were slower than expected. In Family B, additional sequential processing deficits were seen during nonword imitation in that substantially more phoneme sequencing than phoneme substitution errors were made. *CDH18, C4orf21,* and five of the other genes of interest are expressed in the cerebellum, a brain region previously implicated in imaging studies of individuals with *FOXP2* mutations and known to influence temporal coordination of not only motor but also linguistic processes. To what extent the phenotypic similarities and differences in the sequential processing deficit are due to gene-specific influences on the brain remains to be investigated. Results are consistent with the view that, similar to other neurodevelopmental disorders CAS is both phenotypically and genetically heterogeneous and may result from single or multiple variations.

Evaluating motor functions and biomarkers for Fukuyama type congenital muscular dystrophy. *M. Taniguchi[1], R. Harada[2], N. Tatsuya[3], H. Awano[1], L. Tomoko[4], Y. Takeshima[4], K. Kobayashi[5], I. Morioka[1], K. Iijima[1], T. Toda[5].* 1) Pediatrics, Kobe Univ Grad Sch Med, Kobe, Hyogo, Japan; 2) Rehabilitation Medicine, Kobe Univ Grad Sch Med, Kobe, Hyogo, Japan; 3) Radiology, Kobe Univ Grad Sch Med, Kobe, Hyogo, Japan; 4) Pediatrics, Hyogo Medical College, Nishinomiya, Hyogo, Japan; 5) Neurology/Mol Bra Sci, Kobe Univ Grad Sch Med, Kobe, Hyogo, Japan.

Fukuyama type congenital muscular dystrophy (FCMD) is an autosomal recessive, severe childhood muscular dystrophy with brain and eye involvement. FCMD is mainly caused by an ancestral insertion of 3-kb SVA (SINE-VNTR-*Alu*) type retrotransposal element into the 3' untranslated region of the causative gene, *fukutin*. Recently, we testified that pathogenic exon trapping by SVA transposon cause splicing abnormality in FCMD. We also succeeded in optimizing antisense oligonucleotides therapy for FCMD model mice and FCMD myoblasts. Since FCMD is an incurable disease, there has been no biomarkers for FCMD. Moreover, there is few study on natural history of FCMD. There is a need to develop sensitive, non-invasive outcome measures of FCMD patients that can be readily available to human clinical trials in the near future. To find specific serum biomarkers and to comprehend natural history of FCMD patients, we collected serum and clinical data from patients. We tested on serum biomarkers by measuring muscle specific microRNAs. Clinical data contains motor function score, muscle elastography (shear wave elastography (SWE), and whole body muscle computed tomography with ultralow level irradiation. As a result, microRNA 206 (miR206), which is highly expressed in regenerating muscle fibers was significantly overexpressed in FCMD patients compared to normal controls. Correlation coefficient of miR206 with serum CK level, serum creatinine level, and motor function scores were also high. MiR 206 was especially high in FCMD patients with high muscle contents, suggesting remaining sparing capacity of muscle regeneration. SWE showed significantly high elasticity in biceps brachii and brachial muscle but not high in lower extremities in FCMD patients, compared to normal control, because of high content of fat infiltration due to disuse of lower extremities. In conclusion, serum miR206 and SWE is useful for monitoring muscle wasting progression and motor function level of FCMD.   .

Spinal muscular atrophy carrier frequency in Russian Federation. *V.V. Zabnenkova[1], E.L. Dadali[1], M.G. Spiridonova[2], R.A. Zinchenko[1], A.V. Polyakov[1].* 1) Research Centre for Medical Genetics, Moscow, Russian Federation; 2) The Research Institute for Medical Genetics, Tomsk, Russian Federation.

Introduction: The proximal spinal muscular atrophy (SMA) is a severe autosomal recessive neuromuscular disease characterized by degeneration of alpha motor neurons in the spinal cord, resulting in progressive proximal muscle weakness and paralysis. 95% SMA patients have homozygous deletion of *SMN1* gene. The remaining 5% cases are caused by compound heterozygous mutations: *SMN1* deletion on the one allele and a subtle mutation on the other allele. SMA carrier frequency is 1 per 40–50, incidence is 1 per 6000-10000 live births in the general population. SMA carrier frequency has not been estimated in Russia previously. **Objective:** This study sought to evaluate the incidence of deletion carrier state in the gene *SMN1* in Russian Federation. **Methods:** Genomic DNA was isolated from the peripheral blood cells from 2253 individuals of the general population in Russia using Wizard® Genomic DNA Purification Kit (Promega, United States). The number of *SMN1* gene copies was detected using a non-commercial kit, developed in laboratory of RCMG on base of Multiplex Ligation-dependent Probe Amplification (MLPA). The capillary electrophoresis was carried out in an ABI3130 DNA analyzer (Applied Biosystems). **Results:** 63 heterozygous carriers of the exons 7 and/ or 8 *SMN1* gene deletion were identified. The frequency of SMA carriers estimated in this study is 1 in 36 individuals (2.8 %). The calculated incidence of SMA is equal to 1 per 5184. **Conclusions:** Detected high frequency carrier of spinal muscular atrophy in Russia shows the importance of carrier screening. It is highly necessary for IVF program donors and for identifying of asymptomatic carrier couples with no family history but having a risk for offspring with SMA.

2477T

Aicardi-Goutières syndrome and the *ADAR1* dominant negative mutation: A case report. *A.I. Scott[1], A. Myers[2], G.M. Enns[2], T.M. Cowan[1].* 1) Department of Pathology, Stanford University School of Medicine, Stanford, CA; 2) Department of Pediatrics, Stanford University School of Medicine, Stanford, CA.

Aicardi-Goutières syndrome (AGS) [MIM: 225750] is an autoimmune encephalopathy with hallmark features of basal-ganglia calcification, leukodystrophy, and CSF lymphocytosis. Psychomotor retardation, dystonia, and spasticity are present in many cases. While there is clinical and genetic heterogeneity, all six genetic forms abnormally accumulate DNA or RNA and induce an inflammatory response. Despite increased identification of patients with AGS, the relationship between genotype and phenotype remains unclear. Approximately 7% of AGS patients have mutations in an RNA adenosine deaminase (ADAR1), a double stranded RNA editing enzyme. Sixteen *ADAR1* mutations have been described in AGS patients; of these, a single dominant change, G1007R, abolishes normal enzyme function and is predicted to be clinically severe. Within this specific group there is significant heterogeneity: the seven reported probands share features of gait disturbances, dystonia, and neurological involvement, but differ in age of onset, rate of progression, and extent of skin findings. At least two heterozygous parents of affected probands had no noted clinical abnormalities. We describe a new case of the G1007R mutant ADAR1 with an early onset and rapid progression of AGS symptoms. Our patient presented with gait disturbances at 15 months of age following normal development. A brain MRI at 20 months was normal. He is currently four years old and has progressive muscle involvement including truncal hypotonia, choking, and lower extremity spasticity. He has freckling on his extremities: hands, feet, and knees. Whole exome sequencing identified *ADAR1* c.3019G>A (p.G1007R) leading to the diagnosis of AGS. Our case underscores the phenotypic variability seen among patients with ADAR1 G1007R, which can lead to extensive testing; five of the probands had non-specific diagnoses including bilateral striatal necrosis, nonsyndromic spastic paraplegia, and dyschromatosis symmetrica hereditaria before entering research studies to identify a causative mutation. The underlying mechanism of anti-viral immune activation links these patients to the diagnosis of AGS, but the specific disturbances of nucleic acid metabolism may provide clues to the phenotypic variability. Identification of more patients with ADAR1 G1007R will more fully define clinical features and may help identify critical targets of ADAR1 activity.

2478F

Whole Genome Next Generation Sequencing [WGNGS] identifies inherited variants contributing to asperger syndrome in a South African family with apparent autosomal dominant Mendelian inheritance. *M. Kambouris[1,2], Y. Al-Sarraj[3], D. Ahram[4], H. Shaath[3], R. Thompson[3], F. Al-Shaban[3], H. El-Shanti[5,6]. 1) Pathology-Genetics, Sidra Medical & Research Center, Doha, Qatar; 2) Genetics, Yale University School of Medicine, New Haven, CT, USA; 3) Qatar Biomedical Research Institute, Hamad Bin Khalifa University, Doha, Qatar; 4) Translational Medicine, Sidra Medical & Research Center, Doha, Qatar; 5) Pediatrics, University of Jordan School of Medicine, Amman, Jordan; 6) Pediatrics, University of Iowa, Iowa City, IA, USA.*

A South African family with a father and three sons all affected with Asperger syndrome that presents with high intellectual functionality, significant difficulties in social interaction and nonverbal communication, repetitive behaviors and physical gestures was studied by WGNGS and comparative Genome analyses. The father is a high-ranking banker with superb banking skills. He does not interact with colleagues and co-workers except through a single buffer individual. At home, he interacts only with his spouse and is quite distant from all immediate and extended family members. All three affected sons are exceptionally intelligent, learned written & spoken English as a second language by the age of 5, without tutoring just from television and books. The oldest son, published a book in English at the age of 7, but did not graduate high school since he can not undergo the required testing. The second son completed the academic high school curriculum by age 12, but also could not undergo the required testing until the age of 16. The third son completed the high school academic curriculum very early, although he did not attend school until the age of 8, since he refused to wear clothes and remained naked for the first 8 years of his life. All four affected members have certain routines, stereotypic behaviors and gestures which they control to a limited extend. Due to the strong heritability in this family, data was mined for monoallelic variations in the father inherited by all three affected sons (autosomal dominant inheritance) in protein coding genes with in-silico predicted damaging effects that could possibly include a major offending gene. Among others, these include genes and biological pathways associated with Autism Spectrum Disease (ASD): a nonsense mutation *HYAL4* [c.628C>T/p.210Arg>*] in a hyaluronidase that intracellularly degrades the glycosaminoglycan hyaluronan involved in brain function and development and two missense mutations that affect highly conserved amino acids: *PARK2* [c.110C>T/p.37Pro>Leu] a component of a multiprotein E3 ubiquitin ligase complex involved in protein degradation and *FAT1* [c.2563C>A/p.855Gly>Arg], a cadherin required for cell-cell association and actin organization. Intronic, regulatory and and non-coding variants should also have been considered. Determination of a single Autosomal Dominant offending mutation is difficult. This family presents a Mendelian model of the polygenic-multifactorial Asperger variant of ASD.

2479W

Precision medicine in juvenile psychosis at Boston Children's Hospital. *C.A. Brownstein[1], A.H. Beggs[1], P. Agrawal[1], J. Gonzalez-Heydrich[2]. 1) Manton Center for Orphan Disease Research, Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA; 2) Developmental Neuropsychiatry Program, Boston Children's Hospital, Boston MA.*

Diagnostic Sequencing is a cornerstone of Precision Medicine, especially at a tertiary hospital. Two initiatives at BCH are illustrative: 1) the Developmental Neuropsychiatry Program (DNP), and 2) the Manton Center for Orphan Disease Research. The study of rare Mendelian forms of Juvenile Psychosis is an effective way to discover new candidate genes for the condition. Boston Children's Hospital has created the infrastructure needed for large-scale psychiatric research and treatment discovery with the Developmental Neuropsychiatry Program (DNP). The DNP seeks to develop therapeutics to prevent the development of schizophrenia in at-risk children by identifying causative mutations in the youngest patients presenting with psychosis, and providing targeted care for others who present with the same conditions. Once a causative mutation or copy number variation is found and functionally confirmed, we have the ability to identify whether there are other patients with the same mutation or variation at BCH, and assess whether they are in need of psychiatric services. Using this method, we have identified patients with unaddressed psychotic or prodromal symptoms and have some success stories of getting patients and families necessary treatment. We also have some case examples of identifying patients too late- once we identified that 16p13.11 copy number loss could present as juvenile psychosis, we performed a search and identified a family with two psychotic breaks that perhaps could have been prevented. We are able to do this work due to the Manton Center for Orphan Disease Protocol. The Manton Center is one of the first centers in the world solely devoted to the study of rare diseases, focusing on patient-centered research and funding existing research efforts on rare diseases. The Center maintains a general IRB protocol suitable for enrolling subjects with any rare or undiagnosed condition, and provides consenting, enrollment and genotyping services and training, enabling discovery. If something actionable is found, it is CLIA verified and able to be returned to the medical record. Through the use of this common genomic toolkit allowing for seamless transfer between the clinical and research realms, BCH is developing shared informatics resources and intellectual expertise. The success of this program has provided precision medicine to this vulnerable population. .

2480T

Genotype-phenotype correlation in *ADNP*-related syndromic autism. *F. Kooy[1], A. Van Dijck[1], I. Gozes[2], A. Vulto-van Silfhout[3], E. Eichler[4], B. de Vries[3], G. Vandeweyer[1].* 1) University of Antwerp, Antwerp, Belgium; 2) Tel Aviv University, Tel Aviv, Israel; 3) Radbout University, Nijmegen, the Netherlands; 4) University of Washington.

Among the many hundreds of genes linked to autism, only a few have been clearly characterized. Recently, we discovered that ADNP is one of a still very limited number of genes that lead to autism in a substantial proportion of cases. ADNP encodes a neuroprotective protein that is involved in chromatin remodeling. Interestingly, the mutations in the original description of the disorder were all located in the fith and last exon of the gene and were demonstrated to escape non-sense mediated decay and we hypothesized a dominant negative mutational mechanism. Since the description of the first 10 patients, we have collected an additional 50 patients. Detailed and structural clinical information was collected from all as well as the nature of the mutations. In this cohort, mutations in other but the last exon are present and by comparing the genotype with the genotype of all patients, we have been able to estabish a detailled genotype-fenotype correlation. Such information is crucial both in understanding the mutational mechanism as well as for the interpretation of ADNP variants discovered in autistic patients. Strikingly, the identified mutations appear to cluster at specific positions in the gene. Almost one third of the patients have an almost identical 4 bp deletion mutation, either g.49508752_49508755delTTTA or g.49508757_49508760delTTAA in exon 5. Clustering of de novo, rare variants is suggestive of a mutation predisposition mechanism, potentially as a result of a particular local genomic architecture. Mfold analysis (web server for nucleic acid folding and hybridization prediction) showed that the recurrent mutation is located in the stem of the same short hairpin, suggestive of an underlying mechanism involving a DNA repair defect following pausing of a replication fork at these hairpins.

2481F

Characterizing a novel variant in histone demethylase gene *KDM5C* associated with intellectual disability and autism spectrum disorder. *C. Vallianatos, C. Keegan, S. Iwase.* Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Dysregulation of histone methylation has emerged as a major contributor of neurodevelopmental disorders such as autism spectrum disorder (ASD) and intellectual disability (ID). The X chromosome gene *KDM5C* encodes a histone H3 lysine 4 (H3K4) demethylase, and *KDM5C* mutations are frequently associated with syndromic X-linked ID, Claes-Jensen type (MIM 300534). Genome-wide, H3K4 methylation is enriched at promoters and enhancers of actively transcribed loci, and tri-methylated H3K4 directly interacts with transcription machinery to promote gene expression. KDM5C is therefore regarded as a transcriptional repressor and key chromatin regulator of neuronal development and function. How individual *KDM5C* mutations lead to cognitive impairment remains unclear. Here, we report a new *KDM5C* variant and assessment of its molecular and cellular pathogenicity. We performed exome sequencing of a young male with ID, ASD, and developmental abnormalities, and revealed a maternally inherited new missense mutation in *KDM5C*, p.Arg1115His (c.3344G>A). Known *KDM5C* mutations tend to cluster near the JmjC catalytic domain and lead to decreased enzymatic activity, suggesting a loss-of-function pathogenic mechanism. In contrast, p.Arg1115His is distant from the enzymatic core, and lies upstream of a PHD domain (PHD2) which has unknown function. PHD domains can be histone binding modules, however our histone peptide binding studies suggest PHD2 may bind non-histone substrates. We hypothesize p.Arg1115His may affect interaction of KDM5C with known binding partners. We focus on RACK7, a histone binding protein known to interact with KDM5C to suppress over-activation of enhancers. Immunoprecipitation of KDM5C shows binding to RACK7 is dramatically reduced by p.ArgR1115His. KDM5C p.ArgR1115His exhibits normal nuclear localization in mouse cortical neurons, yet leads to decreased protein stability. Our results suggest p.Arg1115His interferes with the KDM5C-RACK7 interaction, an important enhancer-suppressing complex, and reduces KDM5C stability. Current efforts are focused on assessing H3K4 demethylase activity of KDM5C p.ArgR1115His. Future studies will test the ability of this variant to be recruited to chromatin and restore aberrant gene expression in *Kdm5c*-null mouse cortical neurons. Our work informs us about the pathogenicity of this new variant and the role of KDM5C PHD2, and lead to a better understanding of H3K4 methylation dynamics dysregulated in neurodevelopmental disorders.

2482W

SATB2-associated syndrome: Report of a new case associated with a new mutation in the SATB2 gene. *Z.L. Xu, G. Cowing, M. Szybowska, C. Li.* Department of Genetics, McMaster Children's Hospital, Hamilton, ON, Canada.

Special AT-rich sequence-binding protein 2 (*SATB2*) is a highly-conserved gene that encodes a transcription regulator and is involved in chromatin remodeling. *SATB2* haploinsufficiency results in *SATB2*-associated syndrome (SAS;OMIM#608148); a clinically recognizable condition characterized by intellectual disability, limited or absent speech and language, facial dysmorphism that includes hypertelorism, downslanting palpebral fissures, dental anomalies, and cleft palate. Other features of SAS include behavioral problems, sleep disturbances, seizures, and osteopenia. To our knowledge, only ten patients have been described in the literature. We report a 13-year-old male in whom trio-based whole-exome sequencing revealed a unique *de novo* mutation in exon 9 of *SATB2*, c.1286G>A (p.Arg429Gln). The genetic change has not been previously reported but we believe it to be pathogenic based on: 1) clinical phenotype. The proband demonstrates features previously reported in SAS—severe global developmental delay, dysmorphic features with downslanting eyes, prominent low-set ears, a prominent nose, an open-mouthed hypotonic facies as well as high-arched palate, bifid uvula. The patient also had macrodontia and retrognathia. Bilateral 5th finger clinodactyly and 2-3 toe syndactyly were also part of his physical features. Behavioral problems are notable for hyperactivity, aggressiveness, skin-picking, sleep disturbance and autism spectrum disorder. 2) molecular and database information. The mutation is a semi-conserved amino acid substitution that occurs at an evolutionarily conserved position of the gene. It is absent in the normal population from the NHBI exome sequencing project with an allelic frequency of GMAF 0.00140 (A). In summary, whole-exome sequencing identified a new genetic change in the *SATB2* gene that is likely pathogenic in a patient with novel as well as overlapping clinical features of SAS. The case therefore may serve to expand the phenotype of SAS.

2483T

Large-scale untargeted metabolomic profiling in Pitt-Hopkins syndrome uncovers phenotypic-associated amino acid and lipid abnormalities. *J.T. Alaimo, S.H. Elsea.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Transcription factor 4 (*TCF4*) encodes a helix-loop-helix transcription factor that, when haploinsufficient, results in the neurodevelopmental disorder Pitt-Hopkins syndrome (PTHS). PTHS is characterized by severe intellectual disability, absent speech, seizures, breathing abnormalities, behavioral problems, and delayed motor milestones in which more than half fail to walk independently. In addition, natural variation at this locus is associated with the complex disease schizophrenia. The phenotypic spectrum associated with *TCF4* variation suggests a unique role for the protein in pathways mitigating neurodevelopment and cognitive function; therefore, we sought to undercover functional pathways regulated by TCF4 through the application of a small molecule metabolomics screen. We examined plasma samples of 13 individuals with a molecularly confirmed diagnosis of PTHS that were predominately male and ranged in age from 1.5 to 20 years. Our cohort had a history of global developmental delay, absent or sparse speech, seizures and sleep anomalies. Metabolomic profiles from this cohort were significantly enriched for alterations in lipid and amino acid associated pathways. All individuals displayed abnormal lipid profiles, but consistent alterations were observed in fatty acid and phospholipid metabolism. We identified elevated oleamide levels, an endogenously metabolized fatty acid amide associated with sleep problems, a phenotypic feature of our cohort. In addition, abnormalities across palmitic acid metabolism and utilization were identified, including elevated palmitic amide a known marker for schizophrenia. Amino acid abnormities were observed across 12 of 13 samples with consistent alterations found in pathways associated with oxidative stress and mitochondria function, such as methionine sulfoxide and N-acetylaspartate. Interestingly, 3 individuals within our cohort displayed alterations in carnitine metabolism suggesting carnitine biosynthesis defects and were recommended for further clinical testing. Taken together, the application of metabolic profiling in individuals with PTHS suggests that TCF4 plays a functional role in small molecule pathways that may contribute to the phenotypic features of the disorder. Future studies discerning the cellular defects associated with these metabolic alterations will likely present new opportunities for therapeutic interventions in PTHS.

2484F

Exome sequencing identifies a novel mutation in *C10orf2* in a consanguineous family with intellectual disability. *A. Alkhateeb[1,2], S. Aburahma[1], W. Habbab[2], I.R. Thompson[2].* 1) Jordan University of Science and Technology, Irbid, Jordan; 2) QBRI-Hamad Bin Khalifa University, Doha, Qatar.

Intellectual disability is a heterogeneous disease with an increasing number of causal genes and mutations identified. Here we examined a first-cousin-in-marriage Arab family with two male and female sibs affected with intellectual disability. Patients were hypotonic with weakness, delayed speech and walking, bilateral foot drop, absent deep tendon reflexes and no history of epilepsy. MRI of the brain showed delayed myelination for age. The two patients and their parents were subjected to SNP microarray genotyping to identify regions of autozygosity in the patients. Four autozygosity regions were identified on chromosomes 10, 11 and 16. Whole exome sequencing was done for patients and their parents. Data were filtered and analyzed by Ingenuity Variant Analysis tool. Only four variants survived stringent filtering and only three of those resided in the autozygous regions. Two of the three variants were listed in dSNP and predicted benign in Polyphen-2. The third variant c.205A>T (p.I69F) in *C10orf2* gene was not listed in dSNP, localized in a highly conserved region of the protein, and predicted to be possibly damaging by Polyphen-2. Mutations in *C10orf2* gene has been implicated in intellectual disability. This novel mutation is located 10 amino acids upstream of the primase domain that is known to play a critical role in positioning the helicase to its target, and thus, seems likely to affect the helicase function of the protein leading to disease. Our analysis illustrates the power of whole exome and SNP genotyping to identify disease casual mutations.

2485W

***De novo* deletion of chromosome 19p13.3 involving *STK11* in a girl with intellectual disabilities and dysmorphic features without findings of Peutz-Jeghers syndrome: Further delineation of a contiguous gene deletion syndrome.** *C. Long, R. Olson, G. Scharer.* Division of Genetics, Children's Hospitals and Clinics of Minnesota, Minneapolis, MN.

Peutz-Jeghers syndrome (PJS) is a rare hereditary cancer predisposition syndrome characterized by gastrointestinal polyposis and mucocutaneous pigmentation. Onset of characteristic hamartomatous polyps is often within the first 10 years of life, and there is an increased lifetime risk for gastrointestinal and extraintestinal malignancies. The majority of individuals with PJS have a mutation identified in the *STK11* gene. Microdeletions of 19p13.3 involving the *STK11* gene have been previously reported with the majority of individuals (4/6) presenting with either mucocutaneous pigmentation or GI polyps. We present a patient with a *de novo* 740 kb deletion of 19p13.3 involving the *STK11* gene (chr 19: 183996-1223710 / hg18). At 17 years of age, this individual did not have a history of mucocutaneous pigmentation or any identified polyps. Her clinical features included left Duane syndrome, bilateral ear keloid scarring, bifid uvula, scoliosis, developmental delays, mild intellectual disability, and dysmorphic features. Many of her features overlap with the features seen in previously reported individuals with 19p13.3 deletions. The deletion identified in our patient partially overlaps with the previously published reports of 19p13.3 microdeletions involving the *STK11* gene and allows for further characterization of the associated phenotype. Over 40 OMIM genes are encompassed by this deletion, including *STK11*, *ELANE*, *KISS1R*, *ARID3A*, and *GRIN3B*. *ARID3A* is a member of the ARID family of DNA binding proteins; other members of this family, specifically *ARID1A* and *ARID1B*, are associated with Coffin-Siris syndrome (MIM #603024, #614556), a condition characterized by intellectual disabilities and dysmorphic features. Deletion of this gene may contribute to some of the clinical findings seen our patient. In light of the haploinsufficiency of the *STK11* gene identified for this patient, we have recommended age-related PJS screening per the NCCN guidelines. Additional investigation regarding this contiguous gene deletion syndrome is warranted to further delineate the variable findings and the associated lifetime cancer risks.

2486T

Mapping autosomal recessive intellectual disability: Combined microarray and exome sequencing identifies 69 different genes in 192 consanguineous families. *J.B. Vincent[1], R. Harripaul[1], N. Vasli[1], A. Mikhailov[1], M.A. Rafiq[2], K. Mittal[1], C. Windpassinger[3], T.I. Sheikh[1], A. Noor[4], H. Mahmood[1], S. Downey[1], M. Johnson[1], K. Vleuten[1], M. Moradi[5], M. Ayaz[6], F. Naeem[7], A. Heidari[8], I. Ahmed[9], S. Ghadami[10], Z. Agha[2], S. Zeinali[10], R. Qamar[2], H. Mozhdehipanah[5], P. John[9], A. Mir[11], M. Ansar[12], L. French[1], M. Ayub[7].* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth,Clarke Div, Toronto, ON, Canada; 2) COMSATS Institute of Information Technology, Islamabad, Pakistan;; 3) Institute of Human Genetics, Medical University of Graz, Graz, Austria; 4) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada;; 5) Qazvin University of Medical Science, Qazvin, Iran;; 6) Lahore Institute of Research & Development, Lahore, Pakistan;; 7) Department of Psychiatry, Queen's University, Kingston, ON, Canada;; 8) Division of Hematology/Oncology, Hospital for Sick Children, Toronto, ON, Canada;; 9) Atta-ur-Rehman School of Applied Biosciences (ASAB), National University of Sciences and Technology (NUST), Islamabad, Pakistan;; 10) Department of Molecular Medicine, Biotechnology Research Center, Pasteur Institute of Iran, Tehran, Iran;; 11) Human Molecular Genetics Lab, Department of Bioinformatics and Biotechnology, FBAS, International Islamic University, Islamabad, Pakistan;; 12) Department of Biochemistry, Quaid-i-Azam University, Islamabad, Pakistan.

About 1% of children worldwide are affected by intellectual disability (ID). The vast majority with ID currently receive no molecular diagnosis. Knowing the causative gene may have huge benefits for diagnosis, care, overall health and lifespan, and family counseling and planning. Understanding the biological pathways that, when disrupted, may lead to ID, will provide a major step towards identifying therapeutic opportunities. Studies indicate high levels of genetic heterogeneity, with estimates of over 2500 autosomal ID genes, with the majority being recessive. Here, we present findings for a gene mapping/mutation identification project using SNP microarray analysis combined with whole exome sequencing, for 192 Pakistani and Iranian consanguineous, mainly non-syndromic ARID families with multiple affected members. We identified definite or likely causative mutations or CNVs in ~48% of families, including 26 genes not previously reported and 11 genes first reported from this cohort. The 26 new genes include 12 with homozygous loss-of-function mutations (*IMPA1, TMEM135, TRAPPC6B, USP44, MBOAT7, TBC1D23, SLAIN1, CCDC82, MAPK8, MPDZ, PIDD1,* and *UBA7*). The high yield of autosomal recessive mutations for ID signals that this approach not only has excellent clinical potential for consanguineous populations, but will also inform clinical diagnostics, including clinical whole exome and genome sequencing, for outbred populations.

2487F

Coffin-Lowry syndrome: Identification of a novel variant. A case report. *A.I Sanchez[1], J.C Prieto[1,2], P. Sanchez[2].* 1) Instituto de genética humana, Universidad Javeriana, Bogota, Bogota, Colombia; 2) Hospital La victoria SDS, Bogota, Colombia.

Introduction: Coffin-Lowry syndrome (CLS) is a rare X-linked dominant disorder caused by mutations in the RPS6KA3 gene, which encodes a growth factor-regulated serine threonine kinase. CLS affects 1 in 100,000 individuals, being 70-80% of them sporadic cases. It is characterized by severe to profound intellectual disability, global developmental delay, dysmorphic facial features, short stature and skeletal malformations. **Case presentation**: This is a 6 y/o male patient who is the 7th child of a healthy non-consanguineous couple. Family history was remarkable for two sisters and one brother having short stature and intellectual disability. He was born by uncomplicated spontaneous vaginal delivery at home after a full non-controlled term gestation. Birth weight at 38 weeks was 2380 grs; he was treated with crystalline penicillin G because of highly suspicious congenital syphilis and placed under phototherapy because of hiperbilirrubinaemia. Patient was hypotonic since birth and had history of global development delay with hampered verbal communication. Physical examination revealed microcephaly, large forehead, ocular hypertelorism, downslanting palpebral fissures, long philtrum, anteverted nares, thick lips, mild facial coarsening, broad tapering fingers and short stature. Hearing tests, thyroid function tests and MRI of the brain showed no abnormalities, as well as karyotype and microarray-based comparative genomic hybridization. Whole genome sequence analysis on DNA extracted from patient was performed. A novel pathogenic hemizigous mutation in exon 13 in the RPS6KA3 gene was detected. **Discussion**: RPS6KA3 gene is located at Xp22.2 and encodes for the RSK2 protein, which is expressed in developing central nervous system and is known to be involved in neuronal survival, neurite growth, functional maturation, and synaptic plasticity. The variant c.1004T>C (p.L335P) was identified; it was neither found in ExAC nor 1000G. Therefore we propose a novel mutation (single base exchange) which has had result in loss of function of the protein. This case is also noteworthy because patient's sisters had history of intellectual disability and short stature **Conclusions**: To our knowledge, this is the first time this variant is reported in a boy with a classic phenotype of CLS. To date, more than 140 RSK2 mutations have been identified in CLS patients. Further studies are necessary to elucidate the whole correlation between genotype and possible familial cases.

2488W

GRIN2B **encephalopathy – Novel phenotypic, genetic and functional aspects.** *J.R. Lemke[1], K. Platzer[2], H. Yuan[2], W. Chen[2], C. Hu[2], H. Kusomoto[3], H. Schütz[3], B. Laube[1], H.O. Heyne[4], K.L. Helbig[5], N. DiDonato[6], W.B. Dobyns[2], S.F. Traynelis[1], GRIN2B study group.* 1) University of Leipzig, Leipzig, Germany; 2) Emory University School of Medicine, Atlanta, GA, USA; 3) Technical University Darmstadt, Darmstadt, Germany; 4) Ambry Genetics, Aliso Viejo, California, USA; 5) Technical University Dresden, Dresden, Germany; 6) University of Washington, Seattle, Washington, USA.

   Objective: *GRIN2B* encoding the NMDA receptor subunit GluN2B has been associated with a variety of neurodevelopmental disorders. We aimed for a comprehensive delineation of the genotypic and phenotypic spectra, functional characterization of variants as well as exploration of potential prospects of personalized medicine. **Methods:** Molecular and clinical data of 84 individuals with *de novo GRIN2B* variants were collected from several diagnostic and research cohorts as well as from the literature. Functional consequences and response to the use-dependent partial NMDA receptor blocker memantine were investigated in *Xenopus laevis* oocytes and eventually translated into clinics. **Results:** We report 40 novel patients with *de novo GRIN2B* variants and review all 44 previously reported individuals. In 81 cases, variants were classified as pathogenic/likely pathogenic and associated with developmental delay, intellectual disability or autism spectrum disorder as well as muscular hypotonia, movement disorder, cortical visual impairment, cerebral volume loss and epilepsy. Four patients presented with an unusual malformation of cortical development (MCD). Missense variants cluster in transmembrane segments and ligand binding sites. Functional consequences were diverse, revealing various loss- and gain-of-function mechanisms, the latter partially retaining sensitivity to memantine. However, treatment responses in the respective patients still remain to prove significant benefits. **Conclusions:** In addition to previously known features of intellectual disability, epilepsy and autism spectrum disorder, we show that *GRIN2B* encephalopathy is also frequently associated with movement disorder, cortical visual impairment and MCD revealing a novel disease mechanism of channelopathies. The functional characterizations of variants enabled personalized therapeutic approaches which still remain challenging when translated from *in vitro* experiments into patient treatment.

2489T

Whole exome sequence identified disease-causing CNVs of *VPS13B* **responsible for Cohen syndrome in siblings with non-syndromic intellectual disability.** *Y. Enomoto[1], Y. Tsurusaki[1], T. Yokoi[2], M. Minatogawa[2], C. Abe-Hatano[2], K. Ida[2], T. Naruto[1], J. Mitsui[3], S. Tsuji[3], S. Morishita[4], K. Kurosawa[1].* 1) Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Neurology, University of Tokyo Graduate School of Medicine, Tokyo, Japan; 4) Department of Computational Biology and Medical Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Chiba, Japan.

   Cohen syndrome is rare autosomal recessive disease and characterized by persisting hypotonia, truncal obesity, visual impairment, short stature, intellectual disability(ID) and dysmorphic face. Causative gene is *VPS13B*. More than 150 cases with Cohen syndrome have been reported. Most of the cases are from Finnish population. The clinical phenotype is recognizable and homogenous for Finnish cases, but variable for other ethnic origin. Recently, disease-causing variants of *VPS13B* have been identified in the patients with non-syndromic ID by whole exome sequence (WES). We report on Japanese siblings with non-syndromic ID with compound heterozygous CNVs identified by normalized depth calculation using WES data. Older sister was born at 39 weeks of gestation. Birth weight was 2816g (-0.4SD), length 51cm (1.0SD), and OFC 34cm (0.5SD). She was able to speak one word at 1 year and 3 months and walk at 2 years and 6 months. At age of 6 years, she was able to walk very slowly and speak using 2-3 word sentences. She had truncal obesity, hypotonia, myopia, and mild to moderate ID, but did not have microcephaly and short stature. Younger sister was born at 39 weeks of gestation. Birth weight was 2500g (-1.3SD), length 46cm (-1.1SD), and OFC 32cm (-0.6SD). At 2 years and 8 months, her weight was 11.4kg (-0.8SD), length 83.7cm (-1.8SD) and OFC 44cm (-2.7SD). She was not able to walk and speak a comprehensive word. CGH array (8x60k) using standard filter setting which detects signal changes of 3 or more probes could not detect pathogenic CNV. However, normalized depth calculation using the WES data could detect pathogenic compound heterozygous CNVs in *VPS13B* common to the siblings. The two pathogenic CNVs included a deletion of exon8-15 derived from their mother and a deletion of exon 32-33 derived from their father. These results support the idea that the phonotype of Cohen syndrome is variable in individuals of non-Finnish populations and the normalized depth calculation using WES data is highly valuable for detecting the minor CNVs in diagnosis of non-syndromic ID.

2490F

Whole exome sequencing reveals a mutation in *ARMC9* as a cause of mental retardation, ptosis and polydactyly syndrome. *A. Kar[1,2], S. Phadke[3], A. Dalal[1,4].* 1) Diagnostics Division, Centre for DNA Fingerprinting and Diagnostics, Hyderabad, India; 2) Graduate Studies, Manipal University, Manipal, India; 3) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India; 4) Department of Medical Genetics, Kasturba Medical College, Manipal University, Manipal, India.

Intellectual disability has a prevalence of 1 -3% population and results from heterogeneous causes like environmental effect, chromosomal or monogenic causes. More than 230 genes have been reported to be involved in causation of syndromes of intellectual disability. We report on exome sequencing in three siblings in a consanguineous family with short stature, mental retardation, downslanting palpebral fissures, ptosis and polydactyly. Homozygosity mapping followed by whole exome sequencing was done in proband and two affected siblings after obtaining informed consent. Homozygosity mapping revealed five common regions of loss of heterozygosity region constituting about 15.69Mb and harbored 228 genes. Next generation sequencing reads were processed for mapping to reference genome, variant calling and annotation. Variants were filtered for polymorphisms using various databases. Comparison of variants among affected siblings revealed homozygous mutation in Armadillo repeat containing 9 (*ARMC9*) gene in all three. Mutation c.1073G>A in *ARMC9* is a synonymous splice site mutation, which is predicted to be 'disease causing' by various splice site mutation prediction software. Mutation was confirmed by Sanger sequencing in parents, probands, affected and unaffected siblings. *ARMC9* (KU-MEL-1) is known as melanoma/melanocyte antigen and is reported to be expressed in melanoma and melanocytes. It contains LISH1 domain, which is predicted to have involvement in microtubule dynamics and ARM domain, which exhibits binding with proteins due to presence of extensive solvent accessible surface. *ARMC9* is also involved in interaction with *SIAH1* (E3 ubiquitin ligase). Mutation c.1073G>A, which is a splice site mutation may alter downstream sequences and thus may abolish ubiquitination site at Lys441. We propose that mutation in *ARMC9* leads to mental retardation, ptosis and polydactyly syndrome in this family and *ARMC9* may be a novel gene involved in causation of syndromic intellectual disability. Functional studies are ongoing for validation of the results.

2491W

Whole exome sequencing reveals a missense mutation in the *ARX* gene in a family with X-linked non-syndromic mental retardation. *M.B. Petersen[1,2], I.S. Pedersen[3], V.Q. Le[3], A. Ernst[3], H. Krarup[3].* 1) Dept Clinical Genetics, Aalborg University Hosp, Aalborg, Denmark; 2) Dept Clinical Medicine, Aalborg University, Aalborg, Denmark; 3) Section of Molecular Diagnostics, Clinical Biochemistry, Aalborg University Hospital, Aalborg, Denmark.

The *ARX* (Aristaless-related homeobox) gene belongs to a large family of homeodomain transcription factors with critical roles in development. Mutations in the *ARX* gene cause X-linked intellectual disability. The phenotypic spectrum comprises a series of X-linked developmental disorders ranging from lissencephaly to agenesis of the corpus callosum with abnormal genitalia to infantile spasms without brain malformations to syndromic and non-syndromic mental retardation. We describe a five-generation Danish family with three males at the age of 18, 44, and 61 years, respectively, showing mental retardation of unknown reason. Except from large ears, the clinical evaluation did not reveal any distinct dysmorphic feature. Array-CGH and FMR1 analysis were normal in two of the males. According to the pedigree, an X-linked inheritance pattern was strongly suspected. Whole exome sequencing (WES) with targeted analysis of the coding regions of the X chromosome was carried out in two of the affected males, a suspected obligate carrier female (mother of an affected), and a healthy male (brother of an affected). A filtering process searching for nonsynonymous variants and variants in the exon-intron boundaries revealed a novel variant, NM_139058.2:c.1A>G, in the first codon of the *ARX* gene. Disruption of an initiator codon may lead to reinitiation if an alternative initiator codon is present. Recently, premature termination mutations very early in the *ARX* gene have been reported to lead to reinitiation of translation to produce a truncated protein at markedly reduced level. These mutations are associated with a less severe phenotype than truncating mutations located further downstream in *ARX*. The finding of a mutation in the first codon of the *ARX* gene in a family segregating non-syndromic mental retardation supports the observed genotype-phenotype correlation reported for *ARX* mutations.

2492T

Heterozygous variants in *ACTL6A*, encoding a component of the SWI/SNF complex, are associated with intellectual disability. *R. Marom[1], M. Jain[1], L.C. Burrage[1], B.H. Graham[1], C.W. Brown[2], B.B. de Vries[3], S. Stevens[4], A.T. Gunter[5], J.D. Kaplan[5], R.H. Gavrilova[6], M. Shinawi[7], J.A. Rosenfeld[1], J.T. Lu[10], R.A. Gibbs[1,8], C.M. Eng[1], Y. Yang[1], J. Rousseau[9], P.M. Campeau[9], B.H. Lee[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX. Pathogenic variants in genes encoding components of the SWI/SNF complex and related interacting chromatin remodeling proteins have been associated with intellectual disability syndromes. By whole exome sequencing, we identified heterozygous, rare variants in *ACTL6A* (Actin-like 6A), a gene encoding a component of the SWI/SNF complex, in four patients with speech delay and varying degrees of intellectual disability. Other phenotypic features shared by some of our patients include a history of failure to thrive, congenital heart defect and finger and toe abnormalities. Three patients were found to have missense variants in highly conserved amino acid residues – a de novo p.R377W variant (exon 13), a maternally inherited p.R389W variant (exon 13), and p.E227Q (exon 8) with an unknown inheritance (due to the unavailability of parental testing). These three amino acids reside in a region with structural similarity to actin. Missense mutations in the homologous region in yeast actin were found to be dominant lethal (Wertman KF *et al*, Genetics 1992). Interestingly, a previously published study in cells transiently-transfected with *ACTL6A* showed that introducing mutations into these same three residues results in impaired binding of the ACTL6A protein to β-actin and BRG1 (Nishimoto N *et al*, J Cell Science 2012). These findings suggest that the variants identified in our patients may have a deleterious effect on the function of the protein, by disturbing the integrity of the SWI/SNF complex. A fourth patient was found to have a de novo splicing variant in intron 13, and RNA studies using a lymphoblastoid cell line derived from this patient showed abnormal splicing that creates an in-frame deletion of exon 13. Thus, three of the four variants involve exon 13 which is a highly evolutionarily conserved region of the protein. Whole exome sequencing did not detect other variants in genes known to cause intellectual disability that may explain the phenotype seen in these patients. *ACTL6A* is a member of the BAF (Brg/Brahama associated factors) complex that plays an essential role in neurodevelopment. To the best of our knowledge, *ACTL6A* has not been associated, thus far, with intellectual disability syndromes. Thus, heterozygous pathogenic variants in *ACTL6A* gene should be considered in patients with intellectual disability, learning disabilities or developmental language disorder.

2493F

Exome sequencing of 152 consanguineous families with intellectual disability reveals high diagnostic yield and identification of novel candidate genes. *R. Abou Jamra[1,2], M. Reuter[2], H. Tawamie[1,2], R. Buchert[2], T. Froukh[3], O. Hosny Gebril[4], T. Strom[5], S. Hoffjan[6], D. Wieczorek[7], H. Sticht[8], A. Reis[2].* 1) Institute of Human Genetics, University Medical Center Leipzig, Leipzig, Sachsonia, Germany; 2) Institute of Human Genetics, FAU Erlangen-Nürnberg, Erlangen, Germany; 3) Department of Biotechnology and Genetic Engineering, Philadelphia University, Amman, Jordan; 4) National Research Center, Doky, Cairo, Egypt; 5) Helmholtz Zentrum München, Neuherberg, Germany; 6) Institute of Human Genetics, University of Bochum, Bochum, Germany; 7) Institute of Human Genetics, University Duisburg-Essen, Essen, Germany; 8) Institute of Biochemistry, FAU Erlangen-Nürnberg, Erlangen, Germany.

Autosomal recessive inherited neurodevelopmental disorders are highly heterogeneous and many disease-associated genes are still unknown. In this study, we aim at identification of disease genes through confirmation of previously described and presentation of novel candidates, and to assess the diagnostic yield of exome sequencing in consanguineous families. We enrolled 152 consanguineous families with one (29%) or multiple (71%) affected children with intellectual disability. Most affected persons showed additional symptoms including muscular hypotonia, epilepsy and microcephaly. After autozygosity mapping in families and exome sequencing of the index we identified candidate variants in 105 genes. We could establish a genetic diagnosis in 53 families (35%) due to 54 (likely) pathogenic variants in genes already associated with neurodevelopmental disorders. Only four genes were hit recurrently (*AHI1, GRP56, PLA2G6, PRRT2*). In five of these families potentially treatable disorders were diagnosed, and in at least one patient we identified two homozygous variants in different genes leading to a combined dual diagnosis. In addition to recessive variants we also identified pathogenic X-linked variants in boys (*PIGA, SLC6A8*) and dominant de novo variants in known ID genes (*DYRK1A, KMT2B*) in singletons after performing trio analysis as a proof of principle. In the 52 families (34%), we identified convincing variants in candidate genes not previously associated with neurodevelopmental disorders. Of these, 16 were homozygous and truncating in *GRM7, STX1A, KIAA1967, EEF1D, METTL5, GALNT2, SLC44A1, LRRIQ3, MBOAT7, AMZ2, CLMN, SEC23IP, MBNL3, INIP, NARG2, KIAA1467*, and *TRAP1*. We also identified convincing, non-truncating variants in *RXRB, BDH1, C9ORF114, GRAMD1B, EZR, OGDHL, ADIPOR1, EDC3, CEP76, KCTD18, PPFIA1, HMG20A, SKIDA1 (C10orf140), EIF4A2, MAGI2, THG1L, LRCH3, TMTC3, HACL1, TSPAN18, FBXO11, SV2C, LENG8, CACNA2D1, ATP2C2, GCC2, TMEM132D, PTRHD1, KIAA0195, PPRC1, SMURF2, ENO2, NCAPD2, BTN2A2, GTF3C3, CHD1L*. We are aware that some of these could be false positive; however, we obtained supporting functional results and/or further independent families for ten of them. The diagnostic yield was higher in severe cases, in multiplex families, and in cases with detailed clinical description. We further confirm the utility of exome sequencing as first line diagnostic approach and propose 52 convincing candidate genes awaiting confirmation by independent families.

2494W

The TIDE protocol identifies treatable inborn errors of metabolism in 5% of children with unexplained intellectual developmental disorder. *G. Aisha[1], R. Salvarinova[2], G. Horvath[2], M. Connolly[2], M. Demos[2], P. Eydoux[3], H. Vallance[3], G. Sinclair[3], S. Stockler[1], C. van Karnebeek[1,4], TIDE-BC.* 1) BC Children's Hospital, Vancouver, British Columbia, Canada; 2) Dept of Pediatrics, University of British Columbia, Vancouver, Cada; 3) Dept of Pathology and Laboratory Medicine, University Of British Columbia; 4) Centre for Molecular Medicine and Therapeutics, CFRI.

   BACKGROUND: Intellectual developmental disorders (IDD) are characterized by significant impairment of cognitive functions, affecting 2.5% of the population worldwide with significant morbidity and associated healthcare costs. Inborn errors of metabolism (IEM) currently constitute the only group of genetic defects amenable to causal therapy. Early diagnosis prevents or minimizes brain damage. Our literature review identified 89 such treatable IEM; although evidence is limited, therapies are often effective, safe, accessible. **METHODS:** We translated this knowledge into the published TIDE *diagnostic protocol:* The 1st tier comprises metabolic screening tests in blood/urine with potential to identify 62% of treatable IDs. The *second tier* focuses on remaining disorders, requiring 'single test per disease' approach. A freely available App (www.treatable-id.org) supports the protocol. The protocol was superimposed to current diagnostic guidelines in the evaluation of unexplained IDD during 3 years in our 3 divisions in our tertiary care centre. **RESULTS:** In total, we established a causal diagnosis in 53% of 522 IDD patients (incl chromosomal copy number variants, syndromic diagnoses etc). Treatable IEMs were identified in 5% (n=27), including creatine deficiencies, amino-acidopathies, serine deficiencies, metal disorders, vitamin responsive disorders, neurotransmitter diseases, lysosomal storage disorders, organic acidurias etc. Analysis comparing these patients to those diagnosed in our hospital between 2000-2009 revealed that the TIDE protocol reduced 'time to diagnosis' by 6 months (range 1-50months) as well as costs of unnecessary testing (>$1500 per patient). 25% of patients with a treatable IEM presented with isolated stable ID; frequent co-morbidities include autism and seizures. 1st tier tests identified 55% of IEMs; of the 1st and 2nd tier testing, urine creatine metabolites and CSF neurotransmitter analyses identified highest number of IEMs. **DISCUSSION**: Our protocol for treatable forms of ID has proven effective in terms of increasing the diagnostic yield and reducing costs and diagnostic delay. Treatment effects vary from improvement of cognitive development, behavior, epilepsy, psychiatric disturbances or stabilization of disease. Overall better outcomes can be achieved via standard screening for treatable conditions in IDD patients. Coverage of the genes encoding treatable IEMs should be optimized if exome / genome sequencing is performed.

2495T

Genomic variants in *LINGO1* likely cause autosomal recessive intellectual disability and developmental delay. *M. Ansar[1], S. Riazuddin[2], P. Makrythanasis[1,3], M.T. Sarwar[4], Z. Iqbal[5,6], S.A. Paracha[4], J. Khan[4], M. Hussain[5,7], A. Razzaq[5,7], D.L. Polla[5], A. Suhail[4], A. Holmgren[8], D. Misceo[8], A.P.M. de Brouwer[5], M. Guipponi[1,3], F.A. Santoni[1,3], E. Frengen[8], J. Ahmed[4], H. van Bokhoven[5], S. Riazuddin[9,10], S.E. Antonarakis[1,3,11].* 1) Department of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 2) Department of Otorhinolaryngology-Head & Neck Surgery, School of Medicine, University of Maryland, Baltimore, MD, 21201, USA; 3) Service of Genetic Medicine, University Hospitals of Geneva, Geneva, Switzerland; 4) Institute of Basic Medical Sciences (IBMS), Khyber Medical University, Peshawar, Pakistan; 5) Department of Human Genetics, Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, The Netherlands; 6) Department of Neurology, Oslo University Hospital, Oslo, Norway; 7) National Centre of Excellence in Molecular Biology, University of the Punjab, Lahore, Pakistan; 8) Department of Medical Genetics, Oslo University Hospital and University of Oslo, Oslo, Norway; 9) Allama Iqbal Medical College, University of Health Sciences, Lahore, Pakistan; 10) Shaheed Zulfiqar Ali Bhutto Medical University, Pakistan Institute of Medical Sciences, Islamabad, Pakistan; 11) iGE3 Institute of Genetics and Genomics of Geneva, Geneva, Switzerland.

   LINGO1, a transmembrane receptor, is predominantly expressed in the central nervous system and is involved in the inhibition of neuronal myelination, through activation of the NgR1 signaling pathway. Various GWAS and expression studies have implicated increased expression of this gene with Multiple Sclerosis, Essential Tremor and Parkinson's disease. We have studied two unrelated Pakistani consanguineous families from different areas of Pakistan. All patients presented with a similar phenotype consisting of severe intellectual disability, aggressive behavior, speech and motor delay. We performed exome sequencing in order to identify the potential causal variant. We have identified a homozygous missense variant (NM_032808.6:c.869G>A:p.(Arg290His)) in family one and different homozygous variant in family two (NM_032808.6:c.863A>G p.(Tyr288Cys)) in *LINGO1*. Both variants segregated with the phenotype in the respective families and were predicted to be pathogenic by SIFT, PolyPhen and MutationTaster. NgR1 signaling pathway mediated by LINGO1-NgR1 complex, negatively regulates oligodendrocyte differentiation and neuronal survival. Previously mouse and zebrafish models have been described and documented the role of LINGO1 in abnormal neuronal development and central nervous system myelination. Taken together, our results indicate that *LINGO1* missense variants likely cause autosomal recessive intellectual disability. However, further functional studies are warranted to dissect the exact pathophysiological mechanism of the identified variants.

2496F

Bi-allelic *SPATA5* mutations cause severe intellectual disability, hypotonia and hearing impairment. *R. Buchert[1,2], A.I. Nesbitt[3], H. Tawamie[2], I.D. Krantz[4], L. Medne[5], I. Helbig[6,7], D.R. Matalon[4], A. Reis[2], A. Santani[3,8], H. Sticht[9], R.    Intellectual disability is a genetically heterogeneous disorder which is characterized by significant limitations in both intellectual functioning and in adaptive behavior. In a study comprising 152 families with intellectual disability of probably autosomal recessive inheritance we examined an extended consanguineous Syrian family with seven individuals affected with severe intellectual disability, microcephaly, muscular hypotonia and hearing impairment. Autozygosity mapping followed by whole exome sequencing identified a homozygous, segregating variant in *SPATA5* (c.1822_1824del; p.Asp608del). In an unrelated family, we identified compound heterozygous variants in *SPATA5* (c.[2081G>A];[989_991delCAA]; p.[Gly694Glu];[.Thr330del]) in a further individual with global developmental delay, infantile spasms, profound dystonia, and sensorineural hearing loss. Molecular modeling showed that the aspartate at position 608 (p.Asp608) is situated at the subunit interface and forms stabilizing interactions with a lysine at position 517 (p.Lys517) of the adjacent subunit of homohexameric SPATA5. Thus, a deletion of p.Asp608 is expected to cause a loss of this salt bridge and reduce the stability of the hexameric structure as well as the stability of the subunit itself. Similar to p.Asp608, p.Gly694 is also located at the subunit of the interfaces in the hexameric enzyme. A replacement of p.Gly694 by glutamate causes electrostatic repulsion with p.Asp630 of the adjacent protein subunit. Therefore, this alteration is expected to decrease hexamer stability in a similar fashion as p.Asp608del. The alteration p.Thr330del has been previously reported and could not be modeled due to a lack of sequence similarity to known protein structures. Recently, bi-allelic variants in *SPATA5* have been reported in individuals with intellectual disability, microcephaly, epilepsy and hearing loss. The identification of further individuals with a comparable phenotype and bi-allelic mutations in *SPATA5* confirms *SPATA5* as a new candidate gene for intellectual disability and further delineates the associated phenotype.

2497W

***NR2F1* mutations: Human phenotypes and investigation of a mouse model.** *C. Chen[1,2], R. Pautler[1], S. Pedersen[1], A. Raman[1,2], L. Wang[1,2], M. van der Heijden[1,2], J. Yin[1,2], Z. Liu[1,2], C. Schaaf[1,2].* 1) Baylor College of Medicine, Houston, TX; 2) Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX.

   Bosch-Boonstra-Schaaf optic atrophy syndrome (BBSOAS) is an autosomal dominant disorder characterized by optic atrophy and intellectual disability, caused by mutations in *NR2F1*. Other clinical phenotypes include hypotonia, seizures, autism spectrum disorder, oromotor dysfunction, thinning of the corpus callosum, and hearing defects. Structural abnormalities in the brain, such as hippocampal malrotation, occipital stenogyria, and chiasmal misrouting have also been reported. To better understand the disease mechanism, we studied *Nr2f1* heterozygous knockout mouse (*Nr2f1+/-*) as a disease model, given that all human patients identified to date are heterozygous mutation carriers. *Nr2f1+/-* mice manifest structural abnormalities in the brain based on DTI (diffusion tensor imaging). *Nr2f1+/-* mice have decreased hippocampal volume and increased fiber number in entorhinal cortex, however the corpus callosum appears structurally normal. Both hippocampus and entorhinal cortex are known to be critical for memory formation and maintenance. Behavioral studies show that *Nr2f1+/-* mice manifest prolonged retention of fear memory, indicating altered memory extinction. Additionally, neonatal hypotonia was noticed in p6 *Nr2f1+/-*. Although most BBSOAS patients have optic nerve atrophy, *Nr2f1+/-* mice manifest a visual performance that is not significant from wild type littermates (optokinetic reflex test). Given the reduced hippocampal volume and learning/memory abnormality in *Nr2f1+/-* mice, RNA-Seq was performed to compare the differential gene expression between wild type and *Nr2f1+/-* hippocampus. Pathway enrichment analysis showed an up-regulation of matrix metalloproteases (Mmp2, Mmp14, and Mmp15) in *Nr2f1+/-* hippocampus. The up-regulation of Mmp2 in *Nr2f1+/-* hippocampus was further validated by quantitative PCR and western blot analysis. Mmp2 is known to be critical for neuronal wiring, dendritic outgrowth, and spine remodeling. Primary cortical neuronal culture from p0 *Nr2f1+/-* pups shows decreased density of dendritic spine, particularly the stubby-shaped spines and mushroom-shaped spines, suggesting that Nr2f1 is important during the development of the central nervous system. In conclusion, we delineate the clinical spectrum of BBSOAS and characterize *Nr2f1+/-* mice as a potential disease model. The brain structural abnormalities, learning/memory deficit, and dendritic spine abnormalities in *Nr2f1+/-* mice provide insight into the disease mechanisms of BBSOAS.

2498T

Multiple human neuronal models of Lesch-Nyhan disease reveal adenosinergic and metabolic dysfunctions. *L. Crapper[1,2], S. Bell[1,2], H. Peng[1], H. Jinnah[4], J. Visser[5], G. Turecki[1,3], C. Ernst[1,3].* 1) McGill Group for Suicide Studies, McGill, Montreal, Quebec, Canada; 2) Neuroscience, McGill, Montreal, Quebec, Canada; 3) Psychiatry, McGill, Montreal, Quebec, Canada; 4) Neurology, Emory University, Atlanta, Georgia; 5) Neurology, Radboud University, Nijmegen, Netherlands.

   Background: Lesch-Nyhan Disease (LND) is a severe neurodevelopmental disorder caused by mutations in the gene *HPRT1*, characterized by hyperuricemia, dystonia, intellectual disability, and compulsive self-injurious behaviour. Although the disease was first identified in 1963, there is still no treatment for the neurological symptoms, nor has a functional association been established between *HPRT1* mutations and self-injury. Patients with LND have very low levels of dopamine, and it is believed that this contributes to the neurological symptoms, but again the connection of *HPRT1* to dopamine is unknown. **Objectives**: To develop novel *in vitro* models of LND, and determine the molecular impacts of HPRT deficiency in disease relevant cell types. **Methods & Results:** HPRT was reduced in immortalized midbrain neural progenitors using an shRNA mediated knockdown. RNA sequencing in these cell lines revealed large deficits in many genes important to adenosine signalling, and increases in genes related to energy metabolism and protein translation. We then generated induced pluripotent stem cells (iPSCs) from fibroblasts collected from LND patients and controls, which were used to generate forebrain and midbrain neural progenitor cells. These Patient derived neuronal cells showed similar transcriptional changes to the knockdown cell lines, and exhibited related functional changes. Finally, we performed RNA sequencing in the striatum and VTA of HPRT knockout mice, which do not show any of the behavioural deficits associated with LND. HPRT deficient mice do not show any major transcriptional alterations in the adenosine or energy metabolism pathways, and show opposite changes in protein translation. **Conclusions:** Two independent human derived neuronal models of LND reveal cell autonomous phenotypes that are not present in animal models, and may help to explain their lack of phenotype. Together these data present strong evidence for a role of energy metabolism, and adenosine signalling in Lesch-Nyhan Disease.

2499F

Multifaceted approach for understanding phenotypic variability in subjects with 16p11.2 duplication. *J. Dastan[1], C. Chijiwa[2], F. Tang[3], S. Martell[3], Y. Qiao[3], E. Rajcan-Separovic[3,4], M.E.S. Lewis[1,2].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 2) Children's and Women's Health Center of BC, University of British Columbia, Vancouver, Canada; 3) BC Child and Family Research Institute, University of British Columbia, Vancouver, Canada; 4) Department of Pathology, University of British Columbia, Vancouver, Canada.

   Background: Microduplication of 16p11.2 (dup16p11.2) is associated with a broad spectrum of neurodevelopmental disorders (NDD) confounded by variable expressivity. We hypothesized that while some unique features reported in individuals with dup16p11.2 may be explained by the over-expression of its integral genes, co-occurrence of other genetic alterations in the genome may account for the variability in their clinical phenotypes. This hypothesis was explored in two unrelated subjects with NDD who each inherited the dup16p11.2 from an apparently healthy carrier parent. **Results:** Detailed phenotyping analysis was used to find consistent and recognizable features among carriers of dup16p11.2 (published and current study); yet we did not find such evidence among these individuals. *KTCD13* has been identified as a major driver of a mirror brain phenotype of 16p11.2 CNV in zebrafish. However, the data presented here demonstrated that dup16p11.2 did not result in increased protein expression of KCTD13 in either probands or the healthy carrier parent, indicating that *KCTD13* is not the sole cause of microcephaly in cases with dup16p11.2. Finally, whole exome sequencing (WES) was used to investigate the presence of genomic sequence changes in dup16p11.2 carriers that could explain such clinical variability. Compound heterozygous variants of *VPS13B* in proband A and missense variants of *SYNE2* in proband B were identified. Mutations of *VPS13B* cause Cohen syndrome in keeping with proband A's phenotype (ID, microcephaly, facial gestalt, retinal dystrophy, joint hypermobility and episodic neutropenia), mRNA sequence aberration and low RNA expression. The protein encoded by *SYNE2*, Nesprin 2, plays critical roles in neurogenesis in mice. Over-expression of Nesprin 2 identified in proband B and his mother, who did not carry the dup16p112, may partly explain NDD phenotypes segregating in this family via a dominant-negative effect. **Conclusion:** Our study showed that other pathogenic variants in the genome could contribute to inter- and inter- familial clinical variability among dup16p11.2 carriers. This suggests discordance in phenotype of dup16p11.2 carriers warrants further study by WES and individualized genetic assessment and counselling.

2500W

Diagnostic exome sequencing identifies a novel homozygous alteration in *DEAF1* further delineating the phenotypic spectrum. *C. Gund[1], W. Alcaraz[1], A. Sajan[1], Z. Powis[1], A. Vashist[2], P. Suwannarat[2].* 1) Ambry Genetics, Aliso Viejo , CA; 2) Mid-Atlantic Permanente Medical Group, Rockville, MD.

In the last three years, three individuals from two families have been reported with a homozygous *DEAF1* mutation (c.676C>T) who all shared a phenotype characterized by microcephaly, brain abnormalities, and intellectual disability. The affected individuals also demonstrated a variety of other features including hypotonia, feeding difficulties, and behavioral abnormalities. Additionally, an intronic mutation causing exon skipping and which generated a premature stop codon in *DEAF1* was reported to cause disease in three siblings all affected by intellectual disability, autism, dyskinesia, abnormal cranial MRI and epilepsy. Here we report an additional patient with homozygous alterations in *DEAF1*. The patient is a 4 month old Afghani girl with developmental delay, delayed visual maturation, strabismus, hydronephrosis, vesicoureteral reflux and microcephaly as well as dysmorphic features including low posterior hairline, mild synophrys, thick and bushy eyebrows, long eyelashes, downslanting palpebral fissures, low set ears slightly posteriorly rotated with prominent antihelix bilaterally and Darwinian tubercle on the right, micrognathia, depressed nasal bridge, broad nasal tip, bilateral inverted nipples, and overlapping toes. Her head circumference was 38.1 cm (11th percentile). A MRI showed absence of splenium, hypoplastic putamina and other basal ganglia abnormalities, and wide and underdeveloped sylvian fissures. The family history is significant for multiple instances of consanguinity and an older brother who died at 6 months who had an abnormal CT of the brain. Family centered diagnostic exome sequencing (DES) on the proband and her healthy parents revealed a homozygous c.576C>A (p.Y192*) nonsense alteration in *DEAF1*. This alteration was not reported in healthy populations. This patient provides another example of a syndrome associated with homozygous mutations in *DEAF1*. While the patient's phenotype contains elements of previously reported patients, including developmental delay, relative microcephaly, truncal hypotonia, and brain malformations on MRI, the patient is notable for having a number of dysmorphic features not previously reported in homozygous *DEAF1* patients. This could represent an expansion of the phenotypic spectrum or could be the result of another cause such as the effect of an unidentified pathogenic alteration. This is not direct endorsement of Ambry Genetics by Kaiser Permanente or the Mid-Atlantic Permanente Medical Group.

2501T

Refining genotype-phenotype correlations in Iranian patients with AP4 deficiency syndrome. *K. Kahrizi[1], T. Akhtarkhavari[1], Z. Fattahi[1], M. Hosseini[1], S. Abedini[1], M. Mohseni[1], H. Hu[2], L. Mutsant[2], T. Wienker[2], H. Najmabadi[1], H.H. Ropers[2,3].* 1) Genetics Research Center, Tehran, Iran; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany; 3) Institute of Human Genetics, University Medicine, Mainz, Germany.

AP4 deficiency syndrome is characterized by severe intellectual disability, microcephaly, ventriculomegaly, growth retardation and spastic tetraplegia. Up to now, twenty six families have been reported for this syndrome. Since 2011, eleven AP4 deficiency families were identified through studying a large Iranian cohort in more than five hundred intellectually disabled families by conducting whole exome sequencing and for repetitive mutations in unrelated families we applied haplotype analysis. So far, we identified six novel mutations among nine families, including: g.1:114441425T>C (p.372Acceptor), g.1:114442649del (p.331fs) and g.1:114441377_114441378del (p.387fs) in *AP4B1*, g.7:99700490del (p.86fs) and g.7:99703887A>C (p.H333P) in *AP4M1* and g.14:31542174C>T (p.R97X) in *AP4S1*. The novel mutation in *AP4S1* was observed in two unrelated families living in two different cities with small geographic distance; moreover, g.7:99701748G>A (p.E193K) in *AP4M1* was also detected in three unrelated families from the same ethnicity. Haplotype analyses in these families confirmed their identity by descent and eliminated the possibility of a mutational hotspot. Apparently unrelated families with identical mutations reflect the tradition to marry within families in this country. *In this study we* compared phenotype-genotype profiles of eleven Iranian families with 25 patients with previously 17 reported families to show the phenotype similarity and differences in 4 subunits of AP4 complex.

2502F

High risk Northern Finnish population aids in discovery of rare recessive and dominant variants in neurodevelopmental disorders. *M.I. Kurki[1,2], E. Saarentaus[4], O. Pietilainen[2,3], E. Hamalainen[4], J.S. Moilanen[5], J. Körkkö[5], O. Kuismin[5], M. Daly[2,6], A. Palotie[1,2,4], Sequencing Initiative Suomi consortium.* 1) Psychiatric & Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 2) Stanley Center, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Department of Stem Cell and Regenerative Biology, University of Harvard, Cambridge, Massachusetts, USA; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 5) Department of Clinical Genetics, Oulu University Hospital, Medical Research Center Oulu and PEDEGO Research Group, University of Oulu, Oulu, Finland; 6) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA.

Genetic variants with strong reproductive disadvantages are evolutionary constrained and remain generally rare in population. However, these variants can still exist at higher frequencies in young populations, such as Finns, where the negative selection hasn't had time to counteract the effect of genetic drift on rare alleles. Thus, population isolates provide a valuable study design to explore the role of rare genetic variants in complex traits. In Finland, the youngest settlement is in the Northern and Eastern parts of the country, dating back to a small number of founder families only a few centuries ago. In addition, this region has a higher prevalence of both schizophrenia and intellectual disability (ID). We tested this hypothesis by producing whole exome sequence (WES) and GWAS data from 499 patients from Northern Finland with ICD-10 diagnosis of ID of unknown etiology, and their 429 family members (including 164 full trios). The Northern Finland Intellectual Disability Project (NFID) exomes were combined with 13,165 Finnish exomes sequenced in the Sequencing Initiative Suomi project (SISu, http://sisuproject.fi/). As expected, we observed comparable amount of large CNVs and *de novo* mutations as reported in similar patient collections, both of these categories being enriched in the NFID patients. Given the genetic origin of NFID, we expected to observe variants enriched in Finland that are 1) strong acting recessive variants, that seem Mendelian but account for ~1% of a 1% phenotype rather than all of a 1/10000 phenotype, and 2) dominant alleles, with odds ratios in the range of 2-5. As per our hypothesis, we discovered a Finnish-specific recessive cause of ID in 4 cases, homozygosity of a variant in *CRADD* (p=3.5e-07). The variant is not observed in homozygous state in 60,706 individuals worldwide (http://exac.broadinstitute.org/) or in 13,165 SISu. We also recruited multiplex families (2-5 affected) and searched for shared loss-of-function (LoF) variants in LoF intolerant genes (ExAC pLI metric). We observed LoF in 5 affected siblings and their mother in the *INTS6* gene. No *INTS6* LoF's have been observed in 60,706 ExAC individuals or in 13,165 Finnish exomes. We show that an enrichment of deleterious alleles increases power to detect causal and disease associated variants that would require very large sample sizes in more diverse populations.

2503W

The prevalence and architecture of dominant developmental disorders. *J. McRae, Deciphering Developmental Disorders Study.* Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

Individuals with severe, undiagnosed developmental disorders (DDs) are enriched for damaging *de novo* mutations in developmentally important genes. We exome sequenced 4,293 families with individuals with DDs, and meta-analysed these data with published data on 3,287 individuals with similar disorders. We identified 94 genes enriched for damaging *de novo* mutation at genome-wide significance (P < 7 x 10[-7]), including 14 genes for which compelling data for causation was previously lacking. We estimated that we have statistical power to detect ~45% of all haploinsufficient genes, and that most haploinsufficient genes causing DDs have already been discovered. Our large number of genome-wide significant findings allow us to compare empirically the power to detect novel DD-associated genes using exome or genome sequencing. We find that, at current cost differentials, exome sequencing has much greater power for novel gene discovery for genetically heterogeneous disorders. Finally, we estimate that 43% of our cohort carry pathogenic de novo mutations in coding sequences, with approximately half operating by a loss-of-function mechanism, and the remainder being gain-of-function or dominant negative in action. By extrapolating from the DDD cohort to the general population, we estimate that de novo dominant developmental disorders have an average birth prevalence of 1 in 213-448 (0.22-0.47% of live births), depending on parental age. Subsequent to these analyses in 4,293 families, we have sequenced another 3,663 families, nearly doubling our cohort to 7,956 families and will describe updated analyses within this larger dataset.

2504T

Hepatosplenomegaly as the initial manifestation of Coffin-Siris syndrome caused by an *ARID1B* **mutation.** *K. Takano[1], M. Motobayashi[2], T. Yamaguchi[1], K. Wakui[1], Y. Inaba[2], Y. Fukushima[1], T. Kosho[1].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 2) Department of Pediatrics, Shinshu University School of Medicine, Matsumoto, Japan.

Coffin-Siris syndrome (CSS, MIM# 135900) is a rare genetic disorder characterized by developmental delay or intellectual disability (ID), distinctive facial features, hypertrichosis, aplasia or hypoplasia of the distal phalanx or nail of the fifth fingers, and feeding difficulties. CSS is caused by mutations in 5 genes encoding subunits of the BAF complex (*SMARCB1*, *SMARCE1*, *SMARCA4*, *ARID1A*, *ARID1B*) ;and 2 genes related to BAF complex (*PHF6* and *SOX11*) (Kosho et al., 2014). Haploinsufficiency or loss-of-function mutations in *ARID1B* are reported to be the most frequent cause of CSS, and also the most frequent cause of ID through recent exome-based studies on a large cohort of developmental disorders. However, a wide spectrum of phenotypic features has been described in patients with *ARID1B* abnormalities, and it would be difficult to recognize patients with *ARID1B* abnormalities especially in early childhood. Here, we report a 1.7-year-old boy with *ARID1B*-related CSS, presenting with hepatosplenomegaly. The patient was the third child of unrelated Japanese parents and born by normal delivery at term. He was found to have abdominal distension at age 1 month. He entered hospital several times due to recurrent infections since he was 2-months-old. He was fed by nasogastric tube, because of severe feeding difficulties and failure to thrive at age 4 months. When seen by us at 7 months, he presented with hepatosplenomegaly, hypertrichosis, short stature, developmental delay and generalized hypotonia. Screening for mucopolysaccharidoses and lysosomal diseases were negative. G-banded karyotype and chromosomal microarray analysis were normal. He developed acute encephalopathy with biphasic seizures and late reduced diffusion associated with hand, foot and mouth disease at age 10 months. Broad and short fingers were evident at age 1.3 year, and we performed genetic screening using a custom-made NGS-based panel including 49 genes known to cause syndromic or non-syndromic ID. A novel splice-donor site mutation (c.4071+1G>A) in *ARID1B* was detected heterozygously. Previously, a patient with *ARID1B*-related CSS was reported to have hepatomegaly (Vals et al., 2014). Hepatomegaly, therefore, could be a rare but recognizable feature of *ARID1B*-related CSS.

2505F

Expanding phenotypic spectrum of Takenouchi-Kosaki syndrome. *T. Takenouchi[1,2], A. Ahmad[3], B. O'Conner[3], T. Uehara[1], W. Gahl[4], K. Kosaki[1].* 1) Center for Medical Genetics, Keio University, Tokyo, Japan; 2) Department of Pediatrics, Keio University, Tokyo, Japan; 3) Department of Pediatrics, University of Michigan Medical School, IL; 4) National Human Genome Research Institute, MD.

Introduction: We recently established a new syndromic form of thrombocytopenia caused by mutation in *CDC42*, which is a small GTPase of the Rho family that plays pivotal roles in diverse biological activities including the cell cycle and formation of the actin cytoskeleton. This new entity characterized by intellectual disability and macrothrombopenia is now referred to as *Takenouchi-Kosaki syndrome,* OMIM #616737. The exact phenotypic spectrum of this syndrome still needs to be explored.**Clinical Report:** Three (2 Japanese female and 1 Caucasian male) patients presented with severe developmental delay and thrombocytopenia with increased platelet size on peripheral smear. They all had sensorineural hearing loss and structural brain abnormalities. Two patients had camptodactyly, and lymphedema in lower extremities. One patient had congenital hypothyroidism.**Molecular analysis:** All three patients underwent whole exome sequencing in *trio, which* identified a *de novo* mutation in *CDC42* (p.Tyr64Cys).**Discussion: W**e have identified the three patients carrying the same *de novo* amino acid substitution, p.Tyr64Cys, in *CDC42*. The cardinal features in this new syndrome include macrothrombocytopenia, intellectual disability, sensorineural deafness, and structural brain abnormalities. Associated features included camptodactyly, lymphedema in lower extremities, and congenital hypothyroidism. Examination of platelet count and peripheral blood smear is recommended when seeing patients presenting with intellectual disability/developmental delay.

2506W

Expanding phenotypic spectrum of patients with *WAC* mutations. *T. Uehara[1], T. Takenouchi[1,2], T. Ishige[3], H. Yoshihashi[4], K. Kosaki[1].* 1) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan; 2) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; 3) Department of Pediatrics, Gunma University, Gunma, Japan; 4) Department of Medical Genetics, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

The *WAC* genes maps to chromosome 10p12.1-p11.2 and encoded protein localizes to nuclear speckles and has various functions including regulattion of P53-dependent P21 transcription. Recently, DeSanto et al. identified 5 different heterozygous truncating mutations in the *WAC* gene (Desanto-Shinawi syndrome, MIM 616708) in 6 children. Besides intellectual disabilities and gastrointestinal problems, phenotypic spectrum of *WAC* haploinsufficiency is yet to be delineated. Here, we report two unrelated patients with *WAC* nonsense mutation who were identified through the Japanese nation-wide undiagnosed disease program, Initiative on Rare and Undiagnosed Diseases. Patient 1: A 22-year-old male who had *de novo* heterozygousd *WAC* p.Glu406* mutation on trio exome analysis and severe intellectual disability and rectal and bladder disturbance. Dysmorphic features included unilateral ptosis, universal hypertrichosis, synophrys, downslanting palpebral fissures, high-arched palate, low-hair live, narrow forehead, prominent jaw, and short tapering fingers. He exhibited pancytopenia with hypoplastic bone marrow. Patient 2: A 5-year-old male who had *de novo* heterozygous *WAC* p. Ser560* mutation on trio exome analysis and mild intellectual disability and no gastrointestinal problems. Dysmorphic features included upturned nose, thick lower lip, right accessory auricle, and downslanting palpebral fissures. Here we confirmed that haploinsufficiency in the *WAC* gene leads to syndromic intellectual disability. We suggest that downslanting palpebral fissures and gastrointestinal problems may point to the diagnosis. From a clinical standpoint, it is critical to note that Patient 1 developed pancytopenia with hypoplastic bone marrow because somatic recurrent *WAC* mutations have been shown among patients with acute myeloid leukemia. *WAC* may represent an emerging class of genes which is associated with intellectual disability as germline mutation and hematologic malignancies as somatic mutations. It is to be investigated whether patients with germline *WAC* mutations may be at risk for hematological problems.

2507T

Whole exome sequencing of families with intellectual disability. *J. Inlora[1], R. Sailani[1], J.L. Lynch[1], Z. Zolfaghari[2], O. Aryani[2], M.P. Snyder[1].* 1) Genetics Department, Stanford University, Palo Alto, CA; 2) Special Medical Center for Rare Disorders, Tehran, Iran.

Intellectual disabilities are extensively heterogeneous genetic disorders. Here we performed whole exome sequencing (WES) in three Iranian families with history of mental retardation. The pattern of inheritance is likely autosomal recessive or compound heterozygous. We applied WES to seven affected and seven normal individuals across the three families with a mean coverage of 70x. The genetic variants were analyzed using the Varseq software and filtered against the 1000 Genomes Project, dbSNP, ExAC, the UK10K Project as well as the Iranian Genome Project database. To date, we identified missense mutations in *DUX4L4, RLTPR, FANCI, MCM8* and *FAM83F* as the likely candidates for the disease. To our knowledge, none of these genes were previously reported to be associated with mental retardation. Further studies are being performed to validate the relation of the candidate genes with the phenotype of these families.

2508F

The new phenotypes observed in Coffin-Siris syndrome patients with
ARID1B **mutation.** *Y. Tsurusaki[1], Y. Enomoto[1], T. Yokoi[2], M. Minatogawa[2], C. Hatano-Abe[2], K. Ida[2], T. Naruto[3], K. Kurosawa[2].* 1) Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Human Genetics, Institute of Biomedical Sciences, Tokushima University Graduate School, Tokushima, Japan.

   Coffin-Siris syndrome (CSS; MIM 135900) is a congenital disorder characterized by intellectual disability, growth deficiency, microcephaly, coarse facial features, and hypoplastic or absent fifth fingernails and/or toenails. CSS is genetically caused by mutations in *SMARCB1*, *SMARCA4*, *SMARCE1*, *ARID1A*, *ARID1B*, that are part of the Brahma-associated factor (BAF) ATP-dependent chromatin-remodeling complex and *SOX11*. We examined three CSS-suspected patients by copy number analysis and targeted resequencing. Clinical information and peripheral blood were obtained from the family members after written informed consent. This study was approved by the Institutional Review Board of Kanagawa Children's Medical Center. Copy number analysis were studied by SurePrint G3 Human CGH 8 x 60K microarray (Agilent Technologies) according to the manufacturer's instructions. DNA microarray analysis revealed a 1.0-Mb deletion involving *ARID1B* at 6q25.3 in a CSS patient with vitiligo vulgaris. Targeted resequencing by HaloPlex Target Enrichment System (Agilent Technologies) with oligonucleotide probes targeting 437 genes related to epigenetics. DNA libraries were sequenced using MiSeq with 151-bp paired-end reads. Mapping to human genome hg19 was performed using Burrows-Wheeler Alignment. Aligned reads were processed by Picard to remove PCR duplicates. Variants were called using the Genome Analysis Toolkit, and annotated by ANNOVAR. We identified that *ARID1B* were mutated in remaining two patients: c.3731_3734del (p.S1244Ifs*10) in CSS patient with biliary atresia, and c.5547dup (p.S1851Kfs*5) in CSS patient with chiari malformation. Except for CSS phenotype, the clinical features of our three patients with *ARID1B* mutation showed vitiligo vulgaris, biliary atresia, and chiari malformation, respectively. To date, these phenotypes have not been reported. Our data further support that CSS with *ARID1B* mutations found variable phenotypes.

2509W

Gynecologic and reproductive health issues in patients with Smith-Magenis syndrome. *M.A. Merideth[1], W.J. Introne[2], W.A. Gahl[1,2], A.C.M. Smith[2].* 1) Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Office of the Clinical Director, National Human Genome Research Institute, NIH, Bethesda, MD.

   Objective: To evaluate the gynecologic and reproductive health issues in females with Smith-Magenis syndrome.   **Background:** Smith-Magenis syndrome (SMS, OMIM#182290) is a complex multisystem neurodevelopmental disorder characterized by minor craniofacial abnormalities, otolaryngologic abnormalities, developmental and speech/language delay, cognitive and functional impairment, circadian sleep disorder, and neurobehavioral abnormalities. SMS is caused by heterozygous deletion or mutation of the RAI1 gene on chromosome 17p11.2. Genitourinary anomalies are less frequent but include infantile cervix and/or hypoplastic uterus in females. Detailed information about the gynecologic(GYN) issues in this patient population is sparse.   **Methods:** Nineteen females with SMS were evaluated under an NIH IRB-approved protocol (01-HG-0109) from 2003 to 2016. Evaluation included GYN history, lab testing, review of outside records and physical exam.   **Results:** The patients ranged in age from 5 to 29 years (median 15y). Age at menarche had a median of 12.5 years (range 6-16y); one had precocious puberty. Ten patients reported heavy menstrual periods, 7 of whom were treated with oral contraceptive pills (OCPs) and 3 with progesterone IUDs (1 of whom had problems due to uterine anomaly). Menstrual management issues included reluctance to use pads, discomfort with blood on pads and refusal to take daily ocps. Menstrual hygiene issues led to suppression of menses by continuous OCPs in 3 patients, IUD in 1 patient and hysterectomy in 1 patient. Increased emotional/behavioral issues prior to or at onset of menses were reported in 10 patients. Two patients had increased seizures right before menses. Though no patients had issues with vaginal infections, 3 patients had problems with vaginal insertion of objects. Laboratory testing included normal estradiol, FSH and LH levels in all 7 patients in whom they were checked.   **Conclusions:** Our results indicate a possible increased risk of menorrhagia, catamenial seizures and premenstrual behavioral/emotional issues in females with SMS and warrants further investigation. Management of menses is also an issue in this patient population. Gaining a better understanding of the range of GYN problems in SMS helps to expand the phenotype and is the first step toward developing GYN therapeutic strategies for this potentially vulnerable patient population.

2510T

A variant in *MYH11* **is a cause of familial hiatal hernia.** *M.A. Gilbert[1], R. Rajagopalan[1], B.J. Wilkins[1,2], C.M. Grochowski[1], S.E. Sivilich[3], R.S. Moreland[3], M. Pack[2], D. Piccoli[1], N.B. Spinner[1].* 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 3) Drexel University, Philadelphia, PA.

Congenital diseases of the esophagus represent a diverse group of developmental disorders that are collectively detected in 1 in 3,500-5,000 live births. Hiatal hernia (MIM 142400) is one such disorder and is characterized by localization of both the distal esophagus and proximal stomach above the diaphragm, within the thoracic cavity, rather than below the diaphragm. This disease disrupts the smooth muscle function of the lower esophageal sphincter and predisposes patients to gastroesophageal reflux. Hiatal hernia occurs frequently in the adult population, but is observed rarely in children. Despite its rare occurrence in children, it shows a strong autosomal dominant pattern of inheritance in multiple reports of familial cases suggesting a possible genetic component to the disease. We identified a family of 7 with 5 affected individuals including a father and 4 children, and performed whole exome sequencing to identify a causal gene for this disease. We discovered an insertion of 2 base pairs found at the end of the myosin heavy chain 11 (*MYH11* [MIM 160745]) gene that was shared by all affected family members. MYH11 functions within smooth muscle and is generally involved in contraction. The variant [NM_022844.2(MYH11):c.5798_5799insCA(p.Gln1934Asnfs*90)] results in a frameshift and produces an elongated protein product containing 90 unique amino acids. A previously identified 1 base pair deletion at this same genetic locus also causes a frameshift resulting in an elongated protein containing 90 amino acids, with 89 of them being identical between the two variants. This deletion was shown to alter the function of MYH11 by leading to unregulated motor activity. We therefore believe that the variant we identified is likely to be pathogenic in this family. Further supporting a role for MYH11 in esophageal dysfunction, a mouse model of a zebrafish mutation that disrupts MYH11 regulation [NM_001161775.1(MYH11):c.1516T>C(p.Trp506Arg)] results in esophageal atresia. Esophageal atresia is characterized by an esophageal gap that prevents children from ingesting food and liquids and is fatal if left untreated. In *Myh11* mutant mice, we are able to show smooth muscle hypercontractility, which likely contributes to the development of hiatal hernia. We propose a genetic link between these two seemingly unrelated congenital diseases of the esophagus and suggest a broader role for *MYH11* variants in more common sporadic esophageal and gastrointestinal motility disorders.

2511F

A novel autosomal recessive alteration in the *RYR1* **gene in a patient with profound hypotonia.** *J. Gilfert[1], B. Marr[2], S. Groskin[2], A. Chamberlin[3], S. Tang[3], Z. Powis[3], M. Byler[1], R. Lebel[1].* 1) Section of Medical Genetics, Department of Pediatrics, SUNY Upstate Medical University, Syracuse, NY; 2) Crouse Hospital, Syracuse, NY; 3) Ambry Genetics, Aliso Viejo, CA.

Homozygous and compound heterozygous mutations in the *RYR1* gene have been reported to cause hypotonia, facial weakness, nemaline myopathy, respiratory insufficiency, swallowing disturbances, and ophthalmoplegia. Heterozygous mutations in *RYR1* have been associated with malignant hyperthermia sensitivity, central core disease, multiminicore disease, and spondylocostal dysarthrosis. We report a female neonate homozygous for c.14203C>T (p. R4735W) in exon 98 of the *RYR1* gene, a novel alteration. The phenotype was notable for decreased fetal movement, profound hypotonia, cerebral dysfunction (by EEG), and cerebral atrophy (by MRI). She did not have any skeletal anomalies appreciated on several chest and abdomen radiographs (normal spine, ribs and appendicular girdles, in AP views; humerus 64 mm, normal with normal metaphyses). She died at age 17 days, when artificial support was discontinued at the parents' request. Arginine at amino acid position 4735 is located in the Inter S2-S3 domain, a highly conserved 114-amino acid loop (positions 4,666 – 4779) important for *RYR1* gating. This amino acid is highly conserved in available vertebrate species and is present in the pH-regulated prokaryotic potassium channel KcsA . Structural remodeling based on homology to the known rabbit RYR1 structure revealed that the residue R4735 lies in the VSC (cytoplasmic subdomain of the voltage-sensing like domain, VSL) and at the interface between monomers and contact residues in the EF-hand subdomain of the Central domain, and lies at the end of bundles of helices forming the VSL domain. The residue appears to form contacts with residues on adjacent EF-hand domain and with a network of charged residues lying in the alpha-helices of the VSL domain. p. R4735W is an extremely rare allele in the control population (not in ESP and 1000 genomes and observed in 2 out of 121,158 total alleles studied in ExAC). This alteration is predicted to be probably damaging and tolerated by PolyPhen and SIFT *in silico* algorithms, respectively. An allelic change p.R4735Q, as well as some neighboring missense changes (p.Y4733D, p.G4734E, p.R4737Q, p.R4737W), have been reported in patients with malignant hyperthermia and are currently considered variants of uncertain significance. .

2512W

Variable clinical features in Pompe disease associated with novel mutations. *M. Wencel[1], K. Hall[1], J. Alany-dy[1], J. Simon[1], E. Valenti[1], C. Shambaugh[1], A. Surampalli[1], J. Yang[2], N. Goyal[3], T. Mozaffar[3], V. Kimonis[1].* 1) Division of Genetics and Genomic Medicine, Department of Pediatrics, University of California- Irvine, Orange, CA; 2) Division of Neuromuscular Neurology, Department of Neurology, University of California- Irvine, Orange, CA; 3) Dietitian & Nutrition Services, University of California- Irvine, Orange, CA.

   Pompe disease is a lysosomal storage disorder caused by the deficiency of enzyme acid alpha-glucosidase (GAA) which results in accumulation of glycogen particularly in the skeletal, cardiac, and smooth muscles. The late-onset form with symptoms presenting in childhood through adulthood, is characterized by proximal muscle weakness, respiratory insufficiency, and unlike classic or infantile-onset form typically with no cardiac involvement.   We report our experience with 17 adult patients (4 F/13 M) with Pompe disease at one center, several of whom had unique findings and novel mutations. Patients ranged in ages from 18-69 y. (mean 51 y.) and were diagnosed at a range of 11-65 y (mean 37 y.) often after a history of progressive muscle disease of several years duration. Genetic sequencing revealed that 15/17 individuals had the common c.-32-13T>G adult onset mutation, and eight individuals had 6 novel mutations: c.1594G>A, c.2431delC, c.2655_2656delCG, c. 1951-1952delG-GinsT, c.525_526delTG, and c.1134C>G. A male with the c.1594G>A mutation developed an intracerebral aneurysm at the age of 43 y. and was treated with surgery. Another male with the c.525_526delTG developed testicular cancer and is currently in remission. Cardiomyopathy was noted in an adult with the c.525_526 delTG mutation, and peripheral neuropathy in a male with the c. 1951-1952delGGinsT. Two siblings with the c.2655_2656delCG developed very high antibody titers, one of whom developed a severe infusion reaction. Other clinical features included scoliosis and cardiomyopathy in an adolescent, BiPAP requirement in eleven, tinnitus in five, and one individual was born with partially developed hip and clubfoot. All patients currently receive alglucosidase alfa wi th different response rates in their muscle weakness, pulmonary function, dynamometry, and functional studies. Our patient cohort illustrates the variable range of clinical features, and alert us to the importance of careful monitoring and early management of these complications. Possible genotype-phenotype associations with these novel mutation will emerge with larger studies.

2513T

Continued identification of new genes, pathways and animal models for rare infantile forms of myopathies and neuromuscular disorders. *L.L. Baumbach-Reardon[1], J.M. Hunter[2], M.E. Ahearn[1], C. Balak[1], M. Huentelman[1], S.M. Bernes[3].* 1) TGen, Phoenix, AZ; 2) Ambry Genetics, Aliso Viejo, CA; 3) Phoenix Childrens Hospital, Phoenix, AZ.

   Neuromuscular disorders and myopathies account for a significant proportion of infant and childhood mortality and chronic disease. Phenotypes and genotypes of these disorders cover a broad spectrum but have many overlapping features. As we learn more about the etiology of human disease, we have found that most severe disease causing variants are very rare, only occurring in a single or a few individuals. One of the main goals of our most recent studies was to use next generation sequencing to identify causal mutations for cases in which prior genetic testing and histology did not reveal the disease etiology. Over the past 3 years, we have completed whole exome sequencing (WES) on 203 individuals including 73 affected individuals and additional family members. From these cases, we have identified novel probable pathogenic mutations in genes known to cause disease, as well as in genes not previously associated with disease, in ~30% of cases. These pathogenic variants include de novo, recessive, X-linked, and dominant inheritance patterns. We were able to detect distinct pathogenic mutations in several genes in multiple families (i.e., Nebulin, Titin, and RYR1). However, the majority of cases represent one-time occurrences of a mutation in either a previously known disease-causing gene, such as PLA2G6, or in previously unknown neuromuscular disease (CACNAS1 and COL6A3). Variants in novel genes will require further validation through functional studies. One of our most interesting findings is the detection of three novel pathogenic mutations in families which very much resembled XL-SMA, but instead, had mutations in another X-linked gene, SCLM2, an important gene in transcriptional repression that had not been associated with human disease. The clinical features of these families and our collaborative development of an SCML2 knock-out mouse will be presented, as well as our recent success in creating an XL-SMA targeted knock-in mouse. In summary, we applied WES using the latest NGS instrumentation and technologies to identify the genetic cause of disease in many of these cases. The genetic diversity revealed in these studies demonstrates the continued important clinical utility of WES for undiagnosed cases of infantile and childhood NMD. We continue to evaluate functionality of novel variants through *in vitro* studies, cell culture and animal models.

2514F

Attenuation of cardiomyopathy in Duchenne Muscular Dystrophy mice expressing retinal dystrophin in heart muscle. *A. Vince, M. Woods, A. Wiggins-McDaniel, J. Beckler, S. Myer, B. Wakefield, J. Harkless, R.A. White.* College of Biosciences, Kansas City University of Medicine & Biosciences, Kansas City , MO.

Duchenne Muscular Dystrophy (DMD) is a common neuromuscular disease characterized by progressive muscle degeneration and caused by mutations resulting in the absence of dystrophin. The 260 kDa human retinal dystrophin isoform (Dp260), plays a role similar to the mechanical support mechanism for muscle dystrophin. A human Dp260 transgene (Tg+) has been produced and tested in dystrophin and utrophin deficient double mutant mice (DM) which are excellent clinical models of DMD. We have previously shown that muscle-specific expression of Dp260 in transgenic double mutant DMD-Tg+ animals has striking palliative effects on spinal curvature, pathology and electrophysiology. Cardiomyopathy is also present in over 90% of DMD patients and is responsible for 40% of their deaths. DM mice also exhibit cardiomyopathy. Structural and functional analyses were carried out on the effect of expressing human Dp260 in the hearts of DMD mice. Expression of human Dp260 from the transgene in cardiac muscle was determined using western blotting. Detection of human retinal dystrophin was observed in transgenic mice and DM, Tg+ mice were the only animals that solely expressed the Dp260 and not full length dystrophin. Histopathology analysis was used to determine the effects of Dp260 expression on cardiac pathology in double mutant DMD mice, with and without the retinal dystrophin Tg+. DM mice can have thinning of the left ventricular wall with extensive fibrosis typical of dilated cardiomyopathy whereas DM, Tg+ hearts only showed normal phenotypes. DM mice heart cross-sections showed variability in fibrosis and dilated cardiomyopathy, while all DM, Tg+ mice displayed results more consistent with control mice. Analysis of Dp260 expression on heart function was also conducted on DM-Tg+, DM, and control mice which included measurements of the myocardium size, cardiac output, and fractional shortening (heart function during systole and diastole). EKG data showed a significant decrease in heart rate and left ventricular mass in DM mice while DM, Tg+ mice are normal. Fractional shortening data were not significantly different. The impact of Dp260 expression on lifespan in DM mice was significant. DM, Tg+ mice survive a normal lifespan while DM mice are deceased by 5 months of age. The effect of Dp260 expression in double mutant DMD mice has been examined and positive effects on lifespan are observed along with improvement of the heart ultrastructure and function.

Human patients and mouse modeling identifies striated preferentially expressed gene (SPEG) as a key triad muscle protein potentially involved in excitation-contraction coupling. *P.B. Agrawal, S. Cao, C. Lee, A.H. Beggs, J.J. Widrick.* Department of Medicine, Boston Children's Hospital Boston, MA.

We recently described several patients with centronuclear myopathy and cardiomyopathy caused by mutations in the *SPEG* gene. We now report the generation of a conditional knockout mouse model with inducible *Speg* deletion driven by crossing with various tissue-specific cre-expressing mice. Constitutive knockouts, and those bred with *Acta1*-cre died *in utero* at E19 while those bred with *MCK*-cre lived beyond 6 months of age. *MCK*-cre expression starts at postnatal day 1 (P1), peaks at P10 and stays high after that. *MCK*-cre+ *Speg* KO mice start to grow slower compared to their littermates at around a month of age with a significant weight difference by 3 months. The mean force generated by the *Speg*-KO tibialis anterior muscle at 3 months of age was about one-third of that generated by the WT muscle (386 versus 1209 mN in KO versus control). This force deficit remained after correcting for differences in muscle cross sectional area (128 versus 262 kilopascals in KO versus control) indicating a reduction in the intrinsic contractility of the *Speg* KO muscles. The force-frequency curves of TA muscles from the SPEG mice were shifted downward and to the right, indicating a preferential loss of force at low- to mid-frequencies of stimulation. Electron microscopy of muscles from affected mice demonstrates demonstrated abnormal triad morphology which is consistent with our immunhistochemistry studies showing that SPEG is localized there. Abnormal triads and preferential loss of low-frequency force suggest excitation-contraction failure in SPEG muscles, and work is ongoing to test this hypothesis. Further ongoing investigations include physiological and histopathological analysis, caffeine and single fiber studies . These data suggest that poor muscle function seen in SPEG-deficient mice is consistent with the human myopathy observed in patients with *SPEG* mutations.

2516T

Exploring the diverse genetic landscape of limb-girdle muscular dystrophies from a large cohort of myopathy patients. *B.R. Nallamilli, A. Tanner, Z. Whitt, C. da Silva, S. Mehta, M. Hegde.* Human Genetics, Emory University, Atlanta, GA.

Limb-girdle muscular dystrophies (LGMD) are a group of heterogeneous genetic disorders predominantly involved in proximal muscle weakness with an autosomal recessive or dominant mode of inheritance. To date, more than 30 genes have been shown to be associated with different subtypes of LGMD. The clinical and genetic heterogeneities of LGMD make disease diagnosis complicated and expensive. Recently, MDA and Jain Foundation jointly launched a LGMD sequencing program consisting of a 35 gene NGS panel through Emory Genetics Laboratory (EGL), through which over 2000 patients have been sequenced. Definitive molecular diagnosis has been established in 40% of the patients with the majority having mutations in either of 5 genes *CAPN3*, *DYSF*, *ANO5*, *FKRP* and *COL6A1*, indicating that these are the major contributors to LGMD. Late onset Pompe disease is a rare, but potentially treatable lysosomal storage disorder characterized by progressive glycogen accumulation and muscle weakness, with often a limb-girdle pattern. Therefore it should not be overlooked. We successfully identified more than 21 late onset Pompe patients with pathogenic variants in *GAA* gene. We also identified multiple patients with two pathogenic variants in *TTN* gene indicating the need for further studies in understanding the titin pathophysiological role in recessive muscle disorders. More interestingly, in at least 10% of the patients, pathogenic variants were detected in more than one LGMD genes. For example, one patient clinically diagnosed with LGMD2L but with an unexpected severe progression had homozygous pathogenic variants in both *ANO5* and *SGCA* genes. Similar multigenic combinations of pathogenic variants were detected in other individuals suggesting a possible role of synergestic heterozygosity and digenic contribution to disease presentation and progression. Around 25% of patients have been identified with variants of unknown significance (VOUS) which clearly suggesting the immediate need for further functional analysis to prove pathogenicity and to take the advantage of enrolling in numerous available clinical trials. Increased diagnostic yield observed in LGMD gene panel testing when compared to exome sequencing. Overall, current large scale LGMD sequencing project has tremendously improved our knowledge in understanding the relative prevalence of different subtypes of LGMD, allowing timely management and participation of affected individuals in clinical trials. .

AAV capsid evolution for therapeutic transduction of human skeletal muscle for use in delivery of passive vaccines and muscle gene therapies. *N.K. Paulk[1], G.W. Charville[2], K. Maguire-Nguyen[2], M. Gardner[3], K. Pekrun[1], Y. Zhang[1], B. Yoo[2], M. Tiffany[1], J.G. Vilches-Moure[4], G.K. Lee[5], J.B. Shrager[6], G. Gao[7], M. Farzan[3], T.A. Rando[2], M.A. Kay[1].* 1) Pediatrics and Genetics Depts, Stanford University, Stanford, CA; 2) Neurology and Neurological Science Dept, Stanford University, Stanford, CA; 3) Immunology and Microbial Science Dept, The Scripps Research Institute, Jupiter, FL; 4) Comparative Medicine Dept, Stanford University, Stanford, CA; 5) Surgery Dept, Stanford University, Stanford, CA; 6) Cardiothoracic Surgery Dept, Stanford University, Stanford, CA; 7) Microbiology and Physiological Systems Dept, University of Massachusetts, Worcester, MA.

Our goal is to develop an AAV vector that can transduce human skeletal muscle after intramuscular administration at levels sufficient to express therapeutic levels of antibodies in passive vaccines or transgenes in muscle gene therapies. Yet greater human skeletal muscle transduction is needed than has been achieved with existing serotypes. To engineer novel capsids with unparalleled human skeletal muscle transduction, we utilized primary human skeletal muscle cells from surgical resections to screen diverse libraries of shuffled AAV capsids. Two screens were performed in pools of primary muscle stem cells or myotubes from 6 patients. Six rounds of replicating selection were carried out and the 5 most highly selected variants from each screen were vectorized and validated against existing serotypes with muscle tropism (AAV1, 6 and 8). In primary human muscle stem cells, variants NP22, NP66 and NP94 had significantly increased transduction that ranged from a 10 to 284-fold improvement over AAV1, 6 and 8. In primary human myotubes, NP22, NP66 and NP94 again showed significantly increased transduction that ranged from a 13 to 871-fold improvement over AAV1, 6 and 8. To assess human transduction *in vivo*, we injected xenografted humanized muscle mice with variants expressing luciferase by IM injection and assessed transduction weekly by live imaging and variant NP66 demonstrated the highest sustained transduction over controls. To better predict eventual muscle transduction in humans, we transduced human muscle explants from surgical resections *ex vivo*. Four adults (2 male and 2 female) had healthy skeletal muscle tissue removed for *ex vivo* transduction with luciferase. In all 4 patients, NP22 and NP66 had significantly increased transduction by live fiber imaging as well as luciferase assays on lysed fibers that ranged from a 4 to 116-fold improvement over control serotypes. To support preclinical testing, we assessed transduction in rhesus macaque skeletal muscle explants *ex vivo*. Here again NP22 and NP66 showed a 30 to 57-fold improvement in transduction over control serotypes. Our results show that capsids NP22 and NP66 have highly significant increased human skeletal muscle fiber transduction when assessed *in vitro*, *in vivo* and *ex vivo*. These capsids represent powerful tools to express therapeutic quantities of gene products in humans. .

2518W

Identification of disease causing genes via exome sequencing and expression profiling in patients with mitochondrial disorder. *D.M. Bader[1,2], L.S. Kremer[3], G. Pichler[4], T. Schwarzmayr[3], E. Holzerova[3], R. Kopajtich[3], T. Wieland[3], T.M. Strom[3,5], M. Mann[4], J. Gagneur[1,2], H. Prokisch[3,5].* 1) Computational Biology, Departement of Bioinformatics, Technical University of Munich, Arcisstrasse 21, 80333 München, Germany; 2) Quantitative Biosciences Munich, Gene Center, Department of Biochemistry, Ludwig Maximilian University of Munich, Feodor-Lynen-Strasse 25, 81377 Munich, Germany; 3) Institute for Human Genetics, Helmholtz Zentrum Munich, Ingolstaedter Landstrasse 1, 85764 Neuherberg, Germany; 4) Department of Proteomics and Signal Transduction, Max-Planck Institute of Biochemistry, Am Klopferspitz 18, 82152 Martinsried, Germany; 5) Institute of Human Genetics, Klinikum rechts der Isar, Technical University of Munich, Trogerstrasse 32, 81675 München, Germany.

So far gene expression was mostly studied at the RNA level, however mass-spectrometry (MS) has become more comprehensive. Therefore a proteome-scale quantification is now possible using MS. Here, we are performing an integrative analysis of transcriptome and proteome profiles of 31 fibroblast cell lines of patients affected by mitochondrial disease as a systematic expansion and follow-up of our earlier exome sequencing based studies. We can show that controlling for hidden technical biases rescues the similarity of biological replicates. When correlating the corrected transcriptome and proteome data, proteins that are members of the same complex tend to have widespread post-transcriptional co-regulation. The genes encoding the mitochondrial respiratory chain complex I also have significantly lower RNA to protein correlation than genes of other complexes. Accordingly, we can improve the detection of causal gene candidates compared to exome based diagnosis by screening for protein complex degradation and expression outliers. Starting from twelve (39%) patients with validated causal genes from exome analysis, we could already validate three new causal genes that are found with the help of transcriptome and proteome data. However, further causal gene candidates are still under validation which could boost the diagnosis rate.

2519T

Mitochondrial studies in a novel disorder associated with NUBPL associated mitochondrial complex I deficiency in patients with global developmental delays, ataxia, cerebellar and pons hypoplasia. *V. Kimonis[1], P.S. Eis[2], S. Parikh[3], D. Scott[4], M.K. Koenig[5], A. Maclean[6], S. Tang[7], A.N. Hasso[8], M. Wydro[6], J. Balk[6], E. Chao[1,7], E. Hatchwell[2].* 1) Div Gen, Dept Pediatrics, Univ CA Irvine, Orange, CA, Children's Hospital of Orange County, Orange, CA; 2) Population Diagnostics, Inc., Melville, NY; 3) Center for Pediatric Neurology, Cleveland Clinic, Cleveland, OH; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Departments of Pediatrics and Neurology, The University of Texas Medical School at Houston, Houston, TX; 6) John Innes Centre, Colney Lane, Norwich, UK; 7) Ambry Genetics, Aliso Viejo, CA; 8) Radiological Sciences, School of Medicine, University of California, Irvine, CA.

The *NUBPL* gene (MIM 613621) was first reported as a cause of mitochondrial Complex I deficiency syndrome (MIM 252010) in 2010, and only seven families have been reported worldwide. We now report clinical features of 5 patients in 4 families, representing the largest number of patients diagnosed worldwide with *NUBPL* Complex I deficiency (CID). Patients were diagnosed using Whole Exome Sequencing (WES) and all were found to be compound heterozygous for a *NUBPL* (NM_025152) splicing mutation (c.815-27T>C) that is common in the population (~1% frequency), plus a rarer non-synonymous or splicing mutation (in *trans*) as follows: c.311T>C (p.L104P) in families 1 (cases 1 and 2) and 4 (case 5), c.693+1G>A in family 2 (case 3), and c.545T>C (p.V182A) in family 3 (case 4). We note that in 3 of 4 families (all except family 1), the c.815-27T>C mutation is present in *cis* with c.166G>A (p.G56R), whose pathogenicity remains in question. Primary clinical features of the CID patients, who are presently ages 3-19 years, include onset of neurological symptoms at ages 3-18 months, global developmental delay, ataxia, nystagmus, speech articulation difficulties, and cerebellar dysfunction (brain MRIs show progressive cerebellar and pons hypoplasia) and Leigh like phenotype in one individual. Importantly, despite having a diagnosis of CID, most of the patients tested normal in an electron transport chain assay (fibroblast or muscle), including for Complex I activity. Functional studies in yeast (*Yarrowia lipolytica*) were performed and confirmed the pathogenicity of the non-synonymous *NUBPL* (yeast homolog is Ind1) mutations (L104P and V182A). In addition efficacy of the coenzyme Q10 component of current therapy (e.g., mitochondrial cocktail components) was suggested by improvement in CI activity. Biochemical assays in patient fibroblasts showed mitochondrial functional differences, and differentiated neurons are being utilized to screen for and identify novel therapies for these patients. In summary we present clinical features of a unique new NUBPL associated mitochondrial complex 1 disorder identified by WES and promising treatment studies in yeast and patient fibroblasts. .

2520F

Novel mutation in *ATP5D* **as a cause of mitochondrial ATP synthase deficiency.** *J. Kohler[1,3,4], D. Fisk[2,4], M. Grove[2,3,4], D. Zastrow[1,4], E. Fernandez[1,4], A. Dries[1,4], P. Zornio[1,4], S. Schelley[5], G. Enns[5], U.D.N. Members[8], E. Ashley[1,2,3,4,6], P. Fisher[1,7], J. Bernstein[1,5], M. Wheeler[1,3,4].* 1) Stanford Center for Undiagnosed Diseases, Stanford, CA; 2) Stanford Center for Genomics and Personalized Medicine, Stanford, CA; 3) Stanford Center for Inherited Cardiovascular Disease, Stanford, CA; 4) Division of Cardiovascular Medicine, Stanford University, Stanford, CA; 5) Department of Pediatrics, Stanford University, Stanford, CA; 6) Department of Genetics, Stanford University, Stanford, CA; 7) Department of Neurology, Stanford University, Stanford, CA; 8) National Institutes of Health, Bethesda, MD.

Mitochondrial diseases are challenging to diagnose given their wide clinical variability and nonspecific clinical findings.   Here we describe a 7-year old Mexican female who presented at 2 days of age with hypoglycemia (glucose 28), lactic acidosis (lactate 34mm/L), and hyperammonemia (ammonia 200umol/L) worsened by dextrose infusion. Extensive metabolic evaluation was nonspecific. Laboratory testing including fibroblast analysis for electron transport chain enzyme assembly, pyruvate carboxylase/pyruvate dehydrogenase deficiency, and mitochondrial DNA sequence analysis were normal. Brain MRI with MR spectroscopy showed no specific abnormalities. Through childhood she had several hospitalizations for metabolic decompensation, lactic acidosis and rhabdomyolysis. She was treated with metabolic cocktail. She is developmentally normal between episodes and has a history of resolved dilated cardiomyopathy. Further genetic workup including clinical whole exome sequencing were uninformative.   Exome reanalysis at the Stanford Center for Undiagnosed Diseases filtered variants by quality, frequency, predicted functional effect, and inheritance pattern, resulting in 95 rare homozygous variants, 6 of which were in mitochondrial genes. Final manual curation identified a variant [c.245C>T(p.P82L)] in the *ATP5D* gene, Sanger-confirmed homozygous in the proband and heterozygous in each parent. *ATP5D* encodes the δ subunit of mitochondrial ATP synthase, one of five subunits in its F1 complex, that combines with the γ and ε subunits to form the central stalk. The P82 residue is conserved to yeast; the variant is predicted damaging by in-silico models. Native gel electrophoresis was performed to assess if the *ATP5D* variant impacted F1 complex, and confirmed decreased activity and normal assembly of mitochondrial ATP synthase in mitochondria from patient fibroblasts.   *ATP5D* variants have not been previously associated with disease. However, pathogenic missense variants in genes encoding the α and ε subunits of the F1 complex have been described in patients with ATP synthase deficiency (ATPsd), a clinically heterogeneous mitochondrial disorder involving neonatal-onset hypotonia, respiratory distress, encephalopathy, lactic acidosis, hyperammonemia, and cardiomyopathy. Our patient's initial presentation and subsequent episodes of decompensation are consistent with ATPsd. Given the overlapping phenotype and pathophysiology, we report a compelling novel gene-disease association.

2521W

KIF5A **mutations cause an infantile onset phenotype including severe myoclonus with evidence of mitochondrial dysfunction.** *J. Duis[1], S. Dean[2], C. Applegate[1], A. Harper[3], R. Xiao[4], W. He[4], J.D. Dollar[5], L.R. Sun[2], M. Biderman Waberski[6], T.O. Crawford[2], A. Hamosh[1], C. Stafstrom[2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins, Baltimore, MD; 2) Pediatric Neurology Johns Hopkins School of Medicine Baltimore, MD; 3) Carolinas Pediatric Neurology Care Charlotte, NC; 4) Department of Molecular and Human Genetics Baylor Miraca Genetics Laboratories Baylor College of Medicine Houston, TX; 5) Carolinas Pathology Group, Charlotte, NC; 6) National Institutes of Health Bethesda, MD.

Objective: Missense mutations in kinesin family member 5A (*KIF5A*) are known to cause spastic paraplegia 10 characterized by adult onset spastic paraparesis. We report two patients with novel *de novo KIF5A* frameshift mutations resulting in severe infantile onset myoclonus, with associated negative EEG findings, hypotonia, optic nerve abnormalities, oral motor dysfunction, dysphagia, apnea, and early developmental arrest. Methods: Genetic testing to identify DNA variants included whole exome sequencing, mitochondrial DNA sequencing and solution-based hybrid capture of targeted genes coupled with next-generation sequencing using the Illumina® HiSeq platform. Results: Sequencing analysis revealed de novo c.2854delC and c.2934delG variants in *KIF5A,* both of which create a frameshift mutation that results in a stop-loss with read through the normal termination codon to produce an elongated protein. Enzymatic testing of muscle from the second case suggested complex IV deficiency supportive of mitochondrial dysfunction. EEG studies revealed no epileptiform correlate to clinical myoclonus. Conclusions: Our two cases expand the phenotypic spectrum of *KIF5A* mutations to include a neonatal-onset myoclonic disorder associated with presumed dominant negative stop-loss frameshift mutations with predicted alteration and elongation of the carboxy-terminus (C-terminus) of the protein. Biochemical evidence of mitochondrial dysfunction in the setting of an abnormal kinesin "motor" suggests a role of impaired mitochondrial trafficking. Additionally, we hypothesize that interrupted binding of the GABA receptor plays a role in the severe myoclonus. These results highlight the role of expanded testing and whole exome sequencing in critically ill infants and emphasize the importance of accurate test interpretation.

2522T

Increased survival and improvement of neurological phenotype by anaplerotic therapy in a fish model of propionic acidemia. *V.M. Ginocchio[1], E. De Felice[1], S.E. Hofherr[2], F.T. Barrows[3], R.M. Sepe[4], P. Sordino[4], F.G. Salierno[1], I. Conte[1], N. Brunetti-Pierri[1,5].* 1) Telethon Institute of Genetics and Medicine (TIGEM), Pozzuoli, Italy; 2) Department of Lab Medicine, Children's National Medical Center, Washington, DC, USA; 3) USDA Agricultural Research Service, Bozeman, MT, USA; 4) Stazione Zoologica Anton Dohrn, Naples, Italy; 5) Department of Translational Medicine, Federico II University of Naples, Italy.

Propionic acidemia (PA) is an autosomal recessive inborn error of metabolism caused by deficiency of the mitochondrial propionyl-CoA carboxylase (PCC). The disease presents with acute, recurrent and life-threatening crises of metabolic decompensation starting from the newborn period. Patients also suffer from multi-organ complications, neurological dysfunction, and cardiomyopathy. Despite available treatments, disease mortality and morbidity remain elevated and investigation of novel and more effective therapies is highly needed. We generated a PA model in medaka fishes (*Oryzias latipes*) using TALENs targeting the *pccb* medaka gene, encoding one of the subunits of PCC. The *pccb-/-* medaka showed defective hatching, developmental delay, reduced locomotor activity, and early lethality. Livers and hearts of *pccb-/-* larvae exhibited increased lipid droplets, likely as a consequence of impaired mitochondrial beta-oxidation. Importantly, *pccb-/-* larvae showed a significant increase in the levels of C3 (propionylcarnitine), the biochemical hallmark of the disease. Non-protein energy sources and carnitine improved the survival of *pccb-/-* larvae. Because PCC deficiency induces depletion of Krebs cycle intermediates, we investigated the efficacy of an anaplerotic therapy in *pccb-/-* medaka. The anaplerotic therapy comprising sodium citrate, ornithine alpha-ketoglutarate, and glutamine resulted in significant improvements of both survival and locomotor activity in *pccb-/-* larvae. In summary, we generated a fish model of PA recapitulating the clinical and biochemical features of human patients. Anaplerotic therapy supplying intermediates of the Krebs cycle significantly improved the fish phenotype and has high potential for clinical translation. Given its small size, easy handling and large number of progeny, the PA medaka model is suitable for large-scale drug screening and rapid investigation of novel drugs.

2523F

Phenotypic heterogeneity of 2,4-Dienoyl-CoA Reductase deficiency caused by start loss NADK2 variant detected in Undiagnosed Disease Network subject. *J. Phillips, J. Cogan, T. Reimschisel, J. Gauthier, A. Robertson, A. Bican, T. McGregor, J. Newman, R. Hamid.* Dept Ped, Path, Micro, Immun, & Med, Vanderbilt Univ Sch Med, Nashville, TN.

Dienoyl-CoA reductase deficiency (DECRD) is a rare autosomal recessive disorder of mitochondrial β-oxidation of unsaturated fatty acids (OMIM 616034). DECR is crucial for the oxidation of polyunsaturated fatty acids and reduces conjugated Δ2, Δ4-dienoyl-CoAs to a Δ3-enoyl-CoA in an NADPH-dependent reaction. Until now DECR deficiency has been reported in only two patients whose disease courses were severe and unremitting; one patient died at 4 months and the other at 5 years of age. The first had failure to thrive, hypotonia, microcephaly and delayed milestones. The second developed metabolic acidosis, severe encephalopathy and leukodystrophy. Both had hyperlysinemia and DECR activities were 17% in muscle and 10% in fibroblasts, respectively. Here, we report an affected 15 year old female (third known case) with normal intelligence and a mild clinical and biochemical phenotype. She was referred to the undiagnosed diseases network (UDN) for a diagnostic workup. Her symptoms started at age 9 years and consisted of decreased visual acuity, bilateral optic atrophy, nystagmus, lower extremity weakness, numbness and difficulty walking. Limb weakness was episodic in nature and is accompanied with elevations of liver enzymes and creatinine kinase of up to 18k. Her neurological symptoms are currently stable. MRI showed stable optic pathway atrophy and volume loss. EMG showed chronic axonal sensorimotor peripheral neuropathy and mild proximal neuropathy. Urine organic acid showed highly elevated lactic and pyruvic acid. Plasma amino acids were within normal limits other than mean lysine and proline levels that were 3.7 and 2.5 times the upper limits of normal. Negative molecular studies included mitochondrial DNA sequencing and comprehensive muscular dystrophy panel. Whole exome sequencing showed homozygosity for a c.1A>G; p. Met1Val start loss mutation in the primary transcript (NM_001085411.1) of NADK2 which encodes the 442 amino acid isoform. This variant alters the start codon, has not been previously reported, is absent from external reference databases including 1000G/EVS/ExAC, and was heterozygous both of the patient's parents. This patient's near normal intelligence and stable disease expands the phenotypic heterogeneity and pleiotropism, as well as the prognosis associated with DECRD. Our results further suggest that attention should be paid to cases of hyperlysinemia especially those with visual loss and neurological phenotypes as some may also have DECRD.

2524W

Hyperammonemia induces hepatic autophagy and its enhancement improves the clearance of ammonia *in vivo*. *L.R. Soria[1], N. Pastore[2,3], P. Annunziata[1], E. Polishchuk[1], R. Polishchuk[1], E. Nusco[1], A. Ballabio[1,2,3,4], N. Brunetti-Pierri[1,4].* 1) Telethon Institute of Genetics and Medicine (TIGEM), Pozzuoli, Italy; 2) Department of Molecular and Human Genetics; Baylor College of Medicine; Houston, TX, USA; 3) Jan and Dan Duncan Neurological Research Institute; Texas Children's Hospital; Houston, TX, USA; 4) Department of Translational Medicine, Federico II University, Naples, Italy.

The urea cycle is the main pathway in mammals for nitrogen detoxification. Systemic ammonia is elevated in patients with an inherited or acquired impairment of hepatic ammonia detoxification. Hyperammonemia may result in irreversible brain damage if not treated early and thoroughly and available treatments are often inadequate. Ammonia has been found in cell cultures to stimulate autophagy, a conserved catabolic process that degrades cytoplasmic components and organelles in the lysosome. Therefore, we investigated whether autophagy is also induced *in vivo* and whether modulation of autophagy plays a role in the severity of hyperammonemia. We confirmed that ammonia induced autophagy in cells and we found that it stimulates nuclear translocation of TFEB, a master regulator of autophagy and lysosomal function. Liver autophagy was found to be activated in C57BL/6 wild-type mice during acute hyperammonemia induced by intraperitoneal (i.p.) injections of ammonium chloride. Increased hepatic autophagy was also observed in ornithine transcarbamylase-deficient mice, a mouse model of the most common and severe inborn error of urea synthesis. Suppression of autophagy by colchicine or vinblastine severely impaired the clearance of ammonia following an i.p. ammonia load. Furthermore, TFEB liver-specific knockout mice showed a defect of ammonia handling compared to control mice, suggesting that hepatic autophagy is an important mechanism for ammonia detoxification. Moreover, enhancement of autophagy by liver-directed gene transfer of TFEB mediated by intravenous injection of a helper-dependent adenoviral vector protected against acute hyperammonemia. In addition, ammonia detoxification was ameliorated by autophagy-inducing small molecules. Autophagy activation was associated with increased ureagenesis and higher levels of N-acetylglutamate precursors, ATP, and aspartate that activate and fuel the urea cycle. Importantly, pharmacological enhancement of autophagy reduced blood ammonia in models of both acute and chronic hyperammonemia, i.e. thioacetamide-induced liver failure and diet supplemented with ammonium acetate, respectively. In summary, our data show that hepatic autophagy is activated by hyperammonemia, deficiency of autophagy impairs ammonia handling, and its enhancement can be exploited therapeutically for both acute and chronic hyperammonemia.

2525T

***NAXE* mutations disrupt the cellular NAD(P)HX repair system and cause a lethal neurometabolic disorder of early childhood.** *E. Koňaříková[1,2], L.S. Kremer[1,2], K. Danhauser[3], D. Herebian[3], D. Petkovic Ramadža[4], D. Piekutowska-Abramczuk[5], A. Seibt[3], W. Müller-Felber[6], T.B. Haack[1,2], R. Płoski[7], K. Lohmeier[3], D. Schneider[8], D. Klee[9], D. Rokicki[10], E. To safeguard the cell from the accumulation of potentially harmful metabolic intermediates, specific repair mechanisms have evolved. *APOA1BP,* now renamed *NAXE,* encodes an epimerase essential in the cellular metabolite repair for NADHX and NADPHX. The enzyme catalyzes the epimerization of NAD(P)HX, thereby avoiding the accumulation of toxic metabolites. The clinical importance of the NAD(P)HX repair system has been unknown. Exome sequencing revealed pathogenic biallelic mutations in *NAXE* in children from four families with (sub-) acute onset ataxia, cerebellar edema, spinal myelopathy, and skin lesions. Lactate was elevated in cerebrospinal fluid of all affected individuals. Disease onset was during the second year of life and clinical signs as well as episodes of deterioration were triggered by febrile infections. Disease course was rapidly progressive, leading to coma and finally to death in all affected individuals. NAXE protein levels were undetectable in fibroblasts from affected individuals of three families. In these fibroblasts we measured highly elevated concentrations of the toxic metabolite cyclic-NADHX, confirming a deficiency of the mitochondrial NAD(P)HX repair system. Finally, NAD or nicotinic acid (vitamin B3) supplementation might have important therapeutic implications for this fatal disorder.

   [;Introduction]; We report a case of Leigh syndrome possessing a c.55C>T, p(P19S) mutation in *NDUFA1*. *NDUFA1* encodes MWFE, which plays an important role in complex 1 assembly, function, and stability. We review the clinical phenotype induced by *NDUFA1* mutations. [;Case Report]; The patient was an 11-year-old boy. He had axial hypotonia and horizontal nystagmus at 5 months. At 10 months, afebrile generalized seizure was observed and the plasma lactate (44.9 mg/dL) and pyruvate levels (2.07 mg/dL) were elevated. At 17 months, brain magnetic resonance imaging (MRI) revealed bilateral lesions in the substantia nigra and globus pallidus; moderate intellectual disability and hearing difficulty were noted. He walked independently at 2 years 6 months. At 5 years, a muscle biopsy showed mild type 2B fiber atrophy. Fibroblast complex I enzymatic activities were 27.6% of control. A single missense mutation (P19S) in the X-linked *NDUFA1* gene was detected. Oral administration of vitamin B_1 and coenzyme Q_{10} began at age 3; consequently, the lactate and pyruvate levels decreased and the MRI lesions diminished. At 7 years, his ataxia was aggravated, resulting in difficulty sitting and walking; brain MRI showed new lesions in the bilateral putamen and medulla. Although his ataxia and muscle weakness gradually improved, at 10 years, he presented central apnea, intention tremor, and dysphagia. Brain MRI showed cerebellar atrophy and symmetric T2 hyperintensities in the cervical cord. After 1 year, his weakness mildly improved. [;Conclusion]; *NDUFA1* is reportedly involved in the assembly and function of complex☐by interacting with other subunits encoded by mitochondrial DNA. Four previously reported patients and our case with *NDUFA1* mutations presented with Leigh syndrome and prominent infratentorial lesions, cerebellum and brainstem. Moreover, our case showed spinal cord involvement.

   Mitochondrial complex I deficiency results in a plethora of often severe clinical phenotypes presenting already in early childhood. Here we report three complex I deficient adult subjects with relatively mild clinical symptoms, including isolated, progressive exercise induced myalgia and exercise intolerance but with normal later development. Exome sequencing and targeted exome sequencing revealed compound heterozygous mutations in *TMEM126B*, encoding for a complex I assembly factor. Further biochemical analysis of subject fibroblasts revealed a severe complex I deficiency caused by a defective assembly. Lentiviral complementation with the wild-type cDNA restored the complex I deficiency, demonstrating the pathogenic nature of these mutations. Further complexome analysis of one subject indicated that the complex I assembly defect occurred at the stage of its membrane module assembly. Our results show that TMEM126B defects can lead to complex I deficiencies and interestingly, symptoms could only occur after exercise.

Complex I deficiency is the most common biochemical phenotype observed in individuals with mitochondrial disease. With 44 structural subunits and over 10 assembly factors, it is unsurprising that complex I deficiency is associated with clinical and genetic heterogeneity. Massively parallel sequencing (MPS) technologies including custom, targeted gene panels or unbiased whole exome sequencing (WES) are hugely powerful in identifying the underlying genetic defect in a clinical diagnostic setting, yet many individuals remain without a genetic diagnosis. These cases may harbor mutations in poorly understood or uncharacterized genes, and their diagnosis relies upon characterization of these orphan genes. Complexome profiling recently identified TMEM126B as a component of the mitochondrial complex I assembly (MCIA) complex alongside the ACAD9, ECSIT, NDUFAF1 and TIMMDC1 proteins. We describe the clinical, biochemical and molecular findings in six cases of mitochondrial disease from four unrelated families with biallelic *TMEM126B* variants at c.635G>T, p.(Gly212Val) or c.401delA, p.(Asn134Ilefs*2). We provide functional evidence to support the pathogenicity of these *TMEM126B* variants, with evidence of founder effects for both variants, and establish defects within this gene as a cause of complex I deficiency in association with either pure adult-onset myopathy, or in one case, a severe multisystem presentation (chronic renal failure and cardiomyopathy) in infancy. Functional experimentation including viral rescue and complexome profiling of subject cell lines confirms TMEM126B as the tenth complex I assembly factor and validates the importance of both genome wide sequencing and proteomic approaches in characterizing novel disease-associated genes whose physiological roles were previously undetermined.

DNM1L-**related mitochondrial fission defect presenting as spastic paraparesis and optic atrophy.** *M. Tesarova[1], T. Danhelovska[1], M. Rodinova[1], V. Stranecky[2], J. Sladkova[1], A. Vondrackova[1], J. Krizova[1], J. Zamecnik[3], T. Honzik[1], H. Hansikova[1], J. Zeman[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University and General University Hospital in Prague, Prague, Czech Republic; 3) Institute of Pathology and Molecular Medicine, Second Faculty of Medicine, Charles University and Motol University Hospital, Prague, Czech Republic.

An increasing group of mitochondrial disorders is caused by mutations in nuclear genes affecting mitochondrial dynamics and function. *DNM1L* gene encodes the dynamin 1- like protein DNM1L (Drp1) which is crucial in the mitochondrial fusion process as well as fusion of peroxisomes. We describe a patient with novel heterozygous *de novo DNM1L* mutation c. 176C>T (p.Thr59Ile), which further expands the associated clinical spectrum. The patient exhibits axial hypotonia, spastic paraparesis, neo- and paleo-cerebellar syndrome and optic atrophy. Muscle biopsy revealed mild decrease in CI+III activity, increased SDH and decreased COX activity staining in 5% of muscle fibers. Furthermore, regular occurrence of "mega-mitochondria" along elongated mitochondrial network was found in cultured myoblasts which confirms impaired mitochondrial dynamic. Novel mutation c. 176C>T (p.Thr59Ile) in *DNM1L* gene was identified by exome sequencing and affects highly conserved Thr59 in the GTPase domain of the protein. Trp59 has been previously shown to be indispensable for GTPase reaction since it is involved in the positioning of the catalytic water molecule and Mg^{2+} coordination (Wenger et al 2013). All previously described missense mutations in 3 patients with varied phenotype were localized in the middle domain that is important for the self-assembly of the protein and its oligomerization. To conclude, our results further expand clinical phenotypes (including optic atrophy) associated with *DNM1L* mutations that is typical for mitochondrial disorders due to altered mitochondrial dynamics. *Supported by research projects GAČR 14-36804G, RVO-VFN64165/2012 and AZV 16-32341A.*

Mutations in *SLC25A4* encoding the mitochondrial ADP/ATP carrier AAC1 are a well-recognized cause of mitochondrial disease. Several heterozygous *SLC25A4* mutations cause adult-onset autosomal dominant progressive external ophthalmoplegia associated with multiple mitochondrial DNA deletions, whereas recessive *SLC25A4* mutations cause childhood-onset mitochondrial myopathy and cardiomyopathy. Here, we describe the identification by whole exome sequencing of 7 probands harboring dominant, *de novo SLC25A4* mutations. All affected individuals presented at birth, were ventilator-dependent and, where tested, revealed severe combined mitochondrial respiratory chain deficiencies associated with a marked loss of mitochondrial DNA copy number in skeletal muscle. Strikingly, an identical c.239G>A, p.(Arg80His) mutation was present in 4 of the 7 subjects, whilst the other 3 cases harbored the same c.703C>G, p.(Arg235Gly) mutation. Western blot analysis of skeletal muscle revealed a marked decrease of AAC1 protein levels and loss of respiratory chain components. By expressing recombinant mutant AAC1 in *Lactococcus lactis* we showed that both mutations severely impair ADP/ATP transport. Structural analysis suggests the mutations most likely affect the substrate binding and mechanics of the carrier, respectively. Both affected residues point inwards and thus cannot be involved in dimerization of AAC1, excluding this as an explanation of the dominant phenotype. The decreased capacity for transport likely affects mitochondrial DNA maintenance and in turn respiration, causing a severe energy crisis. The confirmation of the pathogenicity of these *de novo SLC25A4* mutations highlights a third distinct clinical phenotype associated with mutation of this gene and demonstrates that early-onset mitochondrial disease can be caused by recurrent *de novo* dominant mutations, which has significant implications for the application and analysis of whole exome sequencing data in mitochondrial disease.

2531T

The results of the *GJB2* gene copy-number analysis in the patients "homozygous" for the *GJB2* mutation. *E.A. Bliznetz, A.V. Polyakov.* Federal State Budgetary Institution "Research Centre for Medical Genetics", 115478 Russian Federation, Moscow, Moskvorechie street, 1.

Although the mutations in the *GJB2* gene sequence make up the majority of variants causing autosomal recessive congenital nonsyndromic hearing loss, few large deletions have been shown to contribute to DFNB1 deafness. Currently, clinical DFNB1 testing for nonsyndromic hearing loss patients includes *GJB2* sequencing and DFNB1 deletion analysis for two common large deletions (*GJB6*-D13S1830 and *GJB6*-D13S1854) in the patients, who carry one or no mutation in the *GJB2* gene sequence, by using ALFP analysis with deletion-specific breakpoint primers or copy-number analysis. While the *GJB6*-D13S1830 and *GJB6*-D13S1854 deletions lie upstream of *GJB2* and don`t affect *GJB2*, two mutations of 920 kb and 101 kb in size, published by Feldmann et al. (2009) and Bliznetz et al. (2014) respectively, directly affect the *GJB2* gene by deletion of the entire *GJB2* gene. These deletions have been observed to cause a false homozygosity of the *GJB2* mutation in compound heterozygous patients or the lack of the *GJB2* gene sequence in patients homozygous for the large deletion. We proposed that there are other large deletions of the *GJB2* gene, concealed by "homozygosity" of the *GJB2* point mutation. Here we investigated copy number changes of sequences in the *GJB2* and *GJB6* genes in 182 unrelated Russian patients, homozygous for the *GJB2* mutation. DNA from their parents was not tested. No copy number changes were detected by using the SALSA® MLPA® test (MRC-Holland). We assume that unidentified large deletions of the *GJB2* gene are extremely rare.

TMTC2 **as a candidate gene responsible for sensorineural hearing loss in children.** *H. Guillen Ahlers[1], M.J. Montoya[1], F. Chevalier[1], C. Erbe[2], C.L. Runge[2], M. Olivier[1].* 1) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Otolaryngology and Communication Sciences, Medical College of Wisconsin, Milwaukee, WI.

Hearing loss affects 1 in 1000 newborns, and 5 in 1000 children 3-17 years old. Even though it is estimated that half of those cases arise from genetic causes, only a limited number of genes have been identified, and most characterized mutations affect very few individuals. We recently investigated a large family of Northern European descent with sensorineural hearing loss. The hearing loss in all affected family members is characterized as bilateral, symmetric, progressive SNHL reaching severe to profound loss in childhood. Audiometric configurations demonstrated a characteristic dip at 1000-2000 Hz. All affected family members wear hearing aids or have undergone cochlear implantation. We discovered the fully penetrant variant rs35725509 in the *TMTC2* gene [MIM 615856] as the likely cause for hearing loss in this family. The nonsynonymous mutation leads to a Val to Ile substitution at position 381 of *TMTC2*, a gene that potentially affects the normal nerve function in the inner ear. The rs35725509 variant is found in the general population (0.8%), suggesting that it may affect hearing in individuals beyond the initial family. To determine whether rs35725509 or additional mutations in the *TMTC2* gene can be identified in other children affected by sensorineural hearing loss, DNA from 7 children with severe sensorineural hearing loss and their immediate family members was collected for exome sequencing. The rs35725509 variant was found in both affected members in one of the families, further suggesting the relevance of this mutation. The rs35725509 variant was the only one identified within the *TMTC2* gene, no additional mutations in the gene were uncovered in these families. A better understanding of genetic causes of hearing loss in children is essential to devise novel treatment options for this debilitating disorder.

2533W

Exome sequencing and bioinformatic analysis of Louisiana Acadian families with extensive family history of Usher syndrome, isolated retinitis pigmentosa, and multigenic intrafamilial mutations. *D. Mercer[1], A. Umrigar[1], A. Musso[2], A. Hurley[2], F. Tsien[1].* 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Dept. of Communication Disorders, School of Allied Health Professions, Louisiana State University Health Sciences Center, New Orleans, LA.

We are conducting a study of Louisiana Acadian families with extensive history of hearing and vision loss. Usher syndrome is an autosomal recessive condition characterized by hearing loss and progressive blindness due to retinitis pigmentosa (RP). It accounts for approximately half of all cases of concurrent deafness and blindness in adults. Though rare, Usher syndrome is more common in certain ethnic populations, including the Louisiana Acadians. The most common mutation in the Acadian population is the USH1C 216G>A mutation. Isolated cases of RP can also occur independently from Usher syndrome. We present two families with variable degrees of hearing loss and retinitis pigmentosa. 1.) Family A is affected by both autosomal recessive Usher syndrome and autosomal dominant isolated RP. The proband is clinically diagnosed with isolated RP and is a heterozygous carrier for the common USH1C mutation. The proband's brother is also affected with isolated RP with no USH1C mutation detected. The proband's two maternal half-brothers are homozygous for the USH1C G>A mutation revealed by PCR and targeted sequencing. An extensive family history spanning five generations revealed eight Usher syndrome affected individuals on the maternal side of the family, while most members of the paternal side of the family were clinically diagnosed with isolated RP. Exome sequencing and bioinformatic analysis revealed mutations of the PRPF3 and RHO genes responsible for the RP in the affected individuals. 2.) The proband from family B is homozygous for the common USH1C G>A mutation. At the current age of 18 years, he does not yet exhibit significant vision loss. Maternal family history spanning six generations identified 3 family members with Usher syndrome showing signs of RP in their 30s, which is a much later age than typically seen for Usher syndrome Type 1; and 8 family members in their 20s with deafness only. Exome sequencing and bioinformatic analysis revealed the presence of both USH1C and USH2A mutations in the proband. The present study demonstrates the prevalence of these rare mutations in isolated communities such as the Louisiana Acadians. In addition, we found multigenic intrafamilial mutations in the Louisiana Acadian families from our study. Genetic awareness in these communities and diagnosis are essential in the prognosis, genetic counseling, and treatment of these families.

2534T

The subtleties of CNVs and the power of targeted genomic enrichment in their detection. *A.O. Taylor[1], D.L. Kolbe[1], C. Sloan-Heggen[1,2], C.J. Nishimura[1], K.L. Frees[1], E.A Black-Ziegelbein[1], K.T. Booth[1], S.S. Ephraim[1], P.T. Ranum[1], D. Wang[1], A.E. Weaver[1], H. Azaiez[1], R.J.H. Smith[1,2].* 1) Otolaryngology, The University of Iowa, Iowa City, IA; 2) Molecular Physiology & Biophysics, The University of Iowa College of Medicine, Iowa City, IA.

Over 90 genes have been implicated in non-syndromic hearing loss (NSHL), making targeted genomic enrichment and massively parallel sequencing (TGE+MPS) an ideal technology by which to provide comprehensive genetic testing as a clinical tool in the evaluation of deaf and hard-of-hearing persons. Here, we illustrate the power of a TGE+MPS panel called OtoSCOPE to detect copy number variation (CNV) using five representative families.   **Case 1:** A 5-year-old Hispanic/Caucasian male with congenital moderate sensorineural hearing loss (SNHL) and hypermetropia underwent computed tomography of the temporal bones, mutation screening of *GJB2/6*, and array comparative genomic hybridization, all of which were uninformative. OtoSCOPE identified homozygosity for the tandem deletion of *STRC-CATSPER2* and a diagnosis of Deafness-Infertility Syndrome was made. **Case 2:** A 7-year-old male was diagnosed with congenital bilateral mild conductive hearing loss. The family history was remarkable for pre-auricular pits in the father, which the child also had, in addition to a second branchial arch sinus tract. OtoSCOPE identified a four-exon deletion in *EYA1* consistent with the diagnosis of branchiootorenal syndrome. **Case 3:** A 5-year-old Irish female was evaluated for congenital severe-to-profound SNHL and a family history remarkable for dominantly inherited maternal hearing loss; the mother also had a white forelock. Prior testing included a Waardenburg panel and whole exome sequencing both of which were non-diagnostic. A small, two-exon, deletion in *SOX10* was detected using OtoSCOPE and Waardenburg syndrome was diagnosed. **Case 4:** A 2-year-old male with congenital bilateral hearing loss was diagnosed with a single exon deletion and a pathogenic missense change in *CDH23* consistent with the diagnosis of USH1D. **Case 5:** A 5-year-old female with congenital profound hearing loss was diagnosed with a two-exon deletion and pathogenic missense variant in *TMC1* consistent with a DFNB7/11 diagnosis.   These cases illustrate the importance of high-resolution CNV detection in deafness. Because CNVs are implicated in up to 20% of deafness, analysis for this type of genetic change must be included in all clinical diagnostics panels used for deafness.

2535F

Identification of *CYP1B1* mutations in families with primary congenital glaucoma. *M. Ansar, B. Gul, F. Hashmi, A. Mehmood, N. Ullah, S. Sajid, E. Ul-lah.* Department of Biochemistry, Faculty of Biological Sciences, Quaid-I-Azam University, Islamabad, 45320, Pakistan.

Primary congenital glaucoma (PCG) is a rare autosomal recessive disorder which generally present during early infancy. The signs and symptoms of PCG include reduced visual acuity, enlargement of globe, blepharospasm, edema, corneal opacification and photophobia. Currently mutations in six genes/loci are known to cause PCG but among these CYP1B1 is the major contributor. For this study we identified seven multiplex Pakistani families which comprised of 24 patients presenting typical clinical features of PCG. Sanger sequencing of CYP1B1 gene in these families identified potentially pathogenic variants in four families, including two novel and two known variants. The identified variants were sequenced in all available samples of each family to confirm the segregation with PCG phenotype. Pathogenicity analysis by bioinformatics tools predicted that all identified variants are disease causing, but one of these (p.Glu229Lys) showed high frequency (0.01423; 41 homozygotes) in the ExAC data. Further sequencing of control DNA samples from various ethnic groups of Pakistan also revealed the high frequency of mutant allele and thus cast doubts on the pathogenic nature of this variant. Our findings indicate that CYP1B1 is the major contributor of PCG in Pakistan and it further highlights the importance of the detailed evaluations before declaring variants as pathogenic.

2536W

Next-generation sequencing-based deafness panel deciphers the genetic etiology of non-syndromic auditory neuropathy spectrum disorder in Han Chinese from Taiwan. *Y.H. Lin[1,2,3], Y.H. Chan[1,3], Y.H. Lin[1,4], C.J. Hsu[1,3], P.L. Chen[2,4,5,6], C.C. Wu[1,5].* 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 3) Department of Otolaryngology, Taichung Tzu Chi Hospital, Buddhist Tzu Chi Medical Foundation, Taichung, Taiwan; 4) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 5) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 6) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan.

Non-syndromic auditory neuropathy spectrum disorder (ANSD) is a common cause of hereditary hearing impairment. Non-syndromic ANSD can be caused by damage to the inner hair cells, synapses, spiral ganglion neurons, auditory nerve, or brainstem auditory nuclei. Corresponding to the heterogeneity in pathology, the rehabilitation outcomes with hearing aids or cochlear implants vary significantly among the patients. Recent studies have revealed that genetic diagnosis is of great help in determining the site of pathology in hereditary hearing impairment. In this study, we performed comprehensive genetic analyses in 40 unrelated ANSD patients of Han Taiwanese ethnicity. All patients underwent a first-tier genetic screening for 3 common deafness genes (*GJB2*, *SLC26A4* and the mitochondrial 12S rRNA gene) and 1 ANSD hotspot in Han Taiwanese (*OTOF* p.E1700Q) using Sanger sequencing. Patients with non-diagnostic genotypes were then subjected to a next-generation sequencing (NGS)-based panel which targets 161 deafness genes, including the 7 documented non-syndromic ANSD genes: *OTOF*, *DFNB59*, *GJB2*, *PCDH9*, *DIAPH3*, *AIFM1*, and the mitochondrial 12S rRNA gene. In total, we confirmed genetic diagnosis in 22 (55%) patients, including 19 with bi-allelic *OTOF* mutations, 2 with bi-allelic *GJB2* mutations, and 1 with homoplasmic m.1555A>G mutation. Of the *OTOF* variants, p.E1700Q was the most prevalent, being homozygous in 8 patients and compound heterozygous with other *OTOF* mutations in 11 patients. We identified 3 novel *OTOF* mutations which had not been reported: p.E841K, c.4961-1G>A, and p.R1735W. Of note, we identified an *OTOF* variant, p.K1992R, which was linked with p.E1700Q on the same haplotype in all the chromosomes of the homozygous and heterozygous patients. As the allele frequency of p.K1992R (0.0006938) in the East Asian population of ExAC was much lower than that of p.E1700Q (0.00743), and p.K1992R was predicted as "probably damaging" by several softwares, we speculated that p.K1992R might be the true mutation leading to ANSD instead of p.E1700Q. We are currently performing immunoprecipitation experiments to validate the pathogenicity of *OTOF* p.K1992R, p.E1700Q, as well as the three novel *OTOF* mutations. In summary, our results demonstrated that *OTOF* mutations are the predominant cause of non-syndromic ANSD in the Taiwanese population, and that targeted NGS is useful in deciphering the genetic etiology of non-syndromic ANSD.

2537T

Resolving the pseudogene mapping complexities of conventional exome sequencing in hearing impairment using 10XGenomics approach. *R. Pellegrino[1], C. Kao[1], F. Mafra[1], J. Garifallou[1], C. Kaminski[1], L. Tian[1], S. Garcia[2], B. Vona[3], T. Haaf[3], H. Hakonarson[1].* 1) The Children´s Hospital of Philadelphia, Philadelphia, PA; 2) 10XGenomics; 3) Institute of Human Genetics, Julius Maximilians University, Wuerzburg, Germany.

Hearing deficiency is a particularly heterogeneous disorder affecting approximately 1 of 1000 newborns every year. Non-syndromic autosomal recessive deafness maps to a number of different non syndromic Hearing Loss and Deafness (DFNB) loci. For example, the DFNB1 locus contains *GJB2* (MIM: 121011) and *GJB6* (MIM: 604418), The stereocilin (*STRC*) gene (MIM: 606440), located in chromosome 15q15.3 within the DFNB16 locus, presents a major mapping challenge for standard next-generation sequencing (STRC) pipelines due to a closely linked pseudogene with 99.6% coding sequence identity. *STRC* also is part of a larger segmental duplication of four genes, *HISPPD2A* (MIM: 610979), *CATSPER2* (MIM: 607249), *STRC*, and *CKMT1A* (MIM: 613415) all of which having mapping issues using current short-read (~200-400 bases) NGS technologies. In fact, ~10% (1,998) of genes in the human exome have highly homologous paralogs (pseudogenes) located elsewhere in the genome that are problematic to map using short read NGS. Genes such as *STRC* are clinically important but largely inaccessible to current NGS and require customized assays to characterize. We use the Chromium instrument (10X Genomics) to generate barcoded reads that identify segments that are immediately contiguous to each other in the genome. The barcoded reads then underwent exome target enrichment using a premium bait design (Agilent SureSelect) containing "bridging baits" spaced within intronic and intergenic regions to preserve long-range information following capture. We subsequently sequenced individuals with hearing loss using the Illumina Hiseq2500 at 85X coverage. We use linked read technology coupled to whole exome sequencing to demonstrate proof-of-principle on samples with clinically validated *STRC* variants/mutations. This approach was able to detect nucleotide variants, indels, and larger structural variants. Importantly, we were also able to accurately phase compound mutations. For example, a suspected compound heterozygous sample with two pathogenic *STRC* variants, c.2303_2313+1del12 and c.5125A>G, were found to be arranged in *cis* instead of *trans*. Thus, linked read sequencing provide an approach to accurately map short NGS reads in *STRC* from its pseudogene and can be used to detect/resolve variants that contribute to congenital hearing impairment.

MAB21L1 **mutation causes anophthalmia and microphthalmia.** *X. Wu[1,2], C. Liu[1,2], Z. Kang[1,2], Z. Li[1,2], Y. Wang[1,2], L. Li[1,2], L. Peng[1,2].* 1) Research Center for Translational Medicine, Shanghai East Hospital, Tongji University School of Medicine,Shanghai,China; 2) Division of Medical Genetics,Tongji University School of Medicine, Shanghai, China.

   Anophthalmia and microphthalmia (AM) are rare ocular anomalies, characterized by complete absence of the globe or short of a total axial length of a globe. Utilizing whole-exome sequencing, we identify a heterozygous mutation, C.151 C>T, (p.Arg51Trp) in *MAB21L1* gene from patients affected by AM in a dominant heritant family. The *MAB21L1* gene, located at 13q13, encodes a 359-amino acid protein similar to *mab21*, a cell fate-determining factor, in *C. elegans*. We further observed the effect of *mab21l1* on the development of eye in zebrafish. In situ hybridization experiments showed that the *mab21l1* mainly expressed in both eye and midbrain. When knockdown of *mab21l1* using specific morpholino, the development of whole oclular was impaired , but could be really rescued by forced-expression mRNA of either wild-type (WT) *mab21l1* or *mab21l2*. TUNEL staining was also performed to detect the level of apoptosis in zebrafish, and showed that the downregulation of *mab21l1* induced a significantly apoptosis. These results thus implicate a vital role of *MAB21L1* in the pathogenesis of anophthalmia and microphthalmia.

Genetic causes of hearing loss in Middle Eastern Arab families. *A.I. Abu Rayyan[1], N. Danial-Farran[2], Z. Brownstein[3], L.A. Kamal[1], S. Gulsuner[4], S. Casadei[4], T. Walsh[4], S. Allon-Shalev[2], M.C. King[4], K.B. Avraham[3], M.N. Kanaan[1].* 1) Biological Sciences , Bethlehem University , Bethlehem , Bethlehem , Palestinian Territory; 2) Genetics Institute, Ha'Emek Medical Center, Afula, Israel; Rappaport Faculty of Medicine, Technion - Israel Institute of Technology, Haifa, Israel; 3) Department of Human Molecular Genetics & Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 4) Department of Medical Genetics and Department of Genome Sciences, University of Washington, Seattle, WA, USA.

   The goal of our project is to discover and characterize genes for inherited hearing loss (HL) by studying highly informative families from the Middle East. We enroll and sample all informative members of families with at least two relatives with HL, which may be dominant or recessive, congenital or later onset, and non-syndromic or syndromic. This report focuses on Arab families from the Palestinian West Bank and northern Israel. For each family, audiologic analysis and primary clinical evaluations were carried out, and genomic DNA was evaluated for mutations in *GJB2* and for several common founder alleles. Families with no such mutations were evaluated by hybridization and multiplexed sequencing, using our panel of all known human and mouse deafness genes (PMID: 21917145). SNVs, indels, and CNVs were identified in exons and proximal regulatory regions. Mutations were interpreted as damaging only if they co-segregated with hearing loss in their families; and were truncating, led to loss of transcript in patient RNA, completely deleted the gene, or were missense mutations with experimentally confirmed functional effect. Of 85 Arab families evaluated by our panel thus far, including 484 participating relatives, 53 families (62%) carried a pathogenic or likely pathogenic mutation in a known deafness gene. A total of 44 different mutations, most not previously reported, were identified in 22 genes and submitted to LOVD and ClinVar. Genes responsible for non-syndromic HL in 41 families were CDH23 (3 families), CLDN14 (3), ESRRB (2), ADGRV1 (2), GPSM2 (1), LOXHD1 (3), MYO15A (7), MYO6 (2), MYO7A (6), OTOA (1), OTOG (1), PCDH15 (1), PTRH2 (1), TBC1D24 (1), TMC1 (1), TRIOBP (3), and USH1C (2); genes for syndromic or other HL phenotypes in 12 families were OTOF (auditory neuropathy, 2), PAX3 (Waardenburg, 3), SLC26A4 (Pendred signs, highly variable across families, 6), and USH1G (RP, 1). The 38% of families with no mutation in any known deafness gene represent a highly informative resource for identification both of additional HL genes and of distant non-coding regulatory mutations. We are evaluating these unresolved families with whole exome and/or whole genome sequencing. We undertake this complete pipeline for approximately 70 new families each year. Supported by NIH R01DC011835 to KBA and MNK.

Exome sequencing and subsequent haplotype analysis of a Scottish Cone-Rod patient, homozygous for a common "Spanish" *CERKL* mutation, points towards a distant common ancestry. *A.J. Cassidy[1], S.V. Brugnatelli[2], C. Ayuso[3], A. Avila-Fernandez[3], D. Zeller[1], D. Lester[2], The Tayside Centre for Genomic Analysis.* 1) Tayside Centre for Genomic Analysis, University of Dundee, Dundee, Tayside, Scotland; 2) School of Science, Engineering & Technology, Abertay University, Dundee, Scotland, UK; 3) Department of Genetics, Fundacion Jimenez Diaz-CIBERER, Madrid, Spain.

Cone–Rod Dystrophy (CRD) is a subset of a group of retinal dystrophies, known as Retinitis Pigmentosa (RP), which together make up the main cause of inherited adult blindness in the developed world. CRD patients generally experience loss of their cone rich central vision in early adulthood, before also losing their rod rich peripheral vision, leading to complete blindness in later life. The genetic cause of most (>50%) RP cases is as yet unknown, especially for those carrying a recessive mutation. Such information can help design future treatments, e.g. viral gene therapy and also in ~10% of cases, the developing field of premature termination codon therapy. In this study we initially identified a pathogenic variation in CERKL (p.Arg257ter) using the Illumina TruSight sequencing panel in an isolated non-familial 59 year old non-consanguineous, Scottish CRD patient. This particular CERKL mutation was first found in a large Spanish CRD family, which was subsequently shown by haplotype analysis of 4 SNP loci, flanking the CERKL gene, to be distantly related to 6 other Spanish CRD families. Following haplotype analysis with the same 4 SNP markers with the Scottish *CERKL* patient we found that 3 of the closest SNPs used to previously link the 7 Spanish families together were also homozygous and in common. One haplotyping SNP, the most distant from the *CERKL* gene, was however shown to be different from the 7 Spanish families and this occurrence is likely to have come from a recombination event in a distant common ancestor of the Scottish and Spanish patient(s). .

Functional analyses of novel mutations in HPS (Hermansky-Pudlak Syndrome)-3, HPS-5 and HPS-6 patients with ocular albinism. *W. Li[1,3], A. Wei[2], Y. Yuan[3], D. Bai[4], Z. Zhou[3], J. Ma[1], Z. Hao[1], J. Yu[3], Y. Zhang[2], L. Yang[3], X. Yang[2], L. Li[4].* 1) Center for Medical Genetics, Beijing Children's Hospital, Capital Medical University, Beijing, China; 2) Department of Dermatology, Beijing Tongren Hospital, Capital Medical University, Beijing, China; 3) Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing , China; 4) Department of Ophthalmology, Beijing Children's Hospital, Capital Medical University, Beijing, China.

Hermansky-Pudlak syndrome (HPS) is a rare recessive disorder characterized by hypopigmentation, bleeding diathesis and other symptoms attitutable to multiple defects in lysosome-related organelles (LROs). Currently, 10 HPS subtypes have been identified with mutations in *HPS1* to *HPS10*. Functional studies have revealed that the encoded proteins of the HPS genes are components of different protein trafficking complexes named HPS protein associated complexes (HPACs) such as BLOC-1, BLOC-2, BLOC-3, and AP-3. HPS3, HPS5 and HPS6 protein consist of the BLOC-2 complex. So far there is no case report of HPS-3, HPS-5 or HPS-6 in Chinese population. Using next-generation sequencing, we have identified 1 case of HPS-3, 1 case of HPS-5, and 3 cases of HPS-6 in Chinese HPS patients with typical ocular albinism together with other variable phenotypes, which have been verified by the absence of platelet dense granules under whole-mount platelet EM. The manifested hypopigmentation in the eyes and hair of these HPS patients was similar to their mouse counterparts such as cocoa (*Hps3*), ruby-eye 2 (*Hps5*) and ruby-eye (*Hps6*). All these patients were compound heterozygotes. We verified the mutations by Sanger sequencing and family transmission. Among these mutations, 8 allelles were previously unreported alleles (PUAs), i.e. 4 frameshift mutations (3 in *HPS6*, 1 in *HPS3*), 3 missense mutations (2 in *HPS5*, 1 in *HPS6*), and 1 nonsense mutation (in *HPS6*). To evaluate their effects on BLOC-2 complex stability, we detected HPS6 protein level in platelets. We found that except null in the HPS-3 patient, HPS6 protein was detectable in all the other HPS patients, suggesting that the effects of compromised BLOC-2 functions are tissue-specific and genotype-specific. Our results suggest that next-generation sequencing is a powerful tool for the identification of HPS patients with autosomal recessive ocular albinism, which may be overlooked in Chinese population. **Key Words:** Hermansky-Pudlak syndrome (HPS); biogenesis of lysosome-related organelles complex-2 (BLOC-2); previously unreported alleles (PUAs); lysosome-related organelles (LROs); genotype-phenotype relationship; albinism.

CRISPR-Cas9 based treatment of myocilin-associated glaucoma. *A. Jain[1], G. Zode[2], R.B. Kasetti[2], F.A. Rann[3], W. Yan[3], K. Bugge[1], C. Searby[1], V. Buffard[1], M.L. Humbert[1], F. Zhang[3], A.F. Clark[2], V.C. Sheffield[1].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) North Texas Eye Research Institute, University of North Texas Health Science Center, Fort Worth, TX; 3) McGovern Institute for Brain Research, Massachusetts Institute of Technology, Cambridge, MA.

Glaucoma is a leading cause of irreversible blindness with elevated intraocular pressure (IOP) being the most important and the only modifiable risk factor. Mutations in myocilin (*MYOC*) lead to its misfolding and endoplasmic reticulum (ER) stress in the trabecular meshwork (TM), the tissue that maintains aqueous humor outflow and regulates IOP. ER stress and/or death of the TM lead to elevated IOP and glaucoma. Mutations in *MYOC* have been reported in both primary open angle glaucoma and juvenile open angle glaucoma. Since the phenotype seems to result from the mutant misfolded protein rather than resulting from loss of myocilin function or haplo-insufficiency, we propose to relieve the ER stress and glaucoma by targeting the *MYOC* gene using CRISPR-Cas9 genome editing technology. Stable cell lines expressing mutant *MYOC* and human primary TM cells, as well as h*MYOC*[Y437H] transgenic mice were treated with adenovirus Ad5-CRISPR-Cas9 virus with *MYOC* and control guide RNAs. Treated and control cells, and mice were evaluated for ER stress and glaucoma phenotypes. Treatment with CRISPR-Cas9 with gRNAs targeting the *MYOC* gene reduces levels of MYOC and ER stress in *MYOC* mutant cells. We will also report on the rescue of glaucoma, during both disease stage and prophylactically, in the mouse model of *MYOC* glaucoma by CRISPR-cas9. This is the first detailed study showing that genome editing targeting the *MYOC* gene can relieve ER stress in TM cells and in transgenic h*MYOC*[Y437H] mouse model of glaucoma. This approach would provide a long-term or a permanent relief to the stress as compared to no current treatment or proposed short-term strategies in MYOC-associated glaucoma patients.
